The proposed method also achieves the best results on the POS tagging task. Similar to the slot tagging task, our method shows the highest mean accuracy of 97.69 with the lowest standard deviation of 0.02. For the baseline models, CNN and RNN performed on par.

CNN-based models have higher variability with high peak performance on this task also, as shown in the violin plot. Similar to the slot tagging task, our method shows the lowest variability, which supports the robustness of this method.

Table 3: Comparison with state-of-the-art approaches in the literature.

7.1.3 Named Entity Recognition

On the NER task, the RNN-based model has a slightly better F1-score (90.15) than the proposed method (90.10). However, our method consistently shows the lowest standard deviation, like as the other tasks, at 0.13. By analyzing the violin plot, we can see that the RNN again shows occasional performance drops for certain cases of poor weight initialization. Unlike the other two tasks, the model utilizing CNN has a relatively poor F1-score and does not show any peaks in performance.

7.2 Training Speed

To compare the efficiency of three models, average training speed (i.e. number of sentences processed per second) is presented in Figure 4. All trainings are performed utilizing a single GeForce GTX 1080 Ti GPU, and the RNN model is implemented using the highly efficient cuDNN LSTM API. It is clear that the proposed method has the highest training speed, followed by CNN and RNN. On average, our method was able to process around 867 sentences per second, which is 6.29% and 16.32% higher than CNN and RNN, respectively.

7.3 Comparison with Published Results

For comparison with published results, we summarize the performance of our best models along with state-of-the-art approaches in Table 3. The proposed method was able to surpass the previous state-of-the-art result on the ATIS dataset with a large margin, even without the CRF layer. With the help of CRF, our method obtains a new state-of-the-art result with a 96.62 F1-score.
For the POS tagging task with PTB WSJ dataset, we obtain a new state-of-the-art result with a 97.73% accuracy with the model without a CRF layer. Interestingly, utilizing a CRF layer on this model degraded the performance on this task whereas it helped with the other two tasks. We hypothesize that this is due to the fact that unlike the other two tasks where there are many hard constraints between labels (e.g. an O tag cannot be followed by I- tags), the label dependencies are more "soft" on POS tagging task. In the latter case, it is possible that naively taking label transition probability into account could have a negative impact on performance.
On the task of recognizing named entities, we obtain a result that is comparable to state-of-the-art with a 91.13 F1-score when a CRF layer is used. Like in slot tagging task, utilizing CRF lead to a significant increase in performance. It is notable that all results from our method are achieved without depending on any hand-crafted or language/task-specific features (e.g. capitalization, character type, gazetteer), whereas most previous approaches utilizes one or more type of such features. This fact supports the generalizability of the proposed method.

8 Conclusion and Future Work

In this paper, we proposed a fast and effective method of using a densely connected network to automatically generate character-level features. With extensive evaluation, it is shown that this method is robust to parameter initialization and has high processing speed compared to conventional methods such as CNN or RNN. This method has also high generalizability and this is supported by the fact that we were able to obtain superior performance without any task or language specific features.
We plan to explore the followings as future work: 1) In this work, we focused on clean text where there are minimal semantic or syntactic errors. We would like to test the robustness of this method against such errors to evaluate whether this method is suitable for real-world applications. 2) Adopting the proposed method and analyzing the effectiveness on other NLP tasks such as neural machine translation or automatic text summarization could also be worth investigating.

Abstract

This study proposes a new neural machine translation (NMT) model based on the encoder-decoder model that incorporates named entity (NE) tags of source-language sentences. Conventional NMT models have two problems enumerated as follows: (i) they tend to have difficulty in translating words with multiple meanings because of the high ambiguity, and (ii) these models' ability to translate compound words seems challenging because the encoder receives a word, a part of the compound word, at each time step. To alleviate these problems, the encoder of the proposed model encodes the input word on the basis of its NE tag at each time step, which could reduce the ambiguity of the input word. Furthermore, the encoder introduces a chunk-level LSTM layer over a word-level LSTM layer and hierarchically encodes a source-language sentence to capture a compound NE as a chunk on the basis of the NE tags. We evaluate the proposed model on an English-to-Japanese translation task with the ASPEC, and English-to-Bulgarian and English-to-Romanian translation tasks with the Europarl corpus. The evaluation results show that the proposed model achieves up to 3.11 point improvement in BLEU.

1 Introduction

Neural machine translation (NMT) models based on the encoder-decoder model, also known as the sequence-to-sequence model (Sutskever et al., 2014), have successfully shown their quality translation. Consequently, various NMT models are studied in the field of machine translation. To date, the most successful model is the bi-directional multi-layered encoder-decoder model with long short term memory (LSTM) (Hochreiter and Schmidhuber, 1997) and an attention mechanism (Luong et al., 2015; Bahdanau et al., 2015), also known as attention-based NMT. LSTM and the attention mechanism are introduced to mitigate the difficulty in handling long sentences in the encoder-decoder model. The conventional attention-based NMT model is known to achieve high translation accuracy in bilingual evaluation understudy (BLEU). However, this model encounters two general problems: (i) it tends to have difficulty in translating words with multiple meanings because their translations have high ambiguity, and (ii) translation of compound words seems difficult because the encoder receives only a word, a part of the compound word, at each time step.

This study proposes a new NMT model based on the encoder-decoder model, incorporating named entity (NE) information in source-language sentences. The proposed model alleviates the problems of the conventional attention-based NMT by incorporating information of NE tags to the encoder and modeling chunk information of NE tags as the encoder's network structures. The encoder of the proposed model

Proceedings of the 27th International Conference on Computational Linguistics, pages 3240–3250
Santa Fe, New Mexico, USA, August 20-26, 2018.

encodes the input word based on its NE tag at each time step to reduce the ambiguity of the input word. Furthermore, the encoder introduces a chunk-level LSTM layer over a word-level LSTM layer and hierarchically encodes a source-language sentence to capture a compound NE as a chunk based on its NE tags. We evaluate the proposed model on an English-to-Japanese translation task with the Asian Scientific Paper Excerpt Corpus (ASPEC) (Nakazawa et al., 2016) and English-to-Bulgarian and English-to-Romanian translation tasks with the Europarl corpus. The evaluation results show that the proposed model achieves up to 3.11 point improvement in BLEU.

The main contributions of this study are as follows:

1. Semantic class information of NE tags is incorporated to the encoder of the attention-based NMT model.

2. Chunk information of NE tags is modeled as a part of network structures in the attention-based NMT model.

2 Related Work

This section describes the attention-based NMT model, a previous NMT model incorporating linguistic features of source-language sentences, and previous NMT models based on chunks/phrases.

2.1 Attention-based NMT Model

The attention-based NMT model is an NMT model, wherein an attention mechanism is introduced in the encoder-decoder model. The encoder-decoder model consists of two recurrent neural networks (RNNs), namely, an encoder and a decoder. Gated Recurrent Unit (Cho et al., 2014) or LSTM is typically used as units of RNNs. In this work, LSTM is employed as units of RNNs.

Given a word sequence of the source language $x = (x_1, x_2, \ldots, x_j, \ldots, x_{T_x})$, the encoder generates a hidden vector $(h_1, h_2, \ldots, h_j, \ldots, h_{T_x})$. Each hidden state of the encoder $h_j \in \mathbb{R}^{d\times 1}$ is calculated using LSTM, given the previous state $h_{j-1} \in \mathbb{R}^{d\times 1}$ and the input word x_j, as follows:

$$h_j = f_{enc}(h_{j-1}, E_x(x_j)), \tag{1}$$

where f_{enc} is the encoder's LSTM, E_x is an embedding layer, and $E_x(x_j)$ is an embedding vector of the word x_j.

Then, the decoder sequentially generates a word sequence of the target language $y = (y_1, y_2, \ldots, y_i, \ldots, y_{T_y})$, given the final state of the encoder, h_{T_x}. The decoder outputs a word sequence having the maximum logarithmic likelihood with respect to the input word sequence x as the output word sequence y:

$$\log p(y|x) = \sum_{i=1}^{T_y} \log p(y_i|y_{1:i-1}, h_{T_x}). \tag{2}$$

The probability distribution of the output word y_i is calculated from the hidden state $\bar{h_i}$ of the decoder:

$$p(y_i|y_{1:i-1}, h_{T_x}) = softmax(proj(\bar{h_i})), \tag{3}$$

where $proj$ is a projection function to resize a decoder's hidden state to a vector, wherein the vector's dimension is the target vocabulary size. $softmax$ is a softmax function to convert the projected vector o into a probability distribution by normalizing each element of o as follows:

$$o = proj(\bar{h_i}), \tag{4}$$

$$softmax(o) = \frac{\exp(o)}{\sum_{k=1}^{K} \exp(o_k)}, \tag{5}$$

where K is the vocabulary size of the target language.

To prevent deterioration of the translation performance for long source-language sentences, the attention-based NMT tries to capture the relation between the states in the encoder and the decoder, and the decoder generates the translations by referring to the history of the hidden states in the encoder. In particular, the alignment score a_i is calculated on the basis of the similarity between the decoder's hidden state $\bar{h_i}$ and each of the encoder's hidden states $c = (h_1, h_2, \ldots, h_j, \ldots, h_{T_x})$. The context vector s_i is calculated as the weighted average, where a weight is a_i, over all the encoder's hidden states:

$$a_i(j) = \frac{\exp(\bar{h_i} \cdot h_j)}{\sum_{j'=1}^{T_x} \exp(\bar{h_i} \cdot h_{j'})}, \tag{6}$$

$$s_i = \sum_{j=1}^{T_x} a_i(j) h_j, \tag{7}$$

where T_x is the length of the source-language sentence x, and $\cdot$ denotes the inner product. In the decoder, the probability distribution of the output word is calculated on the basis of the context vector s_i in addition to the decoder's hidden state $\bar{h_i}$:

$$p(y_i|y_{1:i-1}, c) = softmax(proj([\bar{h_i}; s_i])), \tag{8}$$

where [;] denotes the concatenation of the two vectors.

2.2 Linguistic Input Features for NMT

Sennrich and Haddow (2016) have improved the attention-based NMT model by using the linguistic features of source-language sentences. In particular, the encoder receives the lemma, subword tags, POS tags, and dependency labels of source-language sentences in addition to source-language words. A lemma is the original form of the word. Subword tags express prefix, stem, and suffix. A POS tag is part-of-speech information of a word, such as a noun or a verb. Moreover, a dependency label indicates a syntactic relation between words, such as a head and dependents. The encoder converts each of the linguistic features into its embedding vector, and then generates hidden states $(h_1, h_2, \ldots, h_j, \ldots, h_{T_x})$ from the word embedding vectors of source-language words $x = (x_1, x_2, \ldots, x_j, \ldots, x_{T_x})$ and the linguistic feature's embedding vectors as follows:

$$h_j = f_{enc}(h_{j-1}, (E_{word}(x_j)[\,;\, {}^{|F|}_{k=1} E_k(x_{jk})])), \tag{9}$$

where E_{word} is an embedding layer for source-language words, E_k is an embedding layer for the k-th type of linguistic features, and $|F|$ is the number of types of linguistic features (i.e., $|F|$ = 4). Note that the model has not used NE tags as a linguistic feature, and the incorporation of NE tags into NMT is still under exploration.

2.3 NMT Based on Chunk/Phrase Units

Ishiwatari et al. (2017) have improved the attention-based NMT by designing chunk-based decoders, each of which models global dependencies by a chunk-level decoder and local word dependencies by a word-level decoder. In their decoders, the chunk-level decoder first generates a chunk representation. Then, the word-level decoder predicts each target word from the chunk representation.

Wang et al. (2017) have improved attention-based NMT by integrating a phrase memory, which stores target phrases provided by a statistical machine translation (SMT) (Pal et al., 2010) model, to perform a phrase-by-phrase translation rather than a word-by-word translation. Their model dynamically selects a word or phrase to be output at each decoding step.

Meanwhile Ishiwatari et al. (2017) and Wang et al. (2017) have incorporated chunks identified by a chunker and a SMT model, respectively, our work focuses on chunk information of NE tags. Note that our proposed model can incorporate general chunk information, such as chunks found by a chunker. We will leave this aspect for future work.

3 NMT Incorporating NE Tags

In this section, we propose a new NMT model, incorporating NE tags of source-language sentences. By considering NE types of source-language words, we aim to improve translation performance for words with multiple meanings. Furthermore, by using chunk information of NE tags (e.g., IO or BIO information), we aim to improve translation performance for compound words.

The proposed model assumes that an NE tag is attached to each word in source-language sentences by using an NE tagger. The proposed model receives the sequence of NE tags along with the sequence of source-language words and generates each encoder's hidden state on the basis of not only source-language words but also NE tags. Furthermore, the proposed model introduces a chunk-level LSTM layer over a word-level LSTM layer into the encoder and hierarchically encodes a source-language sentence.

In Section 3.1, we overview NE tags, and in Section 3.2, we describe the model architecture of the proposed model.

3.1 Named Entity (NE)

NEs are words/phrases for specific entities, such as the name of persons, organizations, and locations. Moreover, NEs are sometimes extended to include time expressions and numerical representations. In CoNLL2003 shared task[1], the four types of NEs, namely 'person', 'organization', 'location', and 'names of miscellaneous', have been used. In Message Understanding Conference (MUC)[2], the seven kinds of NEs, namely 'person', 'location', 'organization', 'time', 'date', 'money', and 'percent', have been used. Information Retrieval and Extraction Exercise (IREX)[3] have used the eight kinds of NEs, where 'artifact' is added to the NEs used in MUC. Moreover, on Ontonotes 5.0[4], the 18 kinds of NEs have been defined. NEs could be considered as a kind of semantic category of words/phrases. Therefore, NEs have contributed to many NLP tasks, including SMT. Note that NEs have not been used in NMT.

NE Recognition is a classification task to identify NE words/phrases and their NE categories in given input sentences. In the tasks, NEs are usually expressed by chunk tags, such as BIO and IO tags, for words because an NE might be a phrase. For example, the sentence 'I arrived at Tokyo Station at 10:20.' is tagged by BIO2 tags as follows: 'I:O arrived:O at:O Tokyo:B-location Station:I-location at:O 10:20:B-time .:O', where B, I, and O indicate the beginning, inside, and outside of NEs, respectively. In this work, we used IO tags. By IO tags, NE words/phrases are represented as I (inside) and the others are expressed as O (outside). An example of the tagged sentence is as follows: 'I:O arrived:O at:O Tokyo:I-location Station:I-location at:O 10:20:I-time .:O'.

As mentioned above, NE tags include two features: (i) semantic class of words (e.g., location and time) and (ii) chunk information (e.g., I and O). By using the first feature, we aim to decrease the ambiguity of source-language words and improve the performance for words with high ambiguity. By using the second feature, we aim to capture the chunks of compound words and improve the performance for compound words.

3.2 Model Architecture

Figure 1 shows the encoder of the proposed model. The encoder of the proposed model is composed of three components, namely, the embedding layer, word-level LSTM layer, and chunk-level LSTM layer.

The encoder receives the sequence of NE tags, $tag = (tag_1, tag_2, \ldots, tag_i, \ldots, tag_{T_x})$, along with the sequence of source-language words, $x = (x_1, x_2, \ldots, x_i, \ldots, x_{T_x})$, where tag_i denotes the NE tag of x_i. At each time step i, the encoder generates the word embedding vector for the source-language word x_i through a word embedding layer E_x. Additionally, the embedding vector for the NE tag tag_i is generated through a tag embedding layer E_{tag}. Then, these vectors are added:

$$\hat{x}_i \quad = \quad E_x(x_i) + a * E_{tag}(tag_i), \tag{10}$$

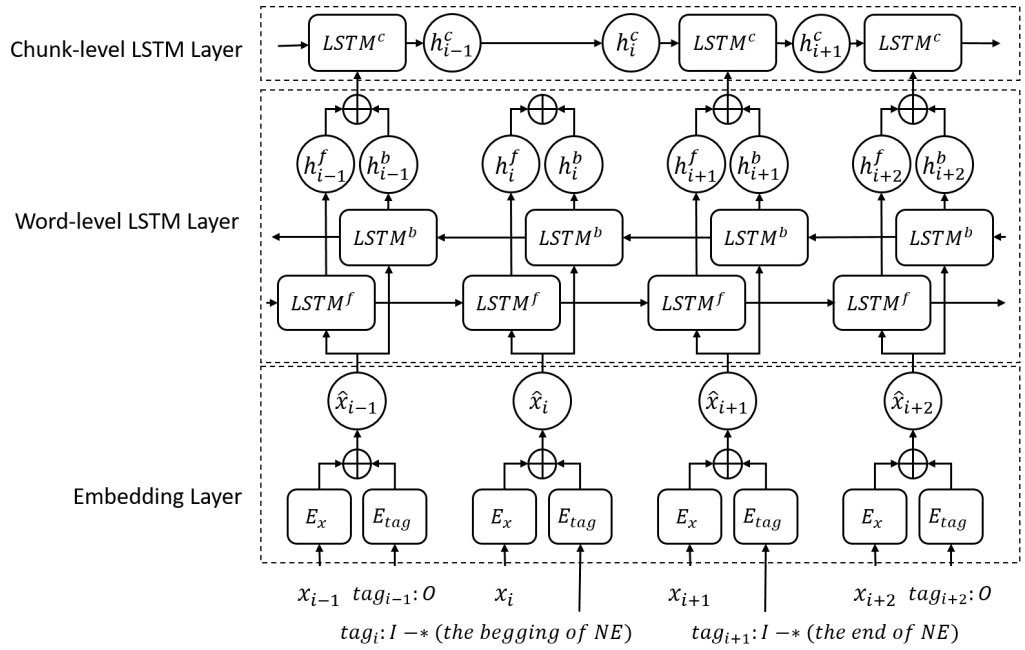

Figure 1: Encoder of the Proposed Model

where a is a parameter to control the influence of NE tags and is optimized in model training. The added vector, $\hat{x}_i$, is fed to a word-level LSTM component.

The word-level LSTM layer is a bi-directional LSTM, which encodes an input sentence by word. The bi-directional LSTM consists of a forward LSTM, $LSTM^f$, and a backward LSTM, $LSTM^b$. The forward LSTM obtains hidden states $(h^f_1, \ldots, h^f_{T_x})$ from the beginning to the end of the sentence:

$$h^f_i = LSTM^f(h^f_{i-1}, \hat{x}_i). \tag{11}$$

The backward LSTM obtains hidden states $(h^b_{T_x}, \ldots, h^b_1)$ from the end to the beginning of the sentence:

$$h^b_i = LSTM^b(h^b_{i+1}, \hat{x}_i). \tag{12}$$

Then, the bi-directional LSTM computes the average of h^f_i and h^b_i as the i-th word-level encoder's hidden state h_i:

$$h_i = (h^f_i + h^b_i)/2. \tag{13}$$

The hidden state h_i is fed to the chunk-level LSTM layer.

The chunk-level LSTM layer is a uni-directional forward LSTM, $LSTM^c$, which receives the hidden states of the word-level layer and encodes a source sentence by chunk identified by NE tags. Based on the chunk information of NE tags, the hidden states of the chunk-level LSTM layer, $(h^c_1, \ldots, h^c_{T_x})$, is calculated as follows:

$$h^c_i = \begin{cases} LSTM^c(h^c_{i-1}, h_i) & \text{if } tag_i \text{ is 'O' or the last part of the NE tags} \\ h^c_{i-1} & \text{otherwise} \end{cases} \tag{14}$$

The decoder of the proposed model is the same as in the conventional attention-based NMT model. The initial state of the decoder is set to the sum of the final state of the word-level LSTM layer and that of the chunk-level LSTM layer.

4 Experiment

This section compares the proposed model, which incorporates NE tags of source sentences, with a conventional NMT model, which does not use NE tags, under English-to-Japanese (En-Jp), English-to-Bulgarian (En-Bg), and English-to-Romanian (En-Ro) translation tasks to confirm the effectiveness of the proposed model.

Table 1: Statistics on Experimental Data (# of parallel sentences)

	Training Data	Development Data	Test Data
En-Jp	1,320,591	1,768	1,802
En-Bg	363,112	3,000	3,000
En-Ro	357,247	1,972	3,000

Table 2: Vocabulary Size

	Source Language	Target Language
En-Jp	78,591	57,771
En-Bg	27,872	30,000
En-Ro	27,651	30,000

4.1 Experimental Data

We evaluated the En-Jp translation performance on the ASPEC, which is used in WAT 2017[5], and the En-Bg and En-Ro translation performance on the Europarl corpus (Koehn, 2005).

The English and Japanese sentences are tokenized by spaCy[6] and KyTea (Neubig et al., 2011), respectively. The Bulgarian and Romanian sentences are tokenized by byte-pair encoding (Sennrich et al., 2016) implemented in sentencepiece[7], where we set the vocabulary size to 30,000. The words that appeared less than five times in the En-Jp training data and those less than twice in the English side of the En-Bg and En-Ro training data were replaced with the special symbol $\langle \text{UNK} \rangle$. In the training, all words were lowercased by lowercase.perl[8], and long sentences with over 50 words were filtered out.

In the En-Jp task, we used the development and test data employed in WAT 2017. In the En-Ro task, we used the newsdev-2016 as the development data and randomly sampled 3,000 parallel sentences from the training data as the test data. In the En-Bg task, we randomly sampled 3,000 parallel sentences from the training data for the development data and test data. The statistics on the experimental data are summarized in Table 1 and Table 2.

We used spaCy NE tagger[9], which was trained from the OntoNotes5.0[10] corpus attached with NE tags, to identify NE tags of English sentences in the proposed model. Table 3 shows the types of NE tags, and Table 4 gives the Top 3 NE types on the training corpus.

4.2 Competing Models

We compared the proposed model (*Proposed*) with the standard attention-based encoder-decoder NMT model, wherein the encoder is two stack bi-directional LSTM and the decoder is two stack forward LSTM (*Baseline*). Note that the proposed model introduces the embedding layer for NE tags and chunk-level forward LSTM layer into *Baseline*. We also compared the proposed model with the simulated model of Sennrich and Haddow (2016) (*Baseline_Concat*). In *Baseline_Concat*, the encoder generates a hidden state from the concatenated vector of the embedding vector for an input word and that for its NE tag at each time step (refer to Equation (9)). The network structures other than the embedding layer are the same as in *Baseline*.

All of the embedding size and hidden size of the encoder and decoder both in the baselines and proposed model are set to 256. The parameter a, which controls the effect of NE tags, is initialized to 0.5.

We used Adam (Kingma and Ba, 2015) with a mini-batch size of 64, 128, and 64 for learning each parameter in the En-Jp, En-BG, and En-Ro tasks, respectively. We also employed a gradient clipping

Table 3: Types of NE Tags

NE Type	Descriptions
PERSON	people, including fictional
NORP	nationalities or religious or political groups
FACILITY	buildings, airports, highways, bridges, etc.
ORG	companies, agencies, institutions, etc.
GPE	countries, cities, states
LOC	non-GPE locations, mountain ranges, bodies of water
PRODUCT	objects, vehicles, foods, etc. (not services.)
EVENT	named hurricanes, battles, wars, sports events, etc.
WORK_OF_ART	titles of books, songs, etc.
LAW	named documents made into laws
LANGUAGE	any named language
DATE	absolute or relative dates or periods
TIME	times smaller than a day
PERCENT	percentage, including '%'
MONEY	monetary values, including unit
QUANTITY	measurements, as of weight or distance
ORDINAL	'first', 'second', etc.
CARDINAL	numerals that do not fall under another type
OTHER	others

Table 4: Top 3 NE Types

Corpus	Top 3 NE Types
En-Jp	O: 94.1%, ORG: 1.65%, CARDINAL: 1.12%
En-Bg	O: 91.3%, ORG: 3.56%, DATE: 1.16%
En-Ro	O: 91.2%, ORG: 3.58%, DATE: 1.16%

Table 5: Experimental Results (BLEU score (%))

	Baseline	*Baseline_Concat*	*Proposed*
En-Jp	29.38	28.17	29.62
En-Bg	37.99	37.48	38.38
En-Ro	34.31	36.77	37.44

technique with the clipping value of 5.0, dropout with the dropout ratio of 0.2, and the weight decay with the coefficient of 1.0×10^{-6}. The training stopped after 30 epochs, and the model that achieved the best BLEU score on the development data, was used for testing.

4.3 Results

We evaluated the translation performances via the case-insensitive BLEU4 metric (Papineni et al., 2002), which is computed by multi-bleu.perl[11]. Table 5 shows the experimental results.

From Table 5, the proposed model is better than *Baseline* for all the translation tasks, which shows that the effectiveness of the incorporation of NE tags of source sentences into NMT. In addition, the proposed model outperforms *Baseline_Concat* for all the translation tasks. This observation indicates that the proposed model makes use of NE tags more effectively than the previous model (Sennrich and Haddow, 2016).

5 Discussion

This work aims to improve the translation performance for compound words and words with multiple meanings by using NE tags of source sentences. In this section, we discussed the effectiveness of the proposed model through actual examples. Table 6 shows the output examples of the baseline model, *Baseline*, and the proposed model for three English sentences.

The word 'first' has multiple meanings in Japanese (e.g., 最初の (beginning), 一つの (one of), 一位の (top)). (a) of Table 6 shows that the proposed model correctly translates the word 'first', whereas the baseline model does not. We guess the reason is that the proposed model could disambiguate the meanings of the word 'first' on the basis of the NE tag 'ORDINAL'.

From (b) in Table 6, the proposed model correctly translates the English phrase 'between 0.2 to 0.5' into the Japanese phrase '０．２～０．５', whereas the baseline model fails and results in 'over- translation' (i.e., the Japanese words '～０．０５' are generated twice). Probably, the reason is that the

[11] http://www.statmt.org/moses/

Table 7: Experimental Results to Confirm the Effectiveness of Chunk Information

	Baseline	*Baseline_Chunk*	*Proposed_IO*	*Proposed*
En-Jp	29.38	28.61	29.51	29.62
En-Bg	37.99	37.55	37.93	38.38
En-Ro	34.31	35.48	35.78	37.44

proposed model could consider the four words as one phrase on the basis of the chunk information (I/O) of the NE tags.

Furthermore, as can be seen from (c) in Table 6, the compound word 'dr - vco' is correctly translated to 'd r - v c o ' by the proposed model, whereas it is wrongly translated by the baseline model. This finding also indicates that the proposed model is better for the translation of compound words. An interesting observation from (c) is that although the NE type of 'dr - vco' is wrong (i.e., the correct type is 'OTHER' although the attached type is 'GPE'), the proposed model translates the compound word correctly. This finding indicates that the chunk information of NE tags could be useful to NMT even if the NE type is not correctly identified.

The above examples indicate that both semantic class information of words (i.e., NE types) and chunk information (i.e., I/O) of NE tags could be helpful to NMT. To quantitatively confirm the pure effectiveness of chunk information of NE tags, we evaluated the performance of the proposed model that uses only chunk information of NE tags (*Proposed_IO*). In particular, *Proposed_IO* receives either of 'I' tag or 'O' tag as the NE tag. In addition, we evaluate the *Baseline* model that naively uses chunk information of NE tags (*Baseline_Chunk*). In *Baseline_Chunk*, each source sentence is preliminarily chunked on the basis of NE tags and each chunk is treated as a word. For example, the two words 'donald:I-PERSON trump:I-PERSON' are concatenated into one chunk 'donald_trump' and the chunk is treated as one word.

Table 7 summarizes their performance. As can be seen from Table 7, *Baseline_Chunk* is worse than *Baseline* in the En-Jp and En-Bg tasks although *Baseline_Chunk* outperforms *Baseline* in the En-Ro task. This finding indicates that the naive incorporation of chunk information of NE tags could have negative effect to NMT. Table 7 also shows that *Proposed_IO* is at least comparable to, or better than, *Baseline*. This observation indicates that only chunk information of NE tags could improve NMT performance in the proposed model. We conjecture that chunking increases vocabulary sizes. Thus, the naive incorporation (i.e., *Baseline_Chunk*) might suffer from the data sparseness problem, whereas *Proposed_IO* might alleviate the sparseness problem by the hierarchical structure of the encoder (i.e., word-level LSTM layer). In addition, Table 7 shows that *Proposed* outperforms *Proposed_IO* for all the tasks. This finding indicates that NE types enable further improvement in NMT performance.

6 Conclusion

We have proposed a new encoder-decoder NMT model, which alleviates the problems of word ambiguities and compound words in the conventional attention-based NMT by incorporating NE tags of source-language sentences. The encoder of the proposed model encodes both input word and NE tag at each time step and has a chunk-level LSTM layer over a word-level LSTM layer to hierarchically encode a source-language sentence.

The experiments on the English-to-Japanese translation task with the ASPEC show that the proposed model achieved 0.24 point improvement in BLEU. In addition, the experiments on the English-to-Bulgarian and English-to-Romanian translation tasks with the Europarl corpus show that the proposed model achieved 0.39 and 3.11 point improvements in BLEU, respectively.

We qualitatively analyzed translation results to investigate the effectiveness of the NE information in the encoder-decoder model and found several examples that show the effectiveness of either semantic class information or chunk information of NE tags.

Finally, we also conducted experiments to evaluate how chunk information (i.e., I/O) of NE tags contributed to improve the translation accuracy without semantic class information. From the experiments, we observed that chunk information could improve the translation accuracy, and the translation accuracy

was further improved by adding semantic information of NE tags.

Future work includes finding good models to incorporate NE tags and verify the effectiveness of the proposed models for other datasets. In addition, we would like to incorporate an NE tagging model to the proposed model to learn both the NE model and machine translation model.

Semantic Parsing of Technical Support Questions

Abhirut Gupta, Anupama Ray, Gargi Dasgupta,
Gautam Singh, **Pooja Aggarwal** and **Prateeti Mohapatra**
IBM Research AI
{abhirutgupta, anupamar, gaargidasgupta,
gautamsi, aggarwal.pooja, pramoh01}@in.ibm.com

Abstract

Technical support problems are very complex. In contrast to regular web queries (that contain few keywords) or factoid questions (which are a few sentences), these problems usually include attributes like a detailed description of what is failing (symptom), steps taken in an effort to remediate the failure (activity), and sometimes a specific request or ask (intent). Automating support is the task of automatically providing answers to these problems given a corpus of solution documents. Traditional approaches to this task rely on information retrieval and are keyword based; looking for keyword overlap between the question and solution documents and ignoring these attributes. We present an approach for semantic parsing of technical questions that uses grammatical structure to extract these attributes as a baseline, and a CRF based model that can improve performance considerably in the presence of annotated data for training. We also demonstrate that combined with reasoning, these attributes help outperform retrieval baselines.

1 Introduction

Technical support services involve enterprises providing after-sales support to users of technology products. Traditionally, this entails employing a large number of human agents to manually diagnose, troubleshoot, and resolve customer problems. However, with ever increasing variety of products and the exponential growth of users, this model doesn't scale. Costs of hiring and training additional talent to keep up with this growth is a huge overhead. There is a clear incentive to automate this process, reducing manual effort and resolution times. Automating technical support refers to the task of automatically understanding user questions, performing diagnosis and troubleshooting, either remotely or in conversation with the user, and providing resolutions. Given the massive potential impact, it is no surprise that the problem draws attention and investment from many large corporations as well as startups (Flinders, 2015), and (Dhoolia et al., 2017).

Automating technical support has a very broad goal, and involves solving various sub-problems like document representation (Yang et al., 2017), identifying and extracting procedures, log analysis, and goal based dialoging (Bordes and Weston, 2016). Each of these problems has a plethora of daunting research challenges that remain largely unsolved. In this paper, we restrict our focus to the problem of understanding questions in technical support and retrieving relevant resolution documents from a corpus of support content. While a complete automation system would also tackle the challenging problem of identifying the troubleshooting/diagnostic procedure from these documents, we assume that a returned "relevant" document contains procedures required for resolving the problem.

As identified in (Gupta et al., 2017) technical support problems are complex, and involve various attributes like failing entities, a detailed description of the problem (symptom), steps taken in an effort to remediate the failure (activity), and sometimes a specific request or ask (intent). Consider two actual support problems in Figure 1 from the software and the hardware domains. The hardware query comprises a problem description with the entity "tape drive", mentioning the symptom "stuck" and an unsuccessful

DB2 Open	105.87

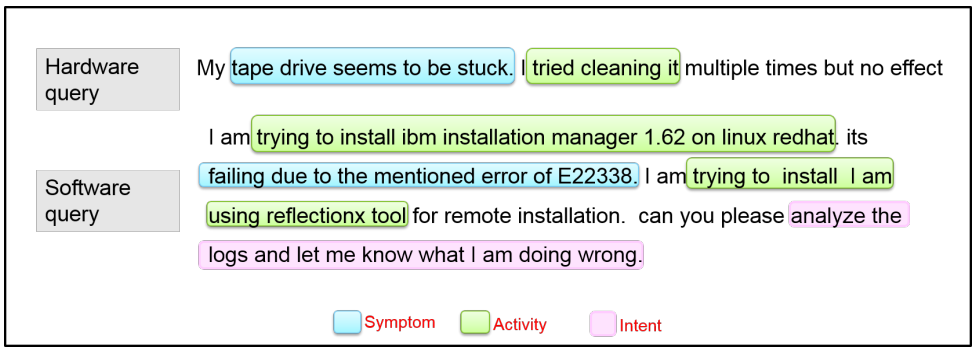

Figure 1: Illustration of Annotation of attributes on a Support ticket

attempt to mitigate the problem by "cleaning". The software question describes relevant details regarding the "failing installation". It also contains an explicit ask from the technician for "analysis of log files". State-of-the-art information retrieval based systems which depend on keywords do not perform well on such queries. For example, without an understanding of the hardware problem description and its attributes, the system might return pages which suggest cleaning the tape drive. For the software query, understanding the explicit ask of log analysis is key to a relevant response. This inherent complexity of questions in this domain differentiates it from traditional Question Answering or Information Retrieval problems. Table 1 compares the average length of questions in popular open QA datasets - WikiQA (Yang et al., 2015) and TREC 2007 QA (Dang et al., 2007), to two datasets in the domain of technical support that we curated. For effective retrieval of documents, it is essential that we extract these attributes (removing noise), and implement reasoning on top.

In this paper, we present a method for semantic parsing of support questions, to extract these attributes, which uses rules based on the grammatical structure of sentences. To the best of our knowledge, we are first to address the complexities of problems in technical support by identifying pertinent semantic attributes, extracting them, and proving their usefulness in retrieving relevant results.

In section 2 we present existing related work. In section 3, we present the details of our model for semantic parsing. The goal of extracting these attributes, however, is to improve quality of returned documents. To emphasize the importance of extracting these attributes, we show marked improvements in retrieval. The datasets used for experiments are discussed in 4 and evaluations are presented in section 5. We conclude the paper with a discussion of the learnings from evaluation and analysis, and directions for future research in section 6.

2 Related Work

The problem of answering natural language questions has received significant attention from the natural language processing research community. Dependency and simple phrase structure grammar models have been around for a while for understanding natural language text. The authors in (de Marneffe and Manning, 2008) parse grammatical relations from text for automated understanding. In Watson Jeopardy (McCord et al., 2012), authors use slot grammar parsing (McCord, 1990b) that decomposes the natural language text to slots, which is widely used for applications like question analysis (McCord et al., 2012), question decomposition, knowledge extraction for QA (Fan et al., 2012), relation extraction,

(Wang et al., 2012), candidate generation (Lally et al., 2012), and analysis and gathering of textual evidence (Murdock et al., 2012). Works focusing on understanding user intent use classifier models or dependency parsing schemes (Li and Roth, 2006; Metzler and Croft, 2005). Other recent works build neural models that represent a question as a continuous-valued vector (Chen et al., 2016). The key difference in these approaches and our problem setting is that they usually work on simpler, entity seeking questions. However questions in support are usually very complex, contain multiple attributes describing the situation that leads to a failure, attempts made to resolve the problem, and explicit asks. The answers to these questions are usually diagnostic or troubleshooting procedures contained in documents which need to be searched based on an understanding of the problem.

(Vtyurina and Clarke, 2016) tackle open domain complex questions by learning keywords from a large supervised dataset of questions and answers. Extraction of such keywords from questions certainly helps retrieval by removing noise. However, in technical support, the multiple types of attributes necessitate their separate extraction and reasoning. "Activity" words extracted from the question as keywords would hurt retrieval unless they are correctly identified, and their matching score is reduced. But, the same word if present as "Intent" would certainly help improve retrieval and their matching score would need to be boosted. Finally, (Yang et al., 2017) presents a system which improves the state of the art for technical support question answering. Their work is complementary to ours, as they address the problem of knowledge representation by constructing a knowledge graph from content and do not delve into the complexities of technical support problems.

To the best of our knowledge, ours is the first attempt that defines important finer attributes in technical support questions, proposes a model to extract them, and performs reasoning to retrieve relevant results.

3 Semantic Parsing And Reasoning

As explained earlier, we identify the following three attributes for technical support questions:

1. **Symptom** - A description of what's failing
2. **Activity** - Steps that have been tried to remediate the problem
3. **Intent** - A specific request or ask

Questions can contain multiple of each attributes. Because of this inherent complexity, it is imperative to parse these attributes for retrieving relevant results. Table 2 shows the frequency distribution of the different attributes in the training set.

Formally, the problem of semantic parsing is formulated as follows. Given a support question Q, which is comprised of a sequence of tokens - $Q = [q_1, q_2, .., q_n]$, we want to extract three sequences S, A and I which denote the symptoms, activities and intents (these sequences are not necessarily contiguous, allowing for multiple symptoms, activities, and intents in the same question).

We present a Semantic Parser to extract these attributes from questions using rules built on the grammatical structure of sentences. We also present a Conditional Random Field model, which, in the presence of large amount of supervision, outperforms the rule based Semantic Parser. However, such annotations are expensive to curate. Details of both the models are presented below.

3.1 Semantic Parser

There are several natural language parsers that allow tokenization and POS tagging. Some also provide a simple description of the grammatical relations in a sentence, but this is not sufficient for several applications. Slot Grammar system has a lexicalist character and treats different grammatical structures in a language independent manner through different rule types. IBM Watson uses two deep parsing components: English Slot Grammar (ESG) followed by Predicate Argument Structure (PAS) for linguistic analysis of text (McCord, 1990a).

ESG works on a sentence to produce a parse tree which has a deep structure (logical analysis) and a surface structure (grammatical analysis). PAS simplifies the ESG parse tree structure to the core semantic meaning. PAS forms a labeled directed graph which is more flexible and requires less knowledge than

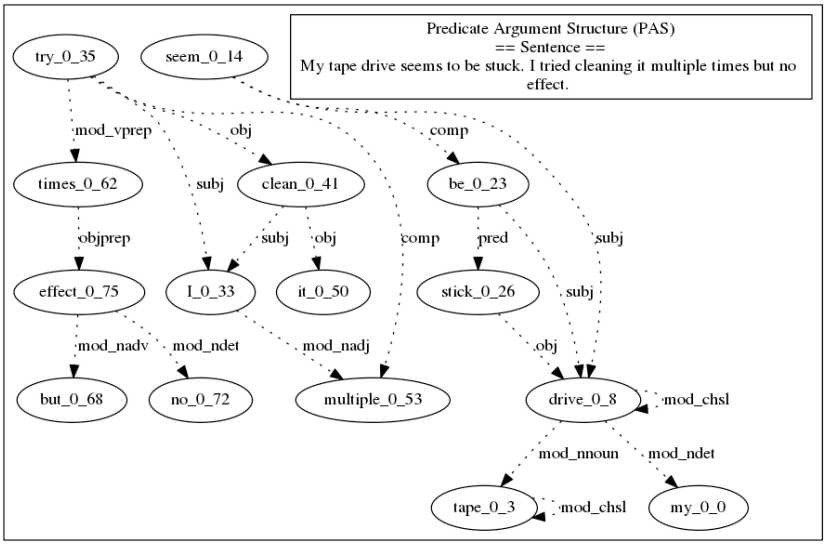

Figure 2: Sample PAS tree

```
pattern = there_is_np(@1) -> vp0[hasLemmaForm("be"),!hasParseFeature("q")]
{
        subj -> var0[hasLemmaForm("there")]
}
{
        pred -> vp1[hasLemmaForm("@1")]
}
```

Figure 3: Example of template that captures cases like “there is error”, “there was error”. “@1” would be replaced by a dictionary word such as *error message, symptom, blocker, expiration, or limitation*

ESG. PAS combines the two dimensions of ESG by omitting nodes with auxiliary verbs, closed class nodes introducing verb phrases, determiners (except for high semantic determiners), forms of *be* with no predicate and with adjective predicate. The negation annotator modifies the standard PAS by retaining some of these nodes, and we use the negation annotator to identify symptoms/problems like *does not work, cannot boot* from a question. Figure 2 shows an PAS tree structure for a sample sentence. While ESG retains syntactic information, PAS only represents semantics. Sentences with a similar meaning but different structures (like the active and passive form of the same sentence), would have varying ESG parses but the same PAS parse. Therefore, it is much more efficient to create patterns on the PAS tree than the ESG tree.

To obtain the attributes from user utterances, we create patterns to be matched to the input query. These patterns are essentially rules written on top of the slot grammar. Since manually specifying all possible rules can get cumbersome, templates are used to represent these patterns. Figure 3 presents a sample template for extracting symptoms like “there is/was an error”. These templates are combined with the dictionary words identified for each attribute (symptom, activity and intent) to form rules that are matched to the PAS tree for extraction. Text spanned by the ESG node, corresponding to the matched PAS node, is extracted and marked as the annotation output for the corresponding attribute. The base lexicon in ESG is augmented with support specific terminologies and Word-Net for wider coverage. Additionally, multi-word entries were added into chunk lexicons to obtain multi-word phrases as a single node in the PAS tree.

3.2 CRF based Parser

The task of extracting attributes from technical support problems can be formulated as a sequence labeling problem. This follows from the observation that these attributes manifest in a rough order -

symptoms, followed by attempts to mitigate, and finally explicit requests. Context words are also important in identifying spans of text for these attributes. CRFs are graphical models that can capture such dependencies among input observations (Lafferty et al., 2001). A CRF defines a conditional distribution $p(y|x)$ where *y* is the corresponding label sequence and *x* is the observed data sequence.The current label at time step t, y_t can be dependent on any of the previous *n* labels, and all the observations in an *n*-order CRF. In our case, the input sequence *x* corresponds to a series of words, while the label sequence *y* corresponds to the symptom, activity, intent or other assigned to the input sequence. The probabilistic model of a label sequence given some sequence of words is mediated in this model through a set of weighted functions f_i:

$$p(y|x) = \frac{exp(\sum_i \sum_t w_i f_i(y_{t-1}, y_t, x, t))}{Z(x)}$$

where the w_i are the weights assigned by the learning algorithm, and $Z(x)$ is a normalization factor over all label sequences.

For training, a manually annotated set of support questions is used. Spans are labeled with the B-I-O encoding, where each word in the query is annotated with one of the following classes (labels): the beginning of a symptom (B-S), inside of a symptom (I-S), the beginning of an activity (B-A), inside of an activity (I-A), the beginning of an intent (B-I), inside of an intent (I-I) or other (O).

To conduct our experiments, we used the linear-chain Stanford CRF implementation (Finkel et al., 2005) . We used current word, previous word, next word, current word character n-gram ($n \leq 6$), presence of word in left window (size = 4), presence of word in right window (size = 4), position of word in the sentence, and current POS tag as features computed using the Stanford NER toolkit.

3.3 Reasoning

We need to use the extracted attributes to perform reasoning on the retrieved results. For example, for the problem in Figure 1, we would not want to return back to the user, pages which detail a procedure for cleaning the tape drive. Similarly, when a user specifies a particular intent, we would ideally like to prioritize matches with this intent over matches with the symptom which might include other diagnostic or resolution procedures. For specifying these priorities, we create a module that weighs query fields in the retrieval engine based on the attribute type of the field. Query fields containing intents are given the highest weights, symptom containing query fields are given slightly lower weight, and fields with activity are given negative weights to suppress results matching this field. The actual values for weights are determined empirically.

4 Dataset and Experimental Setup

Training and evaluation of our parser models is done on a proprietary dataset of 1972 actual customer problems. These utterances have been manually annotated with the identified attributes by SMEs. 80% of this data is set aside for training and validating the CRF model. The rest of the data is used for evaluating both models.

Evaluation of retrieval results is done on two datasets which we call DB2 Prop, and DB2 Open, both of which contain questions and relevant answer links for DB2. The DB2 Prop dataset consists of proprietary user problems for which the correct answer url is provided by SMEs. The DB2 Open dataset is crawled from the developer works website [1]. It consists of user questions and urls extracted from "accepted" answers for those questions. We get manual annotations of attributes on 96 questions from DB2 Prop, and 48 questions from DB2 Open dataset from SMEs, and use these to evaluate retrieval performance.

For evaluation of retrieval results, we use elastic search as the retrieval index. The corpus is a crawl of publicly available technote pages [2] for the DB2 product, which are majority of the answers for both the DB2 Prop and DB2 Open datasets. From the downloaded pages, we extract and index the title and content of the body as document fields. The whole text of the problem is sent to this index (on both document

CRF	78.3	71.20	74.33

fields) as a baseline. The query containing the Semantic Parser extractions are sent with weights on query fields as described in section 3.3.

5 Evaluation

In this section we evaluate our system along two dimensions -

1. Precision, recall and F1 score for the extractions from the Semantic Parser and CRF
2. Relevance of the retrieved results between a whole query baseline and Semantic Parse based query

5.1 Evaluation of Attribute Extraction Models

Since annotations of these attributes were not readily available to us, we had Subject Matter Experts (SMEs) manually annotate 1972 questions from a proprietary ticketing system. The SMEs were asked to identify spans from questions which indicate the problem, efforts in resolving the problem, and explicit requests. 80% of these questions were used for training the CRF model, and the rest were used for evaluating both models. The distribution of symptom, activity and intent in our training dataset is shown in the Table 2. Longer more complex queries often had multiple symptoms, intent and activity (distributions shown in table 2).

As we can see, a large number of support questions have multiple symptoms. We designed two scoring schemes: strict scoring, where an extraction is marked correct only when all the values from ground truth are identified; and partial scoring, where the extraction is marked correct if any one of the values from ground truth is identified. The partial scoring scheme would not harshly evaluate models when most, but not all values of an attribute are extracted. Tables 3 and 4 summarize the performance of all the models. We present results on the strict scoring scheme only for symptoms, since there are very few questions with multiple activities and intents. For an attribute which has just one value in the ground truth, strict and partial scoring are the same. In Table 3, we note that CRF does the best in extracting multiple symptoms. The main reason is that CRF uses feature as well as contextual modeling of the words in the sentence. It inherently being a sequential labeling algorithm, accounts for its 78% precision in identifying all symptoms.

Note that CRF is a supervised learning model and needs manually annotated training data. The rule based Semantic Parser does not have this limitation and instead uses linguistic pattern matching on dependency trees. This renders it more generic and can be applied to problems from other products with minimal intervention. With a typical big service provider supporting close to 7-8k products, this is a useful property. We observe that the CRF outperforms the rule based Semantic Parser on Symptoms for which we have an abundance of training examples. For the other two attributes, the Semantic Parser is slightly better than the CRF.

Table 4: Performance (%) Comparison (Symptom, Activity and Intent): Partial Scoring

Model	Symptom			Activity			Intent		
	Precision	Recall	F1	Precision	Recall	F1	Precision	Recall	F1
Semantic Parser	67.81	58.84	62.17	71.33	37.2	48.64	88.44	59.29	70.63
CRF	88.64	81.60	84.35	70.0	33.33	44.85	93.74	48.67	64.07

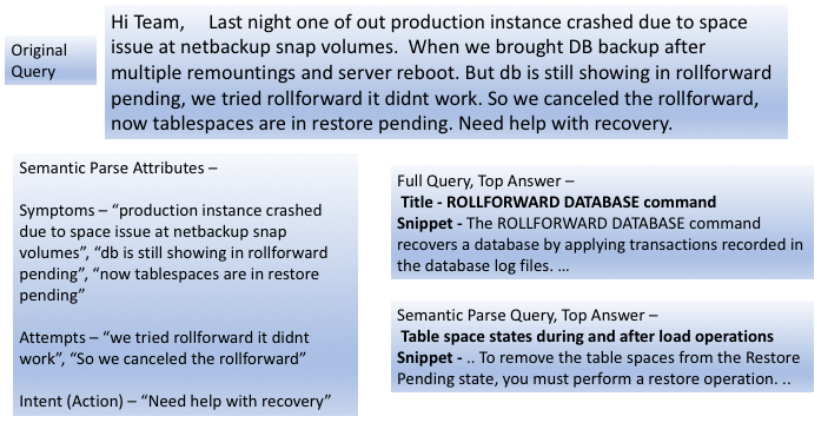

Figure 4: Question with extractions and retrieved results

5.2 Evaluation of retrieved results

As explained in the setup, evaluation of retrieved results is performed using elastic search. Figure 4 gives an example of the top retrieved results using the original query and the Semantic Parse attributes. The baseline query consists of the whole question, and extractions from the Semantic Parser are weighed according to the attribute-type in the reasoner. The highest weight is given to intent extractions, and a negative weight is assigned to attempt extractions. We see that because of repetitions of the token "rollforward" in the original query, the top result returned is about the "ROLLFORWARD DATABASE command". When we give a negative weight to the attempt Semantic Parse extraction, and increase the weight of the symptom extraction (although less than that of the intent extraction), the result about "Table space states" bubbles to the top.

The retrieval results (Precision@k) on the two datasets are presented in Table 5. Precision@k measures the fraction of questions with the correct answer in the top k results.

$$Precision@k = \frac{n_k * 100}{N} \tag{1}$$

where n_k is the number of questions with the correct answer in top k results, and N is the total number of questions.

We see a slight improvement in P@1 on the DB2 Prop dataset, and a 42.9% improvement in P@5. However, on the DB2 Open dataset, we see very slight improvement on the P@1 and no improvement in P@5. On further analysis we find that there are two reasons for this. Firstly, we find that for a large number of the queries, the answer marked as the ground truth is only partially related to the solution, and sometimes it is completely different. Since the accepted answer was assumed to be correct and there is no manual verification of the correctness in this dataset (unlike in DB2 Prop), we find that the confidence on ground truth in DB2 Open is low. Another reason we find is that in DB2 Open, people often attach code snippets and stack traces in the question, which can easily be understood by humans but are difficult for the models to annotate. Identifying and extracting out (and in the future, understanding) these code snippets and stack traces, would improve the accuracy on this dataset further.

Table 5: Retrieval Performance (P@k)

Model	DB2 Prop			DB2 Open		
	P@1	P@3	P@5	P@1	P@3	P@5
Whole Query	7.29	14.58	28.13	25.0	33.33	37.5
Semantic Parse Query	9.38	19.79	40.63	27.08	31.25	37.5

6 Discussion and Future Work

Through our experiments, evaluation and error analysis, we stumble across a number of problems that can be addressed to improve understanding of technical support questions, and increase retrieval accuracy. Some of the interesting problems are detailed below -

- **Sub-division of Activity** Through careful analysis of activity extractions, we find that it can further be split into two classes that help better understanding of the question. The first class are actions or steps that were taken before the problem occurred. For example, in the snippet - *We tried to upgrade the DB2 AESE ON RHEL from 10.5.5 to 11.1 and in upgrade check got orphan rows*, "trying to upgrade DB2" is not a step taken to remediate the problem, but the action that resulted in the error. The second class are actions that are taken to remediate the problem (the activity extraction in figure 4). It is clear that we would not want to exclude documents/procedures containing tokens from the first class from appearing in the results. The challenge with creating such a distinction, we find, is that examples from both these classes manifest in very similar linguistic patterns. Correct distinction between these two classes would probably require us to use position features from the symptom extraction.

- **Identify Stack Traces, Core Dumps, and Code Snippets** As identified in section 5.2, stack traces, core dumps, and code snippets, confuse the Semantic Parser. Returning these poor extractions hurts retrieval performance. Further, if we could truly understand these sections in the way humans do, it would certainly increase efficiency of retrieval.

- **Noisy Intent Extractions** Extraction of patterns like "please help" or "please suggest resolution" as intent, creates noise for retrieval. Such extractions could be filtered if they do not contain entity or action keywords from the domain.

- **Semantic Parsing performance** - We see that the CRF models outperforms the Semantic Parser in the presence of large amounts of training data by leveraging contextual features. However, for cases where training data is not available, it fails to reach comparable performance with the rule based parser. The Semantic Parser also has the advantage of being easily generalizable across products as it works with the semantic parse of sentences. An ideal model would be able to combine these two strengths, being generalizable and being able to leverage contextual features.

Abstract

A great proportion of sequence-to-sequence (Seq2Seq) models for Neural Machine Translation (NMT) adopt Recurrent Neural Network (RNN) to generate translation word by word following a sequential order. As the studies of linguistics have proved that language is not linear word sequence but sequence of complex structure, translation at each step should be conditioned on the whole target-side context. To tackle the problem, we propose a new NMT model that decodes the sequence with the guidance of its structural prediction of the context of the target sequence. Our model generates translation based on the structural prediction of the target-side context so that the translation can be freed from the bind of sequential order. Experimental results demonstrate that our model is more competitive compared with the state-of-the-art methods, and the analysis reflects that our model is also robust to translating sentences of different lengths and it also reduces repetition with the instruction from the target-side context for decoding.

1 Introduction

Deep learning has achieved tremendous success in machine translation, outperforming the traditional linguistic-rule-based and statistical methods. In recent studies of Neural Machine Translation (NMT), most models are based on the sequence-to-sequence (Seq2Seq) model based on the encoder-decoder framework (Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014; Cho et al., 2014) with the attention mechanism (Bahdanau et al., 2014; Luong et al., 2015). While traditional linguistic-rule-based and statistical methods of machine translation require much work of feature engineering, NMT can be trained in the end-to-end fashion. Besides, the attention mechanism can model the alignment relationship between the source text and translation (Bahdanau et al., 2014; Luong et al., 2015), and some recent improved versions of attention have proved successful in this task (Tu et al., 2016; Mi et al., 2016; Meng et al., 2016; Xiong et al., 2017; Vaswani et al., 2017).

However, the decoding pattern of the recent Seq2Seq models is inconsistent with the linguistic analysis. As the conventional decoder translates words in a sequential order, the current generation is highly dependent on the previous generation and it is short of the knowledge about future generation. Nida (1969) pointed out that translation goes through a process of analysis, transfer and reconstruction, involving the deep syntactic and semantic structure of the source and target languages. Language generation involves complex syntactic analysis and semantic integration, instead of a step-by step word generation (Frazier, 1987). Moreover, from the perspective of semantics and pragmatics, the syntactic analysis of utterance can be guided by the global lexical-semantic and discourse information (Altmann and Steedman, 1988; Trueswell et al., 1994, 1993; Tyler and Marslen-Wilson, 1977). In brief, the process of translation is in need of the global information from the target-side context, but the decoding pattern of the conventional Seq2Seq model in NMT does not meet the requirement.

Recent researches in NMT have taken this issue into consideration by the implementation of bidirectional decoding. Some methods of bidirectional decoding (Liu et al., 2016; Cong et al., 2017) rerank the candidate translations with the scores from the bidirectional decoding. However, these bidirectional

Proceedings of the 27th International Conference on Computational Linguistics, pages 3260–3271
Santa Fe, New Mexico, USA, August 20-26, 2018.

decoding methods cannot provide effective complementary information due to the limited search space of beam search.

In this article, we extend the conventional attention-based Seq2Seq model by introducing the deconvolution-based decoder, which is a Convolutional Neural Network (CNN) to perform deconvolution. Recently, deconvolution has been applied to the studies of natural language (Zhang et al., 2017; Shen et al., 2017), which can be regarded as the transposition of the convolution (Long et al., 2015; Noh et al., 2015). Zhang et al. (2017) applied this method to natural language by modeling sentences with a convolution-deconvolution autoencoder. The study of Zhang et al. (2017) showed that the deconvolution solves the problems by reconstructing a representation of high quality irrespective to the order or length. It can be found that deconvolution owns the potential to provide global information for guidance of decoding. Therefore, we follow this idea and propose a new model with deconvolution for NMT.

To be specific, the conventional RNN encoder encodes the source sentences to new representations and sends the final state to the decoder, and the conventional RNN decoder decodes it to the target sentences with the attention to the encoder outputs. In our model, our designed deconvolution-based decoder decodes the final state of the encoder to a matrix representing the global information of the target-side contexts. Each column of the matrix is learned to be close to the word embedding of the target words. The conventional RNN decoder can attend to the columns for the information of the target-side context to perform global decoding in the translation.

Our contributions in this study are illustrated in the following:

- We propose a new model for NMT, which contains a deconvolution-based decoder to provide global information of the target-side contexts to the RNN decoder, so that the model is able to perform global decoding[1].
- Experimental results demonstrate that our model outperforms the baseline models in both the Chinese-to-English translation and the English-to-Vietnamese translation, outperforming the Seq2Seq model in the BLEU score evaluation with the advantages of BLEU score 2.82 and 1.54 respectively.
- The analysis shows that our model that performs global decoding is more capable of reducing repetition and more robust to the translation of sentences of different lengths, and the case study reflects that it is able to capture the syntactic structure for the translation and has a better reflection of the semantic meaning of the source text.

2 Model

In the following, we introduce the details of our model, including the encoder, the deconvolution-based decoder and the conventional RNN-based decoder. The functions of each decoder are illustrated below to show how they collaborate to improve the quality of the translation.

2.1 Encoder

In our model, the encoder reads the embeddings of the input text sequence $x = \{x_1, ..., x_n\}$ and encodes a sequence of encoder outputs $h = \{h_1, ..., h_n\}$. The final hidden state h_n is sent to the decoder as the initial state for it to decode a sequence of output text. The encoder outputs provide the information of the source-side contexts to our RNN-Based decoder through the attention mechanism.

The encoder in our model is a bidirectional LSTM (Hochreiter and Schmidhuber, 1997), which reads the input in two directions to generate two sequences of hidden states $\overrightarrow{h} = \{\overrightarrow{h_1}, \overrightarrow{h_2}, \overrightarrow{h_3}, ..., \overrightarrow{h_n}\}$ and $\overleftarrow{h} = \{\overleftarrow{h_1}, \overleftarrow{h_2}, \overleftarrow{h_3}, ..., \overleftarrow{h_n}\}$, where:

$$\overrightarrow{h_i} = LSTM(x_i, \overrightarrow{h_{i-1}}, C_{i-1}) \quad (1)$$

$$\overleftarrow{h_i} = LSTM(x_i, \overleftarrow{h_{i-1}}, C_{i-1}) \quad (2)$$

The encoder outputs corresponding to each time step are concatenated as $h_i = [\overrightarrow{h_i}; \overleftarrow{h_i}]$.

[1]The code is released in `https://github.com/lancopku/DeconvDec`

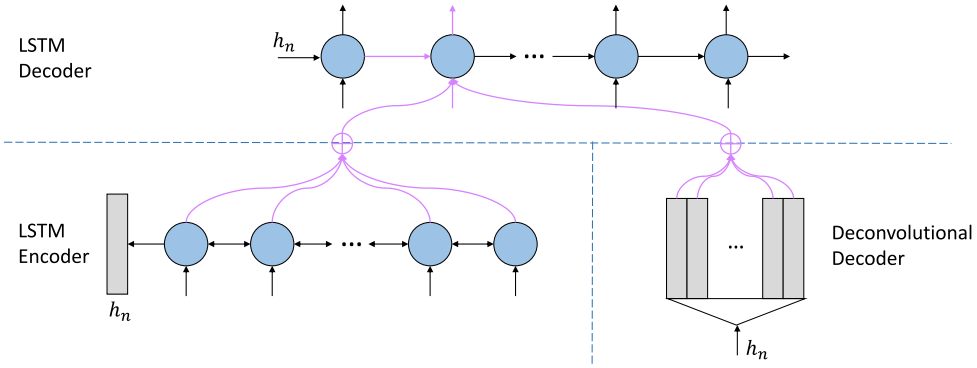

Figure 1: Model architecture. There are three components in the proposed model, i.e., the LSTM encoder, the deconvolution-based decoder, and the conventional LSTM decoder. The encoder distills the input sentence into a state h_n, which is then used in the deconvolution-based decoder to obtain the global information of the target-side contexts. Based on the target-side contexts and the input-side contexts, the conventional LSTM decoder generates the output from the state h_n.

2.2 Deconvolution-Based Decoder

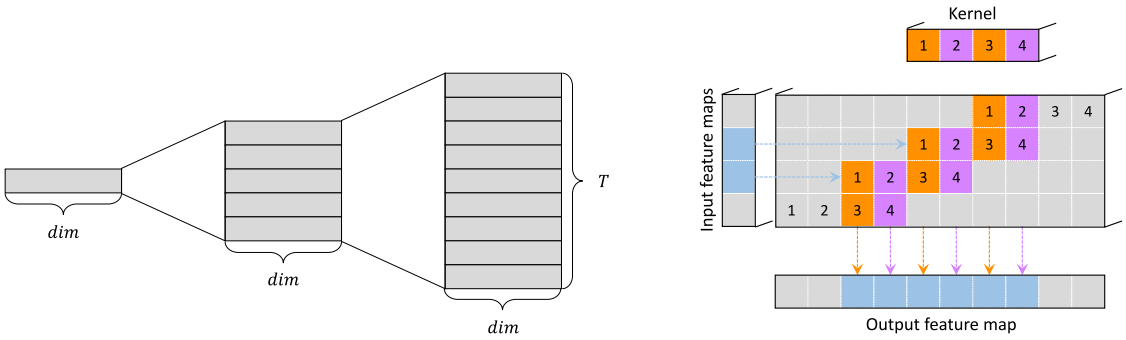
In our model, there are two decoders, which perform different tasks for the whole decoding process. While the RNN-based decoder is similar to the conventional decoder, which decodes the output text sequence in a sequential order and attends to the annotations of the encoder via the attention mechanism, our proposed deconvolution-based decoder does not decode the text but provide global information of the target-side contexts to the RNN-based decoder so that it can decode structurally instead of sequentially. To be specific, the deconvolution-based decoder learns to generate the word embedding matrix of the target text sequence.

In order to provide global information of the target-side contexts to the RNN decoder, we implement a multilayer CNN as the deconvolution-based decoder to perform deconvolution. With deconvolution, it is available for a vector or a small matrix to be transformed to a large matrix. In our model, the deconvolution is implemented on the final states in both directions from the encoder. As words in our model are represented with word embedding vectors, sentences can be formed as word embedding matrices. In our model, the deconvolution-based decoder is designed to learn word embedding matrices of the target sequences with the representation matrix from the encoder. As the conjugate operation of convolution, deconvolution expands the dimension of the input representation to a matrix of our designed size. There are L layers in the deconvolution, each of which has f_l filters of kernel size k_l. The i^{th} filter $W_l^i \in R^{k \times dim}$ (dim refers to the size of the input representation vector) with stride s_l^i and padding p_l^i performs deconvolution on the input representation matrix $I \in R^{m \times dim}$ ($m \times dim$ refers to the size of the input representation matrix), the final hidden state of the encoder. The computation of convolution is illustrated as below:

$$c_l^i = g(W_l^i * X + b) \tag{3}$$

where X refers to the convolved matrix and g refers to non-linear activation function, which is ReLU (Nair and Hinton, 2010) following Zhang et al. (2017), and deconvolution is its transposed operation. With the input I, our objective of the deconvolution operation is to generate a word embedding matrix $E \in R^{T \times dim}$ where T refers to the sentence length designed for the output text sequence, which is a hyper-parameter. At the l^{th} layer, deconvolution generates a matrix $E_l \in R^{T_l \times dim}$ where $T_l = T_{l-1} \times s_l + k_l - 2 \times p_l$. With the control of stride and kernel size, the height of the matrix can be assigned, and with the control of the number of filters, the width of the matrix can also be assigned. In our model, they are the length of the output sequence and the dimension of the word embedding respectively.

The deconvolution-based decoder can generate meaningful representation with information different from that in the conventional RNN decoder. The conventional RNN decoder generates sequence in a way similar to Markov Decision Process, which is highly dependent on the previous generation and follows



(a) Deconvolution-based decoder. (b) Deconvolution.

Figure 2: Deconvolution-based decoder. On the right shows an example of a 1d deconvolution on a input of size 2 with a kernel of size 4, a padding of 1 and, a stride of 2. The depth means the dimension of the channel, which is dim in our case.

a strict sequential order, so it contains high sequential dependency. On the contrary, the deconvolution-based decoder generates a word embedding matrix depending on the representation from the encoder without considering the order, which does not have the problem of long-term dependency. Moreover, although it is not capable as the RNN encoder to generate coherent text, it reveals the information of the text from a global perspective, including syntactic and semantic features.

2.3 RNN-Based Decoder

Different from the deconvolution-based decoder, the RNN-based decoder is responsible for decoding the representation h_n to generate the translation $y = \{y_1, ..., y_m\}$. With the final encoder state as the initial state, the decoder is initialized to decode in sequential order, until it generates the token representing the end of sentence. During decoding, the attention mechanism is applied for the decoder to extract the information from the source-side contexts, which are the annotations of the encoder, as well as the information from the target-side contexts, which are the outputs of the deconvolution-based decoder.

For the RNN-based decoder, we implement a unidirectional LSTM. The output of the RNN-based decoder at each time step is sent into a feed-forward neural network to be projected into the space of the target vocabulary $Y \in R^{|Y| \times dim}$ for the prediction of the translated word. At each time step, the decoder generates a word y_t by sampling from a conditional probability distribution of the target vocabulary P_{vocab}, where:

$$P_{vocab} = softmax(W_o v_t) \tag{4}$$

$$v_t = g(s_t, c_t, \tilde{c}_t) \tag{5}$$

$$s_t = LSTM(y_{t-1}, s_{t-1}, C_{t-1}) \tag{6}$$

where $g(\cdot)$ refers to non-linear activation function, and c_t and $\tilde{c}_t$ are the outputs of the attention mechanism, which are illustrated in the following.

The attention mechanism in our model is the global attention mechanism (Luong et al., 2015). Different from the conventional attention mechanism, which only computes the attention scores on the source-side contexts, the attention mechanism in our model consists of two parts. The first one is similar to the conventional one, attending to the source-side contexts from the encoder, but the second one is original, which attends to the target-side contexts, which is the word embedding matrix generated by the deconvolution-based decoder. By attending to the encoder annotations, the model computes the attention $\alpha_{t,i}$ of the RNN-based decoder output s_t on the annotations of the encoder h_i and generates the context vector c_t. Similarly, by attending to the outputs of the deconvolution-based decoder, the RNN-based decoder computes the attentions of s_t on each column E_i of its matrix E and generates the context vector

$\tilde{c}_t$:

$$c_t = \sum_{i=1}^{n} \alpha_{t,i} h_i \tag{7}$$

$$\tilde{c}_t = \sum_{i=1}^{n} \tilde{\alpha}_{t,i} E_i \tag{8}$$

where $\alpha_{t,i}$ and $\tilde{\alpha}_{t,i}$ are defined as below (as they are computed in the same way, they are both represented by $\alpha_{t,i}$ and the annotations are represented by x_i):

$$\alpha_{t,i} = \frac{exp(e_{t,i})}{\sum_{j=1}^{n} exp(e_{t,j})} \tag{9}$$

$$e_{t,i} = s_{t-1}^{\top} W_a x_i \tag{10}$$

2.4 Training

The training for the Seq2Seq model is usually based on maximum likelihood estimation. Given the parameters θ and source text x, the model generates a sequence $\tilde{y}$. The learning process is to minimize the negative log-likelihood between the generated text $\tilde{y}$ and reference y, which in our context is the sequence in target language for machine translation:

$$\mathcal{L} = -\frac{1}{N} \sum_{i=1}^{N} \sum_{t=1}^{T} \log P(y_t^{(i)} | \tilde{y}_{<t}^{(i)}, x^{(i)}, \theta) \tag{11}$$

where the loss function is equivalent to maximizing the conditional probability of sequence y given parameters θ and source sequence x.

However, as there are two decoders in our model, the loss function should also be designed for the deconvolution-based decoder. In our model, we compute the smooth L1 loss between the generated matrix of the deconvolution-based decoder E and the word embedding matrix $\tilde{E}$ (which both contain M elements), which is more robust to outliers (Girshick, 2015), as well as the cross-entropy loss between the prediction of the deconvolution-based decoder $\hat{y}$ and reference y given the parameters of the encoder and the deconvolution-based decoder $\theta^{'}$. Therefore, the generated matrix E can be closer to the word embedding matrix $\tilde{E}$, and it contains information beneficial to the prediction of the target words. Moreover, for the cross entropy loss of the deconvolution-based decoder, we apply the method of Ma et al. (2018a) as it increases no parameter for the prediction by computing the cosine similarity between the output and the word embeddings. To sum up, the loss function is defined as below:

$$\mathcal{L} = -\frac{1}{N} \sum_{i=1}^{N} (\sum_{t=1}^{T} \log P(y_t^{(i)} | \tilde{y}_{<t}^{(i)}, x^{(i)}, \theta) + \sum_{m=1}^{M} smooth_{L1}(E_m - \tilde{E}_m) + \sum_{t=1}^{T} \log P(y_t^{(i)} | x^{(i)}, \theta^{'})) \tag{12}$$

where smooth L1 loss is defined below:

$$smooth_{L1}(x, y) = \begin{cases} 0.5 \mid\mid x - y \mid\mid_2^2 & \text{if } \mid\mid x - y \mid\mid < 1 \\ \mid\mid x - y \mid\mid_1 - 0.5 & \text{if } \mid\mid x - y \mid\mid \geq 1 \end{cases} \tag{13}$$

We have tested L1 loss, L2 loss as well as smooth L1 loss in our experiments and found that smooth L1 loss encourages the model to reach the best performance.

3 Experiment

3.1 Datasets

We evaluate our proposed model on the NIST translation task for the Chinese-to-English translation and provide the analysis on the same task. Moreover, in order to evaluate the performance of our model on

the low-resource translation, we also evaluate our model on the IWLST 2015 (Cettolo et al., 2015) for the English-to-Vietnamese translation task.

Chinese-to-English Translation For the NIST translation task, we train our model on 1.25M sentence pairs extracted from LDC2002E18, LDC2003E07, LDC2003E14, Hansards portion of LDC2004T07, LDC2004T08 and LDC2005T06, with 27.9M Chinese words and 34.5M English words. Following Wang et al. (2016), we validate our model on the dataset for the NIST 2002 translation task and tested our model on that for the NIST 2003, 2004, 2005, 2006 translation tasks. We use the most frequent 30K words for both the Chinese vocabulary and the English vocabulary, which includes around 97.4% and 99.5% of the Chinese and English words in the training data. The sentence pairs longer than 50 words are filtered. The evaluation metric is BLEU (Papineni et al., 2002).

English-to-Vietnamese Translation The data is from the translated TED talks, containing around 133K training sentence pairs provided by the IWSLT 2015 Evaluation Campaign (Cettolo et al., 2015). We follow the studies of Huang et al. (2017), and use the same preprocessing methods as well as the same validation and the test set. The validation set is the TED tst2012 with 1553 sentences and the test set is the TED tst2013 with 1268 sentences. The English vocabulary is 17.7K words and the Vietnamese vocabulary is 7K words. The evaluation metric is also BLEU score.

3.2 Setting

We implement the models on PyTorch[2], and the experiments are conducted on an NVIDIA 1080Ti GPU. Both the size of word embedding and the number of units in the hidden layers are 512, and the batch size is 64. We use Adam optimizer (Kingma and Ba, 2014) to train the model with the setting $\beta_1 = 0.9$, $\beta_2 = 0.98$ and $\epsilon = 1 \times 10^{-9}$ following Vaswani et al. (2017), and we initialize the learning rate to 0.0003.

Gradient clipping is applied so that the norm of the gradients cannot be larger than a constant, which is 10 in our experiments. Dropout is used with the dropout rate set to 0.3 for the Chinese-to-English translation and 0.4 for the English-to-Vietnamese translation, based on the performance on the validation set.

Based on the performance on the validation set, we use beam search with a beam width of 10 to generate translation for the evaluation and test, and we normalize the log-likelihood scores by sentence length.

3.3 Baselines

For the Chinese-to-English translation, we compare our model with the state-of-the-art NMT systems for the task.

- **Moses** An open source phrase-based translation system with default configurations and a 4-gram language model trained on the training data for the target language;
- **RNNsearch** An attention-based Seq2Seq with fine-tuned hyperparameters (Bahdanau et al., 2014);
- **Coverage** The method extends RNNSearch with a coverage model for the attention mechanism that tackles the problem of over-translation and under-translation (Tu et al., 2016);
- **Lattice** The Seq2Seq model with a word-lattice-based RNN encoder that tackles the problem of tokenization in NMT (Su et al., 2016);
- **InterAtten** The Seq2Seq model that records the interactive history of decoding (Meng et al., 2016);
- **MemDec** Based on the RNNSearch, it is equipped with external memory that the model reads and writes during decoding (Wang et al., 2016).

For the English-to-Vietnamese translation, we compare our model with the recent NMT models for this task, and we present the results of the baselines reported in their articles.

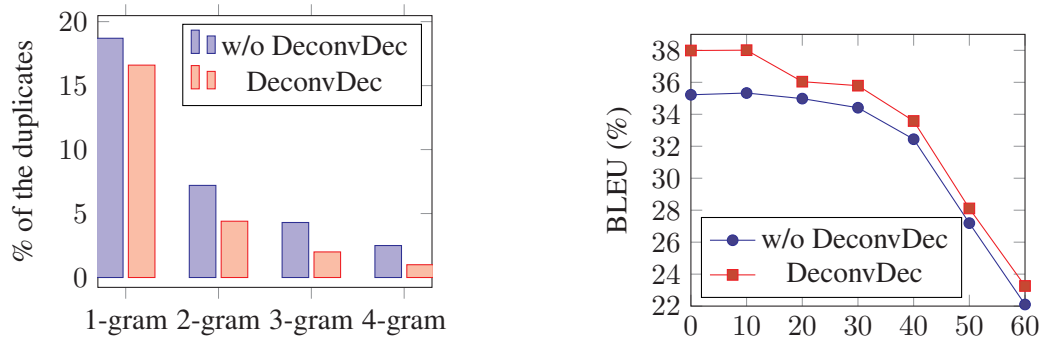
4 Results and Analysis

4.1 Results

Table 1 shows the overall results of the models on the Chinese-to-English translation task. Beside our reimplementation of the attention-based Seq2Seq model, we report the results of the recent NMT models, which are results in their original articles or improved results of the reimplementation. To facilitate fair comparison, we compare with the baselines that are trained on the same training data. The results have shown that for the NIST 2003, 2004, 2005 and 2006 translation tasks, our model with the deconvolution-based decoder outperforms the baselines, and the advantage of BLEU score over the attention-based Seq2Seq model is 2.82 on average compared with our reimplementation of the attention-based Seq2Seq model. From the results mentioned above, it can be inferred that the global information of the target-side contexts retrieved from the deconvolution-based decoder is contributive to the translation. Our analysis and case study in the following can further demonstrate how the deconvolution-based decoder improves the attention-based Seq2Seq model.

Table 2 presents the results of the models on the English-to-Vietnamese translation. Compared with the attention-based Seq2Seq model, including the implementation with the strongest performance, our model with the deconvolution-based decoder can outperform it with the advantage of BLEU score 1.54. We also display the most recent model NPMT (Huang et al., 2017) trained and tested on the dataset.



(a) Percentage of the duplicates at the sentence level.

(b) BLEU scores on sentences of different lengths

Figure 3: **Percentage of the duplicates at sentence level and the BLEU scores on sentences of different lengths** Tested on the NIST 2003 dataset. The red bar and line indicate the performance of our model, and the blue bar and line indicate that of the attention-based SeqSeq model.

Compared with NPMT, our model has an advantage of BLEU score 0.78. It can be indicated that for the low-resource translation, the information from the deconvolution-based decoder is important, which brings significant improvement to the conventional attention-based Seq2Seq model.

4.2 Analysis

As our model generates translation with global information from the deconvolution-based decoder, it should learn to reduce repetition as it can learn to avoid generating same contents according to the conjecture by the deconvolution-based decoder about the target-side contexts. In order to test whether our model can mitigate the problem of repetition in translation, we test the repetition on the NIST 2003 dataset, following See et al. (2017). The proportions of the duplicates of 1-gram, 2-gram, 3-gram and 4-gram in each sentence are calculated. Results on Figure 3(a) show that our model generates less repetitive translation. In particular, the proportion of duplicates of our model is less than half of that of the conventional Seq2Seq model.

Moreover, to validate its robustness on different sentence-length levels, we test the BLEU scores on sentences of length no shorter than 10 to 60 of the NIST 2003 dataset. According to the results on Figure 3(b), though with the increase in length, the performance of our model is always stronger than the Seq2Seq model. However, with the increase of length, the advantage of our model becomes smaller. This is consistent with our hypothesis. Since the length of generation of the deconvolution-based decoder is assigned a particular value (30 words in Chinese-to-English translation) due to the limited computation resources, there is not enough global target-side information for translating long sentences (say, longer than 30 words). In our future work, we will delve into this problem and conduct further research to reduce computation cost.

Figure 4 presents the attention heatmaps of the RNN-based decoder on the generated matrix of the deconvolution-based decoder in the English-to-Vietnamese translation. They reflect that the RNN-based decoder has diverse local focuses on the self-contained target-side contexts at different time steps. Contrary to the conventional attention on the source-side contexts which captures the corresponding annotations, it focuses on groups of the columns of the generated matrix from the deconvolution-based decoder. With the guidance of the information of global decoding, the model generates translation of higher accuracy and higher coherence. However, as the deconvolution-based decoder is not responsible for generating translation, it is hard to interpret what each column of the generated matrix represents. Moreover, as it does not capture alignment relationship as the conventional attention mechanism does, it is our future work to improve the attention on the outputs of the deconvolution-based decoder and explain the group focuses as shown in the heatmaps.

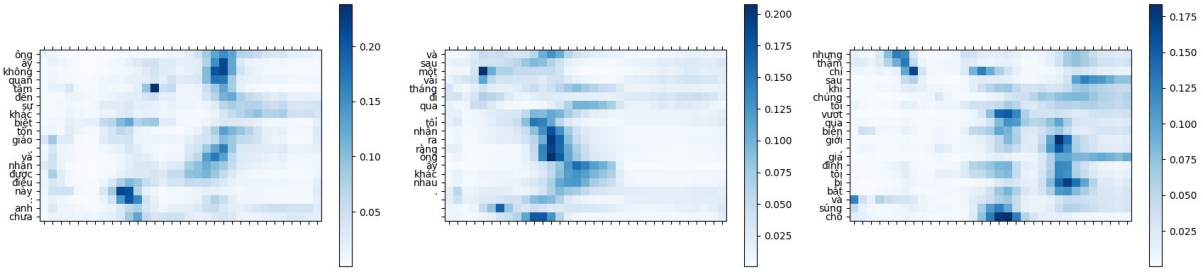


Figure 4: **Attention heatmaps of the RNN-based decoder on the deconvolution-based decoder** Words on the left refer to the translation of the RNN-based decoder. The heatmaps show that the RNN-based decoder can focus on certain parts of the outputs from the deconvolution-based decoder.

4.3 Case Study

Table 3 demonstrates three examples of the translation of our model in comparison with the Seq2Seq model and the golden translation. In Table 3(a), while the Seq2Seq model cannot recognize the objects of the main clause and the infinitive, causing inaccuracy and repetition, our model better captures the syntactic structure of the sentence and translates the main idea of the source text, though leaving the information "that causes disease". In Table 3(b), the source sentence is more complicated. With a temporal adverbial clause, its syntactic structure is more complex than simple sentence. The translation of the conventional Seq2Seq model cannot capture the syntactic information in the source text and regards the "parliament members" as the argument of the predicate "talk". Moreover, it is confused by the word "中期", meaning "middle", and translates "mid - autumn festival". In comparison, our model can recognize the adverbial clause and the main clause as well as their syntactic structures. In Table 3(c), it can be shown that when translating the long and relatively complex text, the baseline model makes a series of mistake of repetition. In contrast, the translation generated by our model though repeats the word "disaster", it is much more coherent and more semantically consistent with the source text as it successfully presents "sent 250,000 yuan" corresponding to the source text "调拨25万元人民币", while the baseline cannot translate the content.

5 Related Work

In the following, we review the studies in NMT and the application of deconvolution in NLP.

Kalchbrenner and Blunsom (2013); Cho et al. (2014); Sutskever et al. (2014) studied the application of the encoder-decoder framework on the machine translation task, which launched the development of NMT. Another significant innovation in this field is the attention mechanism, which builds connection between the translated contents and the source text (Bahdanau et al., 2014; Luong et al., 2015). To improve the quality of NMT, researchers have focused on improving the attention mechanism. Tu et al. (2016) and Mi et al. (2016) modeled coverage in the NMT, Meng et al. (2016) and Xiong et al. (2017) incorporated the external memory to the attention, and Xia et al. (2017) as well as Lin et al. (2018a) utilized the information from the previous generation by target-side attention and memory for attention history respectively. For more target-side information, Ma et al. (2018b) incorporated bag of words as target. A breakthrough of NMT in recent years is that Vaswani et al. (2017) invented a model only with the attention mechanism that reached the state-of-the-art performance.

Although many researches in NLP focused on the application of RNN, CNN is also an important type of network for the study of language (Kim, 2014; Kalchbrenner et al., 2014; Zhang et al., 2015; Lin et al., 2018b). Also, its application in NMT has been successful (Gehring et al., 2017). Recently, deconvolution was applied to modeling text (Zhang et al., 2017; Shen et al., 2017), which is able to construct a representation of high quality with the self-contained information.

Table 3: Two examples of the translation of our model in comparison with the conventional attention-based Seq2Seq model on the NIST 2003 Chinese-to-English translation task. The errors in the translation are colored in red and the successful translation of some particular contents are colored in yellow (e.g., the contents that the model successfully translates but the other does not).

6 Conclusion and Future Work

In this paper, we propose a new model with the global decoding mechanism. With our deconvolution-based decoder, which provides global information of the target-side contexts, the model can effectively exploit the information for the inference of syntactic structure and semantic meaning in the translation. Experimental results on the Chinese-to-English translation and English-to-Vietnamese translation demonstrate that our model outperforms the baseline models, and the analysis shows that our model generates less repetitive translation and demonstrates higher robustness to the sentences of different lengths. Furthermore, the case study shows that the translation of our model better observes the syntactic and semantic requirements for the translation and generates coherent and accurate translation with fewer irrelevant contents.

In the future, we will further develop analysis of the mechanism of deconvolution in NMT and try to figure out its generalized patterns for the construction of the target-side contexts.

Abstract

Question Answering over Knowledge Bases (KB-QA), which automatically answer natural language questions based on the facts contained by a knowledge base, is one of the most important natural language processing (NLP) tasks. Simple questions constitute a large part of questions queried on the web, still being a challenge to QA systems. In this work, we propose to conduct pattern extraction and entity linking first, and put forward pattern revising procedure to mitigate the error propagation problem. In order to learn to rank candidate subject-predicate pairs to enable the relevant facts retrieval given a question, we propose to do joint fact selection enhanced by relation detection. Multi-level encodings and multi-dimension information are leveraged to strengthen the whole procedure. The experimental results demonstrate that our approach sets a new record in this task, outperforming the current state-of-the-art by an absolute large margin.

1 Introduction

As the amount of the knowledge bases (KBs) grows, such as DBpedia[1], Freebase[2], and WikiData[3], people are paying more attention to seeking effective methods for accessing these precious intellectual resources. While knowledge bases are usually very large and not easily accessible for users. KB-QA (Unger et al., 2014), which takes natural language as query language, is a more user-friendly solution, and has become a research focus in recent years. At the same time the growing amount of data has led to a heterogeneous data landscape where QA systems struggle to keep up with the volume, variety and veracity of the underlying knowledge.

Simple question answering over knowledge bases, which answers a question using a single fact in knowledge bases, is not simple at all and far from being solved. This is the setup of the SimpleQuestions benchmark recently presented by Bordes et al. (2015). The task of KB-QA for simple questions could be put as follows. Let $\mathcal{G} = (s_i, p_i, o_i)$ be a background knowledge base represented as a set of triples, where s_i represents a subject entity, p_i a predicate (also denoted as relation), and o_i an object entity. Given a natural language question represented as an utterance $q = w_1, ..., w_n$, the task of simple question answering is to find a triple $(\hat{s}, \hat{p}, \hat{o}) \in \mathcal{G}$ such that $\hat{o}$ is the intended answer for question q. This task can be formulated to finding the best matches of subject $\hat{s}$ and predicate $\hat{p}$.

$$\hat{s}, \hat{p} = \arg\max_{s,p \in \mathcal{G}} p(s, p|q) \tag{1}$$

The setup of using a single fact to answer a question seems simple, while there are many existing challenges faced by QA systems. One challenge is the extremely complex language used in question utterance. On one hand, in many different ways natural language is used to express the same information need. On the other hand, the same word used in different sentences may express different meaning. For example, two questions "*who created Apple Inc.*" and "*who started Apple*" have the same meaning and

[1] http://dbpedia.org

Proceedings of the 27th International Conference on Computational Linguistics, pages 3272–3282
Santa Fe, New Mexico, USA, August 20-26, 2018.

in order to retrieve the correct answer we need to map the meaning conveyed by them to the "*founder*" relation in KB. The word "*Apple*" in the questions refers to the "*Apple Corporation*" instead of the fruit "*apple*". Natural language is complex while KB is much more universal. Another challenge is the vast amount of facts in large scale KB.

KB is quite large to some extent. KB has a huge number of fact triples and entities. A common and effective way to remain only a small subset of facts and entities is to conduct entity linking of a question over KB firstly. There are some work conducting entity linking by searching n-gram words of a question among all entity names (Bordes et al., 2015; Golub and He, 2016). While some other work propose a special-purpose sequence labeling network to focus on more probable candidates in question utterance, then linking them to entities (Dai et al., 2016; Yin et al., 2016b). Previous approaches assume that their preceding steps are correct to produce a good result for next procedure. While it should be pointed out that both the labeling and the entity linking process may lead to error propagation problems. For example, if the previous steps provide a wrong labeling result or don't recall the gold subject entity in the generated candidates, the following procedure can't make a good choice to retrieve the gold subject and predicate pair.

Faced with these problems and following previous work, we propose to do pattern extraction and entity linking first to extract possible entity mention and question pattern[4], and reduce the large number of candidate entities in KB. Due to the performance of the pattern extraction step, we observe that there is a certain proportion of bad cases in the extracted mention-pattern pairs. So we propose a novel pattern revising procedure to improve the quality of the extracted patterns. Then the extracted mentions are used to identify candidate entities in KB that the question refers to. This is the entity linking procedure. The candidate fact pool is formed by incorporating all the predicates connected to the corresponding subjects. The next step is to select the gold subject and predicate from the candidate fact pool.

For one question, there may be a large set of candidate entities. It is unrealistic to use all of them to generate candidate facts in practice. In this case, we need to let the candidate entities which are more likely to generate the gold fact get ahead of the rest. Previous methods rarely considered the information contained in the question pattern or candidate entities when doing subject selection. So we conduct relation detection, which identifies the KB predicate that a question utterance refers to, to reorder the entity linking results. Enhanced entity linking provides a strong support to generate high-quality candidate subjects.

In SimpleQuestions benchmark, a question, such as "which release was desperado the release track off of?", asks a direct relation of an entity called "desperado". While there are dozens of entities named "desperado" in Freebase which linked to different types and predicates[5]. Previous work either conduct relation inference firstly (Dai et al., 2016), or conduct entity linking firstly (Yih et al., 2015) may lead to no recall problem. In our framework, we propose to do joint fact selection to alleviate the problem. We leverage entities' name information and type information to represent entities' different aspects. As for predicates, we use the unique relation name and dispersive words information. In order to represent the sentence utterance properly, char-level and word-level encodings both are incorporated. The experimental results demonstrate the effectiveness of the proposed approach.

To sum up, our main contributions are: (1) We propose to conduct pattern extraction and entity linking, and put forward pattern revising procedure to mitigate the error propagation problem. (2) In order to learn to rank candidate subject-predicate pairs to enable the relevant facts retrieval given a question, we propose to do joint fact selection enhanced by relation detection. Multi-level encodings and multi-dimension information are leveraged to strengthen the whole procedure. (3) Our approach sets a new record in Simple KB-QA task, outperforming the current state-of-the-art by an absolute large margin.

[4]The question pattern of a question is produced by substituting the possible entity mention with a special token "#head_entity#" in original question. For example, for the question "*what position does carlos gomez play*", the correct entity mention is "*carlos gomez*", and the pattern should be "*what position does #head_entity# play*".

[5]Some predicate sets linked to these entities which has the same name "desperado", contains the gold predicate "music/release_track/recording" in common.

2 Related Work

The research of KB-QA has evolved from earlier domain-specific QA (Zelle and Mooney, 1996; Tang et al., 2001) to open-domain QA based on large-scale KB. There are two mainstream research directions for the KB-QA task. One of the promising approaches is semantic parsing (Cai and Yates, 2013; Yih et al., 2015; Yih et al., 2016; Reddy et al., 2016), which uses logic language CCG (zettlemoyer and Collins, 2009; zettlemoyer and Collins, 2012; Kwiatkowski et al., 2013; Reddy et al., 2014; Choi et al., 2015) or DCS (Berant et al., 2013) to map a question to its formal logical form to query on a KB. The other category exploit vector space embedding approaches (Bordes et al., 2014a; Bordes et al., 2014b; Bordes et al., 2015; Dong et al., 2015; Xu et al., 2016a; Xu et al., 2016b; Hao et al., 2017; Lukovnikov et al., 2017) to measure the semantic similarity between question utterance and candidate resources in the background KB, such that the correct supporting evidence will be the nearest neighbor of the question utterance in the learned vector space.

Instead of measuring the similarity between a question and an evidence triple with a single model, Yih et al. (2015) adopt a multi-stage approach. In each stage, one element of the triple is compared with the question utterance to produce a partial similarity score by a dedicated model. Then these partial scores are combined to generate the overall measurement condition. Dong et al. (2015) use three columns of CNNs to represent questions respectively when dealing with different answer aspects. Xu et al. (2016a; 2016b) incorporate Wikipedia free text to address KB-QA problems, in which they use multi-channel CNNs to extract relations. Dai et al. (2016) employ a conditional factoid factorization by inferring the target relation first and then the target subject associated with the candidate relations. Yin et al. (2016b) stack an attentive maxpooling above convolution layer to model the match of candidate predicates and questions. Lukovnikov et al. (2017) train a neural network, which contains a nested word/character-level question encoder, for answering simple questions in an end-to-end manner. In this work, we propose a two-stage framework, which exploit multi-dimension information leveraging multi-level encodings to compute semantic similarity, to tackle the problem of simple KB-QA.

Relation detection for KB-QA starts with feature-rich approaches (Yao and Van Durme, 2014) towards usages of vector space embedding models (Yih et al., 2016; Xu et al., 2016a; Golub and He, 2016; Yu et al., 2017). Actually many of the mentioned researches could support large relation dictionary, fitting the goal of open-domain question answering. Some work (Yin et al., 2016b; Yu et al., 2017) split relations into word sequences for single-relation detection. Golub and He (2016) propose a generative model for relation detection which predicts relation in a character-level sequence-to-sequence manner. Many researches have proved that relation detection benefit for KB-QA task. In our approach, we use relation detection enhance entity linking results, generating a more focused candidate subject set.

Conducting fact selection in KB-QA is inspired by work on answer selection (Yu et al., 2014; Yin et al., 2016b) which looks for correct answers from some candidates given a question. In machine comprehension (Yin et al., 2016a) scenario, the answer candidates are raw text, not structured information as facts in KB are. In our joint fact selection procedure, we leverage multi-level encodings of question utterance and subject-predicate pairs to measure their similarity in order to get the retrieved answer.

3 Overview of Simple Question Answering

The goal of simple KB-QA task could be formulated as follows. Given a natural language question q, the system returns the answer $(\hat{s}, \hat{p})$. The architecture of our proposed framework is shown in Figure 1, which illustrates the basic flow of our approach. In our approach, we conduct pattern-revising enhanced pattern extraction and entity linking to identify each question's corresponding pattern and mention, and generate candidate subjects together with their corresponding candidate facts from Freebase. Then a multi-level encoding based deep neural network is employed to select fact from the generated candidate facts, i.e. the joint fact selection procedure, in which relation detection is leveraged to reorder the entity linking results. The similarity score between the question utterance and each corresponding candidate fact is calculated, and the candidate fact with the highest score will be selected as the final predicted answer to the question.

Freebase (Bollacker et al., 2008) is utilized as our background KB, which has more than 3 billion facts,

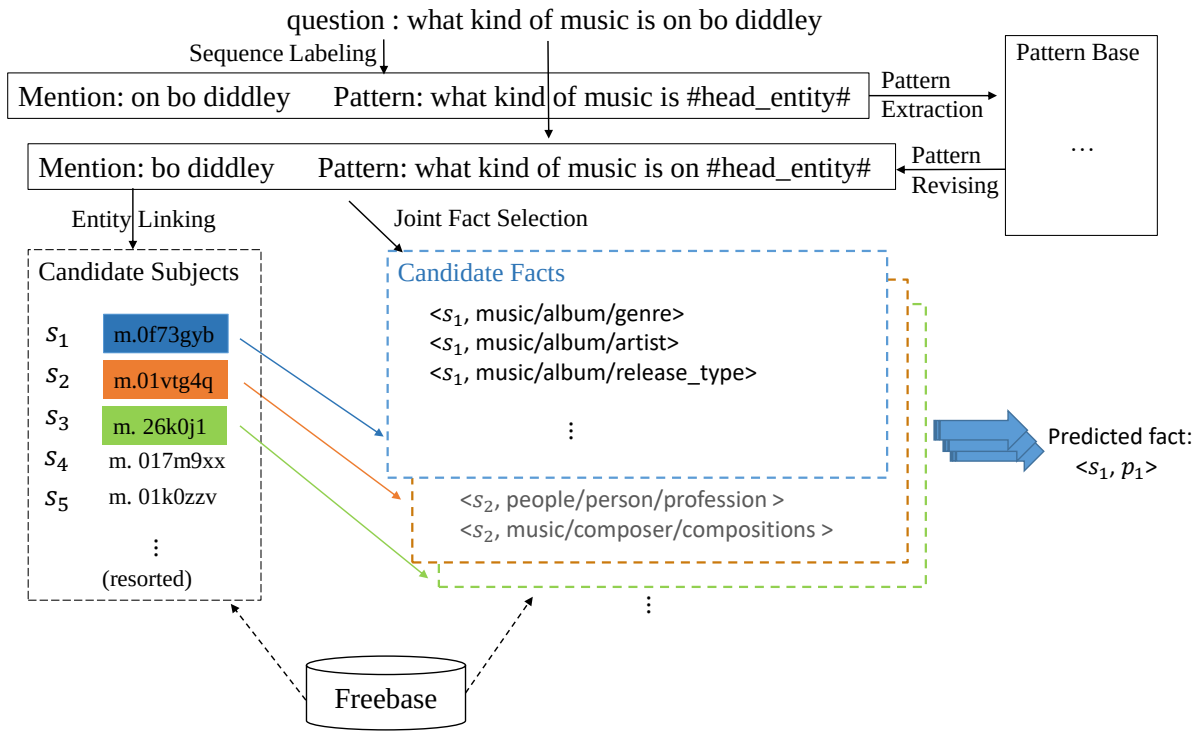

Figure 1: The overview of our proposed simple question answering approach, which is tailored via first stage of *pattern extraction and entity linking* enhanced by pattern revising, and second stage of *joint fact selection* which learns to rank candidate subject-predicate pairs to enable the relevant facts retrieval given a question.

and is used as the supporting KB for many QA tasks. We use SimpleQuestions dataset as our benchmark. The SimpleQuestions dataset consists of more than one hundred thousand simple questions which can be answered with a single fact in Freebase. We will give more detail in Section 6.1.

4 Pattern Extraction and Entity Linking

Given a question, two problems should be carefully tackled: (1) identifying the mention span in the question that refers to an entity in KB, (2) and generating candidate entities in KB that the question should refers to. So we conduct pattern extraction and entity linking procedure, which is enhanced by pattern revising. This is the first stage of our approach.

Given a question, the first stage should provide a set of top-N subject candidates. Generally, we should use all N-grams to retrieve the candidate subjects in KB in order to guarantee the recall rate. In this case, the candidate space is restricted to entities whose name or alias matches an n-gram of the question, as in (Bordes et al., 2015). However, the candidate pool is too noisy due to the large number of non-subject-mention n-grams. So we try to find a method to split the question utterance into two parts: mention span and question pattern. Mention span should be relatively rare words that refers to an entity in KB, while question pattern usually consists of common words that reflect the relation the question utterance refers to.

Inspired by previous work (Dai et al., 2016; Yin et al., 2016b), the problem could be treated as a sequential labeling task in which we aim to label the relatively rare continuous words of mention span to one kind, and label the relatively common words which belong to question pattern to another kind. This is the question pattern extraction step. The key idea is to train a model to predict the continuous word of text mention span which may refers to the topic entity, similar as Name Entity Recognition (NER). In the training set of SimpleQuestions, the topic entity of each question is labeled. We map the gold entity back to the text to label the text mention span for each question, then train a BiLSTM-CRF model to detect

the subject entity mention span in question utterance. After substituting each subject entity mention span by "#head_entity#", we get the question pattern for each question. Each question is split into (mention, pattern) pair. The extracted patterns are taken in the pattern base.

4.1 Pattern Revising

Due to the performance of sequential labeling model, there are a certain portion of bad cases in our (mention, pattern) pairs result. The more common kind of bad patterns are the ones that have obvious mistakes together with the wrong labeled mention span. The more extreme error type is that, for instance, mention is the question utterance and pattern is null. Based on the principle that question patterns which consist of common words should occur in dataset more than one time and the more times a pattern appears the more likely it is to be correct, we propose a novel pattern revising procedure to correct wrong patterns in order to increase the proportion of "good patterns", following the steps illustrated in Algorithm 1[6]. We keep all the extracted pattern which appears more than one time as the pattern base $P_{n'}$, and all the original questions as the sentence utterance base Q_n. For each question in the sentence utterance base, we reappraise its extracted pattern and try to find whether we can find a more suitable pattern or not.

Algorithm 1 Pattern Revising

Input:
The set of extracted pattern base, $P_{n'}$;
The set of original question utterance base, Q_n;
Output:
The set of the revised Question-Pattern base, Q_P;

for each sentence utterance $q \in Q_n$ **do**
  for each candidate pattern $p \in P_{n'}$ **do**
    split p according to "#head_entity#";
    if all split results are contained in q and p, q satisfy consistency policy **then**
      add p to candidate pattern set q_{cp}
    end if
  end for
  if $|q_{cp}| == 1$ **then**
    set $p \in q_{cp}$ as pattern q_p
  else
    calculate word match count for each $p \in q_{cp}$
    select p with max word match count as pattern q_p
  end if
  add (q, q_p) to Q_P
end for

After getting all the revised pattern, we extract their corresponding mention span for each question utterance. The mention span is used to link entities in KB. Based on the mention span, we use each word of it to retrieve subject entities whose names contain this word, deriving the longest consecutive common subsequence for each candidate subject entity. Then we rank the candidate subject entities according to each entity's longest consecutive common subsequence, similarly as Yin et al. (2016b) did. Top-M ranked entities are kept for each question, denoted as C'_e, and their scores for ranking are denoted as $s_{linker}(e, q)$.

[6]The consistency policy means that the split results combine the words which are in the position of "#head_entity#" should equal to the original question utterance. It is not allowed to have redundant words.

5 Joint Fact Selection

5.1 Relation Detection enhanced Subject Candidates

For one question, there may be a large set of candidate entities. It's unrealistic to use all of them to generate candidate facts in practice. We need to let the candidate entities which are more likely to generate the gold fact get ahead of the rest. So we conduct relation detection to resort the subject candidates. We train a relation detection network which maps each question utterance to their most possible predicate. Predicates are represented from different granularity: predicate-level and word-level. Predicate-level is represented by the predicate name as a single token, while word-level is represented by splitting predicate name into word sequence. Word-level encoding serves as a supplement to predicate-level encoding, mitigating data sparsity[7].

We use question utterance as input for a relation detector to score all predicates connected to entities in C'_e, for each question. The similarity score $s_{rel}(r, q)$ is computed using cosine distance between the LSTM-based encoding of question utterance and the predicate embedding r_{pred}. We extract candidate subjects' notable type on behalf of candidate subjects' type information. Then word-level LSTM-based encoder is leveraged to get the type information embedding:

$$r_{type} = ENC_{type}(w_1, w_2, ...) \tag{2}$$

We represent predicate from different granularity: predicate-level and word-level, jointly considering the corresponding candidate subject's type information:

$$r_{pred} = [e_{pred-lev}; ENC_{word-lev}(w_1, w_2, ...); r_{type}] \tag{3}$$

For each entity $e \in C'_e$ and its associated relation R_e, we generate the final rank score:

$$s_{rank}(e, q) = s_{linker}(e, q) + \alpha(\max_{r \in R_e} s_{rel}(r, q) + \beta) \tag{4}$$

where α and β are constant hyperparameters. Finally top-N ($N < M$) ranked entities are kept for each question to generate fact pool, denoted as $\mathcal{C}_s$.

For each candidate subject entity s in $\mathcal{C}_s$ and its associated predicate set P_s, we can generate candidate fact pairs (s, p) ($p \in P_s$). Then for each question, we have all candidate fact pair pool $\mathcal{C}_{(s,p)}$. From a global perspective, the last is fact selection problem, also a matching task. Given a question q $(mention, pattern)$ and sets of candidate subject entities and predicates, $\mathcal{C}_s = \{s_1, ..., s_n\}$ and $\mathcal{C}_p = \{p_1, ..., p_m\}$ respectively, our fact selection model should jointly returns the subject and predicate that matches the question best. The calculation process is shown in the Figure 2.

5.2 Subject Matching Network

Entity names are used to calculate similarity score with the mention span detected in question utterance. Since the coverage of word embeddings is limited, many words in entity names are out-of-vocabulary (OOV) words, so we leverage character-level RNN-based encoding (the string is seen as a sequence of characters) for mention span and candidate subjects' names, mitigating the high prevalence of OOV problem.

As illustrated in Figure 2, we first look up a character embedding matrix E_c, which is randomly initialized and updated during the training process, to get the character embeddings for the entity name and the mention span. Then the embeddings are fed into an unidirectional LSTM networks, where the last hidden state is taken as the encoding of current sequences. Then we compute cosine similarity $t_{subj}(s, q)$ between the encodings of the entity name and the mention span in string surface-form.

[7]There are a certain portion of predicates' names not appearing in training data.

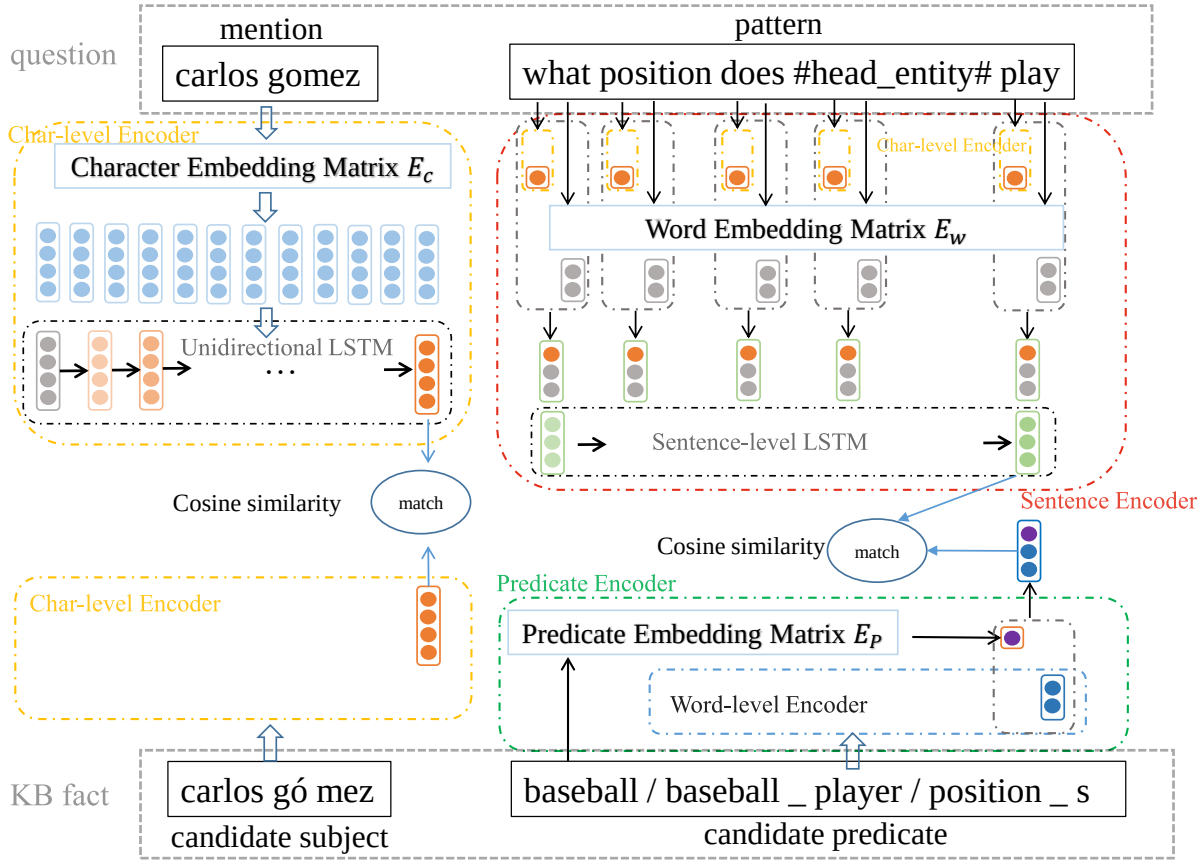

Figure 2: The overview of the proposed fact selection procedure. The mention span in the question utterance and the name of candidate subject are encoded using char-level encoder, then cosine distance is calculated to represent their similarity score. The sentence encoder for question pattern is in a nested structure, both leverage each word's char-level encoding and word embedding. The predicate encoder is similar as in 5.1, utilizing predicate-level encoding and word-level encoding.

5.3 Predicate Matching Network

Predicate matching network tries to match the patterns extracted from question utterance with the corresponding candidate predicates.

[**Question pattern encoder**] The question pattern encoder maps the question pattern to its corresponding predicate in the vector space. The process is done by using a LSTM based encoder network.

As for word representation in pattern utterance, we exploit a nested hierarchical encoding manner, leveraging both character-level and word-level information of each word in question pattern. Char-level encoder is first employed to get the representation for each word, which is a microcosmic operation. Then the microcosmic encoding on character level is concatenated with the macroscopical word embedding, which is randomly initialized and updated during the training process, to get the representation of each word:

$$m_i = [e_{w_i}; ENC_{char-lev}(c_1, ..., c_t)] \tag{5}$$

This is the way how we get the nested word embeddings. For sentence level encoding, we use word-level LSTM encoder network to get question pattern representation:

$$r_{pattern} = ENC_{pattern}(m_1, ..., m_n) \tag{6}$$

[**Predicate encoder**] In the matching procedure, we incorporate the candidate predicate's hierarchical encoding information to measure similarity with question pattern. This is similar with what we did in Section 5.1.

We represent predicate from different granularity: predicate-level and word-level. In detail, the micro-cosmic encoding on word-level is done by using a word-level LSTM based encoder network. Then the encoding is concatenated with its upper macro predicate-level encoding:

$$r_{pred} = [e_{pred-lev}; ENC_{word-lev}(w_1, w_2, ...)] \tag{7}$$

Both predicate-level and word-level encodings are useful to represent the predicate properly. We compute cosine similarity between r_{pred} and $r_{pattern}$ to get the matching score $t_{pred}((s, p), q)$.

5.4 Training

The overall ranking score of a fact triple t is $S(t, q) = t_{subj}(s, q) + t_{pred}((s, p), q)$. Our objective is to minimize the ranking loss:

$$L_{q,t,t'} = [\gamma + S(t', q) - S(t, q)]_+ \tag{8}$$

where γ is a hyper-parameter, t' is a negative triple. Our fact pool consists of all facts whose subject entity is in the top-N entity candidates. For train, we sample 200 negative facts for each ground truth fact; and keep all candidate facts for valid and test.

6 Experiments

6.1 Dataset and Evaluation

SimpleQuestions benchmark is a typical Simple QA task, which provides a set of simple questions that can be answered by a single Freebase triple[8]. This dataset is split into three parts: train (75,910 instances), valid (10,845 instances) and test (21,687 instances) sets. The benchmark also provides two subsets of Freebase: FB2M (2,150,604 entities, 6,701 predicates, 14,180,937 atomic fact triples), FB5M (4,904,397 entities, 7,523 predicates, 22,441,880 atomic fact triples).

The evaluation metric is accuracy. Only a fact that matches the ground truth answer in both subject and predicate is counted as correct.

$$accuracy = \frac{\sum_{\mathrm{i}=1}^{N} 1_{[(\hat{s}_i, \hat{p}_i)=(s_i, p_i)]}}{N} \tag{9}$$

6.2 Experimental Settings

In our approach, three types of embedding matrices are utilized: character embedding matrix, word embedding matrix, and predicate-level KB recource embedding matrix (i.e., the predicate embedding matrix). All of them are randomly initialized and updated during training process. The dimension of character embedding and predicate embedding is set to 100, and 200 for word embedding matrix. The hidden layer size of LSTMs is consistent to their corresponding dimension of the sequences to be processed. The candidate subjects number N is 20. We employ Adagrad (Duchi et al., 2011) to minimize the hinge training loss, where the margin γ is set to 1.0, and negative sample number is 200. All hyperparameters are determined according to the performance on the validation set.

6.3 Results

To demonstrate the effectiveness of the proposed approach, we compare our method with state-of-the-art systems.

Bordes et al. (2015) proposed an implementation of memory network for SimpleQuestions task. Golub and He (2016) tackled Simple QA using a character-level attention-based encoder-decoder LSTM model. A RNN-based approach was proposed by Dai et al. (2016), which utilized a focused pruning method called CFO. Yin et al. (2016b) leveraged an attentive CNN model to deal with the problem of Simple QA, and achieved best experimental result in previous state-of-the-art systems. Lukovnikov et al. (2017) adopted an end-to-end neural network, achieving a relatively good result.

[8]The object entity in the fact triple is the answer to the question utterance.

Approach	Setting	*Accuracy*
Dai et al. (2016)	N-Gram+	62.6*
Bordes et al. (2015)	end-to-end	62.7
Yin et al. (2016b)	passive linker	68.3
Golub and He (2016)	end-to-end	70.9
Lukovnikov et al. (2017)	end-to-end	71.2
Dai et al. (2016)	focused pruning	75.7*
Yin et al. (2016b)	attentive pooling	76.4
Our approach	**pattern-revising + joint fact selection**	**80.2**

Table 1: Comparison with state-of-the-art systems on SimpleQuestions benchmark. When marked with (*), accuracy in FB5M setting is given, otherwise FB2M setting results are shown.

The experimental results demonstrate that our framework sets new record in this task, outperforming the the state-of-the-art by an absolute large margin, achieving a competitive result, as shown in Table 1. From the results, we observe that our framework outperforms the latest end-to-end system record of (Lukovnikov et al., 2017) by 9.0 points, higher than previous best reported system result in (Yin et al., 2016b) by 3.8 points. While our framework exploits a quite simple and universal model which can be easily applied to other simple KB-QA tasks, not using attention model or other complex settings.

6.4 Framework Analysis

In this part, we further discuss the impacts of the augmented components which can be removed in our approach. Table 2 indicates the effectiveness of different parts in the framework.

Approach	Setting	*Accuracy*
our approach	fully integrated	80.2
our approach	w/o pattern revising	77.8
our approach	w/o relation detection	77.5
our approach	w/o both	74.8

Table 2: The ablation results of our approach.

The accuracy of original system is 74.8%. When augmented with pattern revising procedure, the accuracy of our framework increase 2.7 points, indicating that our pattern revising algorithm does lift the quality of generated patterns. The accuracy increase to 77.8 when we use relation detection to resort the results of subject candidates, showing that incorporating predicate and entity type information for reranking candidate entities can promote the quality of the recalled candidates. Either component is important for our framework. The performance decreases obviously when we remove any of them.

6.5 Error Analysis

We perform error analysis on our approach by randomly sampling 100 wrongly answered questions. The errors can be categorized into 4 types.

The most common kind of error (56%) is the wrongly picked subject entity or predicate. Due to the performance of pattern extraction and entity linking procedure, the gold entity may not appear in our candidate subjects. In this case our joint fact selection process can not select the gold subject entity. The probability of selecting wrong subjects is much higher than selecting a wrong predicate. Another kind of error case (22%) could be concluded into the "long drug name" error[9]. Some drug entities' names are quite long (more than 15 words), while mention span in question utterance may be much shorter (less than 4 words). In this case our mention-subject matching network in the joint fact selection process is failed. The third common error (13%) can be classified as "KB error". There are some entities with the

[9]For example, in the question "what is an active ingredient in childrens earache relief", the labeled gold subject "m.0jxn044" has a name longer than 15 words.

same name and the same type, indeed. The KB or the question can't support more evidence to distinguish them. The last type of error (9%) is label error. In the dataset there is a small portion of questions which are repeated, but the labeled subject or predicate is different.

7 Conclusion

In this work, we propose a pattern revising procedure to mitigate the error propagation problem in pattern extraction and entity linking process. In order to learn to rank candidate subject-predicate pairs to enable the relevant facts retrieval given a question, we propose to do joint fact selection enhanced by relation detection. Multi-level encodings and multi-dimension information are leveraged to strengthen the whole procedure. The experimental results demonstrate the effectiveness of the proposed approach.

Abstract

We present a system for Answer Selection that integrates fine-grained Question Classification with a Deep Learning model designed for Answer Selection. We detail the necessary changes to the Question Classification taxonomy and system, the creation of a new Entity Identification system and methods of *highlighting* entities to achieve this objective. Our experiments show that Question Classes are a strong signal to Deep Learning models for Answer Selection, and enable us to outperform the current state of the art in all variations of our experiments except one. In the best configuration, our MRR and MAP scores outperform the current state of the art by between 3 and 5 points on both versions of the TREC Answer Selection test set, a standard dataset for this task.

1 Introduction and Motivation

Question Answering (QA) is the task of automatically generating answers to questions posed in natural language. The task has received significant attention from researchers over several decades with a renewed interest in recent times. Current interest has been partly due to significant improvements in Natural Language Processing, and partly due to the increase in demand for such systems, amongst both the general populace, and corporate entities.

An important subtask of QA is Question Classification (QC), which deals with the classification of questions based on the expected class of the answer. For example, the question "How much does the Capitol Dome weigh?" could be classified into the class "Numeric, Weight", while the question "Name the actress in the movie Titanic" could be classified into the class "Human, Individual". While there exist QA systems that do not make use of QC, the addition of QC to a QA system has been shown to improve its accuracy (Hovy et al., 2001). The specific classification that a QC system uses is called its taxonomy, and taxonomies vary quite widely in both specificity and form.

Intuitively, QC improves QA by reducing the search space of potential answers, thus making the discovery of answers more efficient and accurate. While research into QC is fairly mature, fine grained QC is not always used for QA. For example, Tsai et al. (2015) use very simple rules based partly on question wh-words (i.e. "what", "where", "who", etc.), resulting in 13 question classes. Not only is this number low compared to the 50 classes defined by (Li and Roth, 2002) or the over 120 used by (Hermjakob, 2001), the rules themselves are fairly weak. As an example, Tsai et al. (2015) classify all questions containing "name" under the class "Name" ("Name the country most famous for cheese.")

Most QA systems consist primarily of three components: **a)** a question analysis component, **b)** an Information Extraction (IE) component that extracts a set of candidate sentences, and **c)** an answer extraction component that prunes this set of sentences in order to extract the answer. QC is performed in the first component. Its results are sometimes useful in the IE component, but generally most useful in answer extraction. The other important aspect of the answer extraction component is the analysis of linguistic features. Together, these two elements can be used to prune a set of sentences, some of which might contain the answer to a given question.

Proceedings of the 27th International Conference on Computational Linguistics, pages 3283–3294
Santa Fe, New Mexico, USA, August 20-26, 2018.

This task of selecting, from a list of sentences produced by an IE component, a subset A (where $|A| \geqslant 0$) which contains the answer to a given question is called Answer Selection (AS). For example, given the question "Where is the group Wiggles from?", and two possible sentences (called *candidate sentences*): "the Wiggles are four effervescent performers from the Sydney area: Anthony Field, Murray Cook, Jeff Fatt and Greg Page", and "six of the Wiggles' videos have reached multiplatinum status in Australia", the task would require one to return the first (*positive*) candidate and not the second (*negative*) candidate. We note that AS leaves the task of extracting the Answer from a positive candidate to a downstream task.

Methods of AS rely on establishing some form of relation between the question and each of the answer candidates, such as bag-of-words, tree edit models (Heilman and Smith, 2010), semantic distances based on word embeddings (Wang and Ittycheriah, 2015), or deep learning methods such as Convolutional Neural Networks (Rao et al., 2016). To the best of our knowledge however, this task has not been attempted with extensive use of fine grained QC.

2 Related Work

A lot of the work into using QC for QA took place before the resurgence of Machine Learning. For example, Kwok et al. (2001) introduce a QA system "MULDER", that makes use of wh-phrases, which they define as the interrogative word followed by the words associated with it. Hermjakob (2001) used an extensive QC system consisting of 115 elementary question classes in their work on QA.

2.1 Question Taxonomy and Classification

The specific system of classes used by a QC system is known as a taxonomy, and while several taxonomies are available, we pick that proposed by Li and Roth (2002), for two reasons: **a)** This is one of the most widely used taxonomies, possibly because of the large training set that Li and Roth (2002) provide, **b)** while it has been pointed out that this taxonomy might not have the widest coverage (Mishra and Jain, 2016), we show below that it is most suited for domain independent QA.

This taxonomy originally consisted of fifty fine classes divided amongst six coarse classes. Table 1 provides a complete list of these classes along with the changes we make (described in Section 4.1).

While our work on QC is an extension of the work by Tayyar Madabushi and Lee (2016), a rule-based system that achieved an accuracy of 97.2%, other work on the same taxonomy has involved the use of Linear SVMs by Van-Tu and Anh-Cuong (2016) and Pota et al. (2016) which achieved accuracies of 91.6% and 89.6% respectively. Work using Convolutional Neural Networks (Kim, 2014) and Skip-Thought Vectors (Kiros et al., 2015) have not focused on fine-grained classification.

2.2 Answer Selection

Answer Selection became popular as a task after being proposed by Punyakanok et al. (2004), who modified the TREC QA task to that of AS. This modification does not simplify the task, as extracting relevant sentences is not only as hard as extracting the actual answer, but users often find it more useful to see answers to their questions in their original context (Wang et al., 2007).

Wang et al. (2007) follow a similar approach to Punyakanok et al. (2004), while providing a training set extracted from TREC 8-12 datasets and setting aside the TREC 13 dataset for development (84 questions) and testing (100 questions). AS has since become the standard in measuring the accuracy of Question Answering systems[1] and the dataset has since diverged into two versions: The "Clean Version" (Wang and Ittycheriah, 2015), which has been cleaned to remove questions with no candidate answer sentences and those that have no negative candidate sentences from the development and the test sets; the non-cleaned version called the "Raw Version". Rao et al. (2016) have shown that results from the two datasets are not comparable. Results for this task are reported using two measures, common in Information Retrieval and Question Answering Research: Mean Average Precision (MAP) and Mean

[1] http://www.aclweb.org/aclwiki/index.php?title=Question_Answering_(State_of_the_art)

Reciprocal Rank (MRR). These results are attained using the standard program *trec_eval*, provided by TREC.

Recent work on Answer Selection has depended heavily on word embeddings with the state of the art work on the Raw version by Rao et al. (2016) who rank candidate sentences using a Multi-Perspective Convolutional Neural Network and that on the Clean version by Shen et al. (2017) who use a novel method of sentence pair modelling. Previous work on the same dataset used similar models including that by dos Santos et al. (2016) that made use of Attentive Pooling CNNs and that by Bian et al. (2017) who use a Compare-Aggregate framework. A complete list of work on the dataset is available on the ACL wiki on Question Answering.

3 System Overview and Contribution

In working towards a method of integrating QC into AS, we first redefine the taxonomy provided by Li and Roth (2002) to better suit entity identification, before then modifying the Question Classification system developed by Tayyar Madabushi and Lee (2016) to match this modified taxonomy. We then create an entity identification method to extract entities belonging to those classes in our taxonomy. Finally, we use different methods of "highlighting" entities, so this information can be passed on to *any* model that uses word embeddings. We use the model developed by Rao et al. (2016), which performs AS, to test our method.

In addition to showing the significant impact that Question Classification has on Answer Selection, we make several datasets available so others might exploit QC in Question Answering tasks including a Question Classification API that reflects the modified taxonomy[2].

4 Question Classification

Our experiments with using the taxonomy proposed by Li and Roth (2002) showed the need for changes to allow the classification system to lend itself more easily to Entity Identification and AS. For one, we found that some categorisations would make entity identification harder. For example, the question "What's the world's longest suspension bridge?" is categorised under "Location" while we believe that it is more appropriate to consider a bridge an entity. We base this on the hierarchical classification provided by WordNet (Miller, 1995), an extensive human crafted hierarchical dictionary that has been used as a standard for several different tasks.

Similarly, we disagree with the prioritisation of the classes provided. Prioritisation is important as this particular taxonomy does not allow a question to be a part of two classes. As an example, the question "What country did the ancient Romans refer to as Hibernia?" can be classified as either belonging to the class "Location:Country" or "Entity:termeq" (Equivalent Term). While Li and Roth (2002) categorise this question under the first, we categorise it under the latter, because the question is not about where something is or happens. We also believe that this choice makes it easier for a downstream QA system.

We also found the need for a new class that constitutes either "Human:Individuals" *or* "Human:Groups" (such as companies, teams and universities). This specific requirement is a direct result of the restriction that a question must be classified without prior knowledge of the answer. For example, the question "Who won the Nobel Peace Price in 2012?" is impossible to classify without knowing if the answer was an organisation (as it was in 2012) or an individual (as in 2016), even if we were to ignore the possibility of multiple individuals (as in 2014). To get around this we introduce the class "Human:IndividualOrGroup". We retain the classes "Human:Individuals" and "Human:Groups" for instances where the distinction is clear.

Finally, we find that certain types of entities within certain classes are much more frequent than others in that class. While this could be because of the specific method we use for Entity Identification (Section 5), we create separate classes for these types of entities so as to avoid noise in our AS feature generation. We also expand the class "Location:State" to include the provinces of Canada and the counties of the U.K. We list the taxonomy thus modified in Table 1.

4.1 Modifications to Question Classification

The QC system used by us is an extension of that by Tayyar Madabushi and Lee (2016). It primarily involves: **a)** extracting a Question's Syntactic Map (a structure they define for holding certain types of syntactic information), **b)** identifying the headword of the noun phrase in the question, while handling Entity Identification and phrase detection, and **c)** using rules to map words at different positions in the Syntactic Map to question classes using a hyrarchical structure.

Their system classifies questions as follows: Consider the question "What is the name of the actress from England in the movie 'The Titanic'?". The system identifies its Question Class by analysing the question's parse tree to generate the Question's Syntactic Map, which enables the identification of the headword "actress" using, what they call, "prepositional rolling". This process provides us with the question's wh-word ("What"), the auxiliary verb ("is"), and the headword ("actress"). This information is used by the system to check for the existence of a rule that classifies this question. Such a rule is found by matching the noun "actress" to the rule: 'occupation.n.01' and its hyponyms in this section of the question when the wh-word is 'what' indicate that the question class is hum:ind.

These rules are manually defined using sets of WordNet synsets they call Types. Types are defined by manually picking specific synsets within WordNet and associating them and all their hyponyms to a particular Question Class based on where in a question they appear. In the previous example, the relevant Type is the word occupation and all hyponyms of the synset 'occupation.n.01'. Similarly, the synsets 'people.n.01', 'organization.n.01', 'university.n.01', 'company.n.04', 'socialgroup.n.01', and all of their hyponyms are assigned to the Question Class "Human Group".

For a detailed description, we direct the reader to the original work. However, we describe herein some elements which we have modified, a necessity given our changes to the taxonomy.

4.2 Word Sense Disambiguation and Rule Extensions

A primary difficulty in identifying the specific rule to use once the correct head of the question has been identified arises due to the polysemous nature of some words. For example, the question "What rank did you achieve in the test?" and the question "What rank did she achieve in the military?" both have the same headword "rank" but differ in the meaning of that word (position in ordering versus military status such as captain). The question class assigned to each of these question must also change based on these meanings (Number:order versus Human:title).

As described by Tayyar Madabushi and Lee (2016), words useful in identifying the question class are often nouns, as in the case of the question "What is the name of the *actress* in the Titanic?". However, such words need not always be a noun. In the case of the question "How much does the President get paid?", for example, it is the adverb "much" which allows us to infer that the expected answer is a number and additionally, the word "paid" allows us to infer that the number represents money hence resulting in the question class "number:money" as opposed to the question class "number:weight" as in the case of "How much does the Big Ben weigh?"

Rules defined by the QC system map sub-trees in WordNet to specific question classes. We make changes to the rules to align the classification of questions with the modifications we make to the taxonomy (Table 1) and add further rules where possible to cover a larger section of WordNet. Additionally, there are instances wherein the system makes use of certain heuristics to find the appropriate rule to use, as in the case of questions starting with "How much ..." which sometimes leads to classification errors. To mitigate this problem, we modify the system to return a possible second class when there is ambiguity.

5 Named Entity Recognition

Given that our objective is to "highlight" all entities in candidate answers that belong to the class assigned to a particular question, we require a method of Named Entity Recognition (NER) at the same granularity as our taxonomy. Unsurprisingly, there is no off the shelf NER system that identifies entities with the exact granularity and classes that we classify questions into. To get around this problem we start by relating entities in text to Wikipedia titles and subsequently mapping those titles to our classes. This process of mapping entities in text to Wikipedia titles is called Wikification. The hierarchical tree-structure provided by Wikipedia helps in mapping a large number of titles to a given class by allowing us to map sub-trees to classes.

5.1 Wikification

Wikification was introduced by Mihalcea and Csomai (2007), as a means of automatic keyword extraction and Word Sense Disambiguation. It has since been used for a variety of tasks especially the semantic enrichment of text. A significant advantage of using Wikification is that entities, once identified, are in a normalised format, namely the title of the linked Wikipedia article, thus making entity matching (Section 6) easier.

While simple entity identification involves the direct matching of phrases to Wikipedia titles, more advanced versions of Wikification additionally involve mapping phrases to *related* titles based on the contents of the Wikipedia article. For example, one might choose to map the phrase "the first Briton in space" to the Wikipedia article on "Helen Sharman", who was the first Briton in space. We however, limit ourselves to the simpler version as we are only interested in finding entities and not concepts.

Typically, Wikification involves the identification of potential entities and the subsequent matching of those entities with Wikipedia titles. For example, given a sentence, one could potentially use a Parts of Speech (PoS) tagger to tag the sentences before then extracting sequences of PoS tags that match a predefined set (such as NNP+ or DT*NNP+ and so on). Entities thus extracted could then be matched with Wikipedia titles.

After experimenting with several off the shelf Wikification tools, we found them lacking in the ability to work with Wikipedia Disambiguation pages and topic specific pages. For example, when looking for entities of type "movie" in the sentence "He went to watch the movie 'New York"', we want to be able to match this to the Wikipedia article "New York (film)" and *not* "New York (state)" or "New York City".

5.2 Wikification without PoS Tagging

The obvious way to tag entities in text with Wikipedia titles would be to match every possible phrase in a sentence with every title on Wikipedia. This, however, is impractical as there are over 13.04 million titles in the English Wikipedia. To get around this we run through the titles, and for each title, we split it into its constituent words and save the rest of the title in a file whose name is the first word. Thus, all titles that begin with a particular word are clubbed into a single file and for those titles that are of length one, we add an empty line into the corresponding file. This results in just over 2.1 million files each of which are relatively short and easy to process.

As we sweep through each word in a sentence, we process the file containing Wikipedia titles starting with the same word, and check to see if it contains entities that match the current sentence. This greatly speeds up the process of matching titles to the words in a sentence and provides us with a list of titles that are contained in a given sentence.

We note that this method of Wikification can be used in languages where capitalisation is dissimilar to English or even those languages wherein there is no capitalisation.

5.3 Wikification to Question Classes

Once candidate answers are Wikified, we are then left with the task of mapping these titles to the question classes. We do this by first linking each Wikipedia title to the corresponding DBPedia entry. DBPedia is an attempt to extract structured information from Wikipedia and provides a list of labels and classes associated with each entry. We use these labels and classes to map Wikipedia (and so DBPedia) titles to question classes associated with our taxonomy.

5.4 NER without Wikification

We use the Stanford Named Entity Recogniser (Finkel et al., 2005) to identify entities belonging to the classes "Human Individual", "Human Group" (such as institutions, universities, etc.), and "Location Other", the three classes with compatible granularity. All numeric entities, such as Number:Money, Number:count, and Number:date are identified using an extensive list of regular expressions.

6 Entity Matching

When grading papers, a good maxim to identify plagiarism is "While there is only one way to get it right, there are several ways to get it wrong". We observe that this maxim works because the probability of two students answering a question incorrectly in *the same way* is extremely small, unless of course it's a trick question. Similarly, the chance of candidate answers having the same incorrect entity that also match the class of the question is exceedingly small and machine learning models can make use of this information. To this end, we count the number of occurrences of each entity across all answer candidates of a given question. This requires us to be able to match entities that have been written differently, but are in fact the same.

Entities that have been extracted through Wikification are often normalised "for free." However, there is no simple way to get around this problem in the case of entities extracted through regular expressions, as in the case of numbers and dates where it is common for sentences to contain approximations. For example, consider the question "How many lives were lost in the recent air-crash?", the answer is contained in all of the following sentences: "253 lives were lost in the recent air-crash", "241 passengers and 12 crew died in the recent air-crash", and "around 250 lives were lost in the recent air-crash". This problem is further expanded when the numbers we are dealing with become larger as it is more common for non-technical literature to approximate large numbers. To get around this we round down all numbers to the nearest billion, million, hundred thousand, thousand, hundred or ten.

7 Model Details

We use the Answer Selection model developed by Rao et al. (2016) who rank candidate sentences using a Multi-Perspective Convolutional Neural Network (He et al., 2015a) and a triplet ranking loss function which uses triplets of the question paired with a positive and a negative candidate answer. While other methods model this problem as a pointwise classification problem (He and Lin, 2016; Severyn and Moschitti, 2015), this method models the problem of Answer Selection as a pairwise ranking problem. This involves developing representations for positive and negative answer candidates paired with the question, the primary reason for us choosing this model.

Yet another advantage of this method is that it can make use of existing pointwise models to generate representations which can then be fed into the triplet ranking function. The authors make use of two such pointwise models, one that uses a sentence-level model (He et al., 2015b) and the other that uses a word-level model (He and Lin, 2016). We refrain from elaborating on these methods due to the limitations of space and refer to the reader to the original works.

We make use of the word-level model[3] as we introduce new representations for entities (Section 7.1) which requires us to modify them with answer candidates. The model is additionally initialised with the

[3] `https://github.com/castorini/Castor`

GloVe word embeddings (Pennington et al., 2014) which are also updated during training.

7.1 Highlighting Entities

Having extracted and normalised entities that are contained in each of the answer candidates, we are faced with the task of highlighting these entities within the answer candidates. Before we do this however, we perform some prepossessing steps. We discard any entities that also appear in the question as such entities are unlikely to be the answer. For example, the question "Who is the author of the book, 'The Iron Lady: a biography of Margaret Thatcher"' has, as an answer candidate, the sentence "The iron lady; a biography of Margaret Thatcher by Hugo Young" in which both "Margaret Thatcher" and "Hugo Young" are entities that match the question class, namely "Human Individual". The entity "Margaret Thatcher", however, is discarded as it is also contained in the question.

For each question we count the number of occurrences of each entity across all candidate answers and if the most frequently occurring entity occurs more than twice the number of times the second most frequently occurring one, we pick the first as the maximal entity. For those questions where this is not the case, we pick no maximal entity.

We also create four new "words", *max_entity_left*, *max_entity_right*, *entity_left*, and *entity_right*, which are strings that are not contained in the vocabulary, along with associated word vectors which are randomly initialised with entries between -0.05 and 0.05 and are of the same length as the GloVe word embeddings (300). We then add these embeddings to our embedding dictionary and the words to the vocabulary.

Entities are highlighted in the answer candidates by inserting the words *max_entity_left* and *max_entity_right* on either side of maximal entities, and *entity_left* and *entity_right* around other entities. We also include *entity_left* and *entity_right* at the end of the question and the "words" *max_entity_left* and *max_entity_right* at the end of questions that contain maximal entities. We call this method of highlighting *bracketing*.

A second method of highlighting entities in candidate answers is to replace the entity with a word, a method we call *replacing*. To avoid creating two new words for this method, we reuse two of the four words used above: *max_entity_left* and *entity_left*. Table 2 details the modifications made to an example question and candidate answer using each of the above methods.

Method	Question	Answer Candidate
Original	Who is the author of the book, 'The Iron Lady: a biography of Margaret Thatcher'	in 'The Iron Lady,' Young traces the winding staircase of fortune that transformed the younger daughter of a provincial English grocer into the greatest woman political leader since Catherine the Great.
Bracketing	Who is the author of the book, 'The Iron Lady: a biography of Margaret Thatcher' *max_entity_left max_entity_right entity_left entity_right*	in 'The Iron Lady,' *max_entity_left* Young *max_entity_right* traces the winding staircase of fortune that transformed the younger daughter of a provincial English grocer into the greatest woman political leader since *entity_left* Catherine the Great *entity_right*.
Replacing	Who is the author of the book, 'The Iron Lady: a biography of Margaret Thatcher' *max_entity_left entity_left*	in 'The Iron Lady,' *max_entity_left* traces the winding staircase of fortune that transformed the younger daughter of a provincial English grocer into the greatest woman political leader since *entity_left*.

Table 2: Entities *highlighted* in answer candidates using two different methods. The example assumes that the entity "Young" is a maximal entity.

8 Empirical Evaluation

Having described our method of Question Classification, Entity Identification and Entity Highlighting, we next evaluate our method on the task of AS using different Highlighting methods and training data.

The training data commonly used for this task consists of two sets: The first consists of one hundred manually examined questions and corresponding answers candidates and the second, an automatically

generated set consisting of just over 1200 questions. We found the manually inspected, and hence higher quality test set to be too small for use in this task. However, we also found that the automatically generated training set contained several inconsistencies. To prevent noise, we discarded any questions with answer candidates that contained more than one false positive. We similarly discarded questions from the development set. Thus cleaned, we were left with 1164 questions in the training set and 76 and 60 questions in the Raw and Clean versions of the development set respectively. The development data is what the learning model is optimised on before the best performing model is used to evaluate the test data. To ensure that our results are comparable to those published by others, we make no changes to the test data.

Some question classes cannot have entities highlighted, as in the case of "Description" and "Definition". Some other question classes do not have Entity Identification implemented as we found it impossible to identify all possible elements of the class, as in the case of "Vehicles". We call such questions unhighlighted questions and the rest highlighted questions.

For each of the Clean and Raw versions of the data, we run the model on **a)** unhighlighted data, **b)** data highlighted using *bracketing*, **c)** data highlighted using *replacement*, **d)** unhighlighted data and highlighted data using *bracketing* combined, and **e)** unhighlighted data and highlighted data using *replacement* combined. In cases where we split the data into highlighted and unhighlighted sections, the results are combined to find the MRR and MAP scores of the complete data. The model run on data without entities highlighted (as presented in (Rao et al., 2016)) is the baseline. We also calculate the MRR and MAP scores for the baseline for *each* of these variations as we change the training data in each case. We use the same hyper-parameters as those provided in the implementation of the work by Rao et al. (2016). We include the highlighted versions of the training, development and test data for each of the variations above along with details of the hyper-parameters used, the trained models and the output as part of the supplemental material. We present our results in Table 3.

8.1 Result Analysis

The use of question classes embedded in candidate answers *outperforms the current state of the art in literature in every case except one*. This result (Number 10 in Table 3) is an anomaly that we attribute to over-fitting as we perform no hyper-parameter tuning. The strong performance of the baseline on the unhighlighted data (Sr. No. 1) is expected as answer candidates that are descriptive in nature (as is the case for questions belonging to the classes "Description", "Definition", etc., which also do not have entities identified) must necessarily have a larger overlap with the question. Once again, we ascribe the low performance of the corresponding unhighlighted baseline on the Clean Version (Sr. No. 8) to over-fitting.

The highlighting method of *replacement* performs better than *bracketing* except in the case of the anomaly. We believe this is because Named Entities, with their limited frequency, carry little information. Additionally, the replacement of entities that are phrases with a single frequently occurring word could improve sentence representation.

We expected the combination of the model independently trained on unhighlighted and highlighted data to perform better than that trained on the combination. This is not the case for either version of the test data. As in the case of the anomaly (Sr. No. 10), it is impossible to say if this is a result of over-fitting without performing hyper-parameter tuning on all ten of the models we present.

We also experimented with training different models for each of the coarse classes. We did this by extracting subsets of the training, development and test sets belonging to each of the coarse classes ("HUM", "LOC", ...), training the model on the training subset, optimised on the development subset, and testing it on the test subset. We found these results to be surprisingly poor, and believe this to be a result of deep learning models gaining more from increased data rather than homogeneous data. Homogeneity in data might, in fact, lead to overfitting and hence be detrimental. These results are consistent with results in work by Kyashif (2018) who used the QC system described in this work in task-based and common sense QA, where a similar subdivision led to poorer performance.

Data version		Sr. No.	Question Class	Highlight Method	Train #	Test #	Baseline MRR	Baseline MAP	This Work MRR	This Work MAP

	Reported Baseline Performance (Rao et al., 2016)					68	0.762	0.854		
	Prior state of the art (Shen et al., 2017)					68	0.822	0.899		

Table 3: Results for each of the different highlighting methods on the Raw and Clean data versions. "Reported Perfomance" indicates the performance reported by Rao et al. (2016) when using the word-level model (Section 7) which is our baseline and the model that we adapt. "Implementation Best" represents the performance of the same model on the implementation that we use, and "Prior state of the art" represents the prior state of the art reported in literature for this dataset. Results in parentheses represent results on a subset of the test data.

As part of this work we release the following datasets[4]:

1. We release 3,500 of the total 5,500 training questions along with the 500 test questions originally released by Li and Roth (2002) manually updated with our classification.
2. We release the manually verified question classes for all 1500 questions in the AS task.
3. From the questions contained in the AS task, we release the list of entities identified for each answer candidate for the complete test set and for a highlighted training set of 649 questions.
4. We also make available an Application Programming Interface (API) to the modified Question Classification system we describe in this work[5].

8.2 Additional Advantages

Unlike other systems, a significant advantage of the system presented in this work is the fact that, not only does the system succeed in Answer Selection but in most cases *can also extract the specific factoid answer*, when one is present. When highlighting is possible and a maximal entity exists (as is the case in 60 of the 68 questions in the clean test set), such a maximal entity is nearly always the answer.

[5]API available at: `www.harishmadabushi.com/research/questionclassification/`

9 Error Analysis

One of the biggest source of errors tends to be incorrect entity tagging. This is especially so in the case of dates where we tag the date and the year independently thus allowing for the tagging of entities in candidate answer that only mention the year. Unfortunately, this often leads to incorrectly identified maximal entities when both the date and the year are present. In hindsight, we believe a better approach to dates would have been to combine sequential entities before entity matching, so as to capture exact dates, such as "13 October 1997" as a single entity rather than two different entities, one consisting of the day and month and the other of the year.

A similar source of errors occurs when processing the names of individuals, where common ways of shortening names cause errors in both the entity identification and the entity matching steps. For example, the ex-CEO of GE, Jack Welch, is referred to as GE-Welch and John Welch in some answer candidates.

When a candidate answer has too many entities of the required type, it is often misclassified. For example, the candidate answer "on its billions of kilometres flight toward Saturn, Cassini is scheduled to loop its path around Venus, the Earth and Jupiter to get the gravity boost needed for closing in onto its destination" for the question "What is Cassini's destination?", contains a large number of planetary objects diluting the signal generated by the entity. We believe the solution to this lies in increasing the granularity of the QC taxonomy.

There are some completely unexpected sources of errors as in the case of the question "Who established the Nobel Prize awards?", where all entities that contain the answer ("Alfred Nobel") are discarded as they are contained in the question. A more sophisticated method of establishing which entities are discarded could reduce errors of this kind.

Finally, there are some questions and answer candidates that are incorrectly tagged in the Answer Selection test set. For example, the question "What years did Sacajawea accompany Lewis and Clark on their expedition?" has, amongst its candidate sentences, the following two sentences: "the coin honors the young woman and teen-age mother who accompanied explorers meriwether lewis and william clark to the pacific ocean in 1805", and "in 1804 , toussaint was hired by lewis and clark , not for his own skills but for those of sacagawea." While the first candidate answer is marked as one containing the answer the second is not marked as such. While this is the only error of this kind, we found several other sentence candidates similarly marked as containing the answer when they, in fact, do not. Despite this, *we make no modifications to the test set*.

10 Conclusions and Future Work

We presented in this paper a method of Answer Selection that first required us to redefine a QC taxonomy provided by Li and Roth (2002), modify the Question Classification system developed by Tayyar Madabushi and Lee (2016) to match this modified taxonomy, create an entity identification method to extract entities belonging to those classes in our taxonomy, and finally, to use different methods of highlighting entities, so this information can be passed on to the Answer Selection model developed by Rao et al. (2016).

Our experiments show that Question Classes provide such a strong signal to the Deep Learning Model that we outperform current state of the art in all variations of our experiments except one. In the best configuration, our MRR and MAP scores outperform the current state of the art by between 3 and 5 points on both the Raw and Clean versions of the TrecQA Answer Selection test set.

We plan to test this method on different datasets including WikiQA and the Stanford Question Answering dataset, while also increasing the number of classes in our taxonomy and the number and kinds of entities identified by the our Entity Identification system.

The relatively small size of this dataset combined with the rather high accuracy achieved by current state of the art systems highlights the need for research in the field of AS through QC to move to other datasets. One challenge in doing so could be the lack of QA datasets with QC annotations. We hope that our release of the QC API as part of this work will help in this regard.

Abstract

Answer selection is an important but challenging task. Significant progress has been made in domains where a large amount of labeled training data is available. However, obtaining rich annotated data is a time-consuming and expensive process, creating a substantial barrier for applying answer selection models to a new domain which has limited labeled data. In this paper, we propose Knowledge-aware Attentive Network (KAN), a transfer learning framework for cross-domain answer selection, which uses the knowledge base as a bridge to enable knowledge transfer from the source domain to the target domains. Specifically, we design a knowledge module to integrate the knowledge-based representational learning into answer selection models. The learned knowledge-based representations are shared by source and target domains, which not only leverages large amounts of cross-domain data, but also benefits from a regularization effect that leads to more general representations to help tasks in new domains. To verify the effectiveness of our model, we use SQuAD-T dataset as the source domain and three other datasets (i.e., Yahoo QA, TREC QA and InsuranceQA) as the target domains. The experimental results demonstrate that KAN has remarkable applicability and generality, and consistently outperforms the strong competitors by a noticeable margin for cross-domain answer selection.

1 Introduction

Answer selection, which is a key component of question answering (QA), has attracted increasing attention recently due to its broad applications in natural language processing and information retrieval, such as factoid question answering (Wang et al., 2007) and community-based question answering (Tay et al., 2017). Given a question, answer selection aims to pick out the most relevant answer from a set of candidates. In the literature, answer selection has been extensively studied in the last decade (Severyn and Moschitti, 2015; Wang and Nyberg, 2015; Tan et al., 2016; dos Santos et al., 2016).

Despite the effectiveness of previous studies, answer selection remains a challenge in real-world applications for two reasons. (1) The background information and knowledge beyond the context, which play crucial roles in human text comprehension, have received little attention in recent work for answer selection. (2) Impressive answer selection performances were achieved in domains where a large amount of labeled data is available. However, such fruitful results are subject to an assumption that the test data should be drawn from the same distribution as the training data. Previous studies struggle to cope with answer selection across different data domains. For example, the model trained on SQuAD-T dataset that consists of open-domain factoid questions, is difficult to generalize to the InsuranceQA dataset that consists of non-factoid questions in the insurance domain. In a new domain where its own labeled data is in short supply, obtaining more labels is usually labor-intensive and time-consuming.

Knowledge base (KB), such as YAGO (Weikum et al., 2007), Freebase (Bollacker et al., 2008), provides rich information of relations between entities. It has been widely studied and applied in many tasks (Yang and Mitchell, 2017; Liu et al., 2017). However, its applicability to answer selection has yet to be

Negative Answer	Professor Albus Percival Wulfric Brian ***Dumbledore*** is a major character and protagonist of ***J. K. Rowling***'s ***Harry Potter*** series.

Table 1: Example of QA Candidate Pairs.

well-studied. Considering the example in Table 1, existing context-based models may assign a higher score to the negative answer than the positive answer, since the negative answer is more similar to the given question at word level. However, with the background knowledge, we can correctly identify the positive answer based on the relative facts contained in the knowledge base (KB) such as (*Dumbledore*, *played_by*, *Michael Gambon*), (*Michael Gambon*, *cast_in*, *Harry Potter*). Furthermore, QA datasets in different domains or types might differ from syntactic and lexical features, but relations of knowledge in sentences are coherent in the same knowledge base.

Inspired by recent work on transfer learning (TL) and domain adaptation, in this paper, we study how we can leverage labeled data of source domain and external knowledge in knowledge base to help the answer selection in the new target domain which has only limited labeled data. Although transfer learning was employed in many applications (Mou et al., 2016; Li et al., 2017), its application in answer selection is still a relatively new territory and under-explored.

Our idea of leveraging external knowledge as a bridge between source and target domains is motivated by the observation that the data in different domains shares certain common background knowledge which can possibly be transferred from the source domain to the target domain. Thus, we proposed Knowledge-aware Attentive Network (KAN) for transfer learning on answer selection task. In particular, we design a context-guided attentive convolutional neural network, which incorporates knowledge embeddings into sentence representations, to strengthen the representation learning of documents. The training of the transfer learning is performed in two steps: First, the proposed model is trained with the labeled data from source domain and the external knowledge from knowledge base, called pre-training procedure. We expect that the pre-training learns the knowledge-based representation, which enables domain-independent knowledge to be transferred across domains. In addition, pre-training also gives a good initialization of the model parameters, and therefore training at the latter stage gives a good generalization performance even if the size of the target domain dataset is limited. Second, we fine-tune the model on a target domain dataset which has limited labeled data, with the hope that one can safeguard the performance of answer selection in the target domain by leveraging the shared knowledge learned from knowledge base.

To verify the effectiveness of our model for cross-domain answer selection, we use SQuAD-T data as the source domain and three other datasets (i.e., Yahoo QA, TREC QA and InsuranceQA) as the target domains. The experimental results show that our model consistently outperforms previous methods.

2 Related Work

Answer Selection Recent years have witnessed great successes of applying different neural networks, e.g., convolutional neural network (CNN) (Severyn and Moschitti, 2015) and recurrent models like the long short-term memory (LSTM) (Wang and Nyberg, 2015), into Answer Selection. The key idea behind deep neural networks is to encode the input sentences as vector representations. Based on the representations, an output layer is utilized to provide the matching score of two texts. Instead of learning the representations of the question and the answer separately, some recent studies exploit attention mechanisms to learn the interaction information between questions and answers, which can better focus on relevant parts of the input (Tan et al., 2016; dos Santos et al., 2016; Chen et al., 2017). However, these methods are subject to the amount of labeled data and the limited information provided by contexts. Thus, we attempt to apply transfer learning and knowledge base to address these issues.

Transfer Learning Transfer learning aims to transfer knowledge from the source data to the target data in different domains, tasks, or distributions (Pan and Yang, 2010). Most recent studies in transfer learning for natural language processing employ deep neural networks to learn the shared feature representation between two different datasets (Mou et al., 2016; Li et al., 2017). However, it was not until recent years that the application of transfer learning on QA received extensive attention. Min et al. (2017) and Wiese et al. (2017) both employ supervised transfer learning techniques to pre-train a model from a large-scale dataset. Yuan et al. (2018) and Yu et al. (2018) study unsupervised transfer learning under the circumstance that there is only a little labeled target data or some unlabeled target data. In this paper, to make the shared representation more knowledge-aware, we go deeper into the first kind of researches and incorporate external knowledge into transfer learning framework in our method.

Knowledge Base Application As seen in many other tasks, it is a trend to leverage external knowledge from KBs to enrich the representational learning of deep learning models. Several efforts have been made on integrating knowledge embeddings trained by knowledge embedding methods (Bordes et al., 2013) to learn a knowledge-aware sentence representation on machine reading (Yang and Mitchell, 2017), entity typing (Xin et al., 2018) and relation extraction (Han et al., 2018). In this paper, we aim to develop a more general framework for current models to learn knowledge-aware sentence representations on answer selection task.

Inspired by these researches, we propose a transfer learning method for answer selection task, which leverages external knowledge from knowledge base to enrich the representational learning of QA sentences as well as bridge cross-domain QA datasets.

3 Model

In this section, we present the general framework of our transfer learning method on answer selection, which leverages external knowledge from knowledge base as a bridge connecting cross-domain QA datasets. Given a question q, our model aims to rank a set of candidate answers $A = \{a_1, \ldots, a_n\}$.

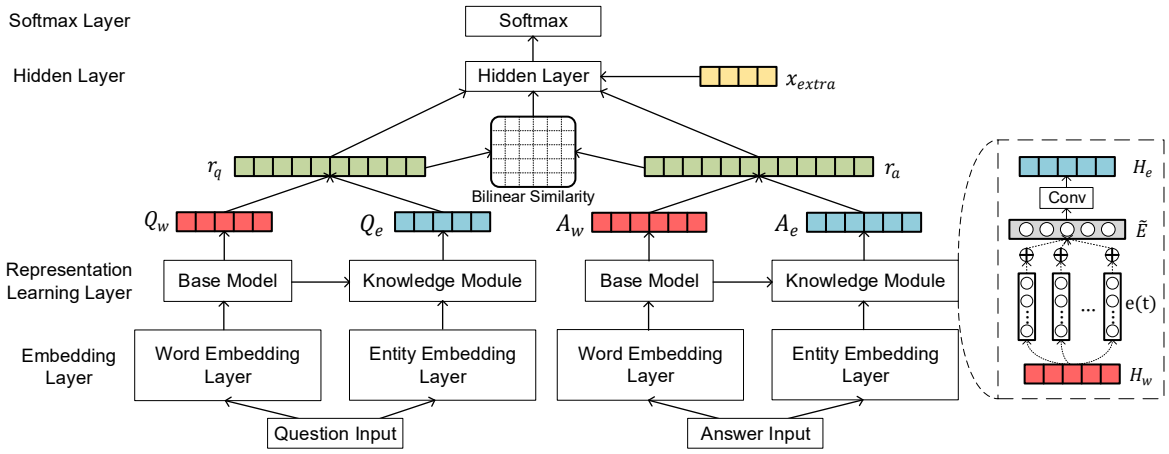

Figure 1: Knowledge-aware Attentive Network for Cross-domain Answer Selection. Blue, red and green matrices denote knowledge-based representations, context-based representations and final knowledge-aware sentence representations, respectively.

As is illustrated in Figure 1, the overall architecture of KAN contains two main components: *Base Model* and *Knowledge Module*. In base model, we employ a pair of deep neural networks to learn the initial context-based representations of questions and answers, separately (Section 3.1). In knowledge module, a context-guided attentive CNN is designed to learn the knowledge-based sentence representation from entities in the sentence (Section 3.2). Afterwards, for both question and answer sentences, there are two different sentence-level representation vectors. Q_w and A_w are learned from base model, while

Q_e and A_e are derived from knowledge module. We obtain the final knowledge-aware attentive sentence representations of question q (i.e., $r_q = [Q_w : Q_e]$) and answer a (i.e., $r_a = [A_w : A_e]$), where [:] is the concatenation operation. There is a fully connected hidden layer before the final binary classification to join all the features (Section 3.3). Finally, a transfer learning method is proposed to transfer the shared knowledge to bridge two different datasets (Section 3.4).

3.1 Base Models

Given a question q and a set of candidate answers $A = \{a_1, \ldots, a_n\}$, we first transform them into vector representations with an embedding layer, and then input these embedding vectors into the base model.

Among numerous deep learning models proposed for answer selection task, we adopt several popular and typical models as our base model to demonstrate the strong applicability and generality of our transfer learning method. The selected base models include: (1) Bi-LSTM, a bidirectional Long-Short Term Memory (Bi-LSTM) network to generate sentence representation (Wang and Nyberg, 2015); (2) Att-LSTM, an Attentive LSTM model with a simple but effective attention mechanism for the purpose of improving the semantic representations for the answers based on the questions (Tan et al., 2016); (3) AP-LSTM, an AP-LSTM model with attentive pooling, a two-way attention mechanism that information from the question and the answer can directly influence the computation of each others representations (dos Santos et al., 2016); and (4) Conv-RNN, a hybrid framework of attention-based Convolutional Recurrent Neural Network (Conv-RNN) (dos Santos et al., 2016) with a similar attention mechanism as Att-LSTM but in the input of the RNN. Note that, unlike the original paper of Conv-RNN, we employ Bi-LSTM as the RNN model instead of the Bi-GRU. For the details of the models, please refer to the original papers.

As for a question vector q and an answer vector a, we obtain the initial context-based sentence representation H_w for the question and the answer from the base model, namely Q_w and A_w.

3.2 Knowledge Module

Knowledge module is responsible for transferring external knowledge from KB into the knowledge-based sentence representations. We first employ n-gram matching to detect all the entity mentions in the sentence, and then retrieve a set of top-K entity candidates from KB for each entity mention. However, the ambiguity issue of the entity is still remained to be tackled, e.g., Santiago can refer to a city or a person. Thus, a context-guided attention mechanism is designed to perform a soft entity linking and learn the knowledge representation for each entity mention simultaneously. We present candidate entities that related to the t-th word in the sentence as $e(t) = \{e_{t_1}, e_{t_2}, \ldots, e_{t_K}\} \in \mathbb{R}^{K \times d_e}$, where d_e is the dimension of the entity embedding in KB. Then, the context-guided knowledge embedding for t-th word is given by

$$m(t) = \tanh\left(W_{em} e(t) + W_{hm} H_w\right), \tag{1}$$

$$\alpha_{t_i} = \frac{exp\left(w_m^T m_{t_i}\right)}{\sum_{m_{t_j} \in m(t)} exp\left(w_m^T m_{t_j}\right)}, \tag{2}$$

$$\widetilde{e_t} = \sum_{e_{t_i} \in e(t)} \alpha_{t_i} e_{t_i}, \tag{3}$$

where W_{em}, W_{hm} and w_m are parameter matrices to be learned. $m(t)$ is a context-guided knowledge vectors, and α_{t_i} denotes the context-guided attention weight that is applied over each candidate entity embedding e_{t_i}. The contextual sentence representations H_w of questions and answers are learned by the base model, while the embeddings of entities in KB are learned by TransE (Bordes et al., 2013).

This procedure produces a context-guided representation for each entity mention in the sentence. Then we apply an CNN layer to learn a higher level knowledge-based sentence representation. The input of the CNN layer are the attentive knowledge embeddings $\widetilde{E} = \{\widetilde{e_1}, \widetilde{e_2}, \ldots, \widetilde{e_L}\} \in \mathbb{R}^{L \times d_e}$.

In the convolution layer, a filter of size n slides over the input embedding matrix to capture the local n-gram information, which is useful to extract the entity features since an entity is likely to be a phrase. Each move computes a hidden layer vector as

$$x_i = [\widetilde{e}_{i-\frac{n-1}{2}}, \ldots, \widetilde{e}_i, \ldots, \widetilde{e}_{i+\frac{n-1}{2}}], \tag{4}$$

$$h_i = \tanh\left(W x_i + b\right), \tag{5}$$

where W and b are the convolution kernel and the bias vector to be learned. Then we employ max-pooling over the hidden layer vectors $h_1, \ldots, h_n$ to generate the final output vector y:

$$y_j = max\left\{h_{1j}, \ldots, h_{nj}\right\}, \tag{6}$$

where y_j and h_{ij} are the j-th value of the output vector y and the hidden vector h_i.

Due to the uncertainty of the length of entities, we exploit several filters of various sizes to obtain n-gram features $\left\{y^{(1)}, y^{(2)}, \ldots, y^{(n)}\right\}$, where $y^{(i)}$ denotes the output vector obtained by the i-th filter. We pass these output vectors through a fully-connected layer to get the final knowledge-based sentence embedding $H_e \in \mathbb{R}^{L \times d_f}$, where d_f is the total filter sizes of CNN and L is the length of the sentence. As for the question q and the answer a, we generate their knowledge-based sentence representations Q_e and A_e as:

$$Q_e = [y_q^{(1)}, y_q^{(2)}, \ldots, y_q^{(n)}]; \quad A_e = [y_a^{(1)}, y_a^{(2)}, \ldots, y_a^{(n)}]. \tag{7}$$

3.3 Training

The initial context-based representations and the knowledge-based representations are concatenated to form the final sentence representations of question q and answer a:

$$r_q = [Q_w : Q_e]; \quad r_a = [A_w : A_e]. \tag{8}$$

Following the ideas in Severyn and Moschitti (2015) and Tay et al. (2017), we incorporate the same additional features into our overall architecture. First, we compute the bilinear similarity score between final question and answer vectors, $s\left(r_q, r_a\right) = r_q^T W r_a$, where $W \in \mathbb{R}^{L \times L}$ is a similarity matrix to be learned. Besides, the same word overlap features $x_{extra} \in \mathbb{R}^4$ as Severyn and Moschitti (2015) and Tay et al. (2017) are also integrated into our model. Thus, the inputs of the hidden layer is a vector $x = [r_q, s(r_q, r_a), r_a, x_{extra}]$, and its output then go through a softmax layer for binary classification:

$$y(q, a) = \text{softmax}\left(W_s x + b_s\right). \tag{9}$$

where $W_s \in \mathbb{R}^{d_x \times 2}$ and $b_s \in \mathbb{R}^2$ are the parameters in the hidden layer. The overall end-to-end model is trained to minimize the cross-entropy loss function:

$$L = -\sum_{i=1}^{N} \left[y_i \log p_i + (1 - y_i) \log\left(1 - p_i\right)\right] + \lambda \|\theta\|_2^2, \tag{10}$$

where p is the output of the softmax layer. θ contains all the parameters of the network and $\lambda\|\theta\|_2^2$ is the L2 regularization.

3.4 Transfer Learning Method

Our goal is to leverage external knowledge from an open-domain knowledge base to bridge cross-domain answer selection data. The transfer learning method between different datasets is divided into two steps: we first initialize the the parameters of model pre-trained on the source dataset, then we further fine-tune on the target dataset. A straightforward way is to fine-tune all the parameters pre-trained by the source data on the target training dataset. Another fashion is to fine-tune a certain part of parameters and keep the rest of parameters fixed during fine-tuning. In our overall model, we present three ways to

fine-tune: (1) Find-tune the entire model; (2) Only find-tune all the weights in the knowledge module. This way aims at sharing the context-based representational learning module learned from the source data and training a better knowledge-based representational learning module with the target training set; (3) Only find-tune all the weights in the base model. On the contrary, this way considers knowledge-based representational learning module a coherent part for transfer, but the context-based representational learning module need to be fine-tuned. Note that for training the model, we followed the same procedure as in Yuan et al. (2018), where pre-trained word embeddings are not updated during training. In this work, so are pre-trained knowledge embeddings.

4 Experiments

4.1 Datasets and Metrics

In the paper, we adopt four widely-used QA datasets for evaluation, including two factoid QA datasets, SQuAD-T and TREC QA, and two community-based QA datasets, InsuranceQA and Yahoo QA. We adopt SQuAD-T as our source dataset for transfer learning due to its high quality and large quantity, while the other datasets are used as target datasets.

- **TREC QA**, collected from TREC QA track 8-13 data (Wang et al., 2007), is a benchmark for open-domain factoid question answering. Most questions are short and factoid-based, and answers are usually consisting trivia information. Following previous works (Tay et al., 2018; Rao et al., 2016), we use Mean Average Precision (MAP) and Mean Reciprocal Rank (MRR) as evaluation metrics.

- **InsuranceQA**, proposed by (Feng et al., 2015), contains community-based question and answer pairs from the insurance domain and is split into a training set, a validation set, and two test sets. For the development and test sets, the InsuranceQA also includes an answer pool of 500 candidate answers for each question. This answer pool was produced by including the correct answer and randomly selected candidates from the complete set of unique answers. The top-1 accuracy of the answer selection is reported.

- **Yahoo QA**, introduced in Tay et al. (2017), is a cleaned version of original Yahoo QA dataset [1], which is an open-domain CQA dataset collected from Yahoo Answers. In their setting, questions and answers that are not in the range of 5 - 50 tokens are filtered. Additionally, 4 negative samples are generated for each question by sampling from the top 1000 hits. Note that almost all the cases in this dataset are non-factoid questions. For this dataset, we use the same metrics as (Tay et al., 2017; Tay et al., 2018), including Precision@1 and MRR.

- **SQuAD-T**, introduced in Min et al. (2017), is a modification of SQuAD dataset (Rajpurkar et al., 2016) for answer selection task. SQuAD is a recent open-domain machine reading QA dataset, in which each case is a pair of context paragraph from Wikipedia and a question created manually, and the answer is a span in the context. The task of SQuAD-T is to classify whether each sentence contains the answer, since its contained context paragraphs are split into sentences.

The statistics of all datasets, i.e., training sets, development sets and testing sets, are given in Table 2.

Dataset	#Question (train/dev/test)	#QA Pairs (train/dev/test)	Question Example
TREC QA	1229/82/100	53417/1148/1517	What was the first Gilbert and Sullivan opera?
InsuranceQA	12887/1000/1800x2	37.1K/500K/900Kx2	Why have renter insurance?
Yahoo QA	50.1K/6.2K/6.2K	253K/31.7K/31.7K	How to maximize returns on your investments?
SQuAD-T	87.1K/10.5K/-	708K/53.6K/-	What sits on top of the main building at Notre Dame?

Table 2: Summary statistics of datasets.

4.2 Experimental Settings

Pre-trained GloVE embeddings[2] of 300 dimensions are adopted as word embeddings. We use a subset of Freebase (FB5M[3]) as our KB, which includes 4,904,397 entities, 7,523 relations, and 22,441,880 facts.

For the base models, we followed exactly the same parameter settings as those in their original papers. For the knowledge module, the width of the convolution filters is set to be 2 and 3, and the number of convolutional feature maps and the attention sizes are set to be 200. For the rest of our models, the final hidden layer size is set to 200 and all other parameters are randomly initialized from [-0.1, 0.1]. The model parameters are regularized with an L2 regularization strength of 0.0001. The learning rate and the dropout rate are set to 0.0005 and 0.5 respectively. The maximum length of sentence is set to be 40. We train all the models in batches with size of 64.

4.3 Results and Analysis

4.3.1 Comparisons Between TL Methods

To evaluate the proposed transfer learning method, we conduct the following comparison experiment with the same base model AP-LSTM (dos Santos et al., 2016), i.e., KAN(AP-LSTM). We first pre-train the models on the source dataset, and then fine-tune the models on target datasets. We also report the ablation tests in terms of discarding the knowledge module (i.e., AP-LSTM) and exploiting several different TL methods as follows:

- **Tgt-Only** is the baseline trained in the training set of target data.
- **Src-Only** is another baseline trained in the training set of source data.
- **Mixed** is to simply mix the training data from both target and source dataset to train the model.
- **Fine-Tune** is a widely used TL method, where we first train a model on the source data, and then use the learned parameters to initialize the model parameters for training another model on the target data. As is presented in Section 3.4, we employ three kinds of fine-tuning methods. Fine-Tune (all) means that we fine-tune all the parameters on the target data. Find-Tune (1) indicates that we fix all the weights of the base model and fine-tune parameters of the rest part of the overall model, while we fix all the weights of the knowledge module in Find-Tune (2).

Model	TL Method	Yahoo QA		TREC QA		InsuranceQA		
		P@1	MRR	MAP	MRR	DEV	TEST1	TEST2
AP-LSTM	(a) Tgt-Only	60.8	76.1	75.9	81.0	69.2	69.8	67.0
	(b) Src-Only	14.5	36.2	74.9	78.1	61.1	62.1	58.8
	(c) Mixed	56.8	73.1	75.1	79.5	69.1	70.2	67.3
	(d) Fine-Tune (all)	72.4	81.9	76.9	82.4	72.2	73.3	70.4
KAN(AP-LSTM)	(e) Tgt-Only	67.2(+6.4)	80.3(+4.2)	78.1(+2.2)	83.1(+2.1)	71.3(+2.1)	71.5(+1.7)	68.8(+1.8)
	(f) Src-Only	15.9(+1.4)	37.4(+1.2)	76.7(+1.8)	81.8(+3.7)	58.1(-3.0)	59.4(-2.7)	56.1(-2.7)

	(h) Fine-Tune (all)	74.2(+1.8)	83.4(+1.5)	78.8(+1.9)	84.1(+1.7)	**74.6**(+2.4)	75.3(+2.0)	72.1(+1.7)
	(i) Fine-Tune (1)	73.0	82.6	78.7	84.1	74.4	**75.6**	**72.6**
	(j) Fine-Tune (2)	**74.4**	**84.0**	**79.7**	**85.0**	74.4	75.2	72.5
Rank 1		60.1	75.5	77.1	83.8	71.7	71.4	68.3
Rank 2		57.3	73.6	78.0	83.4	68.4	71.7	66.4
Rank 3		55.7	73.5	75.0	81.5	70.0	70.1	62.8

Table 3: Comparisons Between TL Methods. The number in the parenthesis indicates the accuracy change over the same TL method in the base model.

Table 3 reports the experimental results of our transfer learning method on Yahoo QA, InsuranceQA and TREC QA and the performance of previous models that achieve the state of the art. To compare the previous competing models, we adopt the best three results on each dataset reported in the literature, which are presented as Rank 1,2,3 in Table 3. Both Yahoo QA and TREC QA results are reported from

[2]http://nlp.stanford.edu/data/glove.6B.zip

[3]https://research.facebook.com/researchers/1543934539189348

Tay et al. (2018), including Tay et al. (2018), Bradbury et al. (2016), Rao et al. (2016) and Tay et al. (2017). For InsuranceQA, they are from Wang et al. (2017), dos Santos et al. (2016), and Wang et al. (2016). There are multiple interesting observations from Table 3 as follows:

(1) Our transfer learning method (row (h,i,j)) outperforms the state-of-the-art results on Yahoo QA, TREC QA and InsuranceQA datasets by about 10%, 2% and 4% respectively.

(2) The results of KAN(AP-LSTM) (row (e-h)) significantly outperform AP-LSTM (row (a-d)), which demonstrates the effectiveness of incorporating external knowledge into the base model. Among these results, Src-Only on InsuranceQA is an exception since the target dataset is completely different from the source dataset in domain, which interferes the training of the knowledge module with the source dataset and brings a negative effect on the performance.

(3) For row (e), (f) and (g), we observe that Src-Only perform much worse than Tgt-Only, which indicates that the source QA dataset is quite different from all the target QA datasets. The greater the difference between the experimental results, the greater the difference between source and target datasets. Thus, we notice that Yahoo QA is the most different from SQuAD-T, and InsuranceQA is also very different from SQuAD-T, while TREC QA is the most similar one. Besides, the performance of Mixed is also worse than Tgt-Only, which implies that simply mixing the training data from two different datasets may lead to the overfitting of the source data.

(4) For row (h), (i) and (j), it can be observed that the Fine-Tune methods outperform the Tgt-Only method (row (e)), demonstrating that pre-training the model parameters on a source dataset is better than randomly initializing them. In specific, fine-tuning all the parameters of the model (row (h)) cannot always achieve the best result, because it may cause overfitting to fine-tune the entire model. For Yahoo QA and TREC QA, only fine-tuning the parameters of the base model (row (j)) achieves the best result. We infer that it is due to the shared knowledge from knowledge base is coherent between the source and target datasets. Conversely, InsuranceQA achieves its best performance with fine-tuning only the weights of the knowledge module (row (i)). Results on InsuranceQA indicate that one should pay attention to fine-tune the knowledge module rather than the base model when domain knowledge of the target dataset is quite different from the source dataset as InsuranceQA and SQuAD-T.

4.3.2 Applicability and Generality of our TL Method

To demonstrate the applicability and generality of our transfer learning method, besides AP-LSTM, we implement the overall transfer learning framework with other three base models, including Conv-RNN (Wang et al., 2017), Bi-LSTM (Wang and Nyberg, 2015), and Att-LSTM (Tan et al., 2016). The experimental results on TREC QA are summarized in Table 4.

From Table 4, we observe a similar result as Section 4.3.1. For these three base models, it makes a significant performance boost to incorporate external knowledge into the overall architecture. Besides, compared with Tgt-Only, Fine-Tune methods perform much better, which demonstrates that our transfer learning framework works on all the given models.

TL	Knowledge	Conv-RNN		Bi-LSTM		Att-LSTM	
Method	Module	MAP	MRR	MAP	MRR	MAP	MRR
Tgt-Only	w/o	77.1	82.4	75.0	80.4	73.5	79.2
	w/	78.0	83.1	77.4	82.5	75.9	80.1
Src-Only	w/o	74.9	78.7	74.1	79.5	72.1	76.9
	w/	76.3	80.2	75.6	81.3	74.8	78.6
Mixed	w/o	76.4	81.0	75.2	80.6	73.3	79.3
	w/	77.6	82.7	77.0	82.4	75.5	80.0
Fine-Tune (all)	w/o	78.3	83.2	76.8	82.3	75.3	79.8
	w/	79.4	**84.8**	78.2	83.6	77.1	81.3
Fine-Tune (1)	w/	78.8	84.0	78.4	83.1	77.7	81.6
Fine-Tune (2)	w/	**79.7**	**84.8**	**78.5**	**83.7**	**77.9**	**81.9**

Table 4: Experiment with Different Base Models.

4.3.3 Size of Target Dataset for Fine-tuning

We conduct experiments to study the relationship between the performance and the amount of training data from the target dataset for fine-tuning the model. We first pre-train the models on SQuAD-T, then vary the training data size of the target dataset, i.e., TREC QA and InsuranceQA, for fine-tuning. Note that we employ the AP-LSTM as the base model (i.e., KAN(AP-LSTM)) and fix all the parameters of the knowledge module during fine-tuning (i.e., Fine-Tune (2)).

The experimental result is summarized in Table 5. In general, fine-tuning with more target data actually improves the overall results. We observe that the performance increase from using 0% to 20% of target training data is substantially larger than latter increases. This result shows that we can achieve a competitive result with a small amount of target labeled data, by using our transfer learning method. Besides, it is obvious to notice that when increasing the number of target training data, the improvement on InsuranceQA is much more significant than that on TREC QA. As is presented in the analysis in Section 4.3.1, the InsuranceQA dataset is much different from the source dataset than the TREC QA dataset, not only in types but also in domains. Thus, the experiment result demonstrates the strong applicability in transferring shared knowledge between diverse datasets, even with limited labeled target data.

Percentage of target	TREC QA		InsuranceQA		
data for fine-tuning	MAP	MRR	DEV	TEST1	TEST2
0%	76.7	81.8	58.1	59.4	56.1
20%	78.1 (1.4)	83.4 (1.7)	72.0 (13.9)	72.8 (13.4)	69.5 (13.4)
40%	78.9 (0.8)	83.7 (0.3)	73.2 (1.2)	74.0 (1.2)	71.1 (1.6)
60%	79.1 (0.2)	84.2 (0.5)	73.6 (0.4)	74.5 (0.5)	71.6 (0.5)
80%	79.3 (0.2)	84.7 (0.5)	74.1 (0.5)	74.9 (0.4)	72.1 (0.6)
100%	79.7 (0.4)	85.0 (0.3)	74.4 (0.3)	75.2 (0.3)	72.5 (0.4)

Table 5: Results of varying sizes of the target datasets used for fine-tuning. The number in the parenthesis indicates the accuracy increases over the previous row.

4.3.4 Completeness of Knowledge Base

To observe the effect of the completeness of KB on the performance, we report the results on TREC QA and InsuranceQA with the incomplete knowledge base that randomly drops 20%-80% knowledge. Note that as the experimental settings in Section 4.3.3, we also employ the AP-LSTM as the base model (i.e., KAN(AP-LSTM)) and fix all the parameters of the knowledge module during fine-tuning (i.e., Fine-Tune (2)). Figure 2 shows that our model is robust and achieves excellent performance on the KB with different completeness. Besides, the more complete the knowledge base we leverage, the better the overall performance, which demonstrates the effectiveness of integrating external knowledge into the proposed method.

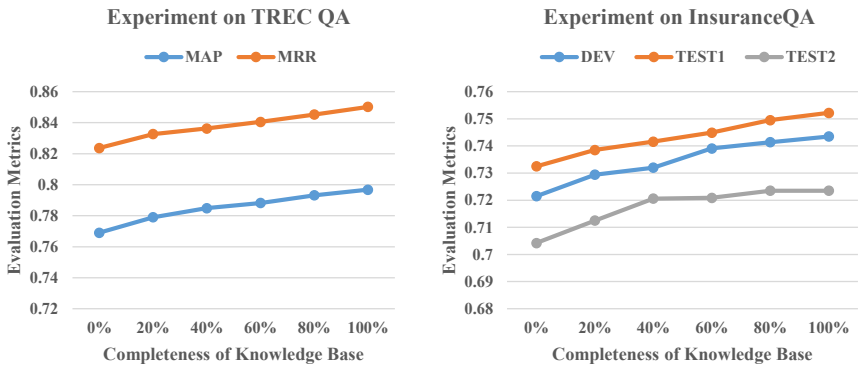

Figure 2: Effect of KB Completeness

5 Conclusion

In this paper, we propose knowledge-aware attentive network (KAN), a novel and general transfer learning framework, for cross-domain answer selection. We incorporate external knowledge from knowledge base into deep learning models to enrich the sentence representational learning and aid in transferring more valuable information between cross-domain datasets. Experimental results on three benchmark datasets demonstrate the superiority of our proposed method on answer selection task. We also conduct experiments to show the applicability and generality of our method and show that a resource-poor dataset can benefit from not only the scale of a resource-rich dataset but also the shared knowledge learned from knowledge base.

Abstract

The most approaches to Knowledge Base Question Answering are based on semantic parsing. In this paper, we address the problem of learning vector representations for complex semantic parses that consist of multiple entities and relations. Previous work largely focused on selecting the correct semantic relations for a question and disregarded the structure of the semantic parse: the connections between entities and the directions of the relations. We propose to use Gated Graph Neural Networks to encode the graph structure of the semantic parse. We show on two data sets that the graph networks outperform all baseline models that do not explicitly model the structure. The error analysis confirms that our approach can successfully process complex semantic parses.

1 Introduction

Knowledge base question answering (QA) is an important natural language processing problem. Given a natural language question, the task is to find a set of entities in a knowledge base (KB) that constitutes the answer. For example, for a question "What is Princess Leia's home planet?" the answer, "Alderaan", could be retrieved from a general-purpose KB, such as Wikidata[1]. A successful KB QA system would ultimately provide a universally accessible natural language interface to factual knowledge (Liang, 2016).

QA requires precise modeling of the question semantics through the entities and relations available in the KB in order to retrieve the correct answer. Figure 1 shows how the above example question could be modeled using Wikidata. The depicted graph structure consists of entities and relations from the KB and the special q-node. Any entity in the KB that can take the place of the q-node will be a part of the answer.

In this paper, we describe a semantic parsing approach to the problem of KB QA. That is, for each input question, we construct an explicit structural semantic parse (*semantic graph*), as in Figure 1. Semantic parses can be deterministically converted to a query to extract the answers from the KB. Similar graphical representations were used in previous work (Yih et al., 2015; Reddy et al., 2016; Bao et al., 2016).

However, the modern semantic parsing approaches usually focus either on the syntactic analysis of the input question (Reddy et al., 2016) or on detecting individual KB relations (Yu et al., 2017), whereas *the structure of the semantic parse* is ignored or only approximately modeled. Reddy et al. (2016) use the syntactic structure of the question to build all possible semantic parses and then apply a linear model with manually defined features to choose the correct parse. A subset of their features encodes basic information about the graph structure of the semantic parse (e.g. number of nodes). The state-of-the-art approach of Yih et al. (2015) and Bao et al. (2016) restricts all semantic parses to a single core relation and a small set of constraints that can be added to it. Their system uses manual features for the constraints and a similarity score between the core relation and the question to model the semantic parses.

The abovementioned systems were evaluated on the WebQuestions data set (Berant et al., 2013). Figure 2 plots results for the state-of-the-art systems by the number of relations that needs to be identified to get the correct answer to a question.[2] For example, the question in Figure 1 requires two relations

[1] https://www.wikidata.org/

[2] We include results for the most recent systems that have published the output on the WebQuestions data set. We compute the number of needed relations from the manual semantic parses provided by Yih et al. (2016).

Proceedings of the 27th International Conference on Computational Linguistics, pages 3306–3317
Santa Fe, New Mexico, USA, August 20-26, 2018.

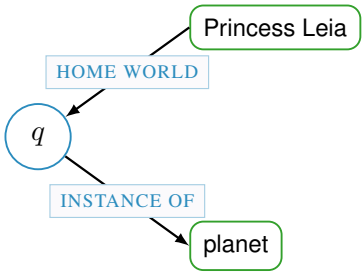

Figure 1: Semantic graph for an example question "What is Princess Leia's home planet?"

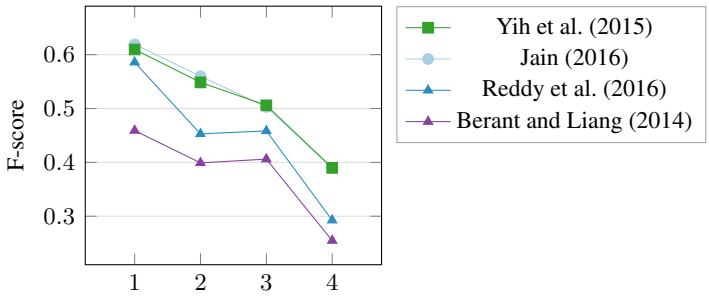

Figure 2: F-score QA results from previous work by the number of relations needed to find the correct answer

to find the answer. It can be clearly seen in Figure 2 that the lack of structure modeling in the modern approaches results in a worse performance on more complex questions that require more than one relation.

We claim that one needs to *explicitly model the semantic structure* to be able to find the correct semantic parse for complex questions. In this paper, we address this gap and investigate ways to encode the structure of a semantic parse and to improve the performance for more complex questions. In particular, we adapt Gated Graph Neural Networks (GGNNs), described in Li et al. (2016), to process and score semantic parses. To verify that GGNNs indeed offer an improvement, we construct a set of baselines based on the previous work that we train and evaluate in the same controlled QA environment. Throughout the experiments, we use the Wikidata open-domain KB (Vrandečić and Krötzsch, 2014) to construct semantic parses and retrieve the answers.[3]

Contributions To summarize, the main contributions of our work are:

(i) Our analysis shows that the current solutions for KB QA do not perform well on complex questions;

(ii) We apply Gated Graph Neural Networks on directed graphs with labeled edges and adapt them to handle a large set of possible entities and relations types from the KB. To the best of our knowledge, we are the first to use GGNNs for semantic parsing and KB QA;

(iii) Our Gated Graph Neural Network implementation for semantic parsing improves performance on complex questions in comparison to strong baselines. The results show a 27.4% improvement of the F-score against the best non-graph model.

Code and data sets Our system can be used with a pre-trained model to answer factual questions with Wikidata or trained anew on any data set that has question-answer pairs. The complete code, the scripts that produce the evaluation data and the installation instructions can be found here: `https://github.com/UKPLab/coling2018-graph-neural-networks-question-answering`.

2 Semantic parsing

2.1 Semantic graphs

We employ structural semantic representations in the form of graphs to encode the meaning of a question. Our *semantic graphs* consist of a question variable node (q), Wikidata entities (Taylor Swift), relation types from Wikidata (PERFORMER) and constraints (see Figure 3 for an example graph with a constraint). The q-node is always present and denotes the answer to the question. That is, all entities from the KB that can take its place so that all relations and constraints hold, constitute the answer to the question.

We write down a graph as a set of edges $\mathcal{E}$. Each edge links the q-node to one or two Wikidata entities (binary or ternary edge). The edge set $\mathcal{E}$ is defined via Wikidata relations and entities. Formally, Wikidata can be described as a very large graph $W = (E, R, I)$, where E is a set of entities, R is a set of binary

[3] At the moment, Wikidata contains more than 40 million entities and 350 million relation instances: `https://www.wikidata.org/wiki/Special:Statistics`

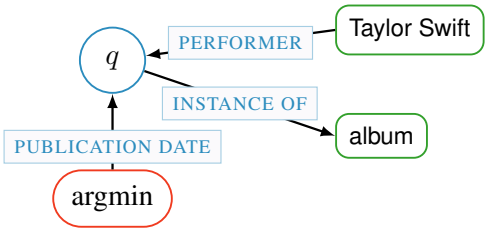

Figure 3: A semantic graph for an example question "What was the first Taylor Swift album?"

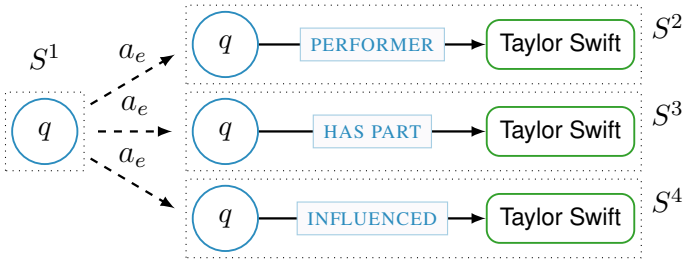

Figure 4: A single graph generation step: applying the add entity action a_e on an empty graph

relation types and I is a collection of relation instances encoded as $r(e_1, e_2),\ \ r \in R,\ \ e_1, e_2 \in E$ (e. g. CAPITAL(Hawaii, Honolulu)). Ternary relation instances in Wikidata are stored as a main relation triple and an attached modifer which itself is also a binary relation: $r_2\big(r_1(e_1, e_2), e_3\big),\ \ r_1, r_2 \in R,\ \ e_1, e_2, e_3 \in E$ (e.g. CHARACTER ROLE$\big($CAST MEMBER(Star Wars, Carrie Fisher), Princess Leia$\big)$. Then, the edge set $\mathcal{E}$ of a semantic graph consists of binary and ternary edges that correspond to Wikidata relation instances with q in place of one of the relation arguments. For temporal relations, the second argument can be either an argmax or an argmin constraint. This means that only entities that have the maximum or the minimum value of that relation are considered for the answer. This definition represents a subset of first-order logic semantic parses restricted to conjunctions of predicates. The graphs are also isomorphic to SPARQL queries that can be used to evaluate a graph against the KB.

Our semantic graphs were inspired by the query graphs of Yih et al. (2015) and their extension in Bao et al. (2016), the key difference being that we do not differentiate between the core relation and modifiers, but rather allow graphs that have multiple independent relations. We also allow relations to attach to other nodes rather than the q-node, enabling longer relation paths between a known entity and the q-node. Thus, the semantic graphs defined here are a superset of the query graphs in Yih et al. (2015) and allow us to model more complex meanings. Consequently, they also correspond to the formalized representations used by Reddy et al. (2014) and the simple λ-DCS (Berant et al., 2013), since those were the foundation for the query graphs (Yih et al., 2015).

2.2 Semantic graph construction

Yih et al. (2015) defined a step-by-step staged graph generation that does not need full syntactic parses and was also adopted in subsequent publications (Bao et al., 2016; Peng et al., 2017). We use the same procedure as Yih et al. (2015) to construct semantic graphs with a set of modifications that allow us to build more expressive and complex graphs.

We define a set of states and a set of actions that can be applied at each state to extend the current semantic graph. A state is a tuple of a graph and a set of free entities: $\mathcal{S} = (\mathcal{E}, \mathcal{F})$, where the graph is $\mathcal{E}$, as defined above, and $\mathcal{F} = \{e | e \in E\}$. The set of free entities $\mathcal{F}$ is the entities that were identified in the question but were not yet added to the graph.[4] The first state is a tuple of an empty graph with no edges and a set of all entities identified in the question $\mathcal{S}^1 = (\{\}, \mathcal{F})$.

Let $\mathcal{A} = \{a_e, a_c, a_m\}$ be the set of actions that can be taken to extend the graph at the current state. The action a_e (*add entity*) pops a free entity e from the set $\mathcal{F}$ at the current state $\mathcal{S}^t$. Then it queries the KB and retrieves the set of available relation types R_e for the entity e. For each relation type $r \in R_e$, it creates a new copy of the graph and adds a new directed edge between the q-node and e with the relation type r: $a_e(\mathcal{E}, \mathcal{F}) = \{\mathcal{E} \cup r(q, e), \mathcal{F} - e \mid e \in \mathcal{F}, r \in R_e\}$. Contrary to Yih et al. (2015) and Bao et al. (2016), we allow two-step paths between the q-node and the entity e: $r(q, d) \wedge r(d, e)$.[5]

The action a_c (*add constraint*) pops a free entity e and follows the same procedure as a_e, but instead of adding a new edge, it adds a modifier to the last added edge of the graph, thus creating a ternary edge: $a_c(\mathcal{E}, \mathcal{F}) = \{\mathcal{E} \cup r_2(r_1(q, e_1), e_2), \mathcal{F} - e_2 \mid e_2 \in \mathcal{F}, r_2 \in R_{e_2}, r_1(q, e_1) \in \mathcal{E}\}$. Finally, the action a_m

[4] We use an off-the-shelf entity linker to identify and disambiguate entity mentions in the question (see Section 4.4).

[5] Freebase relation instances always have an intermediate node and a two-step path corresponds to a single step in Wikidata.

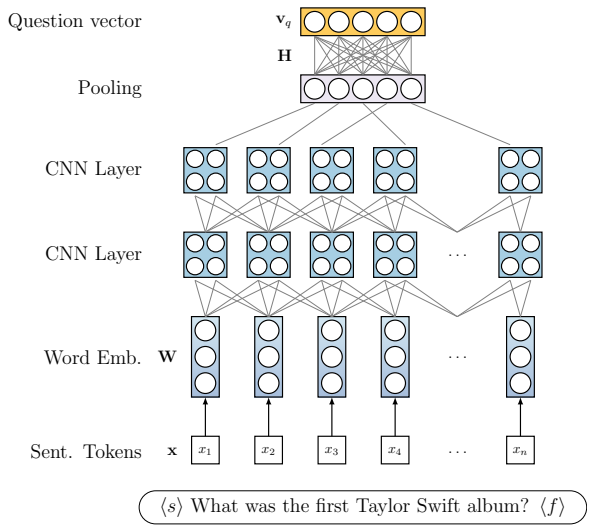

Figure 5: Deep Convolutional Neural Networks (DCNN) architecture, here used to process an example question

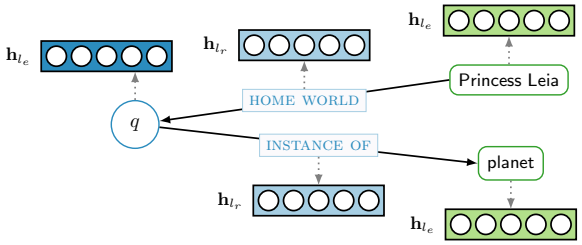

Figure 6: Encoding a graph into initial hidden states

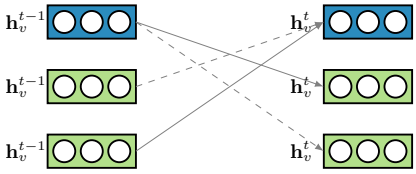

Figure 7: Unrolled recurrence for one timestep, solid lines show updates along the direction of the relation in the graph and the dashed lines in the opposite direction

(*add argmax/argmin*) adds a new edge with either argmax or argmin sorting constraint to the semantic graph: $a_m(\mathcal{E}, \mathcal{F}) = \{\mathcal{E} \cup r(q, \text{argmax}), \mathcal{F}; \mathcal{E} \cup r(q, \text{argmin}), \mathcal{F} \mid r \in R_d\}$, where R_d is a set of KB relation types that allow dates as values. Our semantic graph construction process allows to effectively search the space of possible graphs for a given question through an iterative application of the defined actions $\mathcal{A}$ on the last state $\mathcal{S}^t$ (see, for example, Figure 4).

3 Representation learning

We follow the state-of-the-art approaches for QA (Yih et al., 2015; Dong et al., 2015; Bao et al., 2016) and learn representations for the question and every possible semantic graph. Then we use a simple reward function γ to judge if a semantic graph is a correct semantic parse of the input question. Below we describe the architectures that we use to learn the representations for questions and graphs.

3.1 Deep Convolutional Networks

We use Deep Convolutional Neural Networks (DCNN) to learn a representation for a question. DCNNs have been proven effective for constructing sentence-level representations on a variety of NLP tasks, including named entity recognition (Strubell et al., 2017) and KB QA (Yih et al., 2015; Dong et al., 2015).

The DCNN architecture is depicted in Figure 5, where it is used to map an input question to a fixed-size vector representation. The input question is first tokenized and the special start and end tokens are added to the sequence: $\mathbf{x} = \{\langle s \rangle, x_1, x_2 \ldots x_n, \langle f \rangle\}$. Next, we map the tokens in $\mathbf{x}$ to d_w-dimensional pre-trained word embeddings, using a matrix $\mathbf{W}_{glove} \in \mathbb{R}^{|V_w| \times d_w}$, where $|V_w|$ is the size of the vocabulary. We use 50-dimensional GloVe embeddings that were trained on a 6 billion corpus (Pennington et al., 2014). The sequence of word embeddings is further processed by an array of CNN layers. We apply a pooling operation after the last CNN layer and transform the output with a fully connected layer $\mathbf{H}$ and a ReLU non-linearity. We take the resulting vector $\mathbf{v}_q$ as the representation of the question.

3.2 Gated Graph Neural Networks

Gate Graph Neural Networks (GGNN) process graphs by iteratively updating representations of graph nodes based on the neighboring nodes and relations (Li et al., 2016). We adopt GGNNs for semantic parsing to learn a vector representation of a semantic graph. Li et al. (2016) give a formulation of GGNNs for graphs with labeled nodes and typed directed edges. We extend their formulation to include labeled edges. To the best of our knowledge, we are the first to apply GGNN to semantic parsing and KB QA.

For a graph $\mathcal{E}$, we extract a set of all entities $\mathcal{V}$ in the graph and a set of all relation types $\mathcal{R}$ of its edges. We use labels from Wikidata to compute vectors for entities and relation types (Figure 6). This enables us to directly incorporate the information on millions of entities and hundreds of relation types from the KB. For an entity $e \in \mathcal{V}$ or a relation type $r \in \mathcal{R}$ we retrieve the label and tokenize it: $\mathbf{l} = \{l_1, l_2 \dots l_n\}$. Then we map each token in $\mathbf{l}_e$, $\mathbf{l}_r$ to a word embedding using the matrix $\mathbf{W}_{glove}$, sum them and process with a fully connected layer to get a single label vector: $\mathbf{h}_l = \tanh\big(\mathbf{W}_\mathbf{l}\big[\sum_{n=1}^{|\mathbf{l}|} w_n\big] + \mathbf{b}_\mathbf{l}\big)$. We initialize the hidden states for the graph nodes with the label vectors of the entities: $\mathbf{h}_v^{(1)} = \mathbf{h}_{l_e}$. We further transform the relation label vectors to get directional embeddings for relations types: $\mathbf{h}'_r = \mathbf{W}_{\rightarrow}\mathbf{h}_{l_r}$, $\mathbf{h}''_r = \mathbf{W}_{\leftarrow}\mathbf{h}_{l_r}$. Using the same word embeddings as an input to construct the question and relation representations has been shown successful in previous work (Jain, 2016).

Propagation Model GGNNs are a type of recurrent neural networks. The recurrence is unrolled for a fixed number of steps T and the gating mechanism works akin to Gated Recurrent Units (Cho et al., 2014). The propagation model for GGNN is defined as follows:

$$\begin{aligned}\mathbf{a}_v^{(t)} &= \mathbf{A}_{v:}^\top\big[\mathbf{h}_1^{(t-1)\top} \dots \mathbf{h}_{|\mathcal{V}|}^{(t-1)\top}\big] \\ &\quad + \mathbf{A'}_{r:}^\top\big[\mathbf{h}_1'^\top \dots \mathbf{h}_{|\mathcal{R}|}'^\top, \mathbf{h}_1''^\top \dots \mathbf{h}_{|\mathcal{R}|}''^\top\big]\end{aligned} \quad (1)$$

$$\mathbf{z}_v^t = \sigma\big(\mathbf{W}^z\mathbf{a}_v^{(t)} + \mathbf{U}^z\mathbf{h}_v^{(t-1)} + \mathbf{b}^z\big) \quad (2)$$

$$\mathbf{r}_v^t = \sigma\big(\mathbf{W}^r\mathbf{a}_v^{(t)} + \mathbf{U}^r\mathbf{h}_v^{(t-1)} + \mathbf{b}^r\big) \quad (3)$$

$$\widetilde{\mathbf{h}_v^{(t)}} = \tanh\big(\mathbf{W}\mathbf{a}_v^{(t)} + \mathbf{U}\big(\mathbf{r}_v^t \odot \mathbf{h}_v^{(t-1)}\big) + \mathbf{b}\big) \quad (4)$$

$$\mathbf{h}_v^{(t)} = (1 - \mathbf{z}_v^t) \odot \mathbf{h}_v^{t-1} + \mathbf{z}_v^t \odot \widetilde{\mathbf{h}_v^{(t)}}, \quad (5)$$

where σ is the logistic sigmoid function and $\odot$ is the element-wise multiplication. The matrix $\mathbf{A} \in \mathbb{R}^{|\mathcal{V}|\times 2|\mathcal{V}|}$ stores the structure of the graph: a row of the matrix $\mathbf{A}_{v:}$ records the edges between the node v and the other nodes in the graph (we differentiate between incoming and outgoing edges). The second matrix $\mathbf{A'} \in \mathbb{R}^{|\mathcal{V}|\times 2|\mathcal{R}|}$ stores the relation types of the incoming and outgoing edges.

The main difference from the model defined in Li et al. (2016) is that we compute activations $\mathbf{a}_v^{(t)}$ based on both the node hidden vectors $\mathbf{h}_v^{(t-1)}$ and relation hidden vectors $\mathbf{h}'_r$ (Eq 1). The $\mathbf{z}_v^t$ in Eq 2 and $\mathbf{r}_v^t$ in Eq 3 are update and reset gates, that incorporate information from nodes, relation types and from the previous step to update nodes' hidden states at each iteration. We do not make updates to the hidden vectors of the relations and use them only to pass the information to the nodes' hidden states.

Graph-level Output Vector We unroll the recurrence for $T = 5$ steps in the experiments (Figure 7). To produce a graph-level output vector, we take the hidden vector for the q-node at the last time step $t = T$ and transform it with a fully-connected layer and the ReLU non-linearity: $\mathbf{v}_g = \mathrm{ReLU}\big(\mathbf{W}\mathbf{h}_q^{(t)} + \mathbf{b}\big)$.

4 Experiments

4.1 Data

We use Wikidata to show experimentally that GGNNs are better at learning representations of semantic graphs than previous approaches. Hence, we choose two data sets that can be processed with Wikidata to compare the GGNNs to other models: WebQSP-WD and QALD-7.

WebQSP-WD We derive WebQSP-WD from WebQSP (Yih et al., 2016), which is a corrected version of the popular WebQuestions data set (Berant et al., 2013). WebQSP contains natural language questions, Freebase IDs of the correct answers and SPARQL queries to retrieve them that also use Freebase. Freebase was a common choice of a KB among the previous work, but was discontinued and is no longer up-to-date, including unavailability of APIs and new dumps. The questions in the data set were collected with the Google Suggest API and are thus more 'natural' than manually constructed questions. The answers were retrieved from Freebase with the help of crowd-sourcing. The data set contains both simple questions that can be answered with a single relation as well as complex questions that require multiple relations and constraints. It is a common benchmark for semantic parsers and information retrieval systems and was used in the most recent studies on KB QA. We automatically map Freebase IDs in the WebQSP train and test sets to Wikidata IDs and filter out questions which answers do not have the mapping. We designate

this version of the dataset WebQSP-WD. It is important to note that this does not ensure that a question is answerable with Wikidata as there still might be no relation paths in the KB that connect the entities in the question with the answer.

QALD-7 As the second data set, we use QALD-7 that was developed for Task 4 of the QALD-7 Shared Task, "English question answering over Wikidata" (Usbeck et al., 2017). The QALD-7 data set contains a small number of manually constructed complex questions that were specifically created to test system's ability to process questions with multiple entities and constraints. The data set uses Wikidata IDs for all annotations. We do not train on QALD-7 data set and use it solely for an out-of-domain evaluation. The data set statistics can be found in Table 1.

4.2 Models

We define five models for our experiments, including three baselines and two graph models. We use cosine similarity between the question representation and the semantic graph representation as a reward function that judges whether the semantic graph is the correct parse of the question: $\gamma = \cos(\mathbf{v_s}, \mathbf{v_g})$.

1. STAGG (re-implementation of Yih et al. (2015)) — We implement a model that uses a combination of a neural network and manual features suggested in Yih et al. (2015) and in the follow up work of Bao et al. (2016). The approach of Yih et al. (2015) performed best among the previous work on complex questions (see Figure 2). First, DCNN is used to produce a representation for the input question, as described in Section 3.1. Then, we replace the entity tokens in the input question with a special entity symbol $\langle e \rangle$ and apply DCNN on it again to get a second representation for the question. For each semantic graph, we take the label of the relation in the first edge (*core edge*), tokenize it and likewise apply DCNN on it to get a representation. We produce two representations for the core relation: one that includes the label of the attached entity and one that includes the entity symbol. The manual features include binary indicators for modifiers and constraints in the semantic graphs, as well as features for certain keywords in the question (see Yih et al. (2015) for a detailed description).

   The original system and the models of Yih et al. (2015) and of Bao et al. (2016) are not available and therefore we use our own implementation of their approach. There is a number of small difference with the original model: we use a deep CNN instead of a single CNN layer and train the DCNN together with the manual features, whereas Yih et al. (2015) pre-trained the CNN model on a separate corpus and used its output in the feature model.

2. Single Edge model — We use the DCNN to encode the question and the label of the first edge of a semantic graph. The rest of the information is ignored.

3. Pooled Edges model — We use the DCNN to encode the question and the label of each edge in the semantic graph. To get a fixed-vector representation of the graph, we apply a pooling operation over the representation of the individual edges. This model encodes all information about the semantic graphs, but disregards their structure.

4. Graph Neural Network (GNN) — To judge the effect of the gated graph neural architecture, we also include a model variant that does not use the gating mechanism and directly computes the hidden state as a combination of the activations (Eq 1) and the previous state.

5. Gated Graph Neural Network (GGNN) — We use the GGNN to process semantic parses, as described in Section 3.2. This model encodes all information from semantic graphs, including their structure, into a vector representation. To encode the question we use the same DCNN model (see Section 3.1).

The defined baselines use either manual features to capture the structure of the semantic graph (STAGG), a simple pooling mechanism (Pooled Edges) or disregard the structure completely (Single Edge). The two graph models (GNN and GGNN) make the full use of the graph structure of a semantic parse and encode it with graph neural networks. With this set-up, we are able to demonstrate what effect different levels of inclusion of the graph structure into the model have on the final performance for KB QA. We do

not include the published models of Berant et al. (2013) and Reddy et al. (2014) in the comparison since they were trained on Freebase and are not compatible with Wikidata. We use the more recent STAGG approach to position the graph models against the previous work and the feature-based models.

4.3 Training the model

To train the model, we need positive pairs of questions and semantic graphs. Since WebQSP does not contain semantic parses for Wikidata, we use weak supervision as suggested in Berant et al. (2013). Specifically, we follow Yih et al. (2015) and run our semantic graph construction procedure to create training instances (see Section 2.2). We use the state-of-the-art S-MART entity linking system for noisy data (Yang and Chang, 2015) to extract a set of entities $\mathcal{F}$ from each question.[6] Instead of scoring the semantic graphs with the model, we evaluate each graph against Wikidata and compare the extracted answers to the manual answers in the data set. The semantic graphs that result in a correct answer are stored as positive training instances and the rest of the graphs generated during the same process are used as negative instances. Due to the differences between Freebase and Wikidata, some question can not be answered exactly using Wikidata. We generate positive semantic graphs for 1945 questions out of 2880 (see Table 1) and put 628 as a development set aside.

Practical considerations At each training epoch, we take all positive semantic graphs and up to 100 negative graphs per question. We optimize the maximum margin loss function: $\mathcal{L} = \sum_{g \in C} \max\big(0, (m - \gamma(\mathbf{v}_q, \mathbf{v}_g^+) + \gamma(\mathbf{v}_q, \mathbf{v}_g^-))\big)$, where C is a set of semantic parses for the given question. From the loss function, we compute updates for the GGNN and the DCNN parts of the model.

All models are trained using the Adam optimizer (Kingma and Ba, 2014) with a batch size of 64. We use an early stopping criterion on the development data to determine the number of training epochs. The learning rate is fixed to 0.001 and the other optimization parameters are set as recommended in Kingma and Ba (2014): $\beta_1 = 0.9$, $\beta_2 = 0.999$, $\epsilon = 1e-08$. We apply Dropout (Srivastava et al., 2014) at every fully-connected layer as well as on the embeddings layers. We determine the hyper-parameters, such as the size of the hidden layer, with the random search on the development set (see Table 2). On the 1945 training questions, the GGNN model has usually finished training in under two hours on a single GPU.

	WebQSP-WD (train)	WebQSP-WD (test)	QALD-7
questions	2880	1033	80
complex questions	419	293	42
avg. # of relations per question	1.35	1.39	2.13

Parameter	Tested values	Selected
Hidden layer size	$[32, 64, 128, 256, 512]$	256
CNN filter size	$[32, 64, 128, 256, 512]$	256
Dropout ratio	$\mathcal{U}(0.0, 0.5)$	0.2
# of CNN layers	$[1, 2, 3]$	2
Pooling operation	$[\text{avg}, \text{sum}, \max]$	max

Table 2: Optimized hyper-parameter values

4.4 Inference

We take the steps described in Section 2.2 to construct possible semantic graphs for a question at inference time. For WebQSP-WD, we use the entities produced by S-MART (Yang and Chang, 2015) to start the graph construction. On QALD-7, we use the annotated entities provided by the Shared Task organizers.

Each question and semantic graph are encoded into fixed-size vector representations and the reward function γ is used to score the graphs. The highest scoring graph is used to retrieve the answers from Wikidata. Given the iterative nature of our semantic graph construction procedure, we adopt beam search to speed up the computation. We score the graphs after each step and select the top 10 to proceed.

[6] S-MART is not openly available, but the output on the WebQuestions dataset was made available by Yih et al. (2015): https://github.com/scottyih/STAGG

5 Results

We follow the previous work (Berant et al., 2013) and use precision, recall and F-score to evaluate the models. The measures are computed for each individual question and then macro-averaged. This ensures a fair evaluation, since a system might provide a partially correct answer that is nevertheless better than a complete miss. We compare the graph models to the baselines including the previous state-of-the-art STAGG architecture.[7]

5.1 WebQSP-WD

We compare the results on the WebQSP-WD data set in Table 3. As can be seen, the graph models outperform all other models across precision, recall and F-score, with GGNN showing the best overall result. We confirm thereby that the architecture that encodes the structure of a semantic parse has an advantage over other approaches. To validate the results, we have re-trained the model with different random seeds and observed little variance in the results (F-score, $\sigma = 0.0205$).

The STAGG architecture delivers the worst results in our experiments, the main reason being supposedly that the model had to rely on manually defined features that are less flexible. The Single Edge model outperforms the more complex Pooled Edges model by a noticeable margin. The Single Edge baseline prefers simple graphs that consist of a single edge which is a good strategy to achieve higher recall values.

Since our main goal is to produce better encoding of semantic graphs, we break down the performance of the evaluated models by the number of relations that are needed to find the correct answer.[8] In Figure 8, we see that for the STAGG and Single Edge baselines the performance on more complex questions drops compared to the results on simpler questions. The Pooled Edges model maintains a better performance across questions of different complexity, which shows the benefits of encoding all graph edges. Looking at Figure 8 we also get a further insight into the difference between the Single Edge and the Pooled Edges models. These two models achieve almost identical results on the simple questions, which is to be expected since these models are equivalent when the number of edges is 1. On other questions, the Single Edge baseline performs mostly under the Pooled Edges model, but significantly outperforms it on the questions that need 4 edges to get the correct answer.

We see that the GGNN model offers the best results both on simple and complex questions, as it effectively encodes the structure of semantic graphs. The performance of the model drops for the most complex questions (# of edges ≥ 4). That does not happen for the GNN model variant without the gating mechanism. We conjecture that this happens because GGNN has more parameters than GNN and therefore needs more data to learn. By looking at the model errors on the most complex questions, we could see that GGNN tends to incorrectly predict one of the relations in the graph, which results in a wrong answer. GNN, on the other hand, more often predicts less relations that are needed and therefore gets a non-zero score for a partially correct answer. For example for the question "Who is the prime minister of Spain 2011?", GNN predicts a graph of two relations INSTANCE OF(human) and HEAD OF GOVERNMENT which returns a list of all Spanish prime ministers. The complete correct graph would also include temporal constraints.

[7] Since we use Wikidata and WebQSP-WD, the values reported in this work are not directly comparable to those for Freebase.

[8] We use again the manually constructed queries provided by Yih et al. (2016) to estimate it.

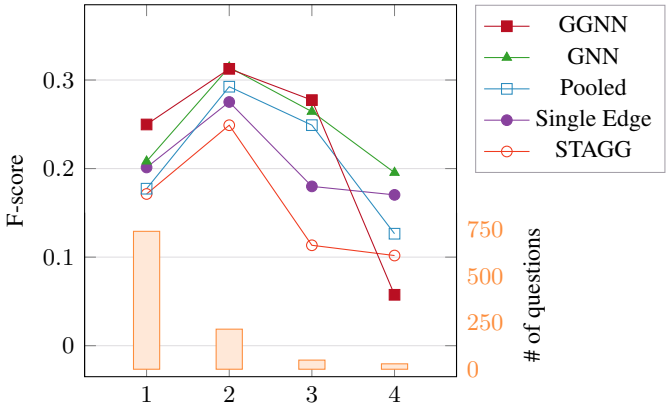

Figure 8: Evaluation results by # of relations needed to find the correct answer (bars show # of questions)

	Pooled	GGNN
F-score > 0.5	22.27%	28.37%
F-score > 0.0	29.82%	37.08%
Entity linker errors	6%	8%
No path to answer	14%	18%
Data set inconsistency	8%	14%
Wrong prediction	72%	60%
hit@10	35.62%	44.05%

Table 5: Manual error analysis results on WebQSP-WD

Notably, GGNN also has the best performance on the most simple semantic parses that only have one edge. In these cases, two nodes in the graph interact with each other through the single edge in both directions. The GGNN is better at capturing this interaction than other models.

5.2 QALD-7

Next, we examine the out-of-domain results on the QALD-7 data set for the five models (see Table 4). The difference in performance is less prominent on this data set, but we can observe the same trends. The Single Edge model outperforms both the STAGG and Pooled Edges baselines. The GGNN delivers the best performance, although overall the best result is worse than on the WebQSP-WD data set. QALD-7 is much smaller, but also more complex on average (cf. the average number of edges needed to find the correct answer in Table 1). Overall, we can conclude that the explicit modeling of the structure of semantic graphs with GGNN results in a better performance both in-domain on WebQSP-WD and out-of-domain on QALD-7 that was only used for evaluation.

5.3 Error analysis

To better understand the difference between the approaches that encode graph structure and the approaches that disregard it, we closely look at the output of GGNN compared to the Pooled Edges model. The first two rows in Table 5 show how often the respective model has returned an answer with F-score higher than 0.5 which is a mostly correct answer and how often it returned an answer that was not just completely wrong (F-score > 0.0). We see that GGNN delivers an acceptable answer almost 25% more often than Pooled Edges model, but there is still a lot of questions that are not answered correctly.

We have manually analyzed 100 sample answers from the two models where the resulting F-score was lower than 0.5 (see rows 3 through 6 in Table 5). Since GGNN makes less mistakes in general, the error propagation from the entity linking takes a slightly larger portion of the final error count. In 18% of the cases, it was impossible to find the answer in Wikidata since there were no path between entities in the question and the answer. For example, for the question "Where did Harper Lee attend high school?", the correct answer "Monroe County High School" is a valid entity in Wikidata, but it is not connected to "Harper Lee" via the EDUCATED AT relation. 14% of the time, the data set contained an inconsistent answer and even though the model has predicted the correct semantic graph, the answers did not match. For example, a correct answer for a question about someone's place of birth is usually a city or a town, yet for a smaller set of questions a city borough (e.g. Manhattan) or a country are listed in the data set.

Overall, in 32% of the cases the error was caused by the gap between the KB and the data set. This lets us put the current results into a perspective with the previously reported numbers for the Freebase KB. If we approximately adjust our results for this kind of errors, we achieve between 0.469 and 0.51 F-score. Reddy et al. (2016) report results for various approaches ranging from 0.404 to 0.503 F-score on the original WebQuestions data set that is a superset of WebQSP-WD (see Section 4.1).

The majority of errors for both models are caused by wrong predictions (row 6 in Table 5). GGNN selects significantly less wrong semantic graphs and more often successfully handles graphs with multiple edges. For example, for a question "What language do people speak in Brazil?", the GGNN model correctly predicts the graph with two edges HOME COUNTRY and NATIVE LANGUAGE to get a list of all languages that are spoken in Brazil. Whereas the other models either select the relation OFFICIAL LANGUAGE that returns only the official language of the country or choose a wrong interpretation altogether. We also look at the hit@10 measure that shows how often the correct semantic graph was in the top 10 scored graphs by the model (row 7 in Table 5). Notably, in 44% of the cases the correct semantic graph was still among the top scored graphs for the GGNN model.

6 Related work

We have focused on the problem of the increasing error rates for complex questions and the encoding of the semantic graph structure. In this paper, we describe a semantic parsing system for KB QA and follow the approach of Yih et al. (2015) who do not rely on syntactic parsing to construct semantic parses. Our semantic graphs do not cover some aspects of the first-order logic, such as negation. Reddy et al. (2016) define a semantic parser that builds first-order logic representations from syntactic dependencies. They further specify how it can be extended with negation in Fancellu et al. (2017).

We only train on the WebQSP-WD data set and we note that more data might be necessary to effectively train the gated graph architecture. Reddy et al. (2014) suggest an unsupervised learning method to learn a model from a large web corpus, while Su et al. (2016) use patterns and crowdsourcing to create new data with specific properties. These techniques can be used to further improve the performance of our model.

An alternative solution to semantic parsing is to build an information extraction pipeline that views the question as a query and the KB as a source of relevant information (Yao et al., 2014). Dong et al. (2015) and Jain (2016) construct a vector representation for the question and use it to directly score candidate answers from the KB. However, such approaches are hard to analyze for errors or to modify with explicit constraints. For example, it is not directly possible to implement the temporal sorting constraint (argmax).

We apply GGNNs to the problem of semantic parsing. Li et al. (2016) have developed the gated architecture based on the graph neural network formulation of Scarselli et al. (2009). Recently, a slightly different design of Graph Convolutional Networks was proven effective on a KB completion task (Schlichtkrull et al., 2018). Kipf and Welling (2017) introduced Graph Convolutional Networks, while Marcheggiani and Titov (2017) employed them for natural language processing for the first time and compared them to other formulations. Graph Convolutional Networks have a similar gated architecture and share most of the same properties with the Gated Graph Neural Networks used.

7 Conclusions

In this work, we have used Gated Graph Neural Networks to encode the structure of the target semantic parse for KB QA. We have shown that disregarding the semantic structure leads to a falling performance on questions that require complex semantic parses to get the correct answers. Our GGNN architecture was able to successfully model the structure of semantic parses. We have compared the performance of GGNNs against the previous work and non-graph models on two data sets and have broken down the results by question complexity. The analysis has shown that the suggested graph architectures do not have the same drop in performance on complex questions and produce better overall results.

Recently, Peng et al. (2017) and Yu et al. (2017) have attempted to incorporate entity linking into a feature based QA model. In the future, we plan to follow their work and integrate GGNNs with entity linking into a single model. We also see possible applications for GGNNs on other semantic parsing tasks, such as text comprehension.

Rethinking the Agreement in Human Evaluation Tasks (Position Paper)

Jacopo Amidei and **Paul Piwek** and **Alistair Willis**
School of Computing and Communications

Milton Keynes, UK

Abstract

Human evaluations are broadly thought to be more valuable the higher the inter-annotator agreement. In this paper we examine this idea. We will describe our experiments and analysis within the area of Automatic Question Generation. Our experiments show how annotators diverge in language annotation tasks due to a range of ineliminable factors. For this reason, we believe that annotation schemes for natural language generation tasks that are aimed at evaluating language quality need to be treated with great care. In particular, an unchecked focus on reduction of disagreement among annotators runs the danger of creating generation goals that reward output that is more distant from, rather than closer to, natural human-like language. We conclude the paper by suggesting a new approach to the use of the agreement metrics in natural language generation evaluation tasks.

1 Introduction

Human evaluations are broadly thought to be more valuable the higher the inter-annotator agreement (IAA). In natural language processing (NLP), IAA is often viewed as a means of assessing the quality of data on a task, in particular, the reliability. Also, it helps to identify poor annotations, provide information on where annotation guidelines can be improved, and establish an upper bound on system performance. Nevertheless some studies, for example (Sampson and Babarczy, 2008), (Kovář 2016) and (Kovář et al., 2016)[1], propose IAA limitations when used in the annotation of natural language generation (NLG)[2], where annotation usually concerns the quality of a generated sentence – including a range of features such as syntax, semantic and pragmatics. Indeed, natural language brings in itself a variability which cannot be reduced, except by weakening its expressive power. For instance, the perception of sentence idiomaticity can change from person to person because of styles, educational and regional difference (for example differences between British and American English for English sentences). Far from being a problem this shows the richness, variability and beauty of human languages.

In this paper we are going to study IAA in the area of Automatic Question Generation (AQG)[3]. We performed experiments which show that there are factors inherent to question annotation that place an upper-bound on IAA. We found subjective bias that cannot be removed by improving the annotation

[1] It is also worth mentioning Martinez Alonso et al. (2016), where the authors use the systematic disagreement in order to train their model. Martinez Alonso et al. raise the discussion about how to distinguish and use potentially relevant from irrelevant disagreement. Although this problem is very interesting and deserves a deep analysis, it goes beyond the scope of the present paper.

[2] In what follows, when we refer to NLG tasks, we consider tasks that require generation of human language and whose possible output space is, as a result, very wide (given that a natural language often allows the same information to be expressed in many different ways). Input may vary, and range from text and data to images. Examples of these are: dialogue generation, question generation, image caption generation, narrative generation, and so on.

[3] Although we focused on the AQG task, we believe the causes we discovered behind annotators' disagreement are more general, and they are likely to apply to different NLG tasks.

Proceedings of the 27th International Conference on Computational Linguistics, pages 3318–3329
Santa Fe, New Mexico, USA, August 20-26, 2018.

guidelines, unless we completely distort the goal of producing human language variability[4]. Our empirical study provides new evidence in strong support of the claim that high IAA is not always desirable. This work shows that for AQG tasks, a low IAA in the evaluation phase is part of the nature of language. More generally, the experimental results suggest that in NLG the ability to automatically generate sentences as similar as possible to human generated ones seems to go in the opposite direction from the achievement of a high IAA evaluation score. Although the Kappa coefficients agreement, normally used for measuring IAA, takes into account some level of randomness introduced by annotators, it might be that the Kappa scales of interpretation used to check IAA are not generally adequate for NLG purposes. Accordingly, we propose to rethink the agreement in human evaluation tasks.

2 Related work and preliminary concepts

Since Carletta's (1996) paper, which introduced the use of the kappa statistic in NLP, several papers have studied the IAA in NLP tasks. Among those, we now describe the most relevant to our work.

Bayerl and Paul (2011) investigate different factors which impact the IAA score, performing a meta-analytic investigation that involves 96 annotation studies. From their analysis, the authors conclude that at least seven factors are determinant in affecting the IAA values. These factors are: "annotation domain, number of categories in a coding scheme, number of annotators in a project, whether annotators received training, the intensity of annotator training, the annotation purpose, and the method used for the calculation of percentage agreements". They conclude their study giving some suggestions to decrease annotator disagreement. Ng et al. (1999) study IAA in the field of word sense disambiguation. The authors found that we can increase the IAA by collapsing sense classes. Indeed, they report that, for the 53 nouns they examined, reducing the nouns' senses from an average of 7.6 per noun to an average of 4, raises the average Kappa score (computed as an average of the Kappa value of the individual nouns) from 0.463 to 0.862. In order to improve the evaluation IAA of the task B defined in the Shared Evaluation Task Challenge (QG -STEC) (Rus et al., 2012), Godwin and Piwek (2016) define an interactive process where the annotators can discuss their opinions about the criteria used in the evaluation. At the end of the evaluation process, repeated three times with three annotators, they achieved high IAA with a pick of 0.94 for one of the five criteria used in the evaluation. In recent work, Novikova et al. (2018), use a rank-based magnitude estimation methodology in order to improve the agreement of human judgements.

The papers we have just presented share the assumption that a high IAA is a desirable goal and they study some ways to increase it. In this paper we reject the assumption that arbitrarily high IAA is always desirable or obtainable. Our paper is more in line with the direction of Sampson and Babarczy (2008), who investigate the upper bounds that can be achieved on IAA. More precisely "the limits to the potential precision of English grammar annotation" are studied. Sampson and Babarczy perform their experiment using the SUSANNE scheme (Sampson, 1995) for a parse-tree structure task. From their study they conclude that discrepancy in IAA emerges for three main reasons: A) violation of an explicit feature of the annotation scheme; B) the lack of a single, unambiguous annotation decision yielded by the scheme, even though the meaning of the text is clear; C) structural ambiguity in the text.

A really interesting survey for understanding of the IAA in NLP is presented by Artstein and Poesio (2008), who give an excellent analysis of the K agreement measures. The authors discuss the mathematics and interpretation of these coefficients and their use in several computational linguistic tasks.

Automatic Question Generation task definition: Automatic question generation is the task "*of automatically generating questions from various inputs such as raw text, database, or semantic representation*" (Rus et al., 2008). This definition, adopted by the AQG community, leaves room for researchers to decide which kind of questions and which kind of input to work with. Following Piwek and Boyer (2012), we can characterize a specific AQG task as relying on three features: what the input is, what the output is and finally the relation between the input and the output.

[4]Since human evaluations are valuable tools for generative system developers — indeed the evaluation results can be used for error analysis — artificial restrictions on annotation schemes can bias system developers towards ignoring important aspect of human language. This problem can be more accentuated if the annotation guidelines are used in order to create a corpus for training purposes.

Given the wide variety of AQG tasks we must specify the task we are interested in to perform our experiments. Regarding the output, we are looking for interrogative English sentences. Having defined the output, we can now move to specify the input and the input/output relationship. As an input we consider English text, where the relation can be described by the following situation: the output question is answered by the input text, that is, the questions are about the input information. In this task the AQG systems, given a text T as an input, generate a question which can be used, for instance, to verify the respondent's knowledge about T. We will give some examples in section 4. For the sake of simplicity, in what follows we will refer to this task as text2text. To our knowledge, at the moment the text2text task is the most studied task in the AQG community.

Gold standard evaluation approach: As a generation task, whose possible output space is very large, text2text faces the problem of the absence of a comprehensive gold standard. A gold standard, usually obtained through human annotations, is thought to be the correct set of solutions for a particular task T, and it is used either for training or evaluated models for T's purpose. Given a task, the gold standard evaluation approach is based on the assumption that we can always define a precise and exhaustive (or near exhaustive) set of outputs for the task.

In NLG the gold standard is a set of natural language words, sentences or more generally texts. Given the huge human ability to use many different expressions to reach the same communicative goal, language generation tasks cannot safely rest on the gold standard approach for evaluation purposes.

In NLP the gold standard approach has been used for evaluation through automatic metrics, which compare the automatic generated sentences against the gold standards. In the last few years many studies in NLP have shed light on the correlation between human judgement and metrics such as BLEU (Papineni et al., 2002)[5]. The results, which have shown this correspondence to be weak[6], cast doubt on the feasibility of use of these metrics to evaluate the overall model quality. Indeed, a model may generate very high quality sentences that are different from the ones in the gold standard set used for evaluation — this is especially possible if we train and evaluate a model with different corpus text.

For the text2text task, this problem can be expressed in the following way: Given a text T it is possible to generate many different correct questions about T. More specifically, given a text T with an answer A relative to T, it is possible to generate different correct questions answered by A. In both cases the questions generated, although good, can be very different from the gold standards previously chosen, and so get a low ranking from automatic metrics. For NLG tasks, the idea of some platonic gold standard which, given a task t, can provide an ideal solution for t, is unrealistic.

As we will see soon, the difficulty of having a platonic gold standard is not just a problem for automatic evaluation metrics but it is also reflected in the difficulty of reaching a high human evaluation agreement.

Annotation guidelines: The absence of a comprehensive gold standard evaluation approach is reflected in the difficulty of formulating precise annotation guidelines. These are either defined in order to annotate corpus data or to give instructions for human evaluation tasks.

The annotation guidelines accompany a particular annotation scheme[7] , and should strictly define the features that the humans have to annotate, as well as how they should be annotated. The goal is that of reducing the annotators' subjective interpretation so as to have a consistent corpus. Indeed, human annotations are prone to subjective bias, so the guidelines have the aim of reducing this subjectivity to make the annotation process more reliable. Although we do not have a standard way to create annotation guidelines, some common ground rules have been defined. Usually a sound annotation guideline introduces at least some criteria which define the annotation task, alongside a description and some examples whose aim is to help the annotators to understand the criteria (see for example, Palmer and Xue (2010) and Pustejovsky and Stubbs (2013)). In a language generation task, where the possible space of outputs cannot be strictly defined, as it is subject to individual human differences, the guideline definition be-

[5]For an exhaustive list of automatic metrics used in NLP we refer to (Gatt and Krahmer, 2017) page 126.

[6]For an in depth discussion about this point we refer again to (Gatt and Krahmer, 2017), especially the section 7.4.1 and the reference there presented.

[7]An annotation scheme determines the conceptual content of the annotation task, for example by identifying the set of legitimate alternatives the annotator can choose from.

comes particularly difficult and there is a high risk of ending up with a set of poorly defined criteria. Far from there being a lack of precision in writing the guideline, here the problem seems to be intrinsic to the nature of human language. A fascinating analogy that aims to explain this point, presented by Geoffrey Sampson in the online page https://www.grsampson.net/RSue.html, is the following:

> Suppose we wanted to be able to say how large particular clouds are – what volume of space they occupy. Clouds are fuzzy things, so one problem would be what we mean by the volume of a cloud – what exactly should we count as its edge? But even if we adopted some precise definition of cloud boundaries, so that it became meaningful to say that this cloud is exactly N cubic yards in size, not N + 1 or N - 1, it might still be beyond mankind's abilities actually to measure clouds so exactly.

As a result of the fuzziness of human language, the criteria defined in an annotation guideline can be quite vague and be left to annotators' interpretation, which can result in a low IAA.

Kappa coefficients for IAA: The IAA measures the agreement between annotators. Thanks to this measurement we can estimate the annotation reliability. Generally, it is believed by the NLP community that the annotations are reliable if annotators agree, to a certain extent, on the category assigned. The kind of extent is determined by the method chosen to measure the agreement. Usually the IAA is performed by Kappa coefficients K[8].

The common theme to a variety of formulations is that K corrects annotators' agreement by the expected chance agreement:

$$K = \frac{P(A) - P(E)}{1 - P(E)}$$

where $P(A)$ is the proportion of times the annotators agree, whereas $P(E)$ is the proportion of times the annotators would be expected to agree by chance.

Kappa coefficients are used with Kappa scales of interpretation. For example, Krippendorff (1980) considers good any data annotation with agreement in the interval [0.8, 1], tentative any data annotation where agreement is in the interval [0.67, 0.8] and to discard any data annotation where agreement is below 0.67 [9]. Given the arbitrary nature of these choices of number, we can find different scales for K interpretation (see for example Landis and Koch (1977) , Green (1997) and for a general discussion Artstein and Poesio (2008)).

Since Carletta (1996), the K coefficients and its scales interpretation have been introduced in the area of NLP. Carletta took these metrics from content analysis in order to "compare results in a standard way across different coding schemes and experiments and to evaluate current developments" specifying that "whether we have reached (or will be able to reach) reasonable level of agreements in our work as a field remains to be seen".

3 The case of Automatic Question Generation

Problem statement: Human language generation tasks, given the richness of human languages, can usually not be evaluated with respect to some platonic gold standard. Given a sentence, different persons can have conflicting opinions about the sentence's ability to fulfill the task for which it was generated. More generally, given a sentence S, different persons can have conflicting opinions about the fluency, the grammaticality, the naturalness, the elegance etc. of S. These discrepancies are reflected, firstly, in the difficulty of generating strong annotation guidelines, and secondly, in the difficulty of reaching

[8] Here we are following the notation used in Carletta (1996). It is worth notice that the K formulation presented catch the most used agreement metrics from the NLP community, such as the π coefficient of Scott (1955) its Fleiss' generalization (Fleiss, 1971), and the k coefficient of Cohen (1960). The α coefficient of Krippendorff (1980) is expressed in a similar way but in term of disagreement. This difference is not relevant to the aim of this paper, so in what follows when we use the term$K$ coefficient we are referring at some instance of the above mentioned metrics. We refer to (Artstein and Poesio, 2008) for an excellent survey of the several agreement coefficients present in the literature.

[9] Arstein and Poesio (2008) note that: *the description of the 0.67 boundary in Krippendorff (1980) was actually "highly tentative and cautious," and in later work Krippendorff clearly consider 0.8 the absolute minimum value of α to accept for any serious purpose: "Even a cutoff point of α = .800 ... is a pretty low standard"* (page 576).

a satisfactory IAA in the evaluation phase — where what is a satisfactory IAA is defined by some K interpretation scales. Given the nature of the tasks in play, we believe it is time to rethink the IAA in the NLG community. Far from being a problem, a low IAA score reflects the richness, variability and beauty of human languages.

IAA in text2text task: A careful examination of the text2text literature shows that the human evaluation IAA, where reported, is usually below 0.6[10]. This means, following the Krippendorff Kappa interpretation scale, that the evaluations are to be considered inadequate for a satisfactory analysis.

It is also worth noticing the absence of shared annotation guidelines in the area. Indeed, we can find a large variety of criteria used in the human evaluations alongside more or less detailed evaluation guidelines. Although this absence is a deficiency in the area, which makes it hard to have a uniform way to check the quality across generation systems, we cannot completely ascribe to it the low IAA reached in the evaluation phases.

About this point we can find an analysis by Sampson and Babarcz (2008). As we said before, the authors perform their experiment using the SUSANNE scheme (Sampson, 1995), which is an annotation guideline of 449 pages. Of the three conclusions they reach in the study, the most interesting to the aims of this paper is the following: "while it is not easy to define watertight boundaries between the categories of a comprehensive structural annotation scheme, limits on inter-annotator agreement are in practice set more by the difficulty of conforming to a well-defined scheme than by the difficulty of making a scheme well defined".

It is worth noting that Sampson and Babarczy's experiment was done with two experts. Despite the fact that the annotation guidelines were very precise and the annotations were done by experts, divergent rank opinions still emerged from the experiment.

Experiments description: The current paper was motivated by our attempt to define annotation guidelines for the text2text task. The methodology we used was that of refining the criteria chosen through several iterations of discussions and pilot evaluations. During these iterations we noticed that regardless of how many changes we made, there remained a divergence in the judgements that we could not reduce by modifying the guidelines.

We started by choosing the criteria to use. We decided to study the evaluation along two dimensions, a linguistic one, which aimed to evaluate the question quality from a grammatical and idiomatic point of view, and a task-oriented one, which aimed to evaluate how well the questions fulfill the task for which they were generated[11]. In the text2text case the task is that of generating a question in relation to a given paragraph. So in the task-oriented dimension we were interested in the degree to which the question was answered by the input text. Although these two dimensions are tacitly shared between researchers, making them explicit has the merit of outlining a common space to check quality across generation systems. Within this dimension we defined four criteria, which we will present in the next section. We aimed for a sound description of each criterion, accompanied by examples. Once we defined the first version of the annotation guideline we tested it by performing a pilot assessment phase.

We tested our evaluation guidelines taking random input paragraphs and questions from the SQuAD dataset (Rajpurkar et al., 2016). We repeated this process three times. In each iteration we took five paragraphs and for each paragraph six questions. All the questions were human generated. Between these, three were taken from the reference questions of the input paragraph (for one of these we automatically swapped some words in order to change the grammaticality), and three were about the topic of the input paragraph, although generated with a different (but with similar topic) paragraph as an input. We asked two volunteers to join us in the process of annotating the questions. Both volunteers were

[10]To our knowledge the only significant exception is (Godwin and Piwek, 2016), where, as we said before, the authors define an interactive process in which the annotators can discuss their opinions about the criteria used in the evaluation. Such a process presupposes that the annotators talk with each other in order to profitably improve the criteria in play. In this we can see at least two difficulties. On the one hand, this process is time consuming and is not practicable in Crowdsourcing evaluations. On the other hand, although the process allows a small set of people to agree among themselves, we could have different results with different groups of people.

[11]Gatt and Krahmer (2017) note that traditionally, in NLP, the linguistic dimension is defined by the *fluency* or *readability* criteria, whereas the task-oriented one is defined in term of *accuracy*, *adequacy*, *relevance* or *correctness* criteria.

Spanish, who had lived several years in the UK or US, but had not formally studied linguistics. Each pilot was performed with four people: two of the authors of this paper and the two volunteers. At the end of each iteration, with the pilot example support, the authors of the present paper discussed the adequacy of the criteria. Based on that discussion we decided how to improve description of and examples for the criteria.

After several iterations we concluded with a final iteration. This time seven annotators, including the two of the authors of this paper, engaged in the annotation task. Between the seven annotators three were native speakers of English. The other five were proficient in English. Three of the annotators had a background in linguistics. Once again we used the input paragraphs from the SQuAD dataset. This time we took two paragraphs and five question for each paragraph. One of the questions was automatically generated by the question generation algorithm freely available at the page https://kjmazidi.pythonanywhere.com/. Three were human generated questions from the SQuAD dataset: two were taken from the reference questions of the input paragraph (for one of these we automatically swapped some words in order to change the grammaticality), and one was about the topic of the input paragraph, although generated with a different input paragraph. The last question was generated by the first author of this paper, who did not personally take part in the evaluation. At the end of the evaluation, the annotators discussed their responses for each criterion and for each question, one by one. During this discussion, we identified a series of differences. As we will see in the next sections, they were based on annotators' subjective taste and experiences. Again, for each criterion, we got a IAA lower than 0.67, with the lowest score being 0.11.

4 A new taxonomy of divergences

We classify the main sources of disagreement we found through our experiments in five categories: i) *Style and taste*; ii) *background knowledge*; iii) *personal assumptions*; iv) *use of common sense inferences*; v) *attention to detail*.

We are going to present some examples for each category in order to explain them. As we said before, we conducted the study along two dimensions, a linguistic one and a task-oriented one. The annotation criteria attempted to characterise these two dimensions. Following the process we described in the previous section, we attempted to improve the criteria by clarifying their descriptions, adding clarifying examples and splitting them into sub-criteria.

In the last version of our evaluation guidelines, we had the following four criteria: i) Pertinence, ii) Grammaticality, iii) Comprehensibility, iv) Fluency. The Pertinence criterion is for the task-oriented dimension. We used this name to underline the need for the question to be directly and strictly related to the paragraph. The linguistic dimension was split into three sub-dimensions or criteria: Grammaticality, Comprehensibility and Fluency. The grammaticality is intended to check possible grammatical errors in the questions. Comprehensibility aims to better frame the grammaticality judgement. Indeed, it can happen that a question, although ungrammatical, is perfectly understandable[12]. That is, it can be possible to work out what the question is asking, even if it is ungrammatical. Finally, the fluency criterion is intended to judge whether the question is idiomatic/natural. The Pertinence criterion is ranked on a scale from 0 to 3, whereas the other criteria use a binary scale. We decided to evaluate the linguistic dimension without providing the paragraph while the task dimension after reading the paragraph. Indeed, we believe that the grammaticality, comprehensibility and idiomaticity of a question can be judged independently of the paragraph from which it was generated. So each annotation was carried out in two stages. First, the annotator was presented with the question in isolation, and asked to provide a judgement on the questions of grammaticality, comprehensibility and fluency. Next, the annotator was presented with both the question and the input text, and asked to provide a judgement on the pertinence.

In our experiments, of the 100 questions we analysed, we found a total of 55 divergences in the linguistic dimensions and a total of 78 divergences in the task-oriented dimension. We present some examples of these divergences in order to explain how the above categories were delineated.

[12]We discuss some examples of this in the next section.

Style and taste: We found some divergences were related to the annotator's taste and their writing style. This kind of divergence emerged in the question on idiomaticity judgements. For example, we notice that American and British English differences played against question idiomaticity. Given the question:

Jean De Rely's illustrated French-language scriptures were first published in what city?

we found divergent judgements because the question sounded awkward to some British annotators, who preferred the use of "which" rather than "what". Similarly, we had divergent judgements with the question:

The adaptive immune system must distinguish between what types of molecules?

where one of the British annotators not only preferred the use of "which" instead of "what", but also marked the question as not idiomatically natural because he preferred the question written in the reverse order: Which types of molecules must the adaptive immune system distinguish between? In a case like this, we can see how the personal writing style influences the evaluation. This eventuality is a result of the fact that, in a generation task, we can use very different sentences, in this case questions, in order to reach the same communicative goal.

Background knowledge: Another issue we found concerned the amount of background knowledge that is needed in order to understand a question. Where annotators did not share relevant background knowledge, they often gave different judgements for a question's comprehensibility and pertinence. For example the question:

How many Time incarnations can a Lord have?

even if not grammatical (the original question is: How many incarnations can a Time Lord have?), was recognised as comprehensible by the annotators who were aware of the 'Doctor Who' television programme, whereas it was marked as not comprehensible by the ones who did not know the show. In the same way, given the paragraph:

Microorganisms or toxins that successfully enter an organism encounter the cells and mechanisms of the innate immune system. The innate response is usually triggered when microbes are identified by pattern recognition receptors, which recognize components that are conserved among broad groups of microorganisms...

the question:

What part of the innate immune system identifies microbes and triggers immune response?

raised divergent opinions for two reasons: on the one hand, it was necessary to know that microorganisms are the same as microbes. On the other, it was necessary to know that the pattern recognition receptors are part of the innate immune system. The lack of this knowledge from some annotators, resulted in a divergence in ranking the pertinence criterion. In these examples, we can see how the annotators' knowledge determines the evaluation. Indeed, personal knowledge and experiences are reflected in the way we generate and understand sentences. So, divergences in knowledge can be reflected in evaluation divergences.

Personal assumptions: Other divergences arose from different annotator assumptions. Also in these cases the divergences emerged predominantly in the question's comprehensibility and pertinence judgements. For example the question:

Which team finished the regular season?

was considered not comprehensible by the annotators who assumed that all teams would finish the season. These annotators considered the question meaningless. In contrast, other annotators considered a scenario in which some teams could not finish the season. In this case the question was marked as comprehensible. A similar problem was found with the question:

What was the win/loss ratio in 2015 for the Carolina Panthers during their regular season?

Given the paragraph:

The Panthers finished the regular season with a 15-1 record, and quarterback Cam Newton was named the NFL Most Valuable Player (MVP)...

one annotator noticed that the question can be marked pertinent under the assumption that the Carolina Panthers in the question and the Panthers in the paragraph are referring to the same team. He did not make this assumption. Other annotators did make this assumption and ranked the question as pertinent. In a similar way to background knowledge and experiences, personal assumptions are reflected in the way we generate and understand sentences. Again, divergences in assumptions can be reflected in divergences in evaluation.

Use of common sense inferences: This kind of divergence emerged predominantly in the question pertinence judgements. For example, given the paragraph:

The availability of the Bible in vernacular languages was important to the spread of the Protestant movement and development of the Reformed church in France. The country had a long history of struggles with the papacy by the time the Protestant Reformation finally arrived. Around 1294, a French version of the Scriptures was prepared by the Roman Catholic priest, Guyard de Moulin. A two-volume illustrated folio paraphrase version based on his manuscript, by Jean de Rély, was printed in Paris in 1487.

the question:

Jean De Rely's illustrated French-language scriptures were first published in what city?

was marked as not pertinent by one annotator who noted that the paragraph provides information about the place where Jean De Rely's scriptures were printed and not where they were published. To consider this question as unambiguously answered by the paragraph it is necessary to assume that the place where the Jean De Rely's illustrated scriptures were printed is the same where they were published. Although this inference goes much further than the information presented in the text, other annotators made it and marked the question as pertinent. Likewise, the question:

When did the first French language bible appear?

was marked as pertinent by one annotator, who inferred the answer 1294 from the paragraph. Other annotators considered the question as not pertinent because the answer cannot be correctly inferred from the paragraph. As a matter of fact, in the text there is no mention of the fact that the Guyard de Moulin version of the Scriptures was the first French language bible to appear and at the same time it is not possible to rigorously reach this conclusion by the information provided by the text. Here we faced another problem: people reason in different ways. Obviously this divergence also emerges in the way people generate, understand, and in this case evaluate, sentences.

Attention to detail: We noticed that in some cases, annotators overlooked some question details. Also in these cases, the divergences emerged predominantly in the question pertinence judgements. For example, given the paragraph:

The most impressive examples of rococo architecture are Czapski Palace (1712-1721), Palace of the Four Winds (1730s) and Visitationist Church (façade 1728-1761).

the question:

What type of architecture is the Palace of Four Windows an impressive example of?

was ranked as pertinent by some annotators who did not notice that the question uses the word "Windows" instead of "Winds", but it was ranked as not pertinent by the annotators who did notice this detail. Another example of this kind of rank divergences is the following. Given the paragraph:

Victorian farms produce nearly 90% of Australian pears and third of apples. It is also a leader in stone fruit production. The main vegetable crops include asparagus, broccoli, carrots, potatoes and tomatoes. Last year, 121,200 tonnes of pears and 270,000 tonnes of tomatoes were produced.

the question:

How many tonnes of tomatoes does Victoria produce?

was ranked as pertinent by some annotators who did not notice that the paragraph was speaking about "last year" production, whereas the question is more general (maybe it is asking for an annual average, which is not mentioned in the paragraph). Other annotators did notice this detail and ranked the question as not pertinent. This problem is linked to the fact the people can generate and interpret sentences to different levels of generality and detail. This is reflected in the way people understand sentences, in this case the questions, in the context from which they are generated.

We conclude this section by observing that together with the five sources of disagreement we have just presented, we found other sources of discrepancy between annotators — which we suppose are present in each annotation task — related to distractions, misunderstanding the guidelines, or forgetting how to apply the guidelines.

IAA, a new research direction: Many studies have shown IAA appearing to depend on several factors, for example: data typology, data ambiguity, the number of categories used in the annotation, the number of annotators, the use of expert or non-expert annotators, and annotators' attention, skills, memory and training. In the present study we found that, in a language generation task such as text2text, we also need to add the following factors: the annotators' background knowledge, their personal taste and personal assumptions, their attention to detail and their inferential skills.

The obvious conclusion we can draw is that human annotators' disagreements are part of the nature of language. Nevertheless, much effort has been spent on trying to understand the source of this disagreement in order that the disagreement can be reduced, for example by modifying the annotation scheme. According to our experiments, we believe that in NLG tasks, attempts to create annotation guidelines that strongly reduce disagreement among annotators, are in danger of missing the goal of producing human language variability. Indeed, such methods can artificially restrict the annotators' language interpretation and their opinion about sentences' goodness. Consequently, the methods do not catch the model's ability to generate language variability.

Rather than regarding the evaluation disagreement as a problem to be fixed, we suggest that it should be thought of as an ineliminable feature of generation tasks, which reflects the variety of human languages and its users. To this end we propose that the scales of K interpretation should be reconsidered,

for example by introducing confidence intervals. These would delineate boundaries within which we expect to find the IAA. An evaluation agreement that falls below the low boundary can suggest that the evaluation is too unreliable to be considered further. At the opposite end, an evaluation agreement that exceeds the upper boundary may suggest that the task was overconstrained and therefore possibly of limited interest. Such an interval, recognising that a greater level of disagreement between annotators—so that the level of disagreement falls inside the boundaries — is not problematic, would take into account the phenomena we have introduced in the previous section. Given a corpus to evaluate, different groups of annotators can end up with different levels of disagreement regarding the quality of that corpus. These differences, mainly due to how language is produced and understood, as long as they lie inside the interval boundaries, can be considered as inherent to the task. Although there is not a general way to determine these intervals — because of the range of tasks in NLG, such confidence intervals should be defined on a task by task basis — we believe a first step could be to analyse the correlation between differences in IAA and growing linguistic difficulty. Indeed, consider a situation where a generative system is evaluated on its capability to produce human-like language (e.g. as in a Turing test). In such a scenario, it is likely to get the best agreement in those cases were the generated language is somewhat simplistic (for example very shallow sentences or sentences clearly ungrammatical or completely out of context). Conversely, in the cases where the generated language is more complex from a semantic point of view, as in our experiments, it is likely achieve lower agreement. If, using high levels of linguistic sophistication, a similar level of agreement can be reached, then it is possible to consider that level as a bottom threshold. Similarly, it can be done with low levels of linguistic sophistication in order to choose a top threshold. We are undertaking some experiments in this direction for text2text tasks.

In the same vein, following the Shared Task and Evaluation Campaigns (STECs) proposal (see for example (Gatt and Belz, 2010)), we believe that for each NLG task, a common and shared evaluation guideline should be defined, maybe together with a corpus data used only for evaluation purposes. Furthermore, inside such a framework, researchers could also share, alongside their results, their methodologies and ideas to attempt to understand and classify any divergences between annotators. A better understanding of these divergences can indeed help us to understand and improve the tasks at hand. For each NLG task, a new IAA interpretation, alongside a shared evaluation guidelines, could bring in each NLG community a uniform way to check the quality across generation systems.

In order to better interpret IAA, instead of focusing exclusively on interannotor agreement, more attention may need to be paid to the internal consistency of the responses of each annotator. We have argued that while there are irreducible differences between annotators' judgements, the judgements of an individual annotator should be consistent, if they are to represent that annotator's particular linguistic abilities and preferences.

Conclusion: In this paper we investigated the IAA problem for a text2text task. We performed some experiments that show how a low IAA is inherent to the task of language annotation. Our experiments have outlined that factors such as: annotators' background knowledge, personal taste, personal assumptions, attention to detail and inferential skills are presents in evaluation judgments. We believe that these kind of factors are intimately connected to the people experiences and their language understanding and use, and cannot be effectively removed by the choice of annotation guidelines. We believe that, in generation tasks, the efforts of reaching a high IAA run the danger of leading research and system building away from the goal of generating text that is natural and human-like (and possibly towards artificial non-natural language). Indeed, it could not take into account the differences that make human language so broad in its meaning and use. For this reason, we suggest new research directions, for example the introduction of confidence intervals for the IAA interpretation and attention on internal annotator consistency. In our opinion such a shift in interpretation would take better account of the richness and variability in human language.

Dependent Gated Reading for Cloze-Style Question Answering

Abstract

We present a novel deep learning architecture to address the cloze-style question answering task. Existing approaches employ reading mechanisms that do not fully exploit the interdependency between the document and the query. In this paper, we propose a novel *dependent gated reading* bidirectional GRU network (DGR) to efficiently model the relationship between the document and the query during encoding and decision making. Our evaluation shows that DGR obtains highly competitive performance on well-known machine comprehension benchmarks such as the Children's Book Test (CBT-NE and CBT-CN) and Who DiD What (WDW, Strict and Relaxed). Finally, we extensively analyze and validate our model by ablation and attention studies.

1 Introduction

Human language comprehension is an important and challenging task for machines that requires semantic understanding and reasoning over clues. The goal of this general task is to read and comprehend the given document and answer queries.

Recently, the cloze-style reading comprehension problem has received increasing attention from the NLP community. A cloze-style query (Taylor, 1953) is a short passage of text containing a blank part, which we must fill with an appropriate token based on the reading and understanding of a related document. The recent introduction of several large-scale datasets of cloze-style question answering made it feasible to train deep learning systems for such task (Onishi et al., 2016; Hill et al., 2015; Hermann et al., 2015). Various deep learning models have been proposed and achieved reasonable results for this task (Yang et al., 2017; Dhingra et al., 2017; Munkhdalai and Yu, 2017; Cui et al., 2017; Trischler et al., 2016; Kadlec et al., 2016; Chen et al., 2016; Cui et al., 2016; Sordoni et al., 2016). The success of recent models are mostly due to two factors: 1) Attention mechanisms (Bahdanau et al., 2014), which allow the model to sharpen its understanding and focus on important and appropriate subparts of the given context; 2) Multi-hop architectures, which read the document and/or the query in multiple passes, allowing the model to re-consider and refocus its understanding in later iterations. Intuitively, both attention mechanisms and multi-hop reading fulfill the necessity of considering the dependency aspects of the given document and the query. Such a consideration enables the model to pay attention to the relevant information and ignore the irrelevant details. Human language comprehension is often performed by jointly reading the document and query to leverage their dependencies and stay focused in reading and avoid losing relevant contextual information. Current state-of-the-art models also attempt to capture this by using the reading of the query to guide the reading of the document (Yang et al., 2017; Dhingra et al., 2017), or using the memory of the document to help interpret the query (Munkhdalai and Yu, 2017). However, these systems only consider uni-directional dependencies. Our primary hypothesis is that we can gain further improvements by considering bidirectional dependencies.

In this paper, we present a novel multi-hop neural network architecture, called Dependent Gated Reading (DGR), which addresses the aforementioned gap and performs dependent reading in both directions. Our model begins with an initial reading step that encodes the given query and document, followed by an

Proceedings of the 27th International Conference on Computational Linguistics, pages 3330–3345
Santa Fe, New Mexico, USA, August 20-26, 2018.

iterative reading module (multi-hop) that employs soft attention to extract the most relevant information from the document and query encodings to augment each other's representation, which are then passed onto the next iteration of reading. Finally, the model performance a final round of attention allocate and aggregate to rank all possible candidates and make prediction.

We evaluate our model on well-known machine comprehension benchmarks such as the Children's Book Test (CBT-NE & CBT-CN), and Who DiD What (WDW, Strict & Relaxed). Our experimental results indicate the effectiveness of DGR by achieving state-of-the-art results on CBT-NE, WDW-Strict, and WDW-Relaxed. In summary, our contributions are as follows: 1) we propose a new deep learning architecture to address the existing gap of reading dependencies between the document and the query. The proposed model outperforms the state-of-the-art for CBT-NE, WDW-Strict, and WDW-Relaxed by $0.5\%, 0.8\%$, and 0.3% respectively; 2) we perform an ablation study and analysis to clarify the strengths and weaknesses of our model while enriching our understanding of the language comprehension task.

2 Related Work

The availability of large-scale datasets (Onishi et al., 2016; Hill et al., 2015; Hermann et al., 2015) has enabled researchers to develop various deep learning-based architectures for language comprehension tasks such as cloze-style question answering.

Sordoni et al. (2016) propose an *Iterative Alternative Attention* (IAA) reader. IAA is a multi-hop comprehension model which uses a GRU network to search for correct answers from the given document. IAA is the first model that does not collapse the query into a single vector. It deploys an iterative alternating attention mechanism that collects evidence from both the document and the query.

Kadlec et al. (2016) Introduce a single-hop model called *Attention Sum Reader* (AS Reader) that uses two bi-directional GRUs (BiGRU) to independently encode the query and the document. It then computes a probability distribution over all document tokens by taking the softmax of the dot product between the query and the token representations. Finally, it introduces a *pointer-sum attention* aggregation mechanism to aggregate the probability of multiple appearances of the same candidate. The candidate with the highest probability will be considered as the answer. Cui et al. (2017) introduce a similar single-hop model called *attention-over-attention* (AOA) reader which uses a two-way attention mechanism to allow the query and document to mutually attend to one another.

Trischler et al. introduce EpiReader (2016), which uses AS Reader to first narrow down the candidates, then replaces the query placeholder with each candidate to yield a different query statement, and estimate the entailment between the document and the different query statements to predict the answer.

Munkhdalai and Yu (2017) (NSE) propose a computational hypothesis testing framework based on memory augmented neural networks. They encode the document and query independently at the beginning and then re-encode the query (but not the document) over multiple iterations (hops). At the end of each iteration, they predict an answer. The final answer is the candidate that obtains the highest probability over all iterations.

Dhingra et al. (2017) extend the AS Reader by proposing *Gated Attention Reader* (GA Reader). GA Reader uses a multi-hop architecture to compute the representation of the documents and query. In each iteration the query is encoded independent of the document and previous iterations, but the document is encoded iterative considering the previous iteration as well as an attention mechanism with multiplicative gating to generate query-specific document representations. GA reader uses the same mechanism for making the final predictions as the AS reader. Yang et al. (2017) further extend the GA Reader with a fine grained gating approach that uses external semantic and syntactic features (i.e. NER, POS, etc) of the tokens to combine the word and character level embeddings and produce a final representation of the words.

Among the aforementioned models, the GA Reader is the closest to our model in that we use a similar architecture that is multi-hop and performs iterative reading. The main distinct between our model and the GA Reader is the reading and encoding of the query. Instead of performing independent reading of query in each iteration, our reading and encoding of the query not only depends on the document but also the reading of previous iterations.

Although cloze-style question answering task is well studied in the literature, the potential of dependent reading and interaction between the document and the query is not rigorously explored. In this paper, we address this gap by proposing a novel deep learning model (DGR). Experimental results demonstrate the effectiveness of our model.

3 Dependent Gated Reading

Figure 1 depicts a high-level view of our proposed Dependent Gate Reading (DGR) model, which follows a fairly standard multi-hop architecture, simulating the multi-step reading and comprehension process of humans.

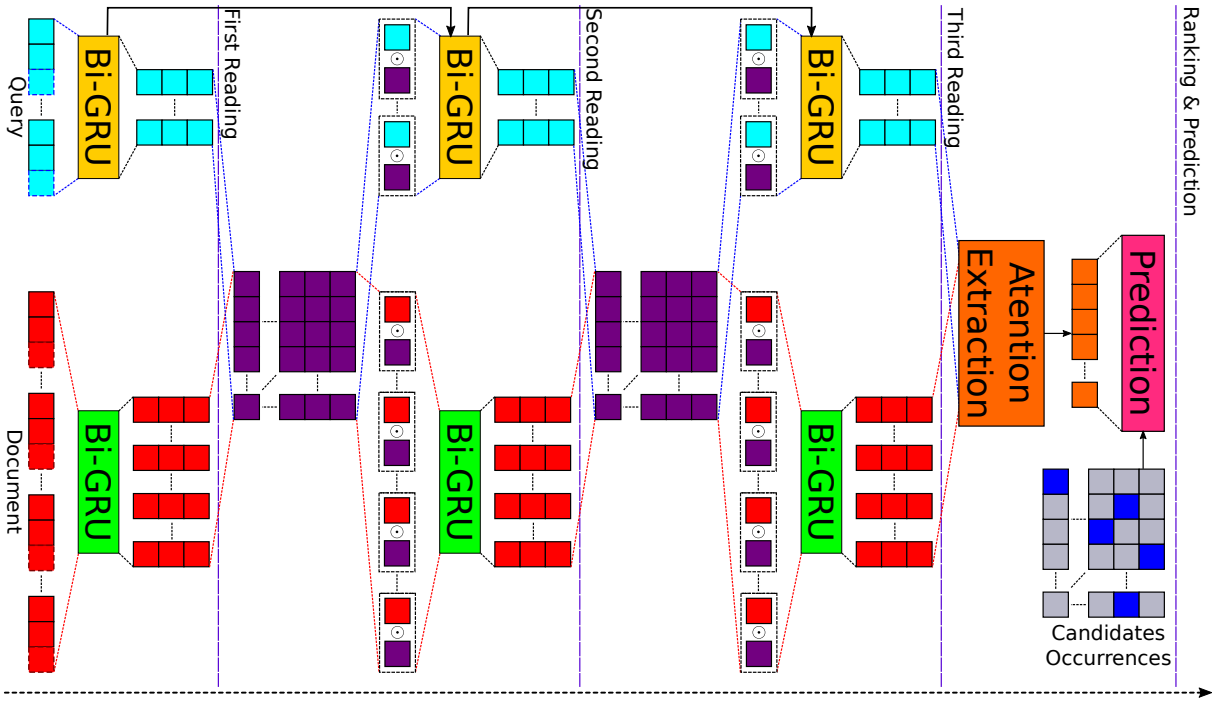

Figure 1: A high-level view of dependent gated reading model (DGR). The data (document d and query q, depicted with red and cyan tensors respectively) flows from left to right. At the first (input) layer, the word representations are shown with black solid borders while the character representations are shown with colored dashed borders. The figure is color coded; relevant tensors and elements are shown with the same color. Note that none of the elements share parameters. The purple matrices extract relevant information between document and query representations. The black arrows between the query BiGRUs (yellow ones) pass the final hidden state of a BiGRU to another one as initialization value for its hidden state.

The input to our model at the training stage can be represented as a tuple (D, Q, C, a), where $D = [d_1, \cdots, d_n]$ is the document of length n, $Q = [q_1, \cdots, q_m]$ is the query of length m with a placeholder, $C = [c_1, \cdots, c_g]$ is a set of g candidates and $a \in C$ is the ground truth answer. Here we assume d_i, q_j are some form of embedding of the individual tokens of document and query. At the testing stage, given the input document D, query Q and candidate set C, the goal is to choose the correct candidate a among C for the placeholder in Q.

DGR can be divided to two major parts: Multi-hop Reading, and Ranking & Prediction.

3.1 Multi-hop Reading of Document and Query

Recurrent networks provide a natural solution for modeling variable length sequences. Consequently, we use bi-directional Gated Recurrent Units (BiGRUs) (Cho et al., 2014) as the main building blocks for encoding the given document and query. For the initial step of our multi-hop reading, the document D and the query q are read with two separate BiGRUs (Equations 1 and 2) where $\hat{d}^0 \in \mathbb{R}^{n \times r}$ and

$\hat{q}^0 \in \mathbb{R}^{m \times r}$ are the first BiGRU reading sequences of D and Q respectively. h^0 consists of two parts, h_f^0 and h_b^0, which record the final output of forward and backward GRU reading of Q respectively. Note that "$-$" in equations means that we do not care about the associated variable and its value.

$$\hat{d}^0, - = BiGRU_{d0}(D, 0) \tag{1}$$

$$\hat{q}^0, h^0 = BiGRU_{q0}(Q, 0) \tag{2}$$

We use $s \in [0, S]$ to denote the reading iteration, with $S + 1$ total iterations. For the initial iteration ($s = 0$), both BiGRUs are fed with a zero vector for the initial hidden state as shown in Equations 1 and 2. Once the document and query encodings ($\hat{d}^s$ and $\hat{q}^s$ respectively) are computed, we employ a soft alignment method to associate the relevant sub-components between the given document and query. In deep learning models, this is often achieved with a soft attention mechanism. We follow the same soft attention mechanism as used in the GA reader (Dhingra et al., 2017), which is described below for completeness.

Given $\hat{d}^s$ and $\hat{q}^s$, we first compute the unnormalized attention weights between the i-th token of the document and the j-th token of the query as the similarity between the corresponding hidden states with Equation 3 (energy function).

$$e_{ij}^s = (\hat{d}_i^s)^T \hat{q}_j^s, \quad \forall i \in [1, n], \forall j \in [1, m], \forall s \in [0, S-1] \tag{3}$$

For each document token and query token, the most relevant semantics from the other context are extracted and composed based on $e_{ij}^s \in \mathbb{R}^{n \times m}$. Equations 4 and 5 provide the specific details of this procedure where $\tilde{d}_i^s \in \mathbb{R}^r$ represents the extracted information from the current reading of the query, $\hat{q}^s$, that is most relevant to the i-th document token by attending to $\hat{d}_i^s$. Similarly $\tilde{q}_j^s \in \mathbb{R}^r$ represents, for the j-th query token, the extracted relevant document information from $\hat{d}^s$ by attending to $\hat{q}_j^s$.

$$\tilde{d}_i^s = \sum_{j=1}^{m} \frac{\exp(e_{ij}^s)}{\sum_{k=1}^{m} \exp(e_{ik}^s)} \hat{q}_j^s, \quad \forall i \in [1, n], \forall s \in [0, S-1] \tag{4}$$

$$\tilde{q}_j^s = \sum_{i=1}^{n} \frac{\exp(e_{ij}^s)}{\sum_{k=1}^{n} \exp(e_{kj}^s)} \hat{d}_i^s, \quad \forall j \in [1, m], \forall s \in [0, S-1] \tag{5}$$

To incorporate the context information, we use element-wise product of the tuples $(\hat{d}_i^s, \tilde{d}_i^s)$ or $(\hat{q}_j^s, \tilde{q}_j^s)$ to produce a new representation of the hidden states for the document and the query as described in Equations 6 and 7.

$$u_i^s = \hat{d}_i^s \odot \tilde{d}_i^s, \quad \forall s \in [0, S-1] \tag{6}$$

$$v_j^s = \hat{q}_j^s \odot \tilde{q}_j^s, \quad \forall s \in [0, S-1] \tag{7}$$

Here $\odot$ stands for element-wise product, and $u^s \in \mathbb{R}^r$ and $v^s \in \mathbb{R}^r$ are the new encodings of the document and query respectively.Note that GA-reader uses the same mechanism to update the document encoding but does not change the query representation according to the document.

We then pass the new document (u^s) and query (v^s) embeddings to the BiGRUs for the next iteration $s + 1$. Note that for query reading, we feed, h^s, the final hidden state of the previous reading (without document based updates) to the BiGRU of the next iteration as the initial hidden state. Intuitively, h^s provides a summary understanding of the query from the previous iteration, without the document modulated updates. By considering both h^s and v^s, this encoding mechanism provides a richer representation of the query. This is formally described by Equations 8 and 9.

$$\hat{d}^{s+1}, - = BiGRU_{ds}(u^s, 0), \forall s \in [0, S-1] \tag{8}$$

$$\hat{q}^{s+1}, h^{s+1} = BiGRU_{qs}(v^s, h^s), \forall s \in [0, S-1] \tag{9}$$

We should note that using the following configuration variations did not yield any improvement to our model: 1) Other choices for gating aggregation strategy (Equations 6 and 7) like addition, concatenation, or applying a transformation function on different sub-members of {element-wise product, concatenation and difference}. 2) Residual connection.

3.2 Ranking & Prediction

Given the final document and query encodings, $\hat{d}^S$ and $\hat{q}^S$, the final stage of our model computes a score for each candidate $c \in C$. This part of our model use the same *point sum attention* aggregation operation as introduced by the Attention Sum (AS) reader (Kadlec et al., 2016), which is also used by the GA reader (Dhingra et al., 2017).

Let idx be the position of the the placeholder in Q, and $\hat{q}^S_{idx}$ be the associated hidden embedding of the placeholder in the given query. We first compute the probability of each token in the document to be the desired answer by computing the dot product between $\hat{q}^S_{idx}$ and $\hat{d}^S_j$ for $j = 1, ..., n$ and then normalize with the softmax function:

$$y = \text{softmax}((\hat{q}^S_{idx})^T \hat{d}^S) \tag{10}$$

where $y \in \mathbb{R}^n$ gives us a normalized attention/probability over all tokens of the document. Next, the probability of each particular candidate $c \in C$ for being the answer is computed by aggregating the document-level attentions of all positions in which c appears:

$$p(c|D, Q) \propto \sum_{i \in I(c,D)} y_i, \quad \forall c \in C \tag{11}$$

where $I(c, D)$ indicates the positions that candidate c appears in the document D (Candidate Occurrences in Figure 1). Finally the prediction is given by $a^* = \textit{argmax}_{c \in C}\ p(c|D, Q)$.

Key differences from the GA reader. Given the strong similarity between our model and the GA reader, it is worth highlighting the three key differences between the two models: (a) Document gated query reading: we compute a document-specific query representations to pass to the next query reading step; (b) Dependent query reading: in each iteration, the input to the query BiGRU comes from the document gated encoding of the query from the last iteration whereas the GA Reader reads the queries independently in all iterations; (c) Dependent query BiGRU initialization: the query BiGRU is initialized with the final hidden states of the query BiGRU from the previous iteration. These key differences in query encoding are designed to better capture the interdependences between query and document and produce richer and more relevant representations of the query and enhance the comprehension and query answering performance.

3.3 Further Enhancements

Following the practice of GA reader, we included several enhancements which have been shown to be helpful in previous work.

Question Evidence Common Word Feature. To generate the final document encoding $\hat{d}^S$, an additional modification of u^{S-1} is introduced before applying Equation 8. Specifically, an additional *Question Evidence Common Word Feature* (qe-comm) (Li et al., 2016) is introduced for each document token, indicating whether the token is present in the query. Assume f_i stands for the qe-comm feature of the i-th document token, therefore, $u^{S-1}_i = [u^{S-1}_i, f_i]$.

Character-level embeddings. Word-level embeddings are good at representing the semantics of the tokens but suffers from out-of-vocabulary (OOV) words and is incapable of representing sub-word morphologies. Character-level embeddings effectively address such limitations (Ling et al., 2015; Dhingra et al., 2016). In this work, we represent a token by concatenating its word embedding and character embedding. To compute the character embedding of a token $w = [x_1, \cdots, x_l]$, we pass w to two GRUs in forward and backward directions respectively. Their outputs are then concatenated and passed through a linear transformation to form the character embedding of the token.

4 Experiments and Evaluation

4.1 Datasets

We evaluate the DGR model on three large-scale language comprehension datasets, Children's Book Test Named Entity (CBT-NE), Common Noun (CBT-CN), and Who Did What (WDW) Strict and Relaxed.

The first two datasets are formed from two subsets of the Children's Book Test (CBT) (Hill et al., 2015). Documents in CBT consist of 20 contiguous sentences from the body of a popular children's book, and queries are formed by replacing a token from the 21^{st} sentence with a placeholder. We experiment on subsets where the replaced token is either a named entity (CBT-NE) or common noun (CBT-CN). Other subsets of CBT have also been studied previously but because simple language models have been able to achieve human-level performance on them, we ignore such subsets (Hill et al., 2015).

The Who Did What (WDW) dataset (Onishi et al., 2016) is constructed from the LDC English Gigaword newswire corpus. Each sample in WDW is formed from two independent articles. One article is considered as the passage to be read and the other article on the same subject is used to form the query. Missing tokens are always person named entities. For this dataset, samples that are easily answered by simple systems are filtered out, which makes the task more challenging. There are two versions for the training set (Strict and Relaxed) while using the same development and test sets. Strict is a small but focused/clean training set while Relaxed is a larger but more noisy training set. We experiment on both of these training sets and report corresponding results on both settings. Statistics of all the aforementioned datasets are summarized in Table 3 of the appendix.

Other datasets for this task include CNN and Daily Mail News (Hermann et al., 2015). Because previous models already achieved human-level performance on these datasets, following Munkhdalai and Yu (2017), we do not include them in our study.

4.2 Training Details & Experimental Setup

We use pre-trained 100-D Glove $6B$ vectors (Pennington et al., 2014) to initialize our word embeddings while randomly initializing the character embedding. All hidden states of BiGRUs have 128 dimensions ($o = 100$ and $r = 128$). The weights are learned by minimizing the negative log-loss (Equation 12) on the training data via the Adam optimizer (Kingma and Ba, 2014). The learning rate is 0.0005. To avoid overfitting, we use dropout (Srivastava et al., 2014) with rate of 0.4 and 0.3 for CBT and WDW respectively as regularization, which is applied to all feedforward connections. While we fix the word embedding, character embeddings are updated during the training to learn effective representations for this task. We use a fairly small batch size of 32 to provide more exploration power to the model.

$$L = \sum_i -\log(p(a|D, Q)) \tag{12}$$

4.3 Results

Table 1 shows the test accuracy of the models on CBT-NE, CBT-CN, WDW-Strict, and WDW-Relaxed. We divide the previous models into four categories: 1) Single models (rows 1-5), 2) Ensemble models (rows 6-9), 3) NSE models (rows 10-14), and 4) the FG model (row 15). Table 1 primarily focuses on comparing models that do not rely on any NLP toolkit features (i.e. POS, NER, etc), with the exception of the FG model which uses additional information about document tokens including POS, NER and word frequency information to produce the embedding of the token.

From Table 1, we can see that DGR achieves the state-of-the-art results on all aforementioned datasets expect for CBT-CN. The targets of CBT-NE, WDW-Strict, and WDW-Relaxed are all Named Entities while the CBT-CN focuses on Common Noun. We believe that our architecture is more suitable for Named Entity targeted comprehension tasks. This phenomenon warrants a closer look in future work. Comparing GA Reader, FG, and DGR (the three models with similar architectures), we see that FG outperform the GA Reader on CBT-CN and WDW-Strict datasets while DGR outperforms both FG and GA Reader results on CBT-NE, WDW-Strict, WDW-Relaxed datasets with noticeable margins. This suggests

Method	Test Accuracy(%)			
	CBT-NE	CBT-CN	WDW-Strict	WDW-Relaxed
AS Reader (Kadlec et al., 2016)	68.6%	63.4%	57.0%	59.0%
EpiReader (Trischler et al., 2016)	69.7%	67.4%	-	-
IAA Reader (Sordoni et al., 2016)	68.6%	69.2%	-	-
AOA Reader (Cui et al., 2017)	72.0%	69.4%	-	-
GA Reader (Dhingra et al., 2017)	74.9%	70.7%	71.2%	72.6%
AS Reader (Ensemble) (Kadlec et al., 2016)	70.6%	68.9%	-	-
EpiReader (Ensemble) (Trischler et al., 2016)	71.8%	70.6%	-	-
IAA Reader (Ensemble) (Sordoni et al., 2016)	72.0%	71.0%	-	-
AOA Reader (Ensemble) (Cui et al., 2017)	74.5%	70.8%	-	-
NSE (T=1) (Munkhdalai and Yu, 2017)	71.1%	69.7%	65.5%	65.3%
NSE Query Gating (T=2) (Munkhdalai and Yu, 2017)	71.5%	70.7%	65.1%	65.5%
NSE Query Gating (T=6) (Munkhdalai and Yu, 2017)	71.4%	72.0%	65.7%	65.8%
NSE Adaptive Computation (T=2) (Munkhdalai and Yu, 2017)	72.1%	71.2%	65.4%	66.0%
NSE Adaptive Computation (T=12) (Munkhdalai and Yu, 2017)	73.2%	71.4%	66.2%	66.7%
FG (Yang et al., 2017)	74.9%	72.0%	71.7%	72.6%
DGR	**75.4%**	70.7%	**72.0%**	**72.9%**

Table 1: Performance of proposed model (DGR) on the test set of CBT-NE, CBT-CN, WDW-Strict, and WDW-Relaxed datasets.

Method	Development Accuracy(%)			
	CBT-NE	CBT-CN	WDW-Strict	WDW-Relaxed
1) DGR	**77.90**	**73.80**	**71.78**	**72.26**
2) DGR - (a)	75.60	72.25	71.04	71.82
3) DGR - (c)	77.50	72.45	71.29	71.93
4) DGR - (a) & (b)	77.85	73.05	71.67	72.20
5) DGR - (a) & (c)	76.00	72.85	71.37	72.13
6) DGR - (a) & (b) & (c)	77.65	73.00	71.61	72.16

Table 2: Ablation study results. Performance of different configurations of the proposed model on the development set of the CBT-NE, CBT-CN, WDW-Strict, and WDW-Relaxed datasets

that while the NLP toolkit features such as POS and NER could help the performance of the comprehension models (specially in CBT-CN), capturing richer dependency interaction between document and query appears to play a more important role for comprehension tasks focusing on Named Entities.

Finally, For each of the three datasets on which our model achieves the state-of-the-art performance, we conducted the one-sided McNemars test to verify the statistical significance of the performance improvement over the main competitor (GA reader). The obtained p-values are 0.03, 0.003, and 0.011 for CBT-NE, WDW-Strict, and WDW-Relaxed respectively, indicating that the performance gain by DGR is statistically significant.

4.4 Ablation Study

We conducted an ablation study on our model to examine the importance and the effect of proposed strategies. We investigate all settings on the development set of the CTB-NE, CBT-CN, WDW-Strict, and WDW-Relaxed datasets. Consider the three key differences of our method from the GA Reader: (a) Document gated query reading — here we compute a document-specific query representations to pass to the next reading layer; (b) Dependent query reading — the query readings are dependent from one layer to the next as the input to the next reading layer comes from the output of previous layer; (c) Dependent BiGRU initialization — query BiGRUs of a later layer are initialized with the final hidden states of previous layer's query BiGRU.

Table 2 shows the ablation study results on the development set of CBT-NE, CBT-CN, WDW-Strict, and WDW-Relaxed for a variety of DGR configurations by removing one or more of the key differences with GA reader. Note that by all removing all three difference elements, configuration 6 reduces to the GA reader.

According to Table 2, DGR achieves the best development accuracy on all datasets which indicates that collectively, the three elements lead to improved effectiveness.

Effect of document dependent reading. Configuration 2 removes the document dependent reading, and retains the other two elements. Interestingly, this configuration achieved the worst performance among all variations. Without proper guiding from the document side, iteratively reading the query actually leads to worse performance than independent query reading. This suggests that document dependent reading is a critical element that helps achieve better reading of query.

Effect of Dependent Query BiGRU initialization. In Configuration 3, we remove the dependent query BiGRU initialization, which results in a performance loss ranging from 0.33% (WDW-relaxed) to 1.35% (CBT-CN), suggesting that this connection provides important information that helps the reading of the query. Note that simply adding dependent query BiGRU initialization to GA reader (configuration 4) leads to a slight improvement over GA reader, which again confirms the usefulness of this channel of information.

Effect of dependent query reading. Unfortunately, we cannot only remove (b) from our model because it will cause dimension mismatch between the document and query representation preventing the gating operation for computing the document gated query representation. Instead, we compare the GA reader (configuration 6) with configure 5, which adds dependent query reading to the GA reader. We can see that adding the dependent query reading to the GA reader actually leads to a slight performance loss. Note that further including document gated reading (configuration 3) improves the performance on CBT-NE, but still fails to outperform GA reader. This points to a potential direction to further improve our model by designing a new mechanism that is capable of document dependent gating without the dependent query reading.

4.5 Analysis

In this section, We first investigate the performance of DGR and its variations on two attributes: the *document length*, and *query length*. Then we show a layer-wise visualization of the energy function (Equation 3) for an instance from the CBT-NE dataset.

4.5.1 Length Study

Among the four datasets that we use in this paper, WDW-Relaxed is the biggest and the most noisy one which makes it as a good candidate for analyzing the trend and behavior of our models.

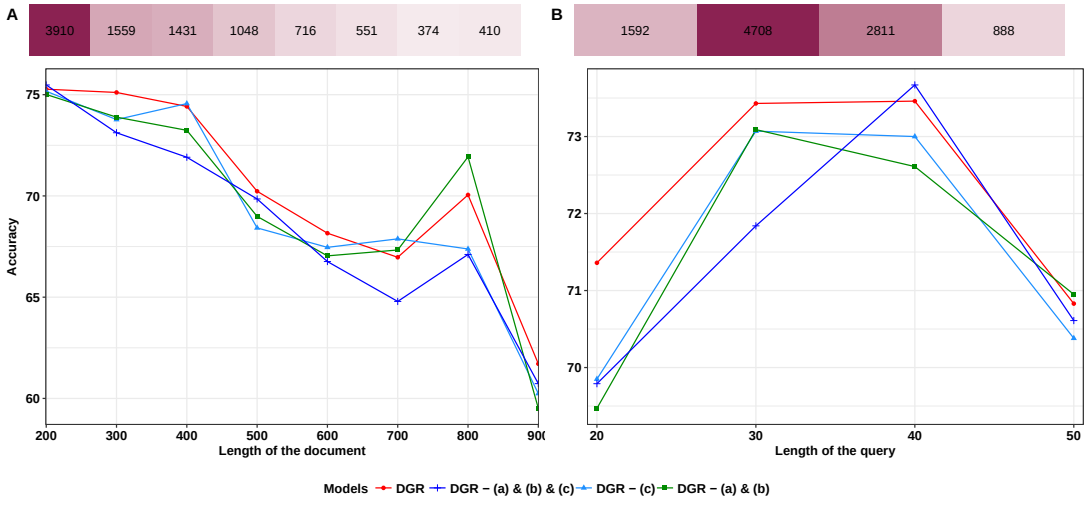

Figure 2: Test accuracy of DGR and its variations against the length of the document (A), and length of the query (B) on the WDW-Relaxed dataset. The bar on top of each figure indicates the number of samples in each interval. Darker color in the bars illustrates more samples.

Figure 2 depicts the performance of DGR and its variations against the length of document (left), and the length of query (right). A bar on top of each diagram indicates the frequency of samples in each

intervals. Each data sample is added to the closet interval.

Overall Figure 2 suggests that DGR achieves highly competitive performance across different document and query lengths in comparison to the other variations including the GA reader. In particular, DGR perform better or similarly to the GA reader ("DGR - (a) & (b) & (c)") in all categories except when query length is between 30 and 40 where GA reader wins with a small margin. Furthermore, we see that "DGR - (a) & (b)" wins over "DGR - (a) & (b) & (c)" in most document length categories. This suggests the positive effect of the connection offered by (c), especially for longer documents.

4.5.2 Attention Study

To gain insights into the influence of the proposed strategies on the internal behavior of the model, we analyze the attention distribution at intermediate layers. We show a visualization of layer-wise normalized aggregated attention weights (energy function, Equation 3) for candidate set over the query (for more examples look at Section C of the appendix). In each figure, the top plots show the layer-wise attention of DGR and the bottom plots show the layer-wise attention of the GA reader, i.e., "DGR - (a) & (b) & (c)". Moreover, the left and middle plot show the aggregated attention of candidates over the whole query while the right plot depicts the aggregated attention of the candidates for the placeholder in the query in the final layer.

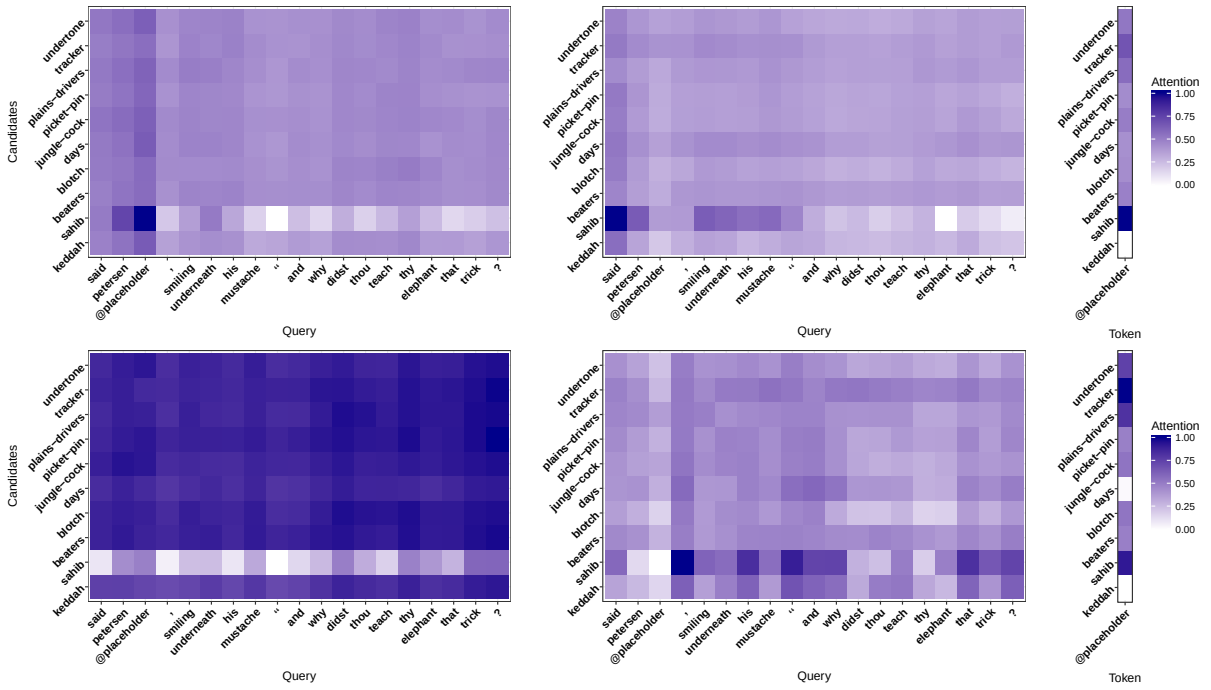

Figure 3: Layer-wise normalized attention visualization of "DGR" (top) and "DGR - (a) & (b) & (c)" (bottom) for a sample from the CBT-NE test set. Darker color illustrates higher attention. Figures only show the aggregated attention of candidates. The gold answer is "sahib".

A generic pattern observed in our study is that GA reader tends to generate more uniform attention distributions while DGR produces more focused attention. In other words, each layer of DGR tends to focus on different sub-parts and examine different hypotheses, illustrating the significant impact of the proposed strategies on the attention mechanism.

5 Conclusion

We proposed a novel cloze-style question answering model (DGR) that efficiently model the relationship between the document and the query. Our model achieves the the state-of-the-art results on several large-scale benchmark datasets such as CBT-NE, WDW-Strict, and WDW-Relaxed. Our extensive analysis

and ablation studies confirm our hypothesis that using a more sophisticated method for modeling the interaction between document and query could yield further improvements.

Table 3: Dataset statistics

B Rule-based Disambiguation Study

In this section, we present a simple rule-based detection strategy for CBT-NE dataset which disambiguates about 30% and 18% of the samples in CBT-NE development and test sets. For each query q, assume w is previous/next next word in the placeholder which start with upper case character. If such a w exists, we look for w in the document d and collect all words that could appears next/before w. After removing all collected words that are not in the candidate list C, the samples is disambiguated and solved if we end up with a single word (answer). We refer to the set of such samples as disambiguated set. Table 4 shows the statistics of this rule-based strategy on the rule-based disambiguated test set of CBT-NE. Furthermore, Table 5 shows a data sample in CBT-NE that is correctly disambiguated with our rule-based approach.

Set	Correct Disambiguation(%)	Wrong Disambiguation(%)	Total Disambiguation
Development	29.65%	0.1%	595
Test	18.36%	0.12%	462

Table 4: Statistics and performance of the proposed rule-based strategy on CBT-NE dataset.

Figure 4 shows the performance of DGR and its variations on the set of data samples in CBT-NE test set that could be disambiguated with the proposed rule-based strategy. Although we use the lower case words in the training process, all models perform substantially well on disambiguating such samples. This observation could demonstrate the effectiveness of the general architecture.

C Attention Study

In this section, we show visualizations of 8 samples of layer-wise normalized attention (energy function, see Equation 3 in the main paper). Each column in Figures 5-12, represents the same layer in "DGR" and "DGR - (a) & (b) & (c)". Also, each row is allocated to a specific model (Top: DGR, and Bottom: DGR - (a) & (b) & (c)).

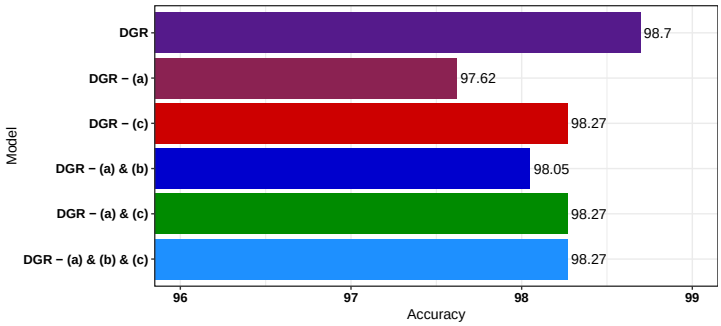

Figure 4: Performance of DGR and its variations on the rule-based disambiguated test set of CBT-NE.

doc[a]	1 Instead of answering , **Jimmy** Skunk began to laugh . 2 “ Who ’s a bug ? ” 3 demanded Old Mr. Toad , more crossly than before . 4 “ There is n’t any bug , Mr. Toad , and I beg your pardon , ” replied **Jimmy** , remembering his politeness . 5 “ I just thought there was . 6 You see , I did n’t know you were under that piece of bark . 7 I hope you will excuse me , Mr. Toad . 8 Have you seen any fat beetles this morning ? ” 9 “ No , ” said Old Mr. Toad grumpily , and yawned and rubbed his eyes . 10 “ Why , ” exclaimed **Jimmy** Skunk , “ I believe you have just waked up ! ” 11 “ What if I have ? ” 12 demanded Old Mr. Toad . 13 “ Oh , nothing , nothing at all , Mr. Toad , ” replied **Jimmy** Skunk , “ only you are the second one I ’ve met this morning who had just waked up . ” 14 “ Who was the other ? ” 15 asked Old Mr. Toad . 16 “ Mr. Blacksnake , ” replied **Jimmy** . 17 “ He inquired for you . ” 18 Old Mr. Toad turned quite pale . 19 “ I – I think I ’ll be moving along , ” said he . 20 XVII OLD MR. a.vlachos@sheffield.ac.uk

Abstract

The recently increased focus on misinformation has stimulated research in fact checking, the task of assessing the truthfulness of a claim. Research in automating this task has been conducted in a variety of disciplines including natural language processing, machine learning, knowledge representation, databases, and journalism. While there has been substantial progress, relevant papers and articles have been published in research communities that are often unaware of each other and use inconsistent terminology, thus impeding understanding and further progress. In this paper we survey automated fact checking research stemming from natural language processing and related disciplines, unifying the task formulations and methodologies across papers and authors. Furthermore, we highlight the use of evidence as an important distinguishing factor among them cutting across task formulations and methods. We conclude with proposing avenues for future NLP research on automated fact checking.

Title and Abstract in Greek

Αναγνώριση Ψευδών Ισχυρισμών:
Ορισμοί, μέθοδοι και κατευθύνσης για μελλοντική έρευνα

Το πρόσφατα αυξημένο ενδιαφέρον για το φαινόμενο της παραπληροφόρησης έχει κινητοποιήσει ερευνητικές προσπάθειες για μεθόδους αναγνώρισης ψευδών ισχυρισμών. Η έρευνα σε αυτοματοποιημένες μεθόδους για το πρόβλημα αυτό διεξάγεται σε διάφορους επιστημονικούς κλάδους, όπως επεξεργασία φυσικής γλώσσας, μηχανική μάθηση, αναπαράσταση γνώσης, βάσεις δεδομένων και δημοσιογραφία. Αν και έχει γίνει σημαντική πρόοδος, τα άρθρα σχετικά με το αντικείμενο δημοσιεύονται στα συνέδρια και τα περιοδικά του κάθε κλάδου και χρησιμοποιούν διαφορετική ορολογία, με συνέπεια να δυσχεραίνεται η περαιτέρω πρόοδος. Στο παρόν άρθρο παρουσιάζουμε μια ανασκόπηση της έρευνας στον αυτόματη αναγνώριση ψευδών ισχυρισμών με κεντρικό άξονα την επεξεργασίας φυσικής γλώσσας, ενοποιώντας ορισμούς και μεθόδους που έχουν προταθεί στη βιβλιογραφία. Μια βασική διάκριση που διαχωρίζει τις ορισμούς και μεθόδους που έχουν προταθεί σε διαφορετικούς κλάδους είναι η χρήση ή μη αποδεικτικών στοιχείων. Η ανασκόπηση στο άρθρο αυτό καταλήγει με κατευθύνσεις για μελλοντική έρευνα στην επεξεργασία φυσικής γλώσσας σχετική με το πρόβλημα αυτό.

1 Introduction

The ability to rapidly distribute information on the internet presents a great opportunity for individuals and organizations to disseminate and consume large amounts of data on almost any subject matter. As many of the barriers required to publish information are effectively removed through the advent of social media, it is possible for content written by any individual or organization to reach an audience of hundreds of millions of readers (Allcott and Gentzkow, 2017). This enhanced ability of reaching audiences

Proceedings of the 27th International Conference on Computational Linguistics, pages 3346–3359
Santa Fe, New Mexico, USA, August 20-26, 2018.

can be used to spread both true and false information, and has become an important concern as it is speculated that this has affected decisions such as public votes, especially since recent studies have shown that false information reached greater audiences (Vosoughi et al., 2018). Consequently, there has been an increased demand for fact checking of online content.

In the domain of journalism, fact checking is the task of assessing whether claims made in written or spoken language are true. This is a task that is normally performed by trained professionals: the fact checker must evaluate previous speeches, debates, legislation and published figures or known facts, and use these, combined with reasoning to reach a verdict. Depending on the complexity of the claim, this process may take from less than one hour to a few days (Hassan et al., 2015a). Due to the large volume of content to be checked, this process has been the subject of calls from the journalism community to develop tooling to automate parts of this task (Cohen et al., 2011; Babakar and Moy, 2016; Graves, 2018). The process of fact checking requires researching and identifying evidence, understanding the context of information and reasoning about what can be inferred from this evidence. The goal of automated fact checking is to reduce the human burden in assessing the veracity of a claim.

In this paper we survey automated fact checking work from the viewpoint of natural language processing (NLP) and related fields such as machine learning, knowledge representation, databases and social media analysis. While it is important to consider social aspects, including how fact checking is communicated and incorporated into social media platforms, these are considered out of scope for this survey. There is a vast body of related works with different motivations and approaches that we can learn from to develop natural language technologies for fact checking. However, because these are conducted in a siloed manner and often without wider awareness of the issue, there is inconsistency in the definitions and lack of communication between disciplines, impeding understanding and further progress. For example, the classification of whether an article title can be supported by content in the body has been interchangeably referred to as both fake news detection (Pomerleau and Rao, 2017), stance classification (Ferreira and Vlachos, 2016) and incongruent headline detection (Chesney et al., 2017).

In this survey we aim to unify the definitions presented in related works and identify common concepts, datasets and modelling approaches. In this process, we summarize key results, highlight limitations and propose some open research challenges. In particular, we detail the different types of evidence used by different approaches and how they affect the NLP requirements on the systems developed. For example, many approaches rely on textual entailment/natural language inference (Dagan et al., 2009), while others rely on knowledge base construction techniques (Ji and Grishman, 2011).

The structure of this survey is as follows: we first discuss fact checking in the context of journalism as this provides definitions and distinctions on key terminology that will be used throughout in the remainder. We then proceed to discussing previous research in automated fact checking in terms of what inputs they expect, what outputs they return and the evidence used in this process. Following this, we provide an overview of the most commonly used datasets and the models developed and evaluated on them. Subsequently, we discuss work related to automated fact checking and conclude by proposing avenues for future NLP research.

2 Fact checking in journalism

Fact checking is an essential component in the process of news reporting. Journalism has been defined by scholars as a "discipline of verification" to separate it from "entertainment, propaganda, fiction, or art" (Shapiro et al., 2013). While fact checking and verification are often used interchangeably, recent work has sought to define them as two distinct but complementary processes (Silverman, 2016). In particular, verification is defined as "scientific-like approach of getting the fact and also the right facts" (Kovach and Rosenstiel, 2014), which often involves verifying the source, date and the location of materials. Fact-checking on the other hand "addresses the claim's logic, coherence and context" (Mantzarlis, 2015). Consequently, verification is a necessary and crucial first step in the process of fact checking as it assesses the trustworthiness of the contexts considered. We adopt this distinction for the remainder of this survey

as it helps highlight key differences between various automated approaches.[1]

A term that has become strongly associated with fact checking is "fake news", especially since its use in the context of the 2016 US presidential elections. However its popularity has resulted in its meaning becoming diluted, as it is used to label claims on a number of aspects not necessarily related to veracity (Vosoughi et al., 2018). The most prominent example of such usage of the term of fake news is its application to media organizations of opposing political sides. Furthermore, it is often grouped together with the term "hate speech" as in the case of recent legislation (Deutsche Welle, 2017), despite the latter being more related to the use of emotive language instead of truth assessment (Rahman, 2012). Therefore we avoid using this term in this survey.

A further consideration is the relation of fact checking with the terms misinformation and disinformation. While the former is the distribution of information that may not be accurate or complete, the latter additionally assumes malicious motives to mislead the reader (Jowett and O' Donnell, 2006). Due to this additional consideration, disinformation is considered a subset of misinformation. Fact checking can help detect misinformation, but not distinguish it from disinformation.

3 Towards Automated Fact Checking

The increased demand for fact checking has stimulated a rapid progress in developing tools and systems to automate the task, or parts thereof (Babakar and Moy, 2016; Graves, 2018). Thus, there has been a diverse array of approaches tailored to specific datasets, domains or subtasks. While they all share the same goal, these approaches utilize different definitions of what the task being automated is. In the following discussion, we highlight the differences between the task definitions used in previous research in the following axes: input, i.e. what is being fact checked, output, i.e. what kinds of verdicts are expected, and the evidence used in the fact checking process.

3.1 Inputs

We first consider the inputs to automated fact checking approaches as their format and content influences the types of evidence used in this process. A frequently considered input to fact checking approaches is subject-predicate-object triples, e.g. `(London, capital_of, UK)`, and is popular across different research communities, including NLP (Nakashole and Mitchell, 2014), data mining (Ciampaglia et al., 2015) and Web search (Bast et al., 2015). The popularity of triples as input stems from the fact that they facilitate fact checking against (semi-)structured knowledge bases such Freebase (Bollacker et al., 2008). However, it is important to acknowledge that approaches using triples as input implicitly assume a non-trivial level of processing in order to convert text, speech or other forms of claims into triples, a task falling under the broad definition of natural language understanding (Woods, 1973).

A second type of input often considered in automated fact checking is textual claims. These tend to be short sentences constructed from longer passages, which is a practice common among human fact checkers on dedicated websites such as PolitiFact[2] and Full Fact[3] with the purpose of including only the context relevant to the claim from the original passage. The availability of fact checked claims on such websites has rendered this format very popular among researchers in NLP.

A useful taxonomy of textual claims was proposed in the context of the HeroX fact checking challenge (Francis and Full Fact, 2016), in which four types of claims were considered:

- **numerical claims** involving numerical properties about entities and comparisons among them
- **entity and event properties** such as professional qualifications and event participants
- **position statements** such as whether a political entity supported a certain policy
- **quote verification** assessing whether the claim states precisely the source of a quote, its content, and the event at which it supposedly occurred.

[1] Note that Mantzarlis and Silverman disagree on whether fact-checking should be considered a subset of verification, or just overlapping with it. While this is in an important question, we do not address it in this survey as it does not affect our analysis.

[2] `http://www.politifact.com/`

[3] `http://www.fullfact.org/`

While some of these claims could be represented as triples, they typically require more complex representations; for example, events typically need to be represented with multiple slots (Doddington et al., 2004) to denote their various participants. Regardless of whether textual claims are verified via a subject-predicate-object triple representation or as text, it is often necessary to disambiguate the entities and their properties. For example, the claim 'Beckham played for Manchester United' is true for the soccer player 'David Beckham', but not true (at the time of writing) for the American football player 'Odel Beckham Jr'. Correctly identifying, disambiguating and grounding entities is the task of Named Entity Linking (McNamee and Dang, 2009). While this must be performed explicitly if converting a claim to a subject-predicate-object triple with reference to a knowledge base, it may also be performed implicitly through the retrieval of appropriate textual evidence if fact checking against textual sources.

Finally, there have been approaches that consider an entire document as their input. These approaches must first identify the claims and then fact check them. This increases the complexity of the task, as approaches are required to extract the claims, either in the form of triples by performing relation extraction (Vlachos and Riedel, 2015) or through a supervised sentence-level classification (Hassan et al., 2015b).

3.2 Sources of evidence

The type of evidence that is used for fact checking influences the model and the types of outputs that the fact checking system can produce. For example, whether the output is a label or whether a justification can be produced depends largely on the information available to the fact checking system.

We first consider task formulations that do not use any evidence beyond the claim itself when predicting its veracity such as the one by Rashkin et al. (2017). In these instances, surface-level linguistic features in the claims are associated with the predicted veracity. We contrast this to how journalists work when fact checking, where they must find knowledge relating to the fact and evaluate the claim given the evidence and context when making the decision as to whether a claim is true or false. The predictions made in task formulations that do not consider evidence beyond the claim are based on surface patterns of how the claim is written rather than considering the current state of the world.

Wang (2017) incorporate additional metadata in fact checking such as the originator of the claim, speaker profile and the media source in which the claim is presented. While these do not provide evidence grounding the claim, the additional context can act as a prior to improve the classification accuracy, and can be used as part of the justification of a verdict.

Knowledge graphs provide a rich collection of structured canonical information about the world stored in a machine readable format that could support the task of fact checking. We observe two types of formulations using this type of evidence. The first approach is to identify/retrieve the element in the knowledge graph that provides the information supporting or refuting the claim at question. For example, Vlachos and Riedel (2015) and Thorne and Vlachos (2017) identify the subject-predicate-object triples from small knowledge graphs to fact check numerical claims. Once the relevant triple had been found, a truth label is computed through a rule based approach that considers the error between the claimed values and the retrieved values from the graph. The key limitation in using knowledge graphs as evidence in this fashion is that it assumes that the true facts relevant to the claim are present in them. However, it is not feasible to capture and store every conceivable fact in the graph in advance of knowing the claim.

The alternative use of a knowledge graph as evidence is to consider its topology in order to predict how likely a claim (expressed as a node in the graph) is to be true (Ciampaglia et al., 2015). While graph topology can be indicative of the plausibility of a fact, nevertheless if a fact is unlikely to occur that does not negate its truthfulness. Furthermore, improbable but believable claims are more likely to become viral and thus in greater need of verification by fact checkers.

Text, such as encyclopedia articles, policy documents, verified news and scientific journals contain information that can be used to fact check claims. Ferreira and Vlachos (2016) use article headlines (single sentences) as evidence to predict whether an article is for, against or observing a claim. The Fake News Challenge (Pomerleau and Rao, 2017) also formulated this part of the fact checking process in the same way, but in contrast to (Ferreira and Vlachos, 2016), entire documents are used as evidence, thus allowing for evidence from multiple sentences to be combined.

The Fact Extraction and VERification (FEVER) task (Thorne et al., 2018) requires combining information from multiple documents and sentences for fact checking. Unlike the aforementioned works which use text as evidence, the evidence is not given but must be retrieved from Wikipedia, a large corpus of encyclopedic articles. Scaling up even further, the triple scoring task of the WSDM cup (Bast et al., 2017) required participants to assess knowledge graph triples considering both Wikipedia and a portion of the web-scale ClueWeb dataset (Gabrilovich et al., 2013).

A different source of text-based evidence is repositories of previously fact checked claims (Hassan et al., 2017b). Systems using such evidence typically match a new claim to claim(s) in such a repository and return the label of the match if one is found. This type of evidence enables the prediction of veracity labels instead of only whether a claim is supported or refuted. However, this evidence is limiting fact checking only to claims similar to the ones already existing in the repository.

As an alternative to using knowledge stored in texts or databases as evidence, aggregate information on the distribution of posts on social networks can provide insights into the veracity of the content. Rumor veracity prediction is the assessment of the macro level behaviors of users' interactions with and distribution of content to predict whether the claims in the content are true or false (Derczynski and Bontcheva, 2015; Derczynski et al., 2017). This crowd behavior provide useful insights, especially in cases where textual sources or structured knowledge bases may be unavailable.

The trustworthiness of the sources used as evidence, i.e. the verification aspect of fact checking in journalistic terms, is rarely considered by automated approaches, despite its obvious importance. Often the sources of evidence are considered given, e.g. Wikipedia or Freebase, as this facilitates development and evaluation, especially when multiple models are considered. Nevertheless, approaches relying on Twitter metadata often consider credibility indicators for the tweets used as evidence in their fact checking process (Liu et al., 2015). Similar to journalism, trustworthiness assessment is often considered as a separate task and we discuss it further in the Related Work section.

3.3 Output

The simplest model for fact checking is to label a claim as true or false as a binary classification task (Nakashole and Mitchell, 2014). However, we must also consider that it is possible in natural language to be purposefully flexible with the degree of truthfulness of the information expressed or express a particular bias using true facts. Journalistic fact checking agencies such as Politifact model the degree of truthfulness on a multi-point scale (ranging from true, mostly-true, half-true, etc). Rather than modeling fact checking as a binary classification, Vlachos and Riedel (2014) suggested modeling this degree of truthfulness as an ordinal classification task. However, the reasoning behind why the manual fact checking agencies have applied these more fine-grained labels is complex, sometimes inconsistent[4] and likely to be difficult to capture and express in our models. Wang et al. (2017) and Rashkin et al. (2017) expect as output multiclass labels following the definitions by the journalists over a multi-point scale but ignoring the ordering among them.

The triple scoring task of the WSDM cup (Bast et al., 2017) expected as output triples scored within a numerical range indicating how likely they are to be true. The evaluation consisted of calculating both the differences between the predicted and the manually annotated scores, as well as the correlation between the rankings produced by the systems and the annotators.

Ferreira and Vlachos (2016) expect as output whether a claim is supported, refuted or just reported by a news article headline. Pomerleau and Rao (2017) added an extra label for the article being irrelevant to the claim, and consider the full article instead of the headline. While this output can be used in the process of fact checking, it is not a complete fact check.

In FEVER (Thorne et al., 2018) the output expected consists of two components: a 3-way classification label about whether a claim is supported/refuted by Wikipedia, or there is not enough information in the latter to Wikipedia it, and in the case of the first two labels, the sentences forming the evidence to reach the verdict. In effect this combines the multiclass labeling output with a ranking task over Wikipedia

[4] http://www.poynter.org/news/can-fact-checkers-agree-what-true-new-study-doesnt-point-answer

sentences. If the label predicted is correct but the evidence retrieved is incorrect, then the answer is considered incorrect, highlighting the importance of evidence in this task formulation. Nevertheless, this output cannot be considered a complete fact check though, unless we restrict world knowledge to Wikipedia. The use of full world knowledge in the justifications was considered in the HeroX shared task (Francis and Full Fact, 2016); while this allowed for complete fact checks, it also necessitated manual verification of the outputs.

4 Fact Checking Datasets

There are currently a limited number of published datasets resources for fact checking. Vlachos and Riedel (2014) collected and released 221 labeled claims in the political domain that had been fact checked by Politifact and Channel4.[5] For each labeled claim, the speaker or originator is provided alongside hyperlinks to the sources used by the fact checker as evidence. The sources range from statistical tables and Excel spreadsheets to PDF reports and documents from The National Archives. While these sources can be readily assessed by human fact checkers, the variety and lack of structure in the evidence makes it difficult to apply machine learning-based approaches to select evidence as separate techniques may be required for the each different document format. Where documents are provided as evidence, we do not know which portions of the document pertain to the claim, which compounds the difficulty of assessing and evaluating a fact checking system, given the need for evidence and accountability. Furthermore, with such a limited number of samples, the scale of this dataset precludes its use for developing machine learning-based fact checking systems.

Wang (2017) released a dataset similar to but an order of magnitude larger than that of Vlachos and Riedel (2014) containing 12.8K labeled claims from Politifact. In addition to the claims, meta-data such as the speaker affiliation and the context in which the claim appears in (e.g. speech, tweet, op-ed piece) is provided. At this scale, this dataset can support training and evaluating a machine learning-based fact checking system. However, the usefulness of the dataset may be limited due the claims being provided without machine-readable evidence beyond originator metadata, meaning that systems can only resort to approaches to fact checking such as text classification or speaker profiling.

Rashkin et al. (2017) collated claims from Politifact without meta-data. In addition, the authors published a dataset of 74K news articles collected from websites deemed as Hoax, Satire, Propaganda and Trusted News. The prediction of whether a news article is true or false is modeled as the task of predicting whether an article originates from one of the websites deemed to be "fake news" according to a US News & World report.[6] This allows systems to fact check using linguistic features, but does not consider evidence, or which aspects of a story are true or false.

Ferreira and Vlachos (2016) released a dataset for rumor debunking using data collected from the Emergent project (Silverman, 2015). For 300 claims, 2,595 corresponding news articles were collected and their stances were labeled as for, against or observing a claim. This dataset was extended for the 2017 Fake News Challenge (Pomerleau and Rao, 2017) dataset which consisted of approximately 50K headline and body pairs derived from the original 300 claims and 2,595 articles.

The HeroX Fast and Furious Fact Checking Challenge (Francis and Full Fact, 2016) released 90 (41 practice and 49 test) labeled claims as part of the competition. Because part of the challenge required identification of appropriate source material, evidence for these claims was not provided and therefore manual evaluation was needed on case-by-case basis. As with the claims collected by Vlachos and Riedel (2014), the size of the dataset prevents its use for training a machine learning-based fact checking system. However, the broad range of types of claims in this dataset highlights a number of forms of misinformation to help identify the requirements for fact checking systems.

Thorne et al. (2018) introduced a fact checking dataset containing 185K claims about properties of entities and concepts which must be verified using articles from Wikipedia. While this restricts the pool of evidence substantially compared to HeroX, it allowed for a challenging evidence selection subtask

[5] http://channel4.com/news/factcheck

[6] www.usnews.com/news/national-news/articles/2016-11-14/avoid-these-fake-news-sites-at-all-costs

that could be feasibly annotated manually at a large scale in the form of sentences selected as evidence. Combined with the labels on the claims, these machine readable fact checks allow training machine learning-based fact checking models.

5 Methods

The majority of the methods used for automated fact checking are supervised: learning a text classifier from some form of labeled data that is provided at training. This trait that is independent of the task input or what sources of evidence are considered. Vlachos and Riedel (2014) suggested fact checking using supervised models, making use of existing statements that had been annotated with verdicts by fact checking agencies and journalists. Wang (2017) and Rashkin et al. (2017) applied this approach to classify the veracity of fake news stories. The main limitation of text classification approaches is that fact checking a claim requires additional world knowledge, typically not provided with the claim itself. While language can indicate whether a sentence is factual (Nakashole and Mitchell, 2014), credible sounding sentences may also be inherently false. Text classification on claims alone has been used for the related task of detecting fact-check worthy claims (Hassan et al., 2017a).

Ciampaglia et al. (2015) use network analysis to predict whether an unobserved triple is likely to appear in a graph by modeling the task as a path ranking problem (Lao et al., 2011). The truth verdict is derived from the cost of traversing a path between the two entities under transitive closure, weighted by the degree of connectedness of the path. Nakashole and Mitchell (2014) combine linguistic features on the subjectivity of the language used with the co-occurrence of a triple with other triples from the same topic, a form of collective classification.

Ferreira and Vlachos (2016) modeled fact checking as a form of Recognizing Textual Entailment (RTE) (Dagan et al., 2009; Bowman et al., 2015), predicting whether a premise, typically (part of) a news article, is *for*, *against*, or *observing* a given claim. The same type of model was used by most of the 50 participating teams in the Fake News Challenge (Pomerleau and Rao, 2017), including most of the top entries (Riedel et al., 2017; Hanselowski et al., 2017).

The RTE-based models assume that the textual evidence to fact check a claim is given. Thus they are inapplicable in cases where this is not provided (as in HeroX), or it is a rather large textual resource such as Wikipedia (as in FEVER). For the latter, Thorne et al. (2018) developed a pipelined approach in which the RTE component is preceded by a document retrieval and a sentence selection component. There is also work focusing exclusively on retrieving sentence-level evidence from related documents for a given claim (Hua and Wang, 2017).

Vlachos and Riedel (2015) and Thorne and Vlachos (2017) use distantly supervised relation extraction (Mintz et al., 2009) to identify surface patterns in text which describe relations between two entities in a knowledge graph. Because these fact checking approaches only focus on statistical properties of entities, identification of positive training examples is simplified to searching for sentences containing numbers that are approximately equal to the values stored in the graph. Extending this approach to entity-entity relations would pose different challenges, as a there may be many relations between the same pair entities that would need to be accurately distinguished for this approach to be used.

A popular type of model often employed by fact checking organizations in their process is that of matching a claim with existing, previously fact checked ones. This reduces the task to sentence-level textual similarity as suggested by Vlachos and Riedel (2014) and implemented in ClaimBuster (Hassan et al., 2017b), Truthteller by The Washington Post[7] and one of the two modes of Full Fact's Live platform.[8] However, it can only be used to fact check repeated or paraphrased claims.

Long et al. (2017) extend the models produced by Wang (2017) and improve accuracy of a simple fact checking system through more extended profiling of the originators of the claims. The most influential feature in this model is the *credit history* of the originator, a metric describing how often the originator's claims are classified as false. This feature introduces a bias in the model that fits with the adage "never

[7] https://www.knightfoundation.org/articles/debuting-truth-teller-washington-post-real-time-lie-detection-service-your-service-not-quite-yet

[8] https://fullfact.org/blog/2017/jun/automated-fact-checking-full-fact/

trust a liar". In the case of previously unannotated sources which may haven no recorded history, this feature would be unavailable. Furthermore, the strong reliance on credit history has some important ethical implications that need to be carefully considered. Despite these limitations, speaker profiling has been shown to be effective in other related studies (Gottipati et al., 2013; Long et al., 2016) and is discussed further in Section 6.

6 Related Tasks

Verification In Section 2, we highlighted the difference between verification and fact checking. While the models considered in Section 4 operate under a closed-world paradigm where we assume that all evidence provided is true, for these fact checking technologies to scale-to and operate on the web, we must also consider information that is of unknown veracity as evidence.

Methods of predicting the authoritativeness of web pages such as PageRank (Brin and Page, 1998) only consider the hyperlink topology. TrustRank (Gyöngyi et al., 2004) provides a framework which incorporates annotated information and predicts the trustworthiness of pages based on graph-connectedness to known-bad nodes rather than the information content. An alternative is Knowledge-based Trustworthiness scoring (Dong et al., 2015), which allows predicting whether the facts extracted from a given document page are likely to be accurate given the method used to extract the facts and the website in which the document is published.

Common Sense Reasoning Fact checking requires the ability to reason about arguments with common sense knowledge. This requires developing systems that go beyond recognizing semantic phenomena more complex than those typically considered in textual entailment tasks. Habernal et al. (2018) introduced a new task and dataset for predicting which implicit *warrant* (the rationale of an argument) is required to support a claim from a given premise. Angeli and Manning (2014) proposed a method of extracting common sense knowledge from WordNet for reasoning about common sense knowledge using Natural Logic and evaluated their approach on a subset of textual entailment problems in the FraCaS test suite (Cooper et al., 1996). It is important to build systems that can reason about both explicit world knowledge and implicit common sense knowledge is an essential step towards automating fact checking.

Subjectivity and Emotive Language Rashkin et al. (2017) assess the reliability of entire news articles by predicting whether the document originates from a website classified as Hoax, Satire or Propaganda. This work is an instance of subjective language detection and does not represent evidence-based fact checking. The authors used supervised classifiers augmented with lexicons including the Linguistic Inquiry and Word Count (LIWC) (Pennebaker et al., 2015), a sentiment lexicon (Wilson et al., 2005), a hedging lexicon (Hyland, 2015), and a novel 'dramatic' language lexicon to identify emotive, subjective and sensational language in the article bodies. Furthermore, analysis of the lexical features using a logistic regression classifier shows that the highest weighted (most distinguishing) features for the unreliable sources included the use of hedge words (such as 'reportedly') or words pertaining to divisive topics (such as 'liberals' or 'Trump'). The authors apply a similar model to the prediction of claims made by politicians from claims collected from Politifact. The addition of the LIWC lexicon which provides an indication of emotive tone and authenticity marginally improved the classification accuracy for simple lexical models.

Deceptive Language Detection There are linguistic cues and features in written text that are useful in identifying deceptive language (Zhou et al., 2004). In the context of detecting deceptive user-generated content - a specific form of disinformation, Mihalcea and Strapparava (2009) use a simple lexical classification model without further feature engineering. Analysis of the model identifies a number of word classes of the LIWC lexicon which pertain only to the deceptive texts. Ott et al. (2011) incorporate the use of psycholinguistic cues to improve classification accuracy. Mihalcea and Strapparava (2009) found that truthful texts were more likely to contain words belonging to the 'optimistic' LIWC class such as 'best', 'hope', and 'determined'. This is corroborated by the study of sentiment in deceptive texts (Ott et al., 2013) which also identified that texts with negative sentiment were more likely to be deceptive. These

feature classes however may be an artifact of the data generation process as crowd-sourced volunteers were first asked to write an honest text and rewrite it to make it deceptive.

Feng et al. (2012) detect deceptive texts and customer-generated reviews through the use of syntactic style rather word-based content. Non-terminal nodes of the constituency parse trees are used as features in conjunction with a lexical model to increase the accuracy over using words alone. Hai et al. (2016) identify deceptive reviews also using lexical features. However, rather than relying on labeled data, the authors induce labels over an unlabeled dataset through a semi-supervised learning approach that exploits a minimal amount labeled data from related tasks in a multi-task learning set up.

Even though linguistic content, emotive language and syntax are useful indicators for detecting deceit, the truthfulness of a statement depends also on the context. Without considering these factors these approaches cannot be used to fact check information alone.

Rumor Detection Rumor detection (Qazvinian et al., 2011) is the task of identifying unverified reports circulating on social media. A prediction is typically based on language subjectivity and growth of readership through a social network. While these are important factors to consider, a sentence can be true or false regardless of whether it is a rumor (Zubiaga et al., 2018).

Speaker Profiling Identifying claims that do not fit with the profile of the originator may provide insights as to whether the information is truthful or not. Furthermore, determining which topics the originator is truthful about may allow for generation of a risk-based approach to fact checking. As mentioned earlier, Long et al. (2017) introduced a notion of credit history which increases the classification accuracy for fake news detection. However, this notion doesn't account for which topics the originator lies about. Furthermore, the assumption that each source has an overall trustworthiness score to be attached to every claim from there is not a valid one, since inaccurate information may be found even on the most reputable of sources.

An alternative is to consider the compatibility of a claim with respect to the originator's profile. This remains an open research area. Feng and Hirst (2013) perform the inverse of this task for deceptive language detection in product reviews by creating an average profile for the targets (products) and using the distance between a review and the target as a feature. The shortcomings of this method are that number of reviews are required for each target. Considering the tasks of verifying automatically extracted information or fact checking for politics, for a new topic the challenge is that there may be insufficient data to create a profile for it.

Pérez-Rosas and Mihalcea (2015) identify author characteristics (such as age and gender) that influence the linguistic choices made by the authors when fabricating information in product reviews. As the affiliation, age and gender of most politicians is public-domain knowledge, it is conceivable that these features may assist fact checking political claims. While the use of meta-data does improve classification accuracy (Wang et al., 2017; Long et al., 2017), for fact checking we must consider the meaning of the claim with respect to ground truth rather than based on the linguistic style of the originator.

Click Bait Detection Intentionally misleading headlines or titles that are designed specifically to encourage a user to click through and visit a website are called click bait. Studies into the detection of click bait have have yielded positive results from relatively simple linguistic features (Chen et al., 2015; Potthast et al., 2016; Chakraborty et al., 2016). These approaches only consider the article headline and do not make use of evidence. We contrast this to the task of detecting headlines which are incongruent to the document body (Chesney et al., 2017), where existing methods for recognizing textual entailment such as those used for the Fake News Challenge (Pomerleau and Rao, 2017) can be applied.

7 Open Research Challenges

In this paper, we provided an NLP-motivated overview of fact checking, considering the case for evidence - similar to how the task is performed by journalists. We highlighted existing works that consider fact checking of claims expressed in text or via knowledge base triples and pointed out their shortcomings, given the need to justify their decisions using evidence.

We did not identify approaches that make use of open-world knowledge. Assessing the ability of a system in an open-world setting will be difficult; the HeroX challenge resorted to fully manual evaluation, which is difficult to scale up, especially for the purposes of developing machine learning-based approaches. Thus we need to consider how to address the information retrieval challenge of the task, including its evaluation. We must also consider the verification of the evidence used, which is ignored under the closed world assumption. Ideally we should consider verification jointly with fact checking, which is in fact how it is conducted in journalism.

The relative scarcity of resources designed explicitly for fact checking, highlights the difficulties in capturing and formalizing the task, especially considering the strong interest in it. While recently published large scale resources such as FEVER can stimulate progress, they only consider simple short sentences (8 words long on average). Thus, there is scope to fact check compound information or complex sentences, and scale up to fact checking at the document level.

Furthermore, in FEVER the justification for the labels is restricted to sentences selected from Wikipedia. This is much unlike the rationales produced by human fact checkers, who synthesize information. The generation of such rationales has attracted attention only recently in NLP (Ling et al., 2017), and automated fact checking could provide an ideal testbed to develop it further.

While text is often used to make a claim, often the evidence need for fact checking appears in other modalities, such as images and videos. Given the recent interest in multi-modal NLP, we argue that this would be an important direction for future research, especially when considering that a lot of the verification efforts in journalism are focused on identifying forged images and footage.

Finally, it is important to acknowledge that the complexity of the fact checking conducted by journalists is for the moment beyond the abilities of the systems we can develop due to the rather complex reasoning needed. Even a simple short statement such as that the "UK, by leaving the EU, will take back control of roughly £350 million per week" takes a substantial amount of work to be checked.[9] In this fact check for example, the first step is to adjust the claim to render it more accurate in terms of its meaning so that the actual fact check can proceed. While this complexity can help stimulate progress in NLP and related fields, it should also calibrate our expectations and promises to society.

Abstract

Prior manual studies of rumours suggested that crowd stance can give insights into the actual rumour veracity. Even though numerous studies of automatic veracity classification of social media rumours have been carried out, none explored the effectiveness of leveraging crowd stance to determine veracity. We use stance as an additional feature to those commonly used in earlier studies. We also model the veracity of a rumour using variants of Hidden Markov Models (HMM) and the collective stance information. This paper demonstrates that HMMs that use stance and tweets' times as the only features for modelling true and false rumours achieve F_1 scores in the range of 80%, outperforming those approaches where stance is used jointly with content and user based features.

1 Introduction

Social media are rife with rumours, which are fast-spreading, unverified pieces of information (Zubiaga et al., 2018). With fake news and misinformation now widely recognised as a major problem for journalists, media, online platforms, and citizens, automatic rumour detection and analysis has become a hot research topic too. Rumour analysis research has focused on Twitter in particular, as it has established itself as the go-to social platform for real-time news (Hu et al., 2012). Twitter's unmoderated nature is also the perfect ground for spreading rumours (Qazvinian et al., 2011). A key focus of prior work on rumour analysis has been *rumour stance classification*, where the stance of each tweet on a given rumour is classified as supporting, denying, questioning or commenting on the rumour (Procter et al., 2013).

Our work builds on the hypothesis that, as rumours evolve over time, so does the stance expressed by the public towards those rumours. In the early stages of a rumour, its actual veracity tends to be unknown. However, as new evidence emerges over time, Twitter users take more pronounced and continuously evolving stance towards the information asserted in the rumour. For instance, in the early stages of a rumour supporting tweets might prevail, simply due to the lack of information to the contrary. However, when authoritative sources or reliable evidence emerge either for or against the rumour, a similar trend tends to be observed in the collective rumour stances. This was first noted in a manual analysis by Mendoza et al. (2010), who found that true rumours tended to be affirmed more than 90% of the time, whereas false rumours were challenged (questioned or denied) 50% of the time. This encourages the use of crowd (or collective) stance as a feature in an automatic rumour veracity classifier.

A rumour consists of a source tweet and several other tweets that responded to the source one—the source tweet contains the rumour. Each of those responding tweets is associated with a particular stance (supporting, denying, questioning or commenting). In this work we make use of the stances of those responding tweets to judge the veracity of the rumour. We refer to the stances of those tweets as crowd or collective stance.

Hidden Markov Models (HMM) are well known for their application in temporal pattern recognition. By regarding the individual stances over a rumour's lifetime as an ordered sequence of observations, we

Proceedings of the 27th International Conference on Computational Linguistics, pages 3360–3370
Santa Fe, New Mexico, USA, August 20-26, 2018.

can then model the actual veracity of a rumour by the hidden part of the HMM. The general assumption is that true and false rumours would have different patterns in the stance distribution over time. Therefore, after training models for *true* and *false* rumours, we can build a binary veracity classifier by comparing sequence occurrence probabilities for the two cases.

This paper investigates whether and to what extent rumour veracity classification can be predicted on the basis of crowd stance. While there is a body of work on automatic veracity classification such as (Castillo et al., 2011; Kwon et al., 2013; Vosoughi, 2015; Wu et al., 2015; Ma et al., 2015; Lukasik et al., 2016), only few have applied stance information as a feature (Liu et al., 2015; Enayet and El-Beltagy, 2017), and none of these studies investigated the collective power of the crowd as a source of stance information, which can then be used as a feature in rumour veracity classification. Here we argue that the content of the posts is not necessarily helpful towards determining the veracity of a story, as the content can be either misleading or inaccurate. We believe it is the aggregation of stances which can provide useful information to determine the veracity. Despite the fact that some of the users will be inevitably mistaken, and sharing the wrong stance, we argue that the aggregation of stances will correct itself towards being a useful feature for veracity classification. The novel contribution of this paper is in demonstrating that collective stance together with the tweets' time as features can indeed boost performance results. We demonstrate that HMM using only stance and time features achieve an F_1 score of around 80%, rendering significantly better results than traditional rich feature engineered approaches that entails stance as additional feature. We also show that our HMM are indeed applicable in case of early rumour detection.

2 Related Work

The veracity classification task aims to determine whether a given rumour can be confirmed as true, debunked as false, or in some cases its truth value is yet to be resolved (i.e. unknown). Related work has tackled the problem in a supervised fashion by applying state-of-the-art machine learning algorithms on features extracted from rumour datasets. One of the key differences between the approaches is the set of features proposed to tackle the problem. The pioneering paper of Castillo et al. (2011) proposed message, user, topic and propagation-based features. In most subsequent studies these features have been used as baselines. Following these feature sets, Kwon et al. (2013) and Kwon et al. (2017) proposed a new set of feature categories: temporal, structural and linguistic and showed their importance in fighting with rumours. Other than Twitter, the Chinese microblogging platform Sina Weibo has been also analysed for rumours. For this Yang et al. (2012) proposed client and location-based features and showed that these help to increase prediction accuracy.

Liu et al. (2015) used the approaches reported by Yang et al. (2012) and Castillo et al. (2011) as baseline systems and compared them against a new approach based on verification features, which include stance of individual tweets, rather than collective stance. Ma et al. (2015) adapted features from earlier studies and proposed to model them over time. Wu et al. (2015) extracted features from message propagation trees. Three categories of features were considered: message, user and report-based. The idea of message propagation was also investigated by Wang and Terano (2015). Vosoughi (2015) tackled veracity classification using three categories of features (linguistic, user oriented and temporal propagation related) and speech recognition inspired machine learning approaches, such as Dynamic Time Wrapping and Hidden Markov Models.

Chen et al. (2016) treated rumour veracity classification as an anomaly detection problem where false rumours are regarded as anomalies. Several features related to the content, crowd opinion and post propagation were used. Chang et al. (2016) put the emphasis on the characteristics of users who post the rumours to determine the veracity. Unlike previous studies, Tong et al. (2017) aimed at blocking rumours rather than detecting them or marking tweets as true or false. Motivated by the fact that later corrections are not as effective, the authors argued that the first post seen by a user is influential for their future opinion and thus it is important to show users rumours only once they are confirmed to be true. Based on this they proposed a reverse-tuple based randomised algorithm to block rumours. The algorithm aimed at producing positive seeds to be shown to users first.

Rumour veracity classification has also been studied in the RumourEval shared task at SemEval 2017 (Derczynski et al., 2017a). Subtask B consisted in determining if each of the rumours in the dataset were true, false or remained unverified. It considered two different settings, one *closed* where participants could not make use of external knowledge bases and another *open* where use of external resources was allowed. Participants viewed the task either as a three-way (Enayet and El-Beltagy, 2017; Wang et al., 2017; Singh et al., 2017) or two-way (Chen et al., 2017; Srivastava et al., 2017), single tweet classification task. The winning system (Enayet and El-Beltagy, 2017) added features more specific to the distribution of stance labels in the tweets replying to the source tweet (percentage of reply tweets classified as either support, deny or query). The survey paper of Zubiaga et al. (2018) provides an extensive summary of current work on rumour verification but also related task such as detection of rumours as well as stance classification of messages involved in rumours.

In this work we propose to use stance only to tackle the rumour verification task. As highlighted earlier, we aim to capture collective stance information for veracity classification. First we investigate the impact of using sequences of individual stances only. In our second approach, we integrate stance and time information into a unified model. Both approaches are based on modelling the state-changes of stances using HMM. Thus the most related studies to ours are Ma et al. (2015) because they model features over time, Vosoughi (2015) due to the use of HMM as well as Chang et al. (2016), Liu et al. (2015) and Enayet and El-Beltagy (2017) because they add the reactions (stances) of the users as additional feature. However, we differ from those because we rely only on the power of collective stance, model this using HMM and apply this model to predict the veracity of rumours.

3 Dataset

The rumour dataset used in this paper (Zubiaga et al., 2016) is the only rumour stance and veracity classified tweet dataset which is publicly available. The authors identified rumours associated with major news events as well as tweets associated with those rumours and then annotated each of the tweets for stance and the rumours for their overall veracity. The dataset consists of rumours that emerged during eight different events. However, three of these events evoked less than five rumours consisting of five or more tweets. Therefore, we limit our experiments to the events detailed in Table 1.

Event	Rumours	True / False
Charlie Hebdo	46	24 / 22
Ferguson Riots	34	2 / 32
Germanwings Crash	12	2 / 10
Ottawa Shooting	31	20 / 11
Sydney Siege	50	33 / 17
Total	173	81 / 92

Table 1: Rumours in five events. Each rumour has at least 10 tweets.

Each of the remaining events consists of several rumours and each rumour of several tweet threads. In the data set each tweet is identified by its unique ID, is associated with exactly one event and a unique rumour ID, has a time stamp and is assigned a stance label. Possible stances σ are *supporting, denying, questioning* and *commenting*. Rumours are marked with their veracity values (*true* or *false*).

4 Method: HMM for Veracity Classification

A Hidden Markov Model is a stochastic model in which the system is presumed to be a Markov process including unobservable hidden states. The hidden system undergoes discrete state changes which trigger the emission of observable signals. Based on these signals the hidden states' properties can be learnt.

4.1 Model Generation

More formally, a HMM describes two random processes

$$\{X_t\}_{t\in\mathbb{N}} \text{ and } \{Y_t\}_{t\in\mathbb{N}} \tag{1}$$

of which only the latter is directly observable. A HMM is defined as a 5-tupel

$$\lambda = \{S, E, A, B, \pi\} \tag{2}$$

where $S = \{s_1; \ldots; s_n\}$ is the set of N possible hidden states, $E = \{e_1; \ldots; e_m\}$ is the alphabet of possible observations—i.e. the system's emissions, $A \in \mathbb{R}^{n\times n}$ is the hidden state transition matrix where a_{ij} denotes the probability of the system changing from state i to j, $B \in \mathbb{R}^{n\times m}$ is the emission probability matrix where $b_i(e_j)$ denotes the probability of observing emission $e_j \in \{Y\}$ when the system is in state s_i and finally the starting state probability vector $\pi \in \mathbb{R}^n$, where $p_i = P(X_1 = s_i)$.

For rumour classification we consider tweets related to five events (see Section 3). Consequently, for classification the system λ is defined as follows:

State Space S

Since there is no a-priori solution to determine the optimal size of S (Rabiner, 1990) we consider various hidden state counts $N = \{n \in \mathbb{N} \mid 1 \leq n \leq 15\}$ and repeat calculations accordingly.

Observation Alphabet E

Unlike prior veracity classification approaches, we do not consider the tweets' textual content. Instead, classification is based on stance information alone. Therefore, we set the observation alphabet to

$$E = \{support, deny, question, comment\} \tag{3}$$

Transition Probabilities

Transition matrix A, emission matrix B and start state probability vector π are chosen at random. Baum-Welch parameter optimization algorithm is used with 10 iterators to learn models' final properties. To avoid particularly suboptimal start value configurations and local optima 100 configurations are tested for every $n \in N$. The best performing model is kept while the others are discarded.

4.2 Class Assignment ε

Training data (see Section 5 for details) is used to learn model λ_{false} for false and model λ_{true} for true rumours. For all remaining rumours ε_i (i.e. the testing data) their respective class $C(\varepsilon_i)$ is assigned as follows:

$$C(\varepsilon_i) = \underset{c\in\{false,true\}}{\operatorname{argmax}} P(\varepsilon_i|\lambda_c) \tag{4}$$

In (4) the expression $P(\varepsilon_i|\lambda_c)$ is calculated by using the Forward-Algorithm for Hidden Markov Models.

4.3 Multi Spaced HMM Including Tweet Time

As described above, the data set contains tweets' time stamps which are used to build ordered sequences of tweets beginning with the first reply to a rumourous tweet and ending with the last, while the actual distance in time between tweets is disregarded.

Therefore, a straightforward extension of the classification framework is the inclusion of actual posting times. Since basic HMM implementations do not support combining discrete (stance) and continuous (time) emissions into a unified model, we applied Multi Spaced Hidden Markov Models (MSHMM) for this purpose.

MSHMM were introduced by Tokuda et al. (2002) and originally used in speech synthesis tasks. While HMM use probability matrices in the discrete case or one dimensional distribution functions in

the continuous case, MSHMM use multi spaced observation probability distributions where the sample space Ω contains G spaces:

$$\Omega = \bigcup_{g=1}^{G} \Omega_g \tag{5}$$

Each Ω_g is a n-dimensional real space R^{n_g} with a space index g. Furthermore, each space has a probability w_g, where

$$\sum_{g=1}^{G} w_g = 1 \tag{6}$$

and an observation probability density function

$$N_g(x), x \in \mathbb{R}^1, \text{where } \int N_g(x)dx = 1 \tag{7}$$

Established algorithms for HMM can be adapted to multi spaced observation probability functions including Baum-Welch-, Viterbi- and Forward-Backward-Algorithm.

For classification of tweets including their time stamps a MSHMM λ' is defined. Here each stance σ is assigned its own 1-dimensional real space $\Omega_\sigma = R^{1_\sigma}$, while space weights w_σ are determined by stances' occurrence counts. Space probability density functions are learned based on the timestamps which have been pre-processed to represent only the time elapsed since the start of the rumour until a replying tweet occurred.

Accordingly, observation alphabet of MSHMM λ' is defined as a random vector $o = (X, x)$, where X is a space index (i.e. a stance) and $x \in \mathbb{R}^1$ the processed timestamp.

Multi spaced observation probability of o is defined as

$$b(o) = \sum_{g \in X} w_g N_g(x) \tag{8}$$

Additionally, state set S, state transition matrix A and starting state probability vector π of system λ' are defined analogue to system λ.

5 Evaluation Settings

To evaluate the performance of the classification framework leave-one-event-out cross validation was performed, following the methodology of Lukasik et al. (2015). This means that we train on $n-1$ events (on all rumours within these events) and test it on an unseen n^{th} event (on all rumours within this event). We use F_1 score to measure classifier performance and compare our results against two baselines. The first one does not make use of stance, whereas the second one integrates stance as one of a set of features. These two baselines have been selected to simulate the impact of collective stance i.e., that collective stance have positive impact on rich traditional feature engineered approaches. However, our results (see Section 6) show that it is important how this collective stance information is used to judge the veracity of rumours. We describe these baselines in more details next.

5.1 Stance Unaware Baseline: B1

As described in Section 2, prior work on tweet veracity classification investigated a wide range of features and classification methods. Most influential is the feature set proposed by Castillo et al. (2011), which we have adopted for training a classification model. We experimented with various classifiers such as simple decision trees, k-nn, etc. but achieved best performance with Random Forests, more precisely, we use a range of 33 different features varying from syntactical, semantic, indicator, user-specific and message-specific categories. Details of our features can be obtained from (Aker et al., 2017b).

5.2 Stance Aware Baseline: B2

Following the approach of Liu et al. (2015), we integrate stance as several features, additional to those used in the first baseline. Since there are four different stance classes, the following additional feature(s) are used:

Relative-Stance-Score

Percentage of supporting, denying, questioning, and commenting stances extracted from tweets within a rumour. To obtain this feature we count e.g. how many individual tweets express support for the rumour and divide it by the total number of tweets. We have in total four features, one of each class. Similar to above, we use Random Forest as the machine learning algorithm.

6 Results

Table 2 details a performance comparison for both our systems, as well as B1 and B2. For completeness we also include a simplistic majority-vote baseline on event level. Using system λ we achieved an F_1 score of 0.756 across the 5 events including 173 rumours. The multi spaced system λ' shows superior performance with an F_1 score of 0.804. Both our systems significantly outperform both baselines' F_1 scores of 0.553 and 0.557 respectively.

System	Precision	Recall	F_1
B1	0.650	0.481	0.553
B2	0.661	0.481	0.557
λ	**0.747**	0.765	0.756^*
λ'	0.690	**0.963**	$\mathbf{0.804}^*$
majority-vote	0.059	0.025	0.035

Table 2: Overall classification scores.

* indicates significant difference to B1 and B2 (Tukey's HSD $p < 0.05$)

Breaking down the results into precision and recall, we can observe that system λ achieves the highest precision score of 0.747, outperforming both baselines (0.650 and 0.661) as well as system λ'. The latter also gives results slightly more precise than the baselines (0.690). Regarding recall system λ' outperforms all other systems by a great margin achieving a score of 0.963. System λ has also much higher recall of 0.765 comparing to the baseline score of 0.481 for B1 and B2.

Additionally, we look at the individual results for each event (Table 3). It can be seen that the performance varies substantially across events and classifiers. This becomes most obvious in case of the Ferguson event, where B1 and B2 fail to deliver a single true positive result—hence the F_1 score of 0. In other events such as Ottawa Shooting and Sydney Siege all systems have acceptable precision in their results. However, only our proposed (MS-)HMM also have a high to very high recall leading to a vastly superior F_1 score in these events. Another interesting observation can be made regarding the Germanwings Crash event where system λ yields perfect classification while B2 achieves exactly the same results as the overall best performing system λ'. However, it also has to be noted that this particular event contains only 12 rumours and these results therefore have limited expressiveness.

Finally, we also examined system λ''s noticeable low F_1 score of 0.4 in the Ferguson event. Looking at the classification outcome on rumour level we observe that this score is largely caused by the unbalanced nature of the event with only 2 of the 34 rumours being actually true. Out of these true rumours the system managed to capture one (λ: 2; B1: 0; B2: 0) while overall misclassifying only three rumours (λ: 1; B1: 4; B2: 5). In fact, the performance of all classifiers concerning this event is much more similar than the particular F_1 scores suggest.

6.1 Early detection of rumours

For an eventual practical application of our rumour classification system it is also important to consider its performance as a function of time, i.e. how many tweets are necessary to achieve a reasonable classification performance. Therefore, we also explore early detection of rumours by confining our systems to the first ten (first five) tweets only during classification. Classification results using shortened

Charlie Hebdo

B2	0.647	0.333	0.440
λ	**0.758**	0.758	0.758
λ'	0.750	**1**	**0.857**

Table 3: Performance across events

sequences are summarized in Table 4. As expected the best scores can be achieved by using complete sequences, which feature a median tweet count of 18. For sequences shortened to the first 10 tweets performance drops down to an F_1 score of 0.658 for system λ and 0.642 for system λ' respectively. Further reducing sequences' length to five tweets leads to worse classification performance. However, performance decrease is considerably lower for system λ' with an F_1 score of 0.618 (λ: 0.524).

Additionally, we also retrained our best performing model λ' on shortened sequences using first 10 and first 5 tweets only. Comparing F_1 scores between training conditions we only find marginal decrease of roughly 1% when using the first 10 tweets. However, narrowing down to the first 5 tweets during model training gives unsatisfactory classification results with an F_1 score 0.529.

Overall it can be seen that given only the first 10 tweets at classification time our models still perform better than the baselines. Using even shorter sequences is only reasonable when utilizing the full potential of MSHMM which were still able to beat the baselines while using only the first 5 tweets.

System	All tweets	First 10	First 5
λ	0.756	**0.658**	0.524
λ'	**0.804**	0.642	**0.618**

Table 4: Early detection F_1 scores

6.2 Using Automatic Stance Labels

Results in Table 2 are obtained using gold stance labels. However, this restricts the idea of stance-based rumour verification to only data where human stance labels are available. To overcome this limitation, we have adopted the state-of-the-art stance classifier of Aker et al. (2017a). It has been evaluated on the RumourEval'2017 shared task A on rumour stance classification (Derczynski et al., 2017b) and achieved the best results, namely 79.02% accuracy. The classifier's performance measure was obtained by the RumourEval organizers. Note that for evaluating our models a subset of the data from shared task A has been used. The system performs standard feature engineering such as the extraction of bag-of-words, sentiments, indicator features, etc, but also adds features that are specific to modelling the stance classification problem such as whether the tweet entails some surprise, doubt, certainty and support terms. Apart from feature extraction the system does not require any further parameters to set nor any domain knowledge.

We label automatically all tweets in our dataset with tweet-level stance information using this classifier. Once these stance labels are obtained, we repeat the evaluation of (MS-)HMMs λ and λ'. Results for systems λ_a and λ'_a with automatic stance labels are shown in Table 5.

Both variants show only slight changes in F_1 score compared to their gold data counterparts. In terms of precision and recall λ_a shows a shift towards recall compared to λ—combined with a corresponding loss in precision. However, system λ'_a remains stable in precision and recall while using automatically generated labels. This demonstrates that our veracity classification approach based on the features stance and time has viable practical applications.

System	Precision	Recall	F_1
λ_a	0.632	0.888	0.738
λ'_a	**0.669**	**0.975**	**0.794**

Table 5: Overall scores using automatic labels

7 Discussion

In our results in Table 2 we showed that overall collective stance indeed is an important feature to consider for the purpose of veracity prediction. However, this depends on how this collective feature is used. When stance is added as additional feature to those features reported by related work (setting B2) we could only gain a neglectable improvement. On the other side, when collective stance was used within HMM we observe superior results indicating that using HMM is a better way for capturing the crowd stance wisdom and applying this effectively on the veracity classification task. In case of baseline B2 we used rather a crude way of capturing the stance wisdom by counting different stance types. However, collective stance might obey some specific patterns of development, as indicated by Mendoza et al. (2010), and capturing these patterns is an important factor. This is where our systems λ and λ' shine and the power of capturing this is reflected in the ample classification performance increase. However, this increase is not distributed equally across all events. In the following paragraphs we are going to raise a few points that likely have contributed to these outcomes:

Our MSHMM λ' overall produces results which are especially distinct from the other models' results by being able to correctly classify 12 rumours where all other models fail. Note that this occurs in only two and one cases for baselines B1 and B2 respectively. Further investigation of these 12 correctly

classified rumours shows that they tend to be shorter than average with a median length of 11 tweets. Interestingly, λ' correctly classifies true rumours in 9 out of the 12 cases, although they contain only 1 to 3 *supporting* stances each.

On the other hand, there are also 15 rumours that are solely misclassified by our HMM λ'. Again, this is less often the case for the baselines with 8 occurrences each for model B1 and B2. As it is also indicated by the comparably lower precision scores, model λ's produces more false positive classifications than the other models, especially concerning the events *Sydney siege* and *Ferguson* (B1: 15; B2: 14; λ: 18; λ': 26). Consequently, all 15 misclassified rumours are false positives. Further investigation of the individual rumours' properties remained inconclusive.

Overall the baselines have a negative bias, i.e. they tend to classify rumours as false. While the actual true/false ratio of all rumours is 46.8% true, model B1 classifies 35% of the rumours as true (B2 34%). On the contrary, λ shows no bias with a ratio of 48%, while λ' has a positive bias with a ratio of 64.3%. This observation is in line with the baselines F_1 score of 0 for rumours related to the *Ferguson riots* event where only 2 out of all 34 rumours are true. Out of these two true rumours one was found by both our models while the other was correctly classified solely by model λ.

We investigated our models' performance on short sequences of tweets to accommodate for the fact that a timely detection of rumours would be of great practical benefit. Naturally, we experience a performance drop when reducing sequences' length. We believe that this is due to the collective stance being expected to stabilize only over time (see Section 1). However, we indeed could show that especially our MSHMM is capable of capturing a rumours' veracity very fast with a high level of recall and sufficient precision, still outperforming the baselines even when using only the first five tweets of a rumour.

Especially the high recall affirms our intend to adapt our framework for the task of rumour detection, which is a necessary step before rumour veracity classification can be performed. It will be interesting to observe in future work whether the model can perform equally well at this task.

As described in Section 6 our model λ' including tweets' times achieved best performance values on this particular data set. This result—as well as the strong result of model λ—shows our HMM-based method's general applicability to the problem at hand. Furthermore, we have demonstrated the general suitability and classification stability of our automated stance annotation framework. Since we seem to have overcome the need for manual annotation when using MSHMM in future work the data sets can be extended to more recent events featuring potentially large amounts of tweets.

However, it is also reasonable to assume that events are heterogeneous in their stance distribution patterns, which might have an impact on classification performance and generalizability across events. Therefore, in subsequent analysis different event types should be considered when training MSHMM. A basic event distinction might be *sharp*, sudden events that also feature a definite ending vs. *soft* events where multiple sub-events occur that trigger new developments in the corresponding discussion threads.

Finally, note that the discussed HMM approach achieves results in the 80% margin in terms of F_1 when it uses gold standard stance. This performance drops insignificantly when the stance information is obtained by automatic methods. With that the stance information is the only dependent variable for the HMM and any performance improvement on that site will, as the results on gold standard stance show, also increase the performance of the HMM-based classifier. This is also valid for new rumours where it can be expected that the current automatic stance detection approach does not perform as well as in the SemEval2017 data and thus have negative impact on the verification results. This is a known problem that there is a performance drop when the system moves to new unseen data. However, the performance gap can be closed with extending training data (obtained either manually or using some distance learning) and focusing more on domain independent features.

8 Conclusions

This paper investigated whether rumour stance alone and combined with tweets' times can be used to predict rumour veracity automatically. We followed two different strategies in applying stance for the verification task. In the first strategy we added stance as an additional feature to those commonly used in earlier studies. We demonstrated that including collective stances observed in sequences of tweets

leads to only neglectable performance increase when using approaches adapted from the literature. The second strategy was to use stance as the only feature to model true and false rumours with discrete HMM. Finally, we employed multi-spaced HMM to jointly model the temporal changes in stance information. We demonstrated that already using stance-based HMM without time information leads to substantially better classification results over the first strategy. Though, the extension to multi-spaced HMM with time incorporated has led to even superior results with an F_1 score of 80.4%.

Next, we will investigate further the integration of temporal information for the rumour detection task. Furthermore, we will explore if veracity classification can be improved further by combining our HMM-based classifier with other state-of-the-art approaches. In addition, we plan to adapt the crowd stance along with HMM for the fake news detection task.

Abstract

Satirical news detection is important in order to prevent the spread of misinformation over the Internet. Existing approaches to capture news satire use machine learning models such as SVM and hierarchical neural networks along with hand-engineered features, but do not explore sentence and document difference. This paper proposes a robust, hierarchical deep neural network approach for satire detection, which is capable of capturing satire both at the sentence level and at the document level. The architecture incorporates pluggable generic neural networks like CNN, GRU, and LSTM. Experimental results on real world news satire dataset show substantial performance gains demonstrating the effectiveness of our proposed approach. An inspection of the learned models reveals the existence of key sentences that control the presence of satire in news.

1 Introduction

In the era of the Internet, online journalism is now a common practice. Online news articles have a major contribution in keeping people informed about what is happening in the world. The usage of Internet to spread news comes with the disadvantage of deception. The presence of deceptive and misleading news articles has been around for a while. Although some news articles often have a disclaimer about it being fake, many other don't and thus readers could be led to believe them to be true. This leads to spread of misinformation, which may also start off a rumour. The importance of the detection of deceptive news is increasing rapidly, as more and more people start relying on online news as their major source of news.

News satire is a genre of deceptive news that is found on the web, with the intent of dispensing satire in the form of legitimate news articles. These articles differ from "fake" news, in the sense that fake news intend to mislead people by providing untrue facts, while satirical news intends to ridicule and criticize something by providing satirical comments or through fictionalized stories. Satire is the intention of the author to be discovered as "fake", unlike fake news, in which the intention is to make make the readers believe in the news as true. Detection of news satire is thus important to control the spread of false stories.

We propose a hierarchical deep neural network model for satirical news detection, that is able to capture satire both at the sentence level and at the document level. The architecture is very extensible and caters to a variety of plug-and-play neural network models such as CNN, LSTM and GRU. This pipelined architecture allows for optimal learning of parameters required to capture satire. We show that our model is able to capture satire more efficiently than existing models, by using only pretrained word embeddings as input, without the aid of any syntactic information or any hand-crafted features. We show that word level semantic information is sufficient for effective detection of satire, with word level syntax information only marginally improving the performance. An analysis of the learned models reveals that news satire is decided by a few key sentences of the news article, the last sentence being one of them.

We use the dataset introduced in (Yang et al., 2017) as the dataset for satire news detection. We trained our proposed plug-and-play hierarchical model end-to-end on the ground truth data. Our model works at the sentence level as opposed to paragraph level attention in (Yang et al., 2017). We perform extensive

Proceedings of the 27th International Conference on Computational Linguistics, pages 3371–3380
Santa Fe, New Mexico, USA, August 20-26, 2018.

experiments on the dataset, fine-tuning the model by plugging different neural network models into the architecture. Experimental results on the dataset shows superior performance of our model compared to existing state-of-the-art approaches.

2 Related Work

Previous approaches for generic deception detection include the use of traditional machine learning model such as SVM (Zhang et al., 2012) and Naive Bayesian models (Oraby et al., 2015). These approaches focus on using linguistic cues and the social network behavior (Conroy et al., 2015) to detect deception. Much work has been done for deception detection on social media platforms (Davidov et al., 2010; Reyes et al., 2012) and opinion spam (Ott et al., 2011; Mukherjee et al., 2012; Mukherjee et al., 2013) In the context of deceptions in news, the field of "fake" news detection has been explored before (Jin et al., 2016; Rubin et al., 2016). These also include the use of machine learning, some of them also leveraging neural networks (Wang, 2017; Ruchansky et al., 2017) for the task.

Existing works towards satirical news detection focus on engineering features to denote satire. (Burfoot and Baldwin, 2009) filter satirical news from true news with headline features, profanity, and slang. (Rubin et al., 2016) propose additional features to classify satirical news, including absurdity, humour, grammar, negative affect, and punctuation. (Yang et al., 2017) further show linguistic features could be incorporated at paragraph level and reveal the different behaviour of each feature at paragraph level and document level. These models heavily rely on linguistic/word features as opposed to our representation learning approach. From these works, we observe that word level features contribute to the detection most while linguistic features only improve the result by a little, so we focus on our model to detect satire without further hand-crafted features.

While features generated with careful hand analysis might contribute a robust classifier, neural network based models, from convolutional neural network (Kim, 2014; Kalchbrenner et al., 2014) to recurrent neural network (Tang et al., 2015), or a hybrid of the two (Lai et al., 2015), have pushed classification task to a new level. Also, the recent advances in learning distributed representations for word semantics in the form of word embeddings (Mikolov et al., 2013; Pennington et al., 2014; Bojanowski et al., 2016) allow for better modeling of semantics both at the sentence and document level. In this work, we utilize the power of neural networks and aim to advance the result of satirical news detection. We pack two separate composition models to further enhance the performance of the learned representation.

3 Model

We propose an approach for building a robust hierarchical neural network architecture for detecting satire news, as shown in Figure 1. We abstract the whole network into two major components, the S and D module. The compositional module S creates a sentence embedding, taking a sequence of word embeddings as inputs. The compositional module D creates a document embedding, which acts as a summarization of the document, taking sentence embeddings as input. We use the learned document embeddings to classify the news as satire or true. This kind of abstraction helped us to fine-tune the architecture by applying different choices of compositional models for the S and D module.

3.1 Word embeddings and Syntax

We use different pretrained word embeddings such as Glove[1] (Pennington et al., 2014) and fastText[2] (Bojanowski et al., 2016) as the initial word embeddings. These pretrained embeddings are (optionally) concatenated with one-hot embeddings that contain the syntax information[3] of the word (Baccianella et al., 2010; Miller, 1995). The various syntactic features used and their corresponding one-hot vector lengths is shown in Table 1. The named entities used are: FACILITY, GPE, GSP, LOCATION, ORGANIZATION, PERSON, NULL(representing no named entity). The SentiWordnet scores are 16 discrete values ranging between 0 and 1, thus requiring a one-hot vector of size 16 to represent each score. These word

[1] https://nlp.stanford.edu/projects/glove

[2] https://github.com/facebookresearch/fastText/blob/master/pretrained-vectors.md

[3] http://www.nltk.org

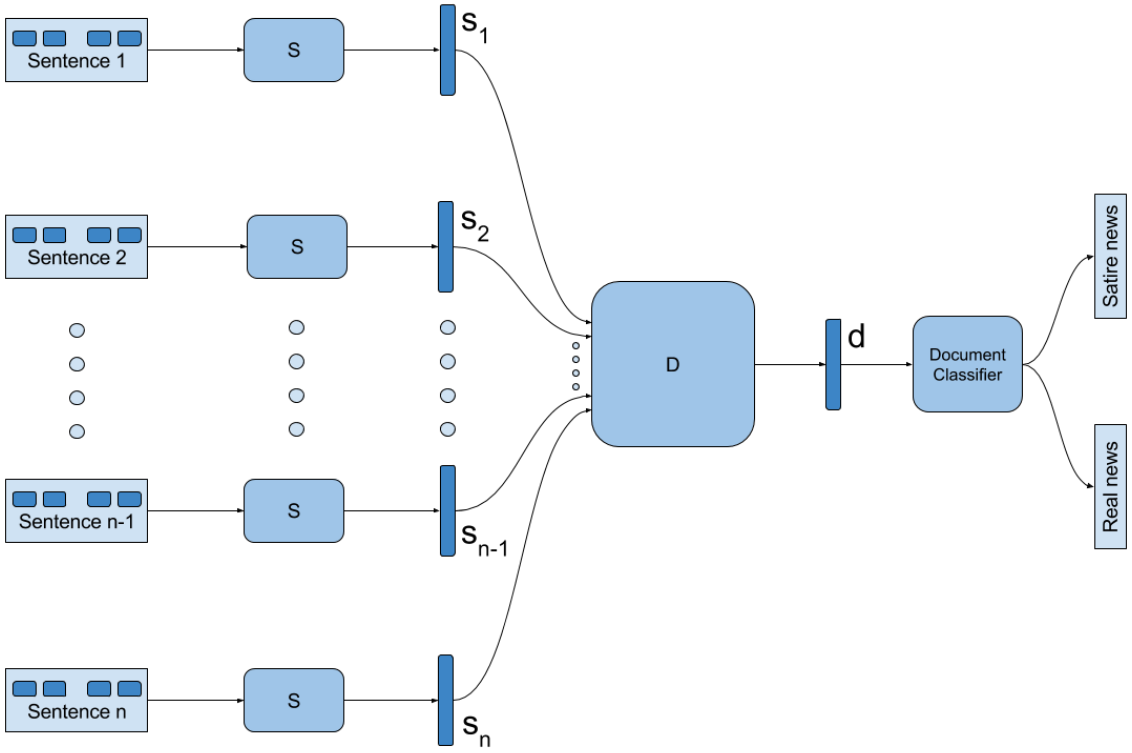

Figure 1: Model Architecture

embeddings (concatenated with syntax information) are multiplied with a weight matrix W_{emb} (learned) to produce a final word embedding, that summarizes the required semantics of the word for capturing satire.

3.2 Sentence (S) Module

The S module takes a sequence of word embeddings as input, and produces a sentence embedding. This module tries to capture the essential information for capturing satire in a news at the sentence level. The various model choices for the S module include Temporal Convolutional neural networks(Kim, 2014) (CNN) and sequential models like Long Short-Term Memory(Hochreiter and Schmidhuber, 1997) (LSTM) and Gated Recurrent Unit(Cho et al., 2014) (GRU).

Let $v_i \in \mathbb{R}^d$ be the d-dimensional word embedding of the i^{th} word of a sentence of length n. We show 3 different models to produce a sentence embedding from the word embeddings. Then, the S module can be represented mathematically as a composition function f that takes a sequences of n word embeddings as input to produce a sentence embedding s. Thus,

$$s = f([v_1, v_2, \dots v_n]) \tag{1}$$

where the choice of the composition function are standard generic neural networks like $LSTM, GRU, CNN$. In the case of LSTM/GRU, we use their deep bidirectional versions, where we stack multiple bidirectional LSTM/GRU on top of each other.

3.3 Document (D) Module

Similar to the S module, D module takes a sequence of sentence embeddings as input and produces a document embedding, capturing information at the document level. The embedding produced by this

Syntax feature	Length
Part-Of-Speech tag	44
SentiWordnet positive score	16
SentiWordnet negative score	16
SentiWordnet objective score	16
Named Entity IOB tag	3
Named Entity tag	7
Topmost Wordnet synset same as word synset	2
Starts with uppercase letter	2
All uppercase letters	2
Is number	2

Table 1: Word level syntax features and their one-hot vector lengths

module is directly used for classification. The choice of compositional models for the D module are the same as those for the S module, i.e. Temporal CNN and sequential neural networks like GRU and LSTM, with the difference that it takes sentence embeddings as input instead of word embeddings.

3.3.1 Attention Layer

This layer performs a weighted average of its inputs, where the weights are learned by a neural network, and serve as attention weights (Bahdanau et al., 2014) for the sentences. Let the outputs of the D module be $\{o_1, o_2, \ldots o_n\}$ for a document containing n sentences. We use a two hidden layer neural network for obtaining the attention weights. We obtain the attention weights, $\hat{a}$, as follows

$$a_i = W_a^{(2)} \cdot \tanh(W_a^{(1)} \cdot o_i) \tag{2}$$

$$a = [a_1, a_2, \ldots a_n] \tag{3}$$

$$\hat{a} = softmax(a) \tag{4}$$

Here, $W_a^{(1)} \in \mathbb{R}^{mk}$ and $W_a^{(2)} \in \mathbb{R}^k$ are weight matrices (trained), with m being the size of the output embeddings and k being the size of the hidden layer of the neural network. The final document embedding d is taken as a weighted sum of the outputs, i.e. $d = \sum_{i=1}^{n} \hat{a}_i \cdot o_i$.

3.3.2 Attentive Concatenate Layer

This layer is applied before the application of the compositional model of the D module, taking input the sentence embeddings obtained from the S module. The layers applies attention over the sentences in context of a particular sentence. Let the sentence embeddings of the sentences be $\{s_1, s_2, \ldots s_n\}$ in a document of n sentences. Let A be the attention module presented above. This layer applies A over the sentence embeddings after concatenating the context sentence embedding, to obtain a weighted average embedding, which is concatenated with context sentence embedding to obtain the output, $o_i = [s_i, t_i]$.

$$t_i = A(\{[s_i, s_1], [s_i, s_2], \ldots [s_i, s_n]\}) \tag{5}$$

3.4 Document Classifier

The final document classifier is a neural network with two hidden layers followed by a softmax layer. This takes a m dimensional document vector, d as a input, and produces a label, l, as Real(0) or Satire(1).

$$l = \arg\max(softmax(W_d^{(2)} \cdot f(W_d^{(1)} \cdot d))) \tag{6}$$

Here, f is the ReLU activation function. $W_d^(1) \in \mathbb{R}^{mk}$ and $W_d^{(2)} \in \mathbb{R}^{2k}$ are the weight matrices.

4 Experimental Evaluation

We now detail the evaluation. We first detail the experiment settings, followed by baselines and finally the results.

4.1 Dataset and Preprocessing

	#Train	#Vali	#Test	#Sent	#Word	#Digit
True	101,268	33,756	33,756	32	734	93
Satire	9538	3,608	3,103	25	587	49

Table 2: The split of the dataset and the average count of sentences, words, and digits per document.

4.1.1 Dataset

We utilize the dataset from (Yang et al., 2017). The satirical news were originally collected from the 14 satirical websites, including Onion, theSpoof, SatireWorld, Beaverton, Ossurworld, DailyCurrent, DailyReport, EnduringVision, Gomerblog, NationalReport, SatireTribune, SatireWire, Syruptrap, and UnconfirmedSources. While the true news is collected from Google News and major news outlets, including CNN, Dailymail, WahingtonPost, NYTimes, TheGuardian, and Fox. For true news, we did not split sources. For satirical news, we used two most popular satirical websites, Onion and theSpoof, which have the largest number of satirical news, for training, while the rest of the sources were chosen randomly for test and validation to yield a richer evaluation set. The split and the description of the dataset can be found in Table 2.

4.1.2 Preprocessing

Sentences occurring twice or more are removed from the dataset. Also, each sentence in the dataset is padded to a length of 100, with a special <PAD> word. For sentences having more than 100 words, we consider the sentence as only the first 100 words. Similarly, each news article (or document) is padded to a length of 100 sentences by adding extra sentences containing the <PAD> word. For documents having more than 100 sentences, we consider only the first 100 sentences.

4.2 Experiment Settings

The whole model is trained end-to-end, i.e. all the parameters (weights) of the model are conditioned on the response variable (True news or Satire news). We experimented with different models by changing the choice of word embeddings, the S module, and the D module. For each model, we trained it for 20 epochs with Mini-batch Stochastic Gradient Descent algorithm. Training loss function used was cross entropy. For learning the optimal parameters for each model, we optimized on either the validation accuracy or the validation F1-score based on whichever performed better (these are listed in Table 3). Sentence embedding size and document embedding size were fixed at 300, for all the models. Word embedding (summarized) size was 300 for all models.

The word embedding for the <PAD> was set to all-zero embedding. We used the word embedding for "unk" as the word embedding for all words whose word embeddings were not available. We used the word embedding for "#" to represent all numbers.

4.3 Baselines

We compare our model with 4 baselines:

- **SVM word+char ngrams**: 1,2-word grams plus bigrams and trigrams of the characters
- **Rubin et al**(Rubin et al., 2016): Unigram and bigrams tf-idf with satirical features proposed in their works. It reports a better result than (Burfoot and Baldwin, 2009) so we omit the comparison with the latter.
- **Le et al**(Le and Mikolov, 2014): Unsupervised method learning distributed representation for document
- **Yang et al**(Yang et al., 2017): A 4 level hierarchical network considering charactors, words, paragraphs, and documents. The also incorporate 4 families of linguistic features at both paragraph level and document level.

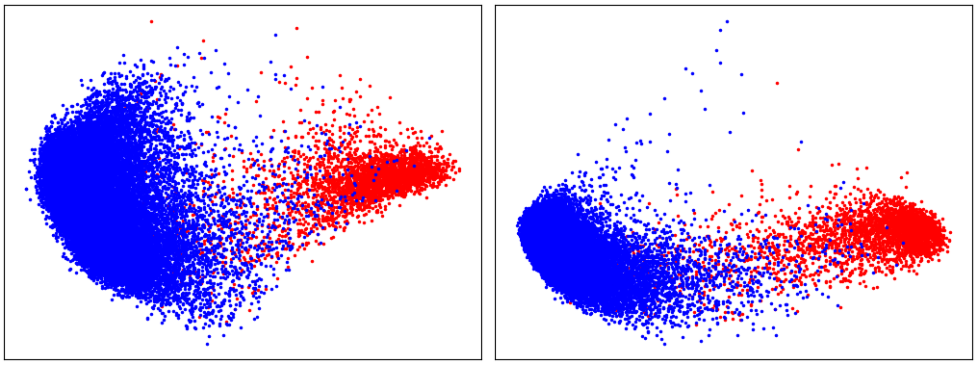
Table 3: Results. Prefix notation; **A: Attentive, D: Deep (3 layers), B: Bidirectional**

The results of the various experiments performed by us, using different choices of word embeddings, S module and D module is summarized in Table 3. Our best model outperforms the baseline models on the dataset. We observe that adding word level syntax information improves the performance only by a small margin. Thus, we can conclude that at the word level, semantic information is more relevant to capture satire than syntax information. For further analysis, we shall refer to the (CNN, A-B-LSTM) model using only Glove embeddings as Model A, and the (B-GRU, A-D-B-GRU) model using Glove and fastText embeddings as Model B.

4.4.1 Analysis of D-module

Figure 2 shows a PCA decomposition of the document embeddings learned by the models, on the test data. We see that satirical news (in red) and real news (in blue) form two separate clusters in both the models. This clearly shows that the embeddings learned by the D module successfully captures satire.

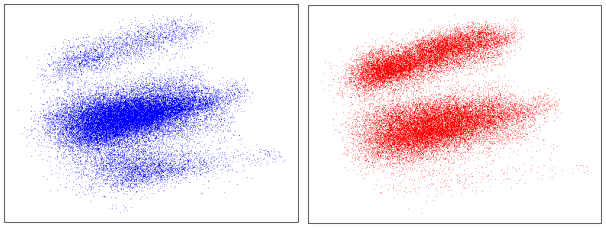


(a) Model A (b) Model B

Figure 2: Visualization of document embeddings of true(blue) and satire(red) news using PCA

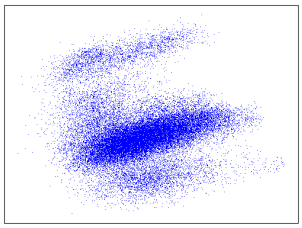
4.4.2 Analysis of S-Module

Applying PCA decomposition on the sentence embeddings learned by Model A reveals a few interesting properties that may be relevant in capturing satire. Figure 3 shows the PCA decomposition of sentence embeddings of news articles from the train and the test data. A closer look at the plots of the train data (Figures 3a) reveal that the sentence embeddings form three clusters. Most of the sentences lie in the central cluster, while some lie the cluster above the central one. A third cluster is observed below the central cluster, and consists mainly of sentences from real news articles. We also note that the density of the upper cluster is higher for satirical news sentences (visibly evident only in the training data), as compared to that for real news. We find that the values along the first principal component (horizontal axis) hold a correlation of **-0.76** with the length of the sentences. This means that having a sentences to the right of the PCA diagram tend of have smaller lengths. It is also worthwhile ot note that the clusters have similar shapes across both classes in train and test explaining that the learned embeddings have decent generalization performances.

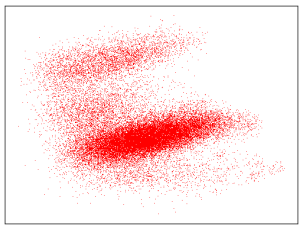


(a) Train: Real news

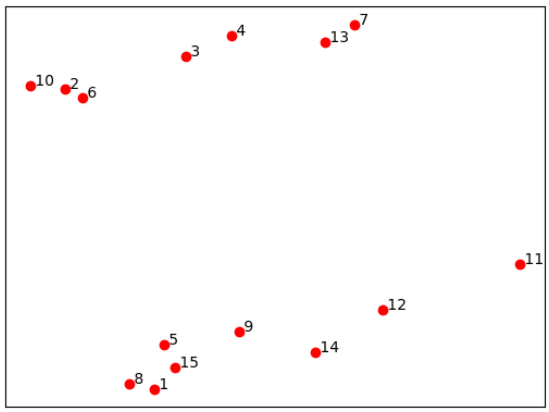
(b) Train: Satire



(c) Test: Real news



(d) Test: Satire



(e) Visualization of sentence embeddings of satire news using PCA

Figure 3: Visualization of sentence embeddings using PCA

We show the PCA decomposition for a satire news article containing 15 sentences (Table 4) in Figure 3e. We clearly see that sentences 2, 3, 4, 6, 7, 10, and 13 (lying in the upper cluster) are separated from the rest of the sentences (lying in the central cluster). The high correlation between the horizontal axis and the length of the sentence is also visible in Figure 3e. It is also interesting to note that sentences 8, 5, 1, 15 in the lower cluster are more verbose as opposed to the upper cluster samples 10, 2, 6 indicating the learned embeddings of the S module could capture verbosity as a fine-grained property of satire.

4.4.3 Analysis of Attention Layer

We normalized the attention weights (using "Min-Max" normalization) of the Attention layer of Model B, such that maximum weight in a news article is 1, and the minimum is 0. Firstly, we observe that the attention weights of the <PAD> sentences are less than 0.01 times the mean attention weight of the other sentences of the news article. This shows the effectiveness of the Attention layer in ignoring <PAD> sentences, thus not adding their contribution in the final document embedding. Next, we observe that the weight (normalized) of the last sentence of a news article is high for satirical news, while is almost 0 for real news. Figure 4a shows the distribution of the attention weights (normalized) over a news article, for a 3 satirical news and 3 real news from the test data. The mean normalized attention weight of the last sentence of satirical news in **0.728**, while the same for real news is **0.07**. Since these weights directly contribute to the document embedding (which we have shown to be able to distinguish satire effectively), they must reflect the amount of satire present in the sentence. Thus, having a higher weight would mean the sentence is more relevant to capture satire. This means that the last sentence of a new article contains

No.	Sentence	Att.
1	OTTAWA With the holiday season drawing near , Prime Minister Harper issued a statement today urging all Canadians to enjoy the time of year that brings us closer to our most beloved industries	0.045
2	" I think that Canadians understand what this season is really about , " the Prime Minister said . "	0.0
3	We ' ve all seen enough Holiday movies to know that what really matters is unfeelingly capitalizing on the emotions of others in order to make millions upon millions of dollars . "	0.268
4	" Actually , now that I mention it , that is what every single other season of the year is also about . "	0.218
5	The statement , released along with a Christmas card featuring the members of the Prime Minister ' s estranged family standing with blank faces in front of a Sears , has already roused the nation into a frenzy of holiday cheer .	0.535
6	" Giving is fine , " said local man Derek Williams , backhand slapping an elderly woman away from a pile of One Direction themed Furbies .	0.588
7	" But what really matters is the opportunity to reward multinationals for doing business in my country . "	0.528
8	Since the statement was released , retail outlets and superstores have made record amounts of money : money which will allow them to make more money , which in turn will be put toward the noble cause of making yet more money.	0.666
9	The Prime Minister has expressed pleasure at the fact that even the innocuous act of giving a gift to a loved one has been subjected to the economics of reckless consumerism .	0.744
10	" Look at all of these Legos , " said the Prime Minister , gesturing at the pile of new boxes of Lego covering Laureen ' s otherwise empty half of the bed .	0.756

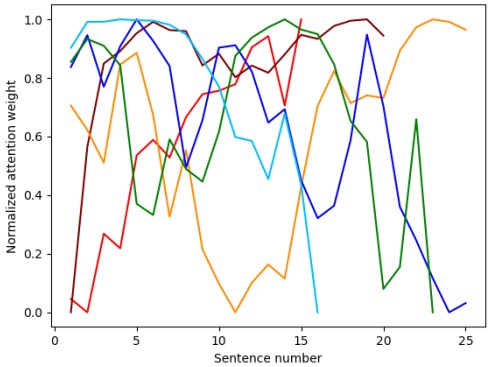
Table 4: Normalized attention weights (from the Attention Layer of Model B) of a satire news article

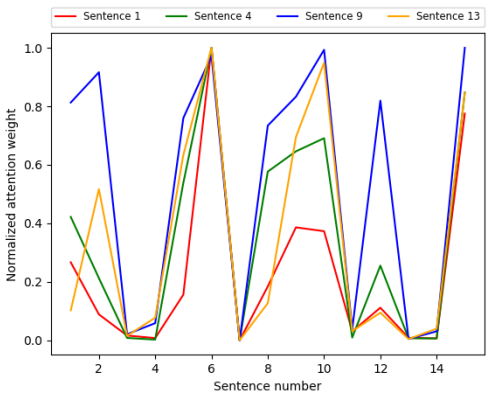
more satirical features if the news is satirical. Therefore, we conclude that the last sentence of a news article is a key feature for detecting satire.

4.4.4 Analysis of Attentive-Concatenate Layer

The normalized attention weights of the Attentive-Concatenate layer reveal that, in the context of each of the sentences of a news article, there are a few key sentences that contain relevant satire information. Figure 4b show the distribution of attention weights (normalized) of the Attentive-Concatenate layer for a few sentences of the news article shown in Table 4. We find that for each sentence, the attention distribution peaks at the same set of sentences (more or less), across all news articles. From this, we can draw the conclusion that these sentences must be more important to capture satire than the other sentences present in the news. For the news article in Table 4, these key sentences are sentence 6, 10, 12 and 15. We also note that the final sentence is one of those key sentences that are important to detect satire. Thus, we conclude that news satire is effectively decided by a few key sentences of the news article.



(a) Attention layer (Real news: [Cyan, Blue, Green], Satire news: [Red, Maroon, Orange])



(b) Attentive-Concatenate Layer

Figure 4: Normalized attention weights

5 Conclusion

We proposed a novel, robust, plug-and-play hierarchical architecture for detecting subtle linguistic nuances like satire in news. Our approach achieves comparable results with the existing state-of-the-art models, without the use of any hand-crafted linguistic feature reflecting satire. This hierarchical approach enables to learn satire features both at the sentence level (learned by S module) and at the document level (learned by D module). An extensive comparison with several state-of-the-art methods for satire news detection was also explored on a real world satire news dataset. We experimented with different choices of initial word embeddings and different S and D modules that include CNN, LSTM and GRU. Experimental results showed slightly superior performance of our proposed architecture with the combination CNN as the S module and a Attentive Deep Bidirectional GRU (3 layers deep) as the D module, using Glove vectors concatenated with syntactic information as the input embeddings to be performing the best. The architecture apart from state-of-the-art detection performances, allowed us to perform fine-grained sentence level analyses giving us a deeper insight into the phenomena of satire. An analysis of the learned models revealed the existence of a few key sentences (including the last sentence) that are important to detect satire. For our future work, we wish to explore Recursive neural networks in order to incorporate the structure of the language for better modeling of sentences.

Abstract

Social media provide platforms to express, discuss, and shape opinions about events and issues in the real world. An important step to analyze the discussions on social media and to assist in healthy decision-making is stance detection. This paper presents an approach to detect the stance of a user toward a topic based on their stances toward other topics and the social media posts of the user. We apply factorization machines, a widely used method in item recommendation, to model user preferences toward topics from the social media data. The experimental results demonstrate that users' posts are useful to model topic preferences and therefore predict stances of silent users.

1 Introduction

Web and social media provide platforms to express, discuss, and shape opinions about events and issues in the real world. However, these platforms suffer from new emerging problems such as filter bubble (Pariser, 2011), echo chamber (Jamieson and Cappella, 2008), and fake news (Lazer et al., 2018). An important step to analyze the argumentation structure of social media and to assist in healthy decision-making is *stance detection* (Mohammad et al., 2016): predicting whether a given text/user is in favor (agree), against (disagree), or neutral toward a target topic (e.g., Donald Trump).

Unfortunately, users rarely make an explicit statement about a topic. For example, computers may easily detect a stance for the topic of the Trans-Pacific Partnership (TPP) from the sentence, "I totally disagree with TPP," containing the topic word 'TPP' with the explicit linguistic pattern "I totally disagree with ..." However, many social media posts may not refer to a topic but only to its related topics, for example, "We should protect Japanese agriculture." We need commonsense knowledge about the topic (e.g., "TPP suppresses Japanese agriculture") to predict the stance (objection to TPP) for such a sentence (see Figure 1). Furthermore, social media users are often *silent* on a topic (Gong et al., 2016): users who are interested in a topic without posting anything related to it are called the *silent majority* (Lassiter, 2007) and *lurkers* (Gong et al., 2015).

This paper presents an approach to detect the stance of a user toward a topic based on: (1) their stances toward other topics, and (2) the social media posts of the user. We apply factorization machines (FMs), a widely used method in item recommendation, to model user preferences toward topics from data consisting of the stance statements and social media posts of users. Contributions of this work are twofold.

1. We present a method to obtain stance statements from tweets and to model topic preferences from the stance statements jointly with the users' tweets.

2. The experimental results demonstrate that users' posts are useful to model topic preferences and therefore predict stances of silent users.

2 Related Work

In many previous studies, social media such as Twitter has been used to make various analyses and predictions with respect to politics. Of these, several studies have focused on the analysis of political leaning such as liberal or conservative (Bakshy et al., 2015; Wong et al., 2016) and the prediction of people's support for parties or candidates during the election period (Tumasjan et al., 2010; Burnap et al., 2016). These studies were realized because social media has become a means for people to publish messages and to acquire information. Furthermore, because social media has become a part of our daily lives, many candidates in the United States presidential election made use of social media to win the election (Hong and Nadler, 2012).

However, few studies have addressed the silent majority (who hardly expresses a stance), limiting the target to users who explicitly expressed their opinions (Gayo-Avello, 2012). In our work, we shed light on the silent majority as well as vocal users (who express stances explicitly). We aim to predict stances of the silent majority by modeling the topic preferences of users with explicit stance statements and ordinary posts.

Stance detection has been extensively studied in recent years as a task to predict a stance of a user or text toward a specific topic (Murakami and Raymond, 2010; Mohammad et al., 2016; Persing and Ng, 2016). However, most studies have depended heavily on labeled training data (Tutek et al., 2016; Liu et al., 2016). Therefore, these methods had difficulty in predicting a stance toward an unseen topic. Accordingly, the SemEval-2016 task 6B released unlabeled data on a topic to be predicted and labeled data on other topics (Mohammad et al., 2016). However, the accuracy on the setting dropped drastically compared with the setting when labeled data for the topic are given. One reason for the relatively low accuracy is that, if no labeled data are available for a new topic, it is impossible to learn expressions that may imply stances for that topic.

One way to overcome this problem is to incorporate external knowledge about the topics. The most relevant work is our previous work (Sasaki et al., 2017). Main goal of this work was to acquire knowledge such as *"those who agree with the TPP also agree with free trade."* We called such knowledge "inter-topic preferences." We used texts on Twitter and modeled inter-topic preferences using matrix factorization. As a side effect of this modeling, we were able to predict the missing stances of users by considering users' explicit stances toward other topics. However, the method of this previous work cannot be applied to the silent majority, who does not explicitly express any stances.

Several studies have focused on the silent majority and lurkers. Gong et al. (2015) defined users who spend most of their time in social media without posting as lurkers, and analyzed the characteristics and behaviors of such users. Gong et al. (2016) named users who did not explicitly mention specific topical issues "i-silent" users, and analyzed their behavior on social media such as Twitter and Facebook.

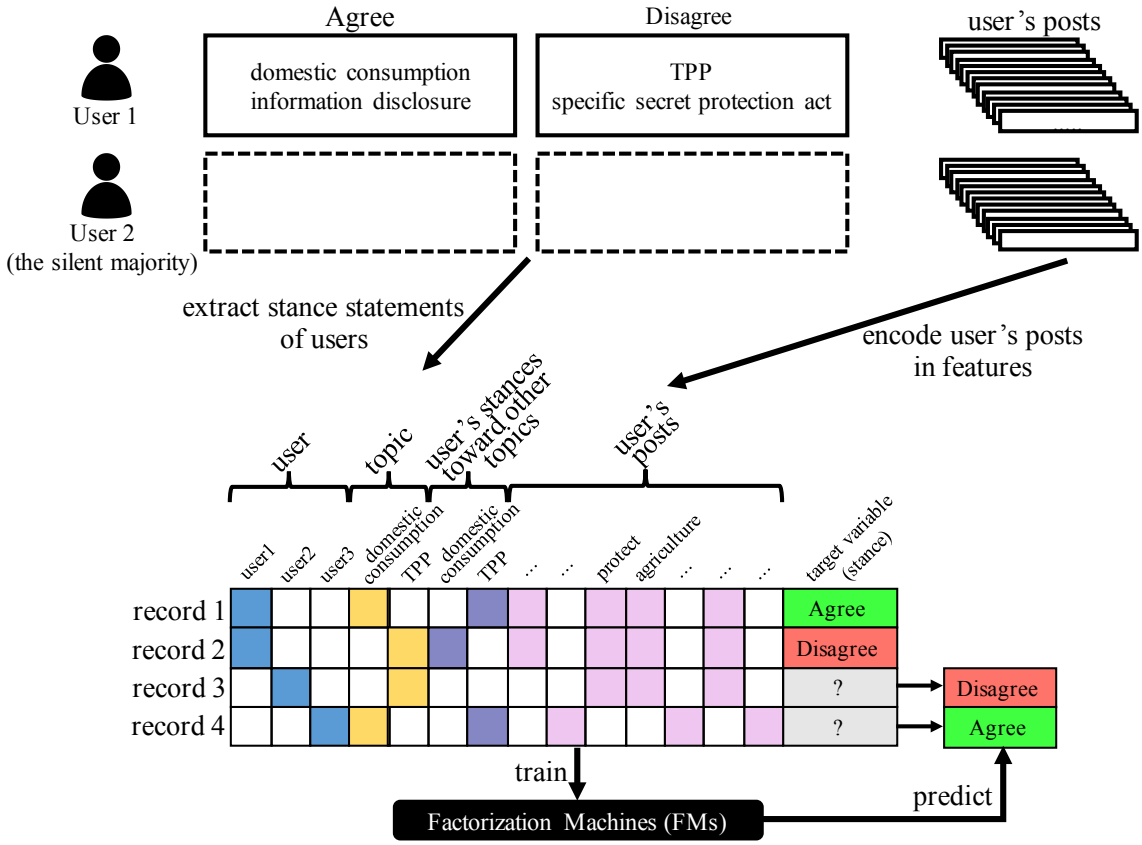

Figure 2: The overview of the proposed method.

They asked the following questions to the users of social media: whether they are interested in specific issues (e.g., healthcare cost and retirement); and whether they have posted on those issues on Twitter or Facebook. In contrast to their work covering only seven issues, we deal with more than 1000 topics. In addition, our method automatically learns the relationships between stances and users' posts. Our method is a versatile method applicable to multiple topics and users, including the silent majority.

Predicting stances of the silent majority is similar to the *cold-start problem* in item recommendation: recommending items to users who have not purchased any items in the past (Schein et al., 2002; Lam et al., 2008). In order to overcome this problem, a recommendation incorporating not only the purchase history of items but also other contexts has been extensively studied as a *context-aware recommendation* (Adomavicius and Tuzhilin, 2015). One method for realizing context-aware recommendation is factorization machines (FMs) (Rendle, 2010; Rendle et al., 2011). In our work, we consider the users' posts as *context* in item recommendation.

3 Proposed Method

The final goal of this work is to construct a user-level stance detection model that can be useful even for the silent users, i.e., users who do not explicitly express any stance. Figure 2 shows the overview of the proposed method. We collect users' stance statements using linguistic patterns that explicitly agree/disagree with topics. For example, we can extract a positive stance toward Donald Trump from the sentence, "*Vote for* Donald Trump", where *vote for* is a linguistic pattern for a positive stance. In addition, we utilize users' posts, for example, "Make America Great Again," as an additional information source to predict a stance of a user. Here, we may think that "Make America Great Again" explicitly agrees with Donald Trump. However, this expression is only applicable to Donald Trump and cannot be used for other general topics. Since it is not practical to manually collect such topic-dependent expressions for a large number of topics, we decided to use topic-independent linguistic patterns to collect users'

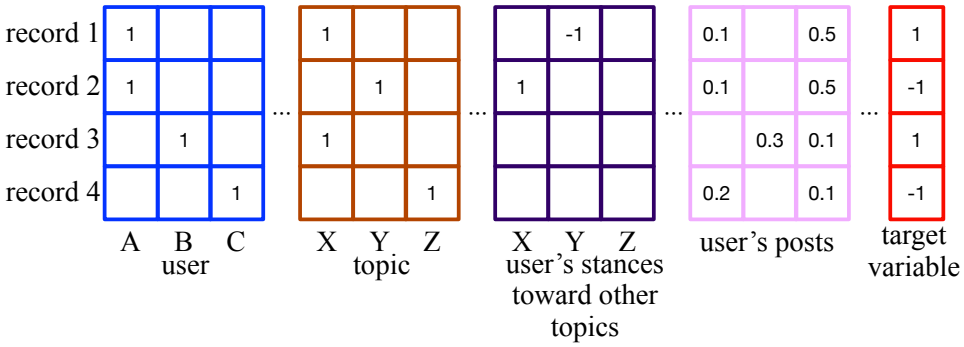

Figure 3: An example of an input of factorization machines.

stances.

In order to model stance statements and users' posts jointly to predict user-level stances, we apply factorization machines (FMs), a widely used and scalable method for recommendation and click-through rate (CTR) predictions, etc. More specifically, we consider that a stance for a topic to analogously correspond to a like/dislike of an item and that a user's post provides additional information for item recommendation. In this section, we first review the formalization of FMs and present definitions of records as an input for FMs. In addition, we explain the details of the linguistic patterns to detect stance statements and the feature extractions used to encode users' posts into FMs.

3.1 Background: factorization machines

FMs predicts a target value (e.g., a rating in item recommendation or a rate in CTR prediction) from n variables (e.g., features of the item) $x_1, ..., x_n$. FMs use second-order feature combinations $x_i x_j$ $(i, j \in \{1, ..., n\})$ as well as first-order features x_i $(i \in \{1, ..., n\})$. Formally, FMs compute a target value using Equation 1,

$$\hat{y}(x) := w_0 + \sum_{i=1}^{n} w_i x_i + \sum_{i=1}^{n} \sum_{j=i+1}^{n} \langle v_i, v_j \rangle x_i x_j. \quad (1)$$

Here, $x_i \in \mathbb{R}$ is the value of the i-th variable, $w_0 \in \mathbb{R}$ is the global bias, $w_i \in \mathbb{R}$ presents the weight of the i-th variable, $v_i \in \mathbb{R}^d$ presents the weight vector used for second-order feature combinations, d is the number of dimensions of the weight vectors, and $\langle v_i, v_j \rangle$ denotes a dot product of two vectors v_i and v_j. We use `tffm`[1] to train a model (i.e., to find the parameters $w_0, ..., w_n$ and $v_1, ..., v_n$ for the given supervision data).

3.2 Applying factorization machines to our task

In order to apply FMs to user-level stance detection, we assume a target variable to present the stance of a user toward a topic: $+1$ (a positive stance to the topic) and -1 (a negative stance to the topic). The user and topic are represented as features for the input to FMs. In this work, we define four types of variables to build a *record* for FMs: user, topic, user's stances toward other topics, and user's posts. Figure 3 shows an example of input records. We describe each type of variable in detail.

user

We define a variable to identify each user in the data. We set 1 to the variable corresponding to the user of a record and 0 to the other variables in this category.

topic

We also define a variable for each topic in the data. We set 1 to the variable for which the target variable presents a stance. Given that a record is associated with a topic, only one variable in this category is set to 1 and one of the variables in this category must be 1.

[1] `https://github.com/geffy/tffm`

user's stances toward other topics

This category of variables indicates stances of the user toward other topics. The number of variables in this category is the same as that in the topic category. A value of this category ranges from -1 (negative to the topic) to $+1$ (positive to the topic). We will explain the values of these features in detail in Section 3.3.

user's posts

Variables in this category encode textual features of posts sent by the user. We describe these variables in detail in Section 3.4.

Let us consider an example where the user A is favor to the topic X, but against to the topic Y. Figure 3 illustrates records for this example. Record 1 presents the stance toward topic X as the target variable and the stance toward Y as other topics. Similarly, record 2 presents the stance toward topic Y as the target variable and the stance toward X as other topics. Given that records 1 and 2 are for the same user, the values for the user's posts are essentially the same. When we ignore the features of the user's posts for simplicity, Equation 3 for the first record is,

$$\begin{aligned} 1 = w_0 + w_{\mathrm{user:A}} + w_{\mathrm{topic:X}} - w_{\mathrm{other:Y}} \\ + \langle v_{\mathrm{user:A}}, v_{\mathrm{topic:X}} \rangle - \langle v_{\mathrm{topic:X}}, v_{\mathrm{other:Y}} \rangle - \langle v_{\mathrm{other:Y}}, v_{\mathrm{user:A}} \rangle. \end{aligned} \tag{2}$$

Here, $\mathrm{user:A}$, $\mathrm{topic:X}$, and $\mathrm{other:Y}$ present the index numbers of features indicating that the user is A, the topic of the target variable is X, and the stance for the other topic is Y, respectively. Similarly, Equation 3 for the second record is,

$$\begin{aligned} -1 = w_0 + w_{\mathrm{user:A}} + w_{\mathrm{topic:Y}} + w_{\mathrm{other:X}} \\ + \langle v_{\mathrm{user:A}}, v_{\mathrm{topic:Y}} \rangle + \langle v_{\mathrm{topic:Y}}, v_{\mathrm{other:X}} \rangle + \langle v_{\mathrm{other:X}}, v_{\mathrm{user:A}} \rangle, \end{aligned} \tag{3}$$

where $\mathrm{topic:Y}$ and $\mathrm{other:X}$ denote the index numbers of features indicating that the topic of the target variable is Y, and the stance for the other topic is X, respectively.

3.3 Extracting stance statements of users

In order to obtain data for target variables and stances on other topics, we extract stance statements of users from SNS data. Throughout this work, we use SNS data consisting of 1,763,164,770 Japanese tweets (444,321 users) crawled from February 6, 2013, to September 30, 2016[2].

Given that Twitter does not have an option to store an explicit indicator about a stance, we use a set of 200 linguistic patterns to automatically extract stance statements from tweets (Sasaki et al., 2017)[3]. The patterns were manually designed to extract stance statements with high-precision and low-recall, for example, "support X" (positive to X) and "X is terrible" (negative to X). We compute a stance value for a user toward a topic as,

$$\frac{(\#\mathrm{pos} - \#\mathrm{neg})}{(\#\mathrm{pos} + \#\mathrm{neg})}. \tag{4}$$

Here, $\#\mathrm{pos}$ and $\#\mathrm{neg}$ present the number of tweets from the user that included positive patterns and negative patterns, respectively, accompanying the target topic.

3.4 Encoding users' posts in features

In order to acquire features based on posts of each user, we focus on posts of users extracted in Section 3.3 not including texts containing positive or negative patterns. Here, tweets including positive or negative patterns are eliminated because, when evaluating the performance of the stance detection for

[2]We used the Twitter API to crawl these tweets. We collected 43B Japanese tweets since February 6, 2013 without a specific purpose. Because the volume of the entire crawled tweets is extremely large, we randomly selected one-sixteenth users based on hash values computed from screen names. We removed retweets from the corpus.

Table 2: Evaluation result of completing missing stances. Each cell presents the accuracy. "Numbers of stances stated" indicates the condition for evaluation. For example, as to ≥ 5, we evaluate the performance for completing missing stances for users who declared their stances toward no less than five topics. Note that, this treatment is applied only for the test portion of the cross validation.

each topic, these patterns are strong clues and it is thought that a proper evaluation could not be performed if they were included. We perform preprocessing on target tweets using the Japanese dependency parsing tool `CaboCha` (Kudo et al., 2004)[4]. We then extracted features about uni-grams, bi-grams and features based on dependencies from posts of each user. Table 1 shows examples of extracted features. Here, we choose only adnominal, adjective → noun phrase, noun phrase → adjective, and noun phrase → verb as features based on dependencies. Verb → noun phrase and triplet such as (subject, predicate, object) are not suitable as features because the number of users using each feature is very small and they become sparse.

4 Evaluation

4.1 Completing missing stances

The first experiment examines how well FMs complete missing stances of users with the additional information from users' posts. In order to measure the performance of the completion, we hide some stances in the matrix and evaluate the accuracy of the prediction. Given that it is impossible to evaluate users who do not express agreement/disagreement, we only select users who declare stances more than once. As a result, a matrix consisting of 326,202 stances was obtained. There are 130,635 users and 1,142 topics in the matrix. In the evaluation, we use 5% of the rows in this matrix as a validation set for parameter tuning and an early stopping of training. We evaluate the accuracy of a 10-fold cross validation with respect to the remainder of the matrix (95% of the rows).

For comparison, we implemented the majority baseline and matrix factorization. The majority baseline predicts a stance of a user based on the stance of the majority (other users) in the training set. For example, if the number of users who expressed disagreement toward "Article 9" exceeded the number of users who expressed agreement, the majority baseline always predicts "disagreement" toward "Article 9". For matrix factorization, we use the same parameters as in Sasaki et al. (2017) ($k = 100$, $\lambda_P = 0.1$,

[4]We used `mecab-ipadic-NEologd` (`https://github.com/neologd/mecab-ipadic-neologd`) as a dictionary.

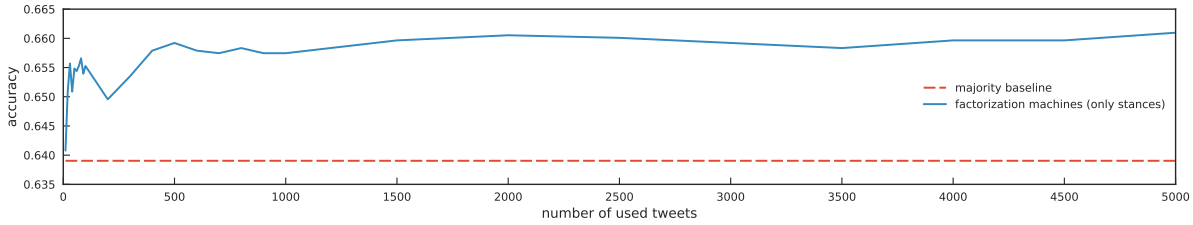

Figure 4: Evaluation result for pseudo-silent majority.

$\lambda_Q = 0.1$). Note that, matrix factorization used in Sasaki et al. (2017) cannot incorporate text information (users' posts). Therefore, we only use stances of users in the baseline method of matrix factorization. For FMs, we set the number of dimensions of the weight vector v_i to $d = 8$.

Table 2 shows the evaluation result. Here, topics that are extremely biased toward an agreement or a disagreement are thought to be inappropriate for the evaluation because stances on such topics can easily be predicted with even a simple model. Therefore, we performed experiments with limited targets considering t_{avg} , which is an average stance on a topic in the data. More specifically, we select targets of $-0.5 \leq t_{avg} \leq 0.5$. Table 2 indicates that, even though the matrix factorization exceeds the majority baseline for instances with numbers of stances stated ≥ 5, the result was lower than the majority baseline for instances with numbers of stances stated ≤ 5. Conversely, all methods of FMs outperformed the majority baseline in most cases. In addition, for the FMs, users' posts contributed to increasing the accuracy compared to a method using only users' stances. From this result, we confirmed that users' posts are useful clues for predicting their stances.

For instances, without stances stated (numbers of stances stated ≤ 0), methods that do not consider users' posts underperform the majority baseline. Conversely, methods utilizing users' posts were better than the majority baseline. This suggests that, even for users without stances stated, it is possible to predict their stances for each topic with a certain degree of accuracy if posts of such users are available. Meanwhile, how many posts for each user are sufficient to make a prediction? In Section 4.2, we focus on these users (pseudo-silent majority). Hereafter, we conducted experiments using the model with topic variables and users' posts variables, which showed the highest performance in numbers of stances stated ≥ 0.

4.2 Evaluation for pseudo-silent majority

In this subsection, we treat users with only one stance as the pseudo silent majority, and perform evaluations and analyses. Note that, it would be preferable to evaluate users who did not declare stances at all as the silent majority. However, since it is virtually impossible for a third person to annotate stances of such users, we defined the pseudo silent majority for this experiment.

For the training data, we used all the users who expressed two or more stances. For the test data, we used users who expressed only one stances and posted more than 5,000 tweets. Then, we changed the number of tweets derived from the pseudo-silent majority, and measured the change in accuracy. Figure 4 shows the evaluation result. This result shows that 500 tweets are enough for predicting stances of a silent user.

4.3 The size of the silent majority

In Sections 4.1 and 4.2, by considering users' posts with our proposed method, we could also predict stances of the pseudo silent majority, which should have characteristics close to the 'real' silent majority. Then, how many users can the proposed method target at? In this work, as described in Section 3.3, we treated 444,321 users as the population. We calculate the number of topics for which users explicitly declared a stance. From this result (Figure 5), we can see that 313,686 (70.60%) of 444,321 users did not explicitly declare stances. The model of Sasaki et al. (2017) cannot be applied to these users.

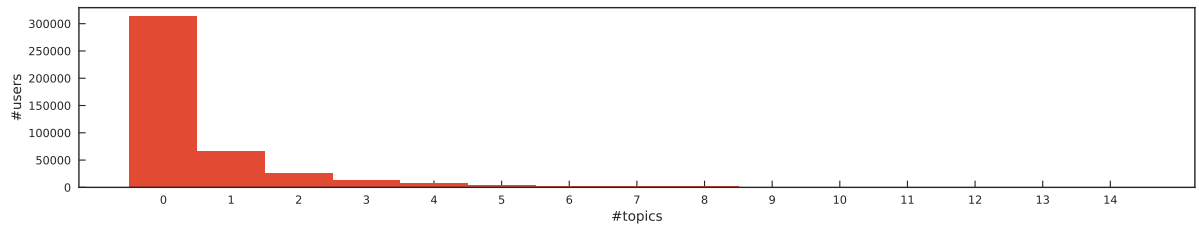

Figure 5: Number of topics for which users explicitly declared a stance.

(Sasaki et al., 2017)				0.2210

Table 3: Spearman's rank correlation coefficient (ρ) between human judgments and similarity of feature vectors obtained via our method.

4.4 Inter-topic preference

In FMs, each variable (user, topic, user's stances to other topics, and users' posts) is expressed as a feature vector. We examine whether inter-topic preferences (e.g., "those who agree with A also agree with B") can be derived from the feature vectors. In this subsection, we perform a quantitative evaluation to verify whether the model could acquire inter-topic preferences.

Here, we use the dataset created in Sasaki et al. (2017). This dataset includes inter-topic preferences given by six to ten crowd workers for 450 topic pairs. An inter-topic preference is defined as one of the following: -1 (*those who agree/disagree with topic A may conversely disagree/agree with topic B*), +1 (*those who agree/disagree with topic A may also agree/disagree with topic B*), and 0 (*no association between A and B*). Then, we obtained the average of the values of the multiple workers. We exclude topics that do not exist in the data used in our study. Thus, we used 221 topic pairs as evaluation targets.

We calculated Spearman's rank correlation coefficient (ρ) between manually created scores and similarities of feature vectors for topic pairs. Table 3 shows the result. The result of the proposed method was are lower than that of matrix factorization. This is probably because the proposed method encourage the model to utilize feature vectors corresponding to users' posts. In other words, stances are represented not only by vectors of topics but also by vectors of other variables. We would like to examine this phenomenon in more detail in the future.

5 Conclusion

In this work, we focused on posts of users on social media. In the evaluation, we confirmed that posts of users contribute to predicting stances of the users. This work dealt with 444,321 users on Twitter, approximately 70% of which do not express any stances for any topics. Using our proposed method, it is possible to target these users by considering their posts. Therefore, our method is useful for analyzing opinions, including those of the silent majority.

However, the performance of the stance detection in this work is not yet sufficient. To improve this performance, there are several points that need to be considered. First, even though features based on

n-gram and dependencies are currently used as features of users' posts, it may be possible to replace these with distributed representations. In recent years, multiple researchers have tried to build distributed representations of sentences (Logeswaran and Lee, 2018; Hill et al., 2016). These methods are known to demonstrate high performance in many tasks. By incorporating these methods into our proposed method, we will be able to express users' posts more compactly, and this is expected to improve the accuracy of predicting users' stances. In addition, FMs used in this work are advantageous because various types of features can be used simultaneously in an input matrix. Therefore, it is expected that social media specific features such as users' follow-follower relationships, retweet relationships, or profile could be useful information for predicting stances.

Moreover, it is possible to overlook the public opinions including the silent majority for each topic with our proposed method. In the future, we hope to apply our proposed method to newly appearing topics. We can then construct a framework that can monitor public opinions on various topics simultaneously. The above system is expected to be one application of our proposed method.

Abstract

The proliferation of misleading information in everyday access media outlets such as social media feeds, news blogs, and online newspapers have made it challenging to identify trustworthy news sources, thus increasing the need for computational tools able to provide insights into the reliability of online content. In this paper, we focus on the automatic identification of fake content in online news. Our contribution is twofold. First, we introduce two novel datasets for the task of fake news detection, covering seven different news domains. We describe the collection, annotation, and validation process in detail and present several exploratory analyses on the identification of linguistic differences in fake and legitimate news content. Second, we conduct a set of learning experiments to build accurate fake news detectors, and show that we can achieve accuracies of up to 76%. In addition, we provide comparative analyses of the automatic and manual identification of fake news.

1 Introduction

Fake news detection has recently attracted a growing interest from the general public and researchers as the circulation of misinformation online increases, particularly in media outlets such as social media feeds, news blogs, and online newspapers. A recent report by the Jumpshot Tech Blog showed that Facebook referrals accounted for 50% of the total traffic to fake news sites and 20% total traffic to reputable websites.[1] Since as many as 62% of U.S. adults consume news on social media (Jeffrey and Elisa, 2016), being able to identify fake content in online sources is a pressing need.

Until now, computational approaches for fake news detection have relied on satirical news sources such as "The Onion" (Rubin et al., 2016), viral news tracking websites such as BuzzFeed (Potthast et al., 2017) and fact-checking websites such as "politiFact" (Wang, 2017) and "Snopes" (Popat et al., 2016). However, the use of these sources poses several challenges and potential drawbacks. For instance, using satirical content as a source for fake content can bring underlying confounding factors into the analysis, such as humor and absurdity. This is particularly the case for satirical news from "The Onion", which has been used in the past to explore other text properties such as humor (Mihalcea and Strapparava, 2005) and irony (Wallace, 2015). Moreover, fact-checking websites are usually constrained to a particular domain of interest, such as politics, and require human expertise to verify the news claims making it difficult to obtain datasets that provide some degree of generalization over other domains (Chen et al., 2015).

In this paper, we develop computational resources and models for the task of fake news detection. We introduce two novel datasets covering seven different domains. One of the datasets is collected by combining manual and crowdsourced annotation approaches, while the second is collected directly from the web. Using these datasets, we conduct several exploratory analyses to identify linguistic properties that are predominantly present in fake news content, and we build fake news detectors relying on linguistic features that achieve accuracies of up to 76%. To place our results in perspective, we compare the performance of the developed classifiers with an empirical human baseline.

2 Related Work

To date, there are two important lines of research into the automated classification of genuine and fake news items. First, on a conceptual level, a distinction has been made between "three types of fake news" (Rubin et al., 2015): serious fabrications (i.e., news items about false and non-existing events or information such as celebrity gossip), hoaxes (i.e., providing false information via, for example, social media with the intention to be picked up by traditional news websites), and satire (i.e., humorous news items that mimic genuine news but contain irony and absurdity). Second, on an operational level, linguistic and fact-checking based approaches have been proposed to discriminate between real and fake news content (Conroy et al., 2015).

The linguistic approach attempts to identify text properties, such as writing style and content, that can help to discriminate real from fake news articles. The underlying assumption for this approach is that linguistic behaviors such as punctuation usage, word type choices, part-of-speech tags, and emotional valence of a text are rather involuntary and therefore outside of the author's control, thus revealing important insights into the nature of the text. The linguistic approach has yielded promising results in differentiating satire from real news (Rubin et al., 2016). Relying in a corpus of satire news (from *The Onion* and *The Beaverton*) and real news (*The Toronto Star* and *The New York Times*) in four domains (civics, science, business, soft news), the authors explored the use of several linguistic features to discriminate between real and satirical news content. The best classification performances were achieved with feature sets representing absurdity, punctuation, and grammar.

On the other hand, fact-checking approaches rely on automated verification of propositions made in the news articles (e.g., "Barack Obama assumed office on a Tuesday") to assess the truthfulness of their claims (Conroy et al., 2015). Knowledge databases such as DBpedia [2] have been used to query the Web in a structured manner. The results of such queries can then be used to test whether different sources also contain information confirming the news claim (e.g., that Barack Obama assumed office on a Tuesday). Other works have used social network activity (e.g., tweets) on a specific news item to assess its credibility, for instance by identifying tweets voicing skepticism about the truthfulness of a claim made in a news article (Hannak et al., 2014; Jin et al., 2014). Although fact-checking approaches are becoming increasingly powerful, a major drawback is that they are built on the premise that the information can be verified using external sources, for instance FakeCheck.org and Snopes.com. However, this is not a straightforward task, as external sources might not be available, particularly for just-published news items. Therefore, the fact-checking approach is predominantly useful for the detection of deception in texts for which external, verifiable information is available.

Furthermore, also related to the current paper is work on the automatic identification of deceptive content, which has explored domains such as forums, consumer reviews websites, online advertising, online dating, and crowdfunding platforms (Warkentin et al., 2010; Ott et al., 2011a; Zhang and Guan, 2008; Toma and Hancock, 2010; Shafqat et al., 2016). While fake news detection is closely related to deception detection (i.e. determining whether or not someone is lying), there are important differences between the two tasks. First, fake news producers usually seek political or financial gain as well as self-promotion while deceivers have motivations that are more socially driven such as self protection, conflict or harm avoidance, impression management or identity concealment. Second, they differ significantly in their target and in the form they propagate: fake news items are usually disseminated at larger scale through the Internet and social media whereas deception is more specifically targeted at individuals. However, since both tasks deal with deceptive content, we hypothesize that there are linguistic aspects that might be shared between these tasks. Thus, we focus on the linguistic approach and build upon an emerging body of research on computer-automated verbal deception detection (Fitzpatrick et al., 2015).

3 Fake News Datasets

As highlighted earlier, the datasets used in previous work have either relied on satirical news (e.g., "The Onion"), which also have confounds such as humor or irony; or used fact-checking websites (e.g., "poli-

	Legitimate	250	700/33	70,975

Table 1: Class distribution and word statistics for fake news datasets

tiFact" or "Snopes"), which are typically focused on only one domain (generally politics). To address these shortcomings, we decided to construct two novel datasets containing fake news covering several news domains and specifically model the deceptive property of fake news. One dataset is collected via crowdsourcing covering six news domains (e.g., business, education). The second dataset is obtained directly from the web and covers celebrity news.

3.1 Crowdsourced Fake News Dataset

Collecting Legitimate News. We started by collecting a dataset of legitimate news belonging to six different domains (sports, business, entertainment, politics, technology, and education). The news were obtained from a variety of mainstream news websites predominantly in the US such as the ABCNews, CNN, USAToday, NewYorkTimes, FoxNews, Bloomberg, and CNET among others.

To ensure the veracity of the news, we conducted manual fact-checking on the news content, which included verifying the news source and cross-referencing information among several sources. Using this approach, we collected 40 news in each of the six domains, for a total of 240 legitimate news.

LEGITIMATE	FAKE
Nintendo Switch game console to launch in March for $299 The Nintendo Switch video game console will sell for about $260 in Japan, starting March 3, the same date as its global rollout in the U.S. and Europe. The Japanese company promises the device will be packed with fun features of all its past machines and more. Nintendo is promising a more immersive, interactive experience with the Switch, including online playing and using the remote controller in games that don't require players to be constantly staring at a display.	**New Nintendo Switch game console to launch in March for $99** Nintendo plans a promotional roll out of it's new Nintendo switch game console. For a limited time, the console will roll out for an introductory price of $99. Nintendo promises to pack the new console with fun features not present in past machines. The new console contains new features such as motion detectors and immerse and interactive gaming. The new introductory price will be available for two months to show the public the new advances in gaming.

Table 2: Sample legitimate and crowdsourced fake news in the Technology domain

LEGITIMATE	FAKE
Kim And Kanye Silence Divorce Rumors With Family Photo. Kanye took to Twitter on Tuesday to share a photo of his family, simply writing, "Happy Holidays." In the picture, seemingly taken at Kris Jenner's annual Christmas Eve party, Kim and a newly blond Kanye pose with their children, North, 3, and Saint, 1. After Kanyes hospitalization, reports that there was trouble in paradise with Kim started brewing. But E! News shut down the speculation with a family source denying the rumors and telling the site, "It's been a very hard couple of months."	**Kim Kardashian Reportedly Cheating With Marquette King as She Gears up for Divorce From Kanye West.** Kim Kardashian is ready to file for divorce from Kanye West but has she REALLY been cheating on him with Oakland Raiders punter Marquette King? The NFL star seemingly took to Twitter to address rumors that they've been getting close amid Kanye's mental breakdown, which were originally started by sports blogger Terez Owens. While he doesn't appear to confirm or deny an affair, her reps said there is "no truth whatsoever" to the reports and labeled the situation "fabricated."

Table 3: Sample legitimate and web fake news in the Celebrity domain

Crowdsourcing Fake News. To generate fake versions of the legitimate news items, we made use of crowdsourcing via Amazon Mechanical Turk (AMT). Despite having been successfully used in the past to collect deceptive data on several domains, including opinion reviews (Ott et al., 2011b), and controversial topics such as abortion and death penalty (Pérez-Rosas and Mihalcea, 2015), the use of

AMT on the news domain poses additional challenges. First, the reporting language used by journalists might differ from AMT workers' language (e.g., journalistic vs. informal style). Second, journalistic articles are usually lengthier than consumer reviews and opinions, thus increasing the difficulty of the task for AMT workers as they would be required to read a full news article and create a fake version from it.

To address the former, we asked the workers to the extent possible to emulate a journalistic style in their writing so we could obtain news with homogeneous writing style. To simplify the fake news production task (and also address the latter challenge), we also opted for working with a shorter version of the original news article. Thus, we manually select a news excerpt – about two or three paragraphs – that summarizes the news article. This process resulted in 240 news excerpts derived from the legitimate news dataset collected earlier.

Next, we set up an AMT task that asked workers to generate a fake version of a given news. Each hit included the legitimate news headline and its corresponding body. We instructed workers to produce both a fake headline and a fake news body within the same topic and length as the original news. Workers were also requested to avoid unrealistic content and to keep the names mentioned in the news. The fake news were produced by unique authors, as we allowed only a single submission per worker. We restricted the submission to workers located in the US as they might be more familiar with news published in the US media. In addition, to ensure crowdsourcing quality, we restricted participation to workers who had an AMT approval rate of at least 95% for previous tasks.

It took approximately five days to collect 240 fake news. Each hit was manually checked for spam and to make sure workers followed the provided guidelines. In general, we received few spam responses and most of the workers followed instructions satisfactorily; the only exceptions were a few cases where they provided only the headline or included unrealistic content. The corpus statistics, including class distribution and word/sentence statistics, are shown in Table 1. Table 2 shows an excerpt of a fake news article in our dataset, along with its legitimate version, in the technology domain.

Interestingly, we observed that AMT workers succeeded in mimicking the reporting style from the original news, which may be partly explained by typical verbal mirroring behaviors that drive individuals to produce utterances that match the grammatical structure of sentences they have recently read (Ireland and Pennebaker, 2010).

Importantly, note that the AMT process of generating news mirrors the fake news production process quite well: similar to the AMT workers, the producers of fake news write for the purpose of generating quick money, and do not undergo the same professional writing training that the writers of legitimate news do.

Throughout the rest of the paper, we refer to this crowdsourced dataset as FakeNewsAMT.

3.2 Web Dataset Celebrity

For our second dataset, we sought to collect news from web sources to identify fake content that naturally occurs on the web. We opted for collecting news from public figures as they are frequently targeted by rumors, hoaxes, and fake reports. We focused mainly on celebrities (actors, singers, socialites, and politicians) and our sources include online magazines such as Entertainment Weekly, People Magazine, RadarOnline, among other tabloid and entertainment-oriented publications. The data was collected in pairs, with one article being legitimate and the other fake. In order to determine if a given celebrity news was legitimate or not, the claims made in the article were evaluated using gossip-checking sites such as "GossipCop.com", and also cross-referenced with information from other entertainment news sources on the web.

During the initial stages of the data collection, we noticed that celebrity news tend to center on sensational topics that sources believe readers want to read about, such as divorces, pregnancies, and fights. Consequently, celebrity news tends to follow certain celebrities more than others further limiting topic diversity in celebrity news. To address this issue, we evaluated several sources to make sure we obtain a diversified pool of celebrities and topics.

Using this approach, we collected a total of 500 news articles, with an even distribution for fake

and legitimate news. The corpus statistics, including class distribution and word/sentence statistics, are shown in Table 1. Table 3 shows a example excerpt of a celebrity fake/legitimate news pairing in the dataset. Throughout the rest of the paper, we refer to this web dataset as Celebrity.

4 Linguistic Features

To build the fake news detection models, we start by extracting several sets of linguistic features:

Ngrams. We extract unigrams and bigrams derived from the bag of words representation of each news article. To account for occasional differences in content length, these features are encoded as tf-idf values.

Punctuation. Previous work on fake news detection (Rubin et al., 2016) as well as on opinion spam (Ott et al., 2011b) suggests that the use of punctuation might be useful to differentiate deceptive from truthful texts. We construct a punctuation feature set consisting of twelve types of punctuation derived from the Linguistic Inquiry and Word Count software (LIWC, Version 1.3.1 2015) (Pennebaker et al., 2015). This includes punctuation characters such as periods, commas, dashes, question marks and exclamation marks.

Psycholinguistic features. We use the LIWC lexicon to extract the proportions of words that fall into psycholinguistic categories. LIWC is based on large lexicons of word categories that represent psycholinguistic processes (e.g., positive emotions, perceptual processes), summary categories (e.g., words per sentence), as well as part-of-speech categories (e.g., articles, verbs). Previous work on verbal deception detection showed that LIWC is a valuable tool for the deception detection in various contexts (e.g., genuine and fake hotel reviews, (Ott et al., 2011b; Ott et al., 2013); prisoners' lies (Bond and Lee, 2005)). In our work, we cluster the single LIWC categories into the following feature sets: summary categories (e.g., analytical thinking, emotional tone), linguistic processes (e.g., function words, pronouns), and psychological processes (e.g., affective processes, social processes). We also test a combined feature set of all the LIWC categories (including punctuation).[3]

Readability. We also extract features that indicate text understandability. These include content features such as the number of characters, complex words, long words, number of syllables, word types, and number of paragraphs, among others content features. We also calculate several readability metrics, including the Flesch-Kincaid, Flesch Reading Ease, Gunning Fog, and the Automatic Readability Index (ARI).

Syntax. Finally, we extract a set of features derived from production rules based on context free grammars (CFG) trees using the Stanford Parser (Klein and Manning, 2003). The CFG derived features consist of all the lexicalized production rules (rules including child nodes) combined with their parent and grandparent node, e.g., *NNˆNP→commission (in this example NN –a noun– is the grandparent node, NP –noun phrase– the parent node, and "commissions" the child node). CFG-based features have been previously shown to be useful for linguistic deception detection (Feng et al., 2012). Features in this set are also encoded as tf-idf values.

5 Automatic Fake News Detection

We conduct several experiments with different combinations of feature sets to explore their predictive separately and jointly. We use a linear SVM classifier and conduct our evaluations using five-fold cross-validation, with accuracy, precision, recall, and F-score as performance metrics. We use the machine learning algorithms implementation available in the caret (Kuhn et al., 2016) and e1071 packages (Meyer et al., 2015) with their default parameters.

Tables 4 and 5 show the results obtained for the different feature sets and the two datasets. Since our datasets contain an even distribution between fake and real news items, we use a random baseline of 50% as reference value. As seen in the tables most of the classifiers obtain performances well above the baseline, which indicates that the task of fake news detection can be effectively addressed using linguistic

[3]The feature sets linguistic processes and punctuation correspond to the 'grammar' and punctuation feature set, respectively, in (Rubin et al., 2016)

features. For the FakeNewsAMT dataset, the best performing classifiers are the ones that rely on stylistic features (i.e., Punctuation and Readability), followed by the ones build using psycholinguistic features drawn from the LIWC lexicon. The classifiers build with the Celebrity dataset show the best performance when using the LIWC features, followed by the ngrams and syntactic features (CFG). Overall, our results suggest that fake news differ from real news mainly in aspects such as writing style (punctuation, readability, syntactic structure) and aspects related to writer's internal processes (LIWC features). Regarding the differences in performance between the two datasets, we believe that they can be attributed to the domain in which the news are generated. For instance, to spot fake news in more serious topics such as technology or education we might need to pay more attention to linguistic aspects of writing whereas to spot fake news in the celebrity domain we might need to focus on writing differences related to people's feelings and perceptions.

Finally, our results show that when using all the features on the two datasets we achieve the best accuracies, with 0.74 and 0.76 respectively. These results suggest that an integrated use of linguistic, syntactic and semantic features is useful to discriminate between real and fake news content.

Features (# features)	Acc.	$F1_{Legit.}$	$F1_{Fake}$
Punctuation (12)	0.71	0.69	0.72
LIWC-Summ (7)	0.61	0.58	0.64
LIWC-LingProc. (21)	0.67	0.66	0.66
LIWC-PsyProc. (40)	0.56	0.56	0.55
LIWC (80)	0.70	0.70	0.70
Readability (26)	0.78	0.77	0.79
Ngrams (634)	0.62	0.62	0.62
CFG (1377)	0.65	0.64	0.65
All Features (2140)	0.74	0.74	0.74

Table 4: Classification results for the FakeNewsAMT dataset collected via crowdsourcing.

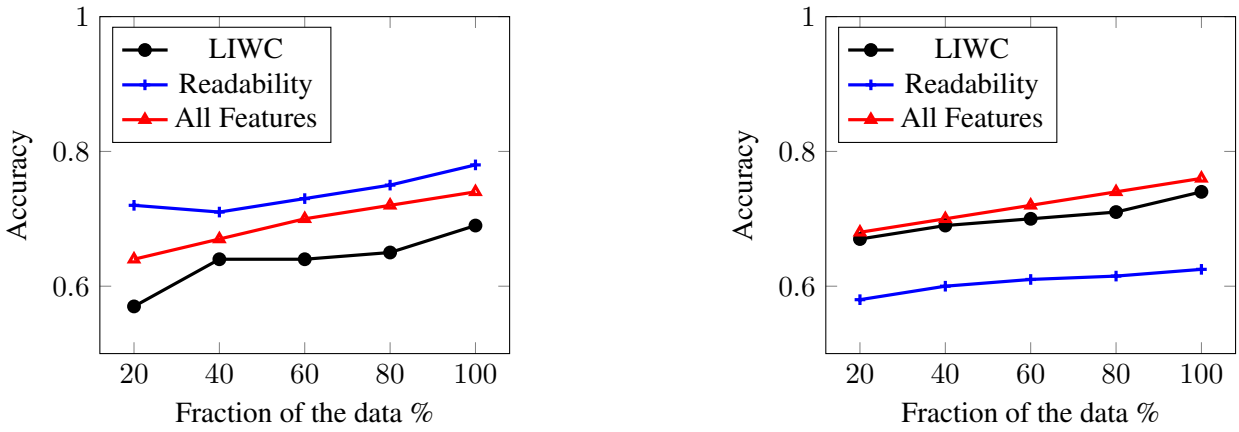
Features (# features)	Acc.	$F1_{Legit.}$	$F1_{Fake}$
Punctuation (12)	0.69	0.69	0.69
LIWC-Summ. (7)	0.67	0.66	0.69
LIWC-LingProc (21)	0.72	0.72	0.71
LIWC-PsyProc (40)	0.67	0.68	0.66
LIWC (80)	0.74	0.74	0.74
Readability (28)	0.62	0.61	0.63
Ngrams (1317)	0.71	0.72	0.71
CFG (2599)	0.72	0.72	0.72
All Features (4048)	0.76	0.77	0.76

Table 5: Classification results for the Celebrity news dataset.

Learning Curves. Next, seeking to investigate whether larger amounts of training data can improve the identification of fake content, we analyzed the learning trend of our best classifiers. Thus, we plot the learning curves of the LIWC features, readability features, and the combination of all features sets using incremental amounts of data as shown in Figures 1a and 1b. Overall, the learning trend in both datasets shows steady improvement, thus suggesting that larger quantities of training data could improve the classification performance.

Cross-domain Analyses. We also explore the applicability of our methods across domains, using the two best feature sets identified during our previous experiments, (*Readability* and *LIWC*), as well as the classifier relying on all the features (*All Features*).

Table 6 shows the results obtained in cross-domain experiments, where we train our models using the



(a) FakeNewsAMT dataset

(b) Celebrity dataset

Figure 1: Learning curves using incremental fraction of the data and three feature sets

Training	Testing	Feature set	Accuracy
FakeNewsAMT	Celebrity	LIWC	0.48
		Readability	0.52
		All Features	0.50
Celebrity	FakeNewsAMT	Complete LIWC	0.60
		Readability	0.65
		All Features	0.64

Table 6: Cross-domain analysis for best performing feature sets.

FakeNewsAMT dataset and test on the Celebrity dataset. Perhaps not surprisingly, there is a significant loss in accuracy as compared to the within-domain results shown in Tables 4 and 5.

Possible explanations for the drop in performance might be (1) that the linguistic properties of deception in one domain are structurally different from those of deception in a second domain, and (2) that the feature sets applied for the cross-domain evaluation, in particular the readability feature set (accuracy = 0.62), were not performing well in the respective domain in the first place. To test this idea, we also applied cross-domain evaluation where we trained the classifiers using the celebrity domain (Celebrity) and tested in the other domain (FakeNewsAMT).

This time, the readability feature set classifier of the Celebrity data yielded an accuracy of 0.65 on the FakeNewsAMT data (compared to the original 0.78) and similarly, the *LIWC* classifier resulted in an accuracy of 0.60 (compared to 0.70). Likewise, the performance using all features dropped from 0.74 and 0.76 to 0.50 and 0.64 for the FakeNewsAMT and celebrity datasets, respectively. Overall, these findings hint at the important role of domain in the fake news detection.

As an additional experiment, we assess the cross-domain classification performance for the six news domains in the FakeNewsAMT dataset. We do this by training on five of the six domains in the dataset, and testing on the remaining one. Table 7 shows the results obtained in these experiments. The politics, education, and technology domains appear to be rather robust against classifiers trained on other domains. The technology and politics domains, moreover, are both classified with a high accuracy of 0.90 and 0.91 with the *Readability* feature set, which may suggest that fake and legitimate news in each of these three domains might be structurally similar to the fake and legitimate content in the other five domains. By contrast, domains such as sports, business and entertainment are less generalizable and might therefore be more domain-dependent. Although further research is needed to consolidate these findings, a possible explanation could be the rather unique content and style of these domains.

Test Domain	Readability	LIWC	All features
Technology	0.90	0.62	0.80
Education	0.84	0.68	0.84
Business	0.53	0.76	0.85
Sports	0.51	0.73	0.81
Politics	0.91	0.73	0.75
Entertainment	0.61	0.70	0.75

Table 7: Cross-domain classification accuracy for the complete LIWC and readability feature sets. Training data consists of all but the test domains in the FakeNewsAMT dataset.

	Agreement	Kappa
FakeNewsAMT	70%	0.38
Celebrity	73%	0.45

Table 8: Agreement among two human annotators on the FakeNewsAMT and the Celebrity datasets.

6 Human Performance

Fake news detection is a challenging task for humans as readers frequently find themselves sharing fake news content or being lured by clickbait headlines. Seeking to identify a human baseline for the fake news detection task, we conducted a study to evaluate the human ability to spot fake news on the two developed datasets. We created an annotation interface that shows an annotator either a fake or a legitimate news article, and asks them to judge its credibility. We asked annotators to select a label of "Fake" or "Legitimate" according to their own perceptions upon reading the news item. We also asked them to indicate whether or not they have read or heard about the presented news item in the past; overall, the annotators read less than 5% of the news before, which we considered a negligible fraction.

Two annotators labeled the news in each dataset. In both cases, the news articles were presented in a random order to avoid annotation bias. Annotators evaluated 480 and 200 news for the FakeNewsAMT and Celebrity datasets respectively. Annotators were not offered a monetary reward and we consider their judgments to be honest as they participated voluntarily in this experiment.

Table 8 shows the observed agreement and Kappa statistics for each dataset. Resulting Kappa values show moderate agreement values with slightly lower Kappa for the FakeNewAMT dataset.

In addition, we evaluate the performance of the automatic fake news classifiers against the human capability to spot fake news. Thus, we compare the accuracy of our system to that of human annotators. Table 9 summarizes the accuracies obtained by the human annotators and our system on the two fake news datasets. The findings indicate that humans are better at detecting fake content in the Celebrity domain than in the other fake news domain. Notably, our system outperforms humans while detecting fake news in more serious and diverse news sources.

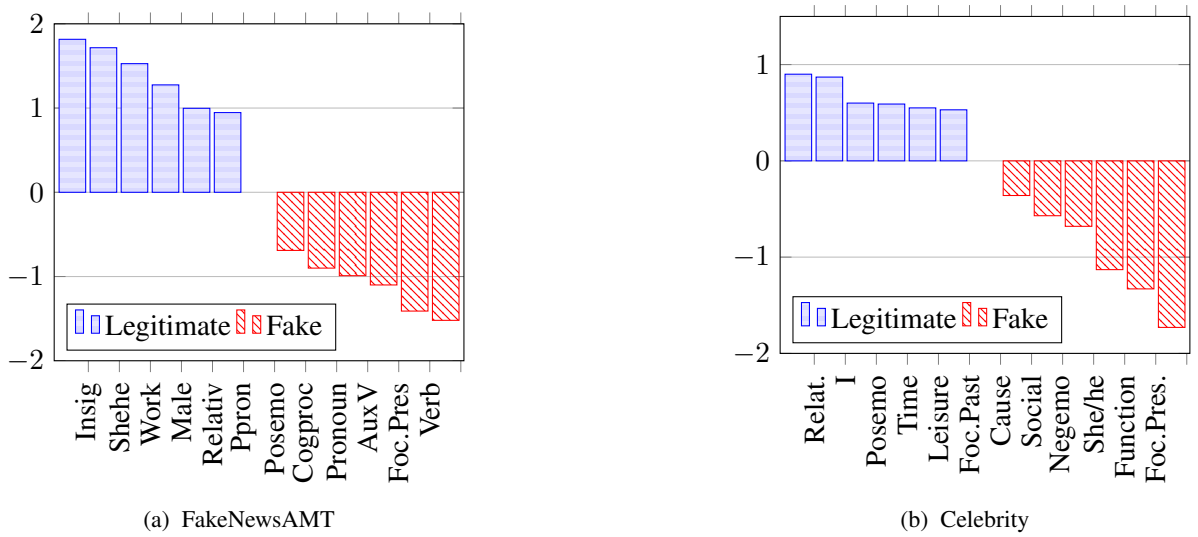
7 Further Insights

Our experiments suggest important differences in fake news content as compared to legitimate news content. Particularly, we observe that classifiers relying on the semantic information encoded in the LIWC lexicon show consistently good performance across domains. To gain further insights into the semantic classes that are associated with fake and legitimate content, we evaluate which classes show significant differences between the two groups of news. To compare both types of content, we subtract the average percentage of words in each LIWC category in the fake news from its corresponding values in the legitimate news set. Therefore, a positive result indicates an association between a LIWC class and legitimate content, and a negative result indicates an association between a LIWC class and fake content. Results for the FakeNewsAMT and Celebrity datasets are shown in Figures 2a and 2b respectively. All the differences shown in the graphs are statically significant (one-tailed t-test, $p < 0.05$).

Figure 2a indicates that the language used to report legitimate content in the FakeNewsAMT dataset

	FakeNewsAMT	Celebrity
A1	0.71	0.80
A2	0.70	0.77
Sys	0.74	0.76

Table 9: Performance of two annotators (A1, A2) and the developed automatic system (Sys) on the fake news datasets



(a) FakeNewsAMT

(b) Celebrity

Figure 2: Language differences in each dataset using the LIWC word categories

often includes words associated with cognitive processes such as insight and differentiation. In addition, legitimate content includes more function words (e.g., pronouns such as he, she), negations, and expressions of relativity. On the other hand, language used when reporting fake content uses more social and positive words, expresses more certainty and focuses on present and future actions. Moreover, the authors of fake news use more adverbs, verbs, and punctuation characters than the authors of legitimate news.

Likewise, the results in Figure 2b show noticeable differences among legitimate and fake content on the celebrity domain. Specifically, legitimate news in tabloid and entertainment magazines seem to use more first person pronouns, talk about time (Relativity,Time, FocusPast), and use positive emotion words (posemo), which interestingly were also found as markers of truth-tellers in previous work on deception detection (Pérez-Rosas and Mihalcea, 2014). On the other hand, fake content in this domain has a predominant use of second person pronouns (he, she), negative emotion words (negemo) and focus on the present (Foc.Pres).

8 Conclusions

With an increasing focus of academic researchers and practitioners alike on the detection of online misinformation, the current investigation allows for two key conclusions.

First, computational linguistics can aide in the process of identifying fake news in an automated manner well above the chance level. The proposed linguistics-driven approach suggests that to differentiate between fake and genuine content it is worthwhile to look at the lexical, syntactic and semantic level of a news item in question. The developed system's performance is comparable to that of humans in this task, with an accuracy up to 76%. Nevertheless, while linguistics features seem promising, we argue that future efforts on misinformation detection should not be limited to these and should also include *meta* features (e.g., number of links to and from an article, comments on the article), features from different modalities (e.g., the visual makeup of a website using computer vision approaches), and embrace the increasing potential of computational approaches to fact verification (Thorne et al., 2018). Thus,

future work might want to explore how hybrid decision models consisting of both fact verification and data-driven machine learning judgments can be integrated.

Second, we showed that it is possible to build resources for the fake news detection task by combining manual and crowsourced annotation approaches. Our paper presented the development of two datasets using these strategies and showed that they exhibit linguistic properties related to deceptive content. Furthermore, different from other available fake news datasets, our dataset consists of actual news excerpts, instead of short statements containing fake news information.

Finally, with the current investigation and dataset, we encourage the research community and practitioners to take on the challenge of tackling misinformation. The datasets introduced in this paper are publicly available at `http://lit.eecs.umich.edu/downloads.html`.

All-in-one: Multi-task Learning for Rumour Verification

Elena Kochkina[1,2], **Maria Liakata**[1,2], **Arkaitz Zubiaga**[1]
[1] University of Warwick, Coventry, United Kingdom

Abstract

Automatic resolution of rumours is a challenging task that can be broken down into smaller components that make up a pipeline, including rumour detection, rumour tracking and stance classification, leading to the final outcome of determining the veracity of a rumour. In previous work, these steps in the process of rumour verification have been developed as separate components where the output of one feeds into the next. We propose a multi-task learning approach that allows joint training of the main and auxiliary tasks, improving the performance of rumour verification. We examine the connection between the dataset properties and the outcomes of the multi-task learning models used.

Title and Abstract in Russian

Три в одном: Многозадачное Обучение для Верификации Слухов

Автоматическая верификация слухов в Интернете - это сложная задача, которая может быть разбита на подзадачи, включающие в себя обнаружение слухов, отслеживание слухов, классификацию отношения пользователей к правдивости этих слухов и, в итоге, разрешение основной задачи - определение достоверности слуха. В предыдущих исследованиях модели для решения каждой из подзадач разрабатывались как отдельные компоненты, где вывод модели для задачи предыдущего этапа являлся вводдом для модели задачи следующего этапа. Мы предлагаем использование многозадачного обучения для совместного обучения основной и вспомогательных задач в одной модели, что позволяет улучшить качество модели верификации слухов. Также мы рассматриваем связь между свойствами набора данных и результатами использования моделей с многозадачным обучением.

1 Introduction

Social media have gained popularity as platforms that enable users to follow events and breaking news (Hu et al., 2012). However, not all information that spreads on social media during such events is accurate. The serious harm that inaccurate information can cause to society in critical situations (Lewandowsky et al., 2012) has led to an increased interest within the scientific community to develop tools to verify information from social media (Shu et al., 2017). Likewise, social media platforms themselves, such as Facebook,[1] are investing significant effort in mitigating the problems caused by misinformation. One of the features that characterises social media is the rapid emergence and spread of new information. This leads to the circulation of rumours, claims that are unverified at the time of posting, and for which eventually evidence proving their true or false nature may come out (DiFonzo and Bordia, 2007). Therefore, a rumour resolution system needs to go through a set of steps, from detecting that a new circulating claim is a rumour, to the ultimate step of determining its veracity value.

[1] https://www.recode.net/2017/2/16/14632726/mark-zuckerberg-facebook-manifesto-fake-news-terrorism

Proceedings of the 27th International Conference on Computational Linguistics, pages 3402–3413
Santa Fe, New Mexico, USA, August 20-26, 2018.

The rumour resolution process has been defined as a pipeline involving four sub-tasks (Zubiaga et al., 2018a) (see Figure 1): (1) rumour detection, determining whether a claim is worth verifying rather than the expression of an opinion; (2) rumour tracking, collecting sources and opinions on a rumour as it unfolds; (3) stance classification, determining the attitude of the sources or users towards the truthfulness of the rumour, and (4) rumour verification, as the ultimate step where the veracity value of the rumour is predicted. These steps can be performed at different times in the life-cycle of a rumour, making this a time-sensitive process. Ideally, rumours can be resolved as either true or false. However, they can also remain unverified when there is no sufficient evidence to determine their veracity (Caplow, 1947).

A recent body of work studies each of these four tasks separately (Lukasik et al., 2016; Liu et al., 2016; Enayet and El-Beltagy, 2017). However, the way these subtasks interact and their integration into a complete rumour resolution system is yet to be explored. In this work we assume that veracity classification is the crucial component of a rumour resolution system, as the final output that determines, given information collected about a rumour at a certain point in time, if the rumour is true, false, or remains unverified. We express the rumour resolution process as a multi-task problem that needs to address a number of challenges, where the veracity classification task is the main task and the rest of the components are auxiliary tasks that can be leveraged to boost the performance of the veracity classifier.

We propose to achieve this setting by using a multi-task learning approach. Multi-task learning (Caruana, 1998) refers to the joint training of multiple tasks, which has gained popularity recently for a range of tasks in Machine Learning and Natural Language Processing (Collobert and Weston, 2008) and has been applied in a number of different tasks and machine learning architectures. Its effectiveness is mainly attributed to learning shared representations of closely related tasks, such that two complementary tasks can give each other 'hints'.

We propose joint learning of the tasks in the verification pipeline, that will allow us to leverage relations between the tasks. We assess the effectiveness of using a multi-task learning approach for the rumour resolution process in four different scenarios: (1) performing single task learning to perform veracity classification, (2) performing multi-task learning that combines stance and veracity classification with the aim of boosting performance of the latter, (3) performing multi-task learning that combines rumour detection and verification, comparing the improvement brought by each of the two auxiliary tasks, and (4) performing multi-task learning that combines rumour detection, stance classification and veracity prediction to improve the performance for veracity. We employ a deep learning architecture that views each subtask as having a sequential nature. We compare our results with a state-of-the-art veracity classification approach introduced by Enayet and El-Beltagy (2017).

While a lot of work reports positive outcomes of the application of multi-task learning to various NLP tasks (Collobert and Weston, 2008; Aguilar et al., 2017; Lan et al., 2017), there are also studies showing that this is not always the case (Alonso and Plank, 2017; Bingel and Søgaard, 2017). Alonso and Plank (2017) were the first to demonstrate that multi-task learning brings benefits only for some combinations of main and auxiliary tasks. They also investigate the relationship between the multi-task learning outcome and the properties of the dataset. We perform a similar analysis to examine the link between the properties of our rumour datasets and the results of the multi-task learning approach used.

Our results show that a multi-task learning scenario that leverages all three subtasks, where veracity classification is the main task and stance classification and rumour detection are auxiliary tasks, leads to substantial improvements over a standard, single task veracity classification system, as well as a majority baseline and a state-of-the-art system. The combination of all three subtasks also outperforms the multi-task learning scenario where only two of the subtasks are combined.

2 Related work

2.1 Rumour classification system

Rumour classification is a complex task that can be represented as a pipeline of sub-tasks. While there are different possibilities for structuring this pipeline, here we adopt the architecture of a rumour classification system proposed in Zubiaga et al. (2018a) (see Figure 1). Thus, a rumour classification system is expressed as a sequence of subtasks, namely rumour detection, rumour tracking, rumour stance classi-

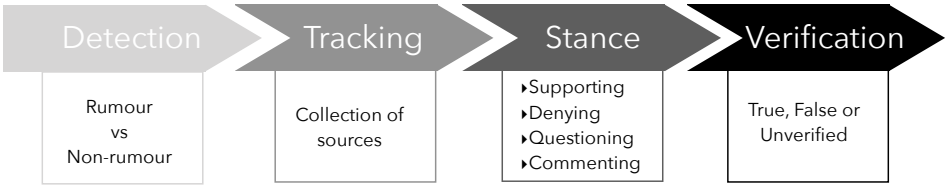

Figure 1: Rumour resolution pipeline.

fication leading to rumour verification. In this work we consider three of these tasks: rumour detection, stance and verification, focusing on the evaluation of the latter. Rumour tracking does not involve classification but rather consists of collecting tweets following up on a rumour in the form of replies.

A recent survey (Zubiaga et al., 2018a) defines rumour detection as the task which distinguishes rumours (unverified pieces of information) from non-rumours (all other circulating information). Here we adhere to this definition. Therefore, once rumour detection is performed, the information classified as a rumour is then fed into the the stance and veracity classification components of a system to ultimately determine the veracity of the rumour.

While we are not aware of previous work tackling the entire rumour classification pipeline, there has been a body of work tackling each of the tasks individually.

Stance classification. An increasing body of work has focused on the stance classification component, i.e. determining whether different posts associated with a rumour support it, deny it, query it, or just comment on it. The stance expressed by users towards a particular rumour can be indicative of the veracity of a rumour, furthermore, it has been shown that rumours attracting higher levels of skepticism in the form of denials and questioning responses are more likely to be proven false later (Mendoza et al., 2010; Procter et al., 2013; Derczynski et al., 2014). Previous work on stance classification (Lukasik et al., 2016; Kochkina et al., 2017; Zubiaga et al., 2017; Zubiaga et al., 2018b) has explored the use of sequential classifiers, treating the task as one that evolves over time; it has been shown that these sequential classifiers substantially outperform standard, non-sequential classifiers.

Rumour detection. Work on rumour detection is more scarce. One of the first approaches was introduced by Zhao et al. (2015), who built a rule-based approach to identify skepticism (e.g. is this true?) and therefore determine that the associated information is a rumour. The limitations of this approach consist in having to wait for responses to arrive, as well as lack of generalisability due to manually-defined rules. Zubiaga et al (2017) proposed a sequential approach to leverage context from earlier posts during an event. The sequential approach achieved significant improvements, especially in terms of recall, where the rule-based approach proved limited.

Rumour verification. Common approaches to rumour verification involve first the collection of corpora of resolved rumours from rumour debunking websites such as snopes.com, emergent.com, politifact.com. Wang (2017) created a dataset based on claims from politifact.com that are annotated for degrees of truthfulness. To resolve these they propose a hybrid convolutional neural network that integrates metadata with text. Twitter is a popular platform to study rumours, while often seeds and annotations for rumours are still taken from rumour debunking websites. Giasemidis et al. (2016) collected a dataset of 72 rumours from Twitter. This work measured trustworthiness of a claim at varying time windows. Boididou et al. (2014; 2017) have focused on tweets that are related to fake images, bringing in the multimedia component into the verification process.

Sequence classification. Works that consider tasks of rumour detection and verification (within their own definition of the tasks, not necessarily aligning with the one used here) also highlighted the importance of a sequential time-sensitive approach when dealing with rumours (Ma et al., 2016; Kwon et al., 2017; Chen et al., 2017). As previous work in the literature has highlighted the importance of sequential classifiers in rumour detection we have decided to use an LSTM based architecture for our experiments.

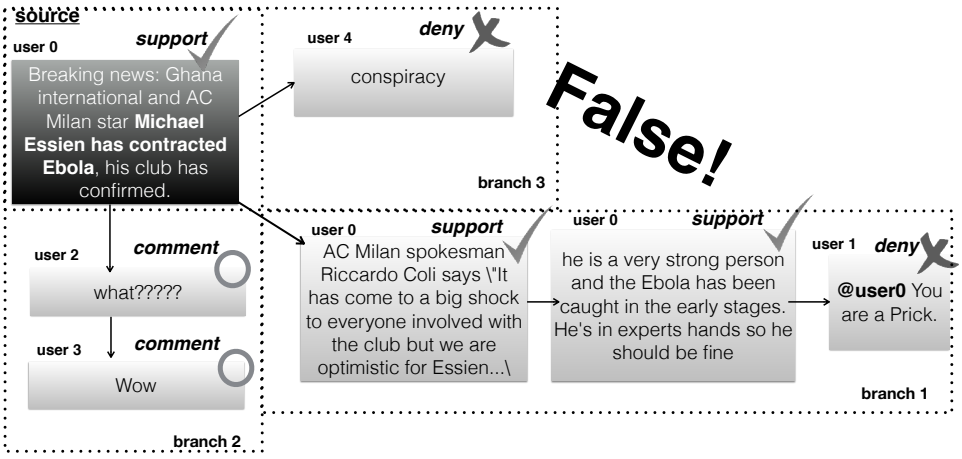

Figure 2: Example of a conversation with 3 branches from the RumourEval dataset.

2.2 Multi-task learning

Multi-task learning refers to the joint learning of several related tasks with a shared representation. In recent years, a multi-task learning approach has been successfully applied in combination with neural networks for a variety of NLP tasks (Collobert and Weston, 2008). In this work we use the most common approach to multi-task learning, namely hard parameter sharing, meaning that different tasks are using the same hidden layer(s). The effectiveness of a multi-task learning approach is attributed to: effectively increasing the size of the training set by using additional datasets for related tasks and regularisation, as the model has to learn a shared representation for multiple tasks there is less risk of overfitting on one of them. In multi-task learning auxiliary tasks can be used to direct the main task to use/learn the features that it otherwise would have ignored or failed to identify due to complex relations between the tasks and features. For example, multi-task learning is particularly useful when potentially helpful features are not used as such for the main task, but become labels in an auxiliary task. This use case is very relevant to this work; stance classification could be used as a feature in a system for veracity classification, as has indeed been the case in previous studies, which have shown a relationship between the two tasks. Zhao et al. (2015) and Enayet and El-Beltagy (2017) have created successful models using this premise. However these studies assume access to stance and veracity labels for the same data, which does not apply in our case as we do not have stance labels for all of the threads in the dataset (see section 3).

3 Data

We use two publicly available datasets of rumours: PHEME (Zubiaga et al., 2016; Zubiaga et al., 2017) and RumourEval (Derczynski et al., 2017) that contain different levels of annotation for the tasks of rumour detection, rumour stance and veracity classification. Both datasets contain Twitter conversation threads associated with different newsworthy events including the Ferguson unrest, the shooting at Charlie Hebdo, the shooting in Ottawa, the hostage situation in Sydney and the crash of a Germanwings plane. Figure 2 shows an example of a conversation discussing a rumour about Michael Essien having contracted Ebola. The conversation consists of a source tweet conveying a rumour and a tree of responses, expressing their opinion towards the claim contained in the source tweet. The veracity label of the rumour is false, while each of the responses could be tagged as either supporting, denying, questioning or commenting on the rumour. Conversations can be decomposed into branches, such that a branch is a linear sequence of tweets starting from a leaf node of the conversation tree and going through its parent nodes up to the source tweet. The conversation on the Figure 2 can be decomposed into three branches.

	Threads	Branches	Tweets	True	False	Unverified	S	D	Q	C
Development	25	215	281	10	12	3	69	11	28	173
Testing	28	772	1049	8	12	8	94	71	106	778
Training	272	3030	4238	127	50	95	841	333	330	2734
Total	325	4017	5568	145	74	106	1004	415	464	3685

Table 1: Number of threads, tweets and class distribution in RumourEval dataset.

3.1 RumourEval

RumourEval is a dataset that was released as part of the SemEval-2017 Task 8 competition (Derczynski et al., 2017). It contains 325 Twitter threads discussing rumours. All conversations in the RumourEval dataset are rumours, therefore this dataset only covers the tasks of rumour stance and veracity classification. It is split into training, testing and development sets. The testing set contains a mix of rumours related to the same events as in the training and development sets, with the addition of two rumours: about Marina Joyce and the health condition of Hillary Clinton. Table 1 shows the number of conversation threads, branches and tweets in each of the sets of the RumourEval dataset, as well as the class distribution for both tasks. In the stance classification task there is a strong class imbalance towards the commenting class, while questioning and denying are minority classes, which holds true for all subsets. For the verification task, the training set contains more true instances than false or unverified, whereas the development and testing sets are more balanced.

3.2 PHEME

We are making available the extended version of the PHEME dataset of rumours and non-rumours related to nine events, each updated with veracity information for each of the rumours[2].

This dataset contains 3 levels of annotation. First, each thread is annotated as either rumour or non-rumour; second, rumours are labeled as either true, false or unverified. And third, a subset (threads used in RumourEval) is annotated for stance classification at the tweet level through crowd-sourcing.

Rumours in this dataset were labeled as true, false and unverified by professional journalists (Zubiaga et al., 2016). While stance can be labeled by non-expert workers as labels can be inferred directly from the text, the rumour verification task is more challenging as it requires analysis of the context, and further understanding of the rumours in order to determine if the underlying story is true, false, or remains unverified. To assess the difficulty of performing the verification task by a non-expert, an author of this paper went through the rumours and annotated them for veracity. The overlap between the non-expert annotator and the journalist was within the range of $60 - 65\%$ on the rumour stories from five largest events.

Table 2 shows the size of each event in the PHEME dataset as well as the label distribution for the tasks of rumour detection and verification. The information about the stance classification task is in table 1. Events differ in size drastically and have different class label proportions. Overall, the PHEME dataset contains fewer rumours than non-rumours, while the majority class for rumours is true.

We perform two types of experiments using different subsets of the PHEME dataset: (1) using the five largest events (see Table 2) and (2) using all nine events. The five largest events create a more balanced dataset as those are major crisis events during which true updates and false information on different aspects of the event were shared and discussed, whereas the 4 smallest events only contain a single rumour story at the core of the event. In both cases, cross-validation experiments are performed by relying on a leave-one-event-out setting, i.e. using all the events except the one left for testing in each case. This set up is more challenging than the one presented in RumourEval, however it is more representative of the real world. We micro-average the performance across events.

Table 2: Number of threads, tweets and class distribution in the PHEME dataset.

4 Models

4.1 Sequential approach

As the benefits of using a sequential approach were suggested by previous studies of rumour stance classification and rumour detection tasks (discussed in Section 2), we are following the branchLSTM approach described in Zubiaga et al. (Zubiaga et al., 2018b). We split the conversations into linear branches and use them as training instances that become an input to a model consisting of an LSTM layer followed by several dense ReLU layers and a softmax layer that predicts class probabilities. As the stance classification task is annotated at the tweet level, we use the output from each time step of LSTM, whereas for the tasks of rumour detection and verification, annotated at the thread level, we are only using outputs from the final time steps (this idea is illustrated in Figure 3). To get per-thread predictions, we use majority voting for each of the branches from the thread. The model is trained using categorical cross entropy loss.

4.2 Multi-task learning approach

We leverage the relationship between the tasks from the rumour classification pipeline in a joint multi-task learning setup. Figure 3 illustrates our approach. At the base of it is a sequential approach, as discussed above, represented by a shared LSTM layer (hard parameter sharing), which is followed by a number of task-specific layers. The possible task combinations are shown as dotted lines on Figure 3 that can be present or absent depending on the combination. We perform experiments in three set ups: joint training of (1) stance or (2) rumour detection together with veracity classification, and (3) learning all three tasks together. The cost function in the multi-task models is a sum of losses from each of the tasks. Datasets for each of the three tasks are not equal in size, therefore when the training instance is lacking a label for one of the tasks, its prediction does not add anything to the loss function, as if it had been predicted correctly.

4.3 Baselines

We compare proposed sequential and multi-task learning approaches with several baselines. First of all, majority vote, a strong baseline which results in high accuracy due to the class imbalance in the veracity classification task. Another strong benchmark is NileTMRG (Enayet and El-Beltagy, 2017), the best veracity classification system from SemEval-2017 Task 8. The NileTMRG model is based on a linear SVM that uses a bag-of-words representation of the tweet concatenated with selected features: presence of URL, presence of hashtag and proportion of supporting, denying and querying tweets in the thread. We have made our own implementation NileTMRG* of the NileTMRG model based on their SemEval paper. This model requires stance labels for each of the tweets in the dataset, however these are not available for the PHEME dataset. To obtain the proportion of different stance labels among responses in the thread, we use our own implementation of the stance classification model from Kochkina et al. (2017). On the RumourEval dataset our implementation NileTMRG* achieves better results than the original NileTMRG score (Enayet and El-Beltagy, 2017) (accuracy 0.570 vs reported 0.536) as it utilises

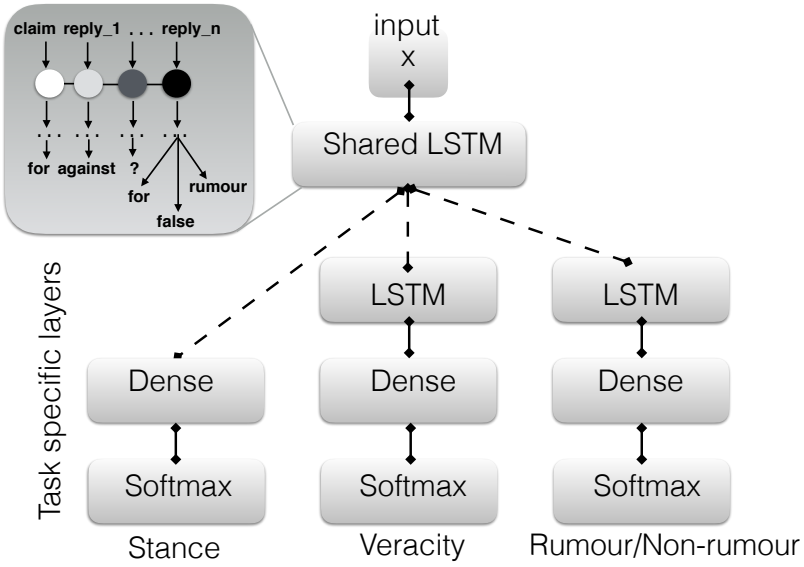

Figure 3: Multi-task learning models. Dotted lines represent that same set up is used for learning one, two or three tasks. Input format is a branch of tweets. Stance classification implies predictions per-tweet, whereas detection and verification tasks only require per-branch output.

a better model for stance classification. The NileTMRG model is a baseline showing the scenario where pipeline tasks are performed sequentially and the outcome of the previous step (stance classification) is an input to the next one (veracity classification). The NileTMRG model has set a precedent in demonstrating that patterns of support are useful indicators of rumour veracity.

4.4 Features

We perform the following pre-processing of the tweets in the datasets: remove nonalphabetic characters, convert all words to lower case and tokenise texts[3]. Once tweet texts are pre-processed, we extract word2vec word embeddings pre-trained on the Google News dataset (300d)[4] (Mikolov et al., 2013) for each word in a tweet and take the average, thus obtaining a tweet representation. This representation was shown to work well for tweets due to their short length (Kochkina et al., 2017).

5 Experiment setup

5.1 Hyperparameters

We determined the optimal set of hyperparameters by testing the performance of our models on the development set for different parameter combinations. We used the Tree of Parzen Estimators (TPE) algorithm[5] to search the parameter space and minimise the loss function expressed as $(1 - macroF)$ for single task, and $(1 - macroF_a)(1 - macroF_b)$ or $(1 - macroF_a)(1 - macroF_b)(1 - macroF_c)$ for multi-task learning of two and three tasks respectively. This loss function gives equal weight to all tasks. The parameter space is defined as follows: the number of dense ReLU layers varies from one to four; the number of LSTM layers is $\{1, 2\}$; the mini-batch size is 32; the number of units in the ReLU layer is $\{300, 400, 500, 600\}$, and in the LSTM layer is $\{100, 200, 300\}$; the strength of the L2 regularisation is $\{10^{-4}, 10^{-3}\}$ and the number of epochs is 50. We performed 30 trials of different parameter combinations optimising for accuracy on the development set in order to choose the best combination. We also use 50% dropout before the output layer. Zero-padding and masks that account

[3]For implementation of all pre-processing routines we use Python 2.7 with the NLTK package

[4]Embeddings were retrieved from `https://code.google.com/archive/p/word2vec/`. Processing was performed using gensim package (Řehůřek and Sojka, 2010).

for the varying lengths of the input branches were used in all our models. Models were implemented[6] using Python 3 and the Keras package.

5.2 Evaluation

The RumourEval dataset was provided with a training/development/testing split. We tune parameters on the development set and then retrain the model on the combined training and development sets before evaluation on the testing set. On the PHEME dataset we perform leave-one-event-out (LOEO) cross-validation, which makes this task set up harder than for RumourEval but closer to the realistic scenario where we want to verify unseen rumours. When choosing parameters, the Charlie Hebdo event was used as the development set as it has balanced labels. We evaluate models using accuracy and macro-averaged F-score as the tasks in the PHEME dataset suffer from a class imbalance.

6 Results and Discussion

The main results of our experiments are presented in Table 3. It shows the results of the multi-task learning models MTL2 with two tasks: Veracity+Stance and Veracity+Detection; MTL3 with three tasks Stance+Veracity+Detection, Majority, NileTMRG* and single task branchLSTM baselines on the main task, veracity classification.

As the datasets contain a significant class imbalance, the majority baseline achieves fairly high accuracy scores. However due to the nature of this task, it is more important for a model to recognize all of the classes, especially false rumours, therefore the macro-averaged F-score is more important for performance evaluation. All models demonstrate improvement over the majority baseline in terms of macro F-score. We observe improvements of multi-task approaches over single task learning in both accuracy and macro F-score, and adding the third task brings further improvement.

MTL2 Veracity+Detection and MTL3 experiments were performed only on the PHEME dataset as the RumourEval dataset consists only of rumours (no rumour detection). On the RumourEval dataset the single task model branchLSTM outperforms the majority baseline, although it does not perform as well as NileTMRG*, while MTL2 shows improvement over both NileTMRG* and branchLSTM. Experiments on the PHEME dataset also show a pattern of increasing scores: MTL2 outperforms single task models and MTL3 outperforms MTL2. Comparing the performance of the MTL2 model using stance as an auxiliary task with the model using rumour detection as an auxiliary task on the PHEME 5 events dataset we observe that both models bring an improvement over the single task branchLSTM baseline.

When using 9 events of the PHEME dataset we observe worse performance than on 5 events. Even though we are adding more training data, the 4 additional events are qualitatively different to the 5 large news-breaking events. Each of these 5 large events contained rumours labeled with all classes as well

Table 4: Per event and per-class results for multi-task learning approach with 3 tasks on PHEME 5 events.

as non-rumours, whereas the 4 additional events are small and the event itself is a false or unverified rumour. This highlights the difficulty of the rumour verification task in a leave-one-event-out setup and the importance of high quality data. NileTMRG* is a very strong baseline, and while the single task branchLSTM model is competitive when we are using 5 largest events, NileTMRG* is only outperformed by the multi-task learning approach.

6.1 Per-event and per-class results analysis

Here we analyse the performance of proposed models on each of the 5 largest events. Figure 4 illustrates the comparison of macro-averaged F-scores of the proposed models for each of the events. Multi-task learning models outperform single task learning approaches for each event. The Ferguson event is the hardest one for all of the models as it has a different class distribution to all other events (see Table 2).

Table 4 shows per event and per class performance of the multi-task learning model that incorporates all three tasks (MTL3). We have analysed similar performance breakdown tables for other models but omit them here because of space constraints. All models tend to predict the majority class (true) the best. As the Ferguson event is strongly dominated by unverified rumours, it is the only event with high performance on the unverified class. Single task models (NileTMRG*, branchLSTM) are better at identifying false than unverified rumours, whereas multitask models (MTL2, MTL3) are better at identifying unverified than false rumours.

6.2 Analysis of data properties

Alonso and Plank (2017) link the gains/losses in performance from multi-task learning with information-theoretical metrics, properties of the label distributions: entropy (indicating the amount of uncertainty in the distribution) and kurtosis (indicating the skewness of the distribution). They have shown that the multi-task learning setup works best for tasks which have label distributions with lower kurtosis and relatively high entropy. Table 5 shows the kurtosis and entropy properties of the label distribution for each of the events in the dataset, as well as token-type ratio (TTR). Each of the events has very different properties; there is a strong difference in properties between larger events (top) and smaller ones (bottom). Smaller events tend to have more extreme values, which may explain that their addition to the evaluation adds further complexity to the task of rumour verification. In line with findings of Alonso and Plank (2017), in our case both auxiliary tasks have on average lower kurtosis than the main

	Kurtosis			Entropy			TTR

Table 5: Properties of the datasets for each of the events and each of the tasks, where S - Stance, V - Veracity, and D - Detection.

task. The stance classification dataset has on average higher entropy than the rumour detection dataset. Whereas Alonso and Plank (2017) were considering low-level linguistically related tasks as auxiliary tasks, such as part-of-speech tagging, we are working with higher level theme-related tasks. Therefore, it is interesting that we still observe similar trends when looking at the same data properties.

7 Conclusions and Future Work

We have proposed a rumour verification model that achieves improved performance for veracity classification by leveraging task relatedness with auxiliary tasks, specifically rumour detection and stance classification, through a multi-task learning approach. We have compared single task learning approaches with the proposed multi-task learning approaches that combine the verification classifier with the stance and rumour detection classifiers individually, as well as with both the rumour detection system and the stance classifier. Our results show that the joint learning of two tasks from the verification pipeline outperforms a single-learning approach to rumour verification. The combination of all three tasks leads to further performance improvements. We have also investigated the link between the properties of the label distribution in the dataset and the outcomes of our multi-task learning models. Our results support findings from previous research (Alonso and Plank, 2017).

In future work we plan to investigate whether further improvements on main and auxiliary tasks are possible with multi-task learning by: adapting the training schedule to account for different dataset sizes, such that none of the tasks dominates the model; by incorporating the hierarchy between tasks into the model. We would like to investigate the effect of adding extra features (such as user features and interactions) on different tasks and at which stage to incorporate them, in private or shared layers.

Abstract

Open Information Extraction (OIE) is the task of the unsupervised creation of structured information from text. OIE is often used as a starting point for a number of downstream tasks including knowledge base construction, relation extraction, and question answering. While OIE methods are targeted at being domain independent, they have been evaluated primarily on newspaper, encyclopedic or general web text. In this article, we evaluate the performance of OIE on scientific texts originating from 10 different disciplines. To do so, we use two state-of-the-art OIE systems using a crowd-sourcing approach. We find that OIE systems perform significantly worse on scientific text than encyclopedic text. We also provide an error analysis and suggest areas of work to reduce errors. Our corpus of sentences and judgments are made available.

1 Introduction

The scientific literature is growing at a rapid rate (Bornmann and Mutz, 2015). To make sense of this flood of literature, for example, to extract cancer pathways (Poon et al., 2014) or find geological features (Leveling, 2015), increasingly requires the application of natural language processing. Given the diversity of information and its constant flux, the use of unsupervised or distantly supervised techniques are of interest (Quirk and Poon, 2017). In this paper, we investigate one such unsupervised method, namely, Open Information Extraction (OIE) (Banko et al., 2007). OIE is the task of the unsupervised creation of structured information from text. OIE is often used as a starting point for a number of downstream tasks including knowledge base construction, relation extraction, and question answering (Mausam, 2016).

While OIE has been applied to the scientific literature before (Groth et al., 2016), we have not found a systematic evaluation of OIE as applied to scientific publications. The most recent evaluations of OIE extraction tools (Gashteovski et al., 2017; Schneider et al., 2017) have instead looked at the performance of these tools on traditional NLP information sources (i.e. encyclopedic and news-wire text). Indeed, as (Schneider et al., 2017) noted, there is little work on the evaluation of OIE systems. Thus, the goal of this paper is to evaluate the performance of the state of the art in OIE systems on scientific text.

Specifically, we aim to test two hypotheses:

1. H1: There is no significant difference in the accuracy of OIE systems on scientific vs. general audience content.

2. H2: There is no significant difference in performance of current state-of-the-art OIE systems on scientific and medical content.

Additionally, we seek to gain insight into the value of unsupervised approaches to information extraction and also provide information useful to implementors of these systems. We note that our evaluation differs from existing OIE evaluations in that we use crowd-sourcing annotations instead of expert annotators. This allows for a larger number of annotators to be used. All of our data, annotations and analyses are made openly available.[1]

Proceedings of the 27th International Conference on Computational Linguistics, pages 3414–3423
Santa Fe, New Mexico, USA, August 20-26, 2018.

The rest of the paper is organized as follows. We begin with a discussion of existing evaluation approaches and then describe the OIE systems that we evaluated. We then proceed to describe the datasets used in the evaluation and the annotation process that was employed. This is followed by the results of the evaluation including an error analysis. Finally, we conclude.

2 Existing Evaluation Approaches

OIE systems analyze sentences and emit relations between one predicate and two or more arguments (e.g. Washington :: was :: president). The arguments and predicates are not fixed to a given domain. (Note, that throughout this paper we use the word 'triple" to refer interchangeably to binary relations.) Existing evaluation approaches for OIE systems have primarily taken a ground truth-based approach. Human annotators analyze sentences and determine correct relations to be extracted. Systems are then evaluated with respect to the overlap or similarity of their extractions to the ground truth annotations, allowing the standard metrics of precision and recall to be reported.

This seems sensible but is actually problematic because of different but equivalent representations of the information in an article. For example, consider the sentence "The patient was treated with Emtricitabine, Etravirine, and Darunavir". One possible extraction is:

(The patient :: was treated with :: Emtricitabine, Etravirine, and Darunavir)

Another possible extraction is:

(The patient :: was treated with :: Emtricitabine)
(The patient :: was treated with :: Etravirine)
(The patient :: was treated with :: Darunavir)

Neither of these is wrong, but by choosing one approach or the other a pre-constructed gold set will falsely penalize a system that uses the other approach.

From such evaluations and their own cross dataset evaluation, (Schneider et al., 2017) list the following common errors committed by OIE systems:

- wrong boundaries around the arguments or predicate of a relation;
- generation of redundant relations from the same sentence;
- wrong extractions (e.g. omitting large parts of a sentence as an argument);
- missing extractions - extractions that should have been extracted from a sentence;
- uninformative extractions that omit critical information from a sentence;

In our evaluation, we take a different approach. We do not define ground truth relation extractions from the sentences in advance. Instead, we manually judge the correctness of each extraction after the fact. We feel that this is the crux of the information extraction challenge. Is what is being extracted correct or not? This approach enables us to consider many more relations through the use of a crowd-sourced annotation process. Our evaluation approach is similar to the qualitative analysis performed in (Schneider et al., 2017) and the evaluation performed in (Gashteovski et al., 2017). However, our evaluation is able to use more judges (5 instead of 2) because we apply crowd sourcing.[2] For our labelling instructions, we adapted those used by (Gashteovski et al., 2017) to the crowd sourcing setting.[3]

As previously noted existing evaluations have also only looked at encyclopedic or newspaper corpora. Several systems (e.g. (Banko et al., 2007; Del Corro and Gemulla, 2013)) have looked at text from the web as well, however, as far as we know, none have specifically looked at evaluation for scientific and medical text.

[2](Schneider et al., 2017) also perform a ground truth based evaluation. This evaluation had many more sentences than ours, but used predefined gold extractions from multiple corpora annotated according to different criteria; illustrating the kinds of issues we mention with such an evaluation method.

[3]Labelling instructions are included in the associated dataset. - `http://dx.doi.org/10.17632/6m5dyx4b58.2#file-7edb4b86-c0e6-4169-aea0-4862d39461d3`

3 Systems

We evaluate two OIE systems (i.e. extractors). The first, OpenIE 4 (Mausam, 2016), descends from two popular OIE systems OLLIE (Fader et al., 2011) and Reverb (Fader et al., 2011). We view this as a baseline system. The second was MinIE (Gashteovski et al., 2017), which is reported as performing better than OLLIE, ClauseIE (Del Corro and Gemulla, 2013) and Stanford OIE (Del Corro and Gemulla, 2013). MinIE focuses on the notion of minimization - producing compact extractions from sentences. In our experience using OIE on scientific text, we have found that these systems often produce overly specific extractions that do not provide the redundancy useful for downstream tasks. Hence, we thought this was a useful package to explore.

We note that both OpenIE 4 and MiniIE support relation extractions that go beyond binary tuples, supporting the extraction of n-ary relations. We note that the most recent version of Open IE (version 5) is focused on n-ary relations. For ease of judgement, we focused on binary relations. Additionally, both systems support the detection of negative relations.

In terms of settings, we used the off the shelf settings for OpenIE 4. For MinIE, we used their "safe mode" option, which uses slightly more aggressive minimization than the standard setting. In the recent evaluation of MiniIE, this setting performed roughly on par with the default options (Gashteovski et al., 2017). Driver code showing how we ran each system is available.[4]

4 Datasets

We used two different data sources in our evaluation. The first dataset (WIKI) was the same set of 200 sentences from Wikipedia used in (Gashteovski et al., 2017). These sentences were randomly selected by the creators of the dataset. This choice allows for a rough comparison between our results and theirs.

The second dataset (SCI) was a set of 220 sentences from the scientific literature. We sourced the sentences from the OA-STM corpus.[5] This corpus is derived from the 10 most published in disciplines. It includes 11 articles each from the following domains: agriculture, astronomy, biology, chemistry, computer science, earth science, engineering, materials science, math, and medicine. The article text is made freely available and the corpus provides both an XML and a simple text version of each article.

We randomly selected 2 sentences with more than two words from each paper using the simple text version of the paper. We maintained the id of the source article and the line number for each sentence.

5 Annotation Process

We employed the following annotation process. Each OIE extractor was applied to both datasets with the settings described above. This resulted in the generation of triples for 199 of the 200 WIKI sentences and 206 of the 220 SCI sentences. That is there were some sentences in which no triples were extracted. We discuss later the sentences in which no triples were extracted. In total 2247 triples were extracted.

The sentences and their corresponding triples were then divided. Each task contained 10 sentences and all of their unique corresponding triples from a particular OIE systems. Half of the ten sentences were randomly selected from SCI and the other half were randomly selected from WIKI. Crowd workers were asked to mark whether a triple was correct, namely, did the triple reflect the consequence of the sentence. Examples of correct and incorrect triples were provided. Complete labelling instructions and the presentation of the HITS can be found with the dataset. All triples were labelled by at least 5 workers.

Note, to ensure the every HIT had 10 sentences, some sentences were duplicated. Furthermore, we did not mandate that all workers complete all HITS.

We followed recommended practices for the use of crowd sourcing in linguistics (Erlewine and Kotek, 2016). We used Amazon Mechanical Turk as a means to present the sentences and their corresponding triples to a crowd for annotation. Within Mechanical Turk tasks are called Human Intelligence Tasks (HITs). To begin, we collected a small set of sentences and triples with known correct answers. We did

[4]See directory "Code for applying information extraction tools" in the associated data - `http://dx.doi.org/10.17632/6m5dyx4b58.2#folder-39ce9705-ccf3-4f95-890a-508ce155ece4`

[5]`http://elsevierlabs.github.io/OA-STM-Corpus/`

this by creating a series of internal HITs and loaded them the Mechanical Turk development environment called the Mechanical Turk Sandbox. The HITs were visible to a trusted group of colleagues who were asked to complete the HITs.

Having an internal team of workers attempt HITs provides us with two valuable aspects of the eventual production HITs. First, internal users are able to provide feedback related to usability and clarity of the task. They were asked to read the instructions and let us know if there was anything that was unclear. After taking the HITs, they are able to ask questions about anomalies or confusing situations they encounter and allow us to determine if specific types of HITs are either not appropriate for the task or might need further explanation in the instructions. In addition to the internal users direct feedback, we were also able to use the Mechanical Turk Requester functionality to monitor how long (in minutes and seconds) it took each worker to complete each HIT. This would come into factor how we decided on how much to pay each Worker per HIT after they were made available to the public.

The second significant outcome from the internal annotations was the generation of a set of 'expected' correct triples. Having a this set of annotations is an integral part of two aspects of our crowdsourcing process. First, it allows us to create a qualification HIT. A qualification HIT is a HIT that is made available to the public with the understanding the Workers will be evaluated based on how closely they matched the annotations of the internal annotators. Based upon this, the Workers with the most matches would be invited to work on additional tasks. Second, we are able to add the internal set of triples randomly amongst the other relations we were seeking to have annotated. This allows us to monitor quality of the individual Workers over the course of the project. Note, none of this data was used in the actual evaluation. It was only for the purposes of qualifying Workers.

We are sensitive to issues that other researchers have in regards to Mechanical Turk Workers earning fair payment in exchange for their contributions to the HITs (Fort et al., 2011) . We used the time estimates from our internal annotation to price the task in order to be above US minimum wage. All workers were qualified before being issued tasks. Overall, we employed 10 crowd workers. On average it took 30 minutes for a worker to complete a HIT. In line with (Crump et al., 2013), we monitored for potential non-performance or spam by looking for long response times and consecutive submitted results. We saw no indicators of low quality responses.

6 Judgement Data and Inter-Annotator Agreement

In total, 11262 judgements were obtained after running the annotation process. Every triple had at least 5 judgements from different annotators. All judgement data is made available.[6] The proportion of overall agreement between annotators is 0.76 with a standard deviation of 0.25 on whether a triple is consequence of the given sentence. We also calculated inter-annotator agreement statistics. Using Krippendorff's alpha inter-annotator agreement was 0.44. This calculation was performed over all data and annotators as Krippendorff's alpha is designed to account for missing data and work across more than two annotators. Additionally, Fleiss' Kappa and Scott's pi were calculated pairwise between all annotators where there were overlapping ratings (i.e. raters had rated at least one triple in common). The average Fleiss's Kappa was 0.41 and the average of Scott's pi was 0.37. Using (Artstein and Poesio, 2008) as a guide, we interpret these statistics as suggesting there is moderate agreement between annotators and that agreement is above random chance. This moderate level of agreement is to be expected as the task itself can be difficult and requires judgement from the annotators at the margin.

Table 1 shows examples of triples that were associated with higher disagreement between annotators. One can see for example, in the third example, that annotators might be confused by the use of a pronoun (him). Another example is in the last sentence of the table, where one can see that there might be disagreement on whether the subsequent prepositional phrase behind light microscope analysis should be included as part of the extracted triple.

We take the variability of judgements into account when using this data to compute the performance of the two extraction tools. Hence, to make assessments as to whether a triple correctly reflects the content

[6] 'aggregated_results_anon.csv' in the associated dataset. - http://dx.doi.org/10.17632/6m5dyx4b58.2#file-03de3c93-8a01-4cd2-bfe5-c5bfeaa4f492

SYSTEM	SOURCE	TRIPLE	PAIRWISE AGREEMENT	SENTENCE
MinIE	SCI	additional QUANT_S_1 on scalp face :: were digitized :: QUANT_O_1 anatomical landmarks	40% False	To coregister MEG and sMRI data, three anatomical landmarks (nasion and right and left preauriculars) as well as an additional 150+ points on the scalp and face were digitized for each subject using the Probe Position Identification (PPI) System (Polhemus, Colchester, VT).
OpenIE 4	WIKI	Dawlish :: to 2nd :: place L:in the Western League	40% True	The previous season had seen him lead Dawlish to 2nd place in the Western League , their highest ever league finishing position .
MiniIE	WIKI	him :: lead Dawlish to 2nd place in :: Western League'	40% False	
MinIE	SCI	$> 250\,\mu\mathrm{m}$ fractions :: be found through :: light microscope analysis to be dominated by amorphous organic matter	40% True	'The $> 250\,\mu\mathrm{m}$ fractions, found through light microscope analysis to be dominated ($> 90\%$) by amorphous organic matter (AOM), were also analysed for $\delta 13C$.

Table 1: Examples of difficult to judge triples and their associated sentences.

from which it is extracted, we rely on the unanimous positive agreement between crowd workers. That is to say that if we have 100% inter-annotator agreement that a triple was correctly extracted we label it as correct.

7 Experimental Results

Table 2 show the results for the combinations of systems and data sources. The CORRECT TRIPLES column contains the number of triples that are labelled as being correct by all annotators. TOTAL TRIPLES are the total number of triples extracted by the given systems over the specified data. Precision is calculated as typical where Correct Triples are treated as true positives. On average, 3.1 triples were extracted per sentence.

Figure 1 shows the performance of extractors in terms of precision as inter-annotator agreement de-

SYSTEM	SOURCE	TOTAL TRIPLES	CORRECT TRIPLES	PRECISION
OpenIE 4 + MinIE	SCI + WIKI	2247	985	0.44
OpenIE 4 + MinIE	WIKI	1101	590	0.54
OpenIE 4 + MinIE	SCI	1146	395	0.34
MinIE	SCI + WIKI	1591	617	0.39
MinIE	WIKI	785	382	0.49
MinIE	SCI	806	235	0.29
OpenIE 4	SCI + WIKI	656	368	0.56
OpenIE 4	WIKI	316	208	0.66
OpenIE 4	SCI	340	160	0.47

Table 2: Results of triples extracted from the SCI and WIKI corpora using the Open IE and MinIE tools.

creases. In this figure, we look only at agreement on triples where the majority agree that the triple is correct. Furthermore, to ease comparison, we only consider triples with 5 judgements this excludes 9 triples. We indicate not only the pair-wise inter-annotator agreement but also the number of annotators who have judged a triple to be correct. For example, at the 40% agreement level at least 3 annotators have agreed that a triple is true. The figure separates the results by extractor and by data source.

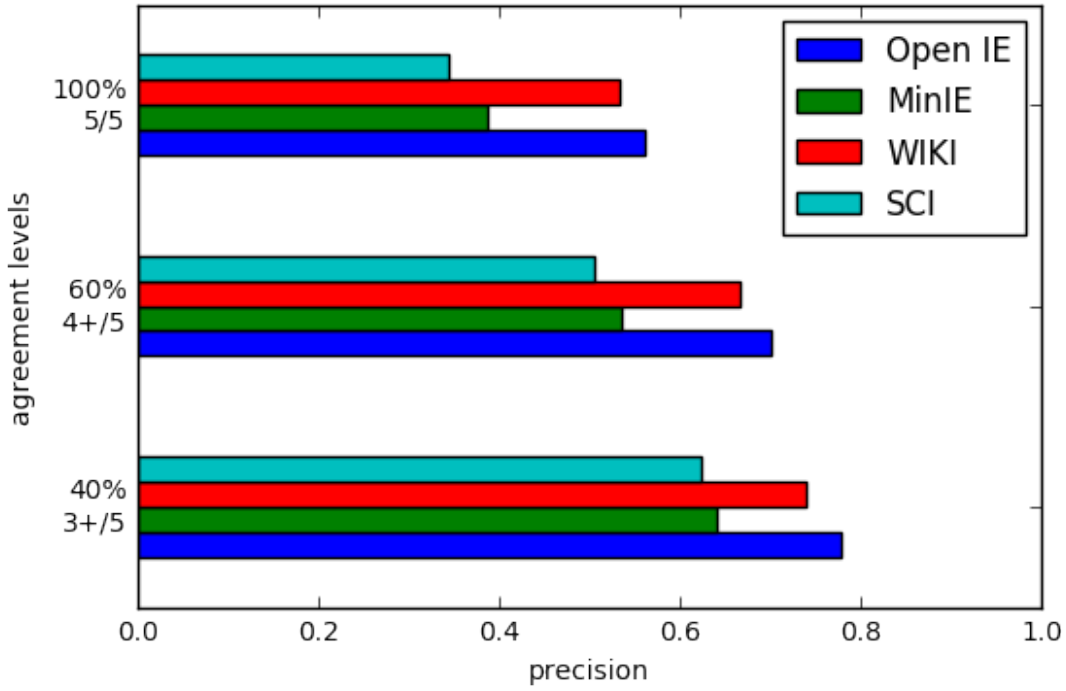

Figure 1: Precision at various agreement levels. Agreement levels are shown as the proportion of overall agreement. In addition, we indicate the the minimum number of annotators who considered relations correct out of the total number of annotators.

We see that as expected the amount of triples agreed to as correct grows larger as we relax the requirement for agreement. For example, analyzing Open IE's results, at the 100% agreement level we see a precision of 0.56 whereas at the 40% agreement level we see a precision of 0.78. Table 3 shows the total number of correct extractions at the three agreement levels.

AGREEMENT	OPEN IE 4 SCI	MINIE SCI	OPEN IE 4 WIKI	MINIE WIKI	OPEN IE 4 TOTAL	MINIE TOTAL
40% (3+/5)	253	462	256	553	509	1015
60% (4+/5)	218	361	241	488	459	849
100% (5/5)	160	235	207	377	367	612

Table 3: Correct triples at different levels of agreement subsetted by system and data source . Agreement levels follow from Figure 1

7.1 Testing H1: Comparing the Performance of OIE on Scientific vs. Encyclopedic Text

From the data, we see that extractors perform better on sentences from Wikipedia (0.54 P) than scientific text (0.34 P). Additionally, we see that there is higher annotator agreement on whether triples extracted from Wikipedia and scientific text are correct or incorrect: 0.80 - SD 0.24 (WIKI) vs. 0.72 - SD 0.25 (SCI). A similar difference in agreement is observed when only looking at triples that are considered to be correct by the majority of annotators: 0.87 - SD 0.21 (WIKI) vs. 0.78 - SD 0.25 (SCI) . In both cases, the difference is significant with p-values < 0.01 using Welch's t-test. The differences between

data sources are also seen when looking at the individual extraction tools. For instance, for Open IE 4 the precision is 0.19 higher for wikipedia extractions over those from scientific text. *With this evidence, we reject our first hypothesis that the performance of these extractors are similar across data sources.*

7.2 Testing H2: Comparing the Performance of Systems

We also compare the output of the two extractors. In terms precision, Open IE 4 performs much better across the two datasets (0.56P vs 0.39P). Looking at triples considered to be correct by the majority of annotators, we see that Open IE 4 has higher inter-annotator agreement 0.87 - SD 0.22 (Open IE) vs 0.81 - SD 0.24 (MinIE). Focusing on scientific and medical text (SCI), again where the triples are majority annotated as being correct, Open IE has higher inter-annotator agreement (Open IE: 0.83 - SD 0.24 vs MiniIE: 0.76 - SD 0.25). In both cases, the difference is significant with p-values < 0.01 using Welch's t-test. This leads us to conclude that Open IE produces triples that annotators are more likely to agree as being correct.

MinIE provides many more correct extractions than OpenIE 4 (935 more across both datasets). The true recall numbers of the two systems can not be calculated with the data available, but the 40% difference in the numbers of correct extractions is strong evidence that the two systems do not have equivalent behavior.

A third indication of differences in their outputs comes from examining the complexity of the extracted relations. Open IE 4 generates longer triples on average (11.5 words) vs. 8.5 words for MinIE across all argument positions. However, Open IE 4 generates shorter relation types than MinIE (Open IE - 3.7 words; MiniIE 6.27 words) and the standard deviation in terms of word length is much more compact for Open IE 4 - 1 word vs 3 words for MinIE. *Overall, our conclusion is that Open IE 4 performs better than MinIE both in terms of precision and compactness of relation types, while not matching MinIE's recall, and thus we reject our second hypothesis.*

7.3 Other Observations

The amount of triples extracted from the scientific text is slightly larger than that extracted from the Wikipedia text. This follows from the fact that the scientific sentences are on average roughly 7 words longer than encyclopedic text.

The results of our experiment also confirm the notion that an unsupervised approach to extracting relations is important. We have identified 698 unique relation types that are part of triples agreed to be correct by all annotators. This number of relation types is derived from only 400 sentences. While not every relation type is essential for downstream tasks, it is clear that building specific extractors for each relation type in a supervised setting would be difficult.

8 Error Analysis

We now look more closely at the various errors that were generated by the two extractors.

Table 4 shows the sentences in which neither extractor produced triples. We see 3 distinct groups. The first are phrases that are incomplete sentences usually originating from headings (e.g. Materials and methods). The next group are descriptive headings potentially coming from paper titles or figure captions. We also see a group with more complex prepositional phrases. In general, these errors could be avoided by being more selective of the sentences used for random selection. Additionally, these systems could look at potentially just extracting noun phrases with variable relation types, hence, expressing a cooccurrence relation.

We also looked at where there was complete agreement by all annotators that a triple extraction was incorrect. In total there were 138 of these triples originating from 76 unique sentences. There were several patterns that appeared in these sentences.

- Long complex sentences led to incorrect extractions. For example, ``Most strikingly, there was a mutant gene-dose-dependent increase in caspase-cleaved TAU fragments, as determined by the caspase-cleaved TAU-specific antibody C3 (Gamblin et al., 2003; Guillozet-Bongaarts et al., 2005), in neurons derived from the isogenic

WIKI	Simultaneously won the " Hope of the World Ballet " Prize .

Table 4: Sentences in which no triples were extracted

`TAU-A152T-iPSCs (Figures 4J and 4K).''`) led to the following triples that were deemed incorrect: `isogenic TAU-A152T-iPSCs :: is :: Figures` and `Gamblin et :: is :: caspase-cleaved TAU-specific antibody C3`

- The use of pronouns as subjects led to triples that were deemed to be incorrect. (e.g. `''So he was forced to requisition not only the public treasury of Gades but also the wealth from its temples.` led to the following incorrect triples: `he :: was forced :: to requisition not only the public treasury of Gades but also the wealth from its temples` and `he :: to requisition :: not only the public treasury of Gades but also the wealth from its temples.`

- Complex mathematical formula often generated incorrect triples

- MinIE as part of its extraction process substitutes quantities with variables (e.g. QUANT_1). We included this potential in our labelling instructions but this often led to triples that were labelled as incorrect by the annotators. We believe this source of error could stem from the given instructions.

- Reuse of abbreviations as adjectives also led to incorrect triples. For example, "BMP antagonists" and "BMP pathway" in the following sentence: `We also observed significant transcriptional changes in WNT and BMP pathway components such as an increase in the WNT pathway inhibitor DKK-1 and BMP antagonists, such as GREMLIN-1 and BAMBI (Figures 2B-2D), which are known transcriptional targets of BMP signaling (Grotewold et al., 2001).` led to the following triples that were labelled incorrect: `BMP antagonists :: are known ::` and `increase :: is :: bmp pathway component.`

We also see similar errors to those pointed out by (Schneider et al., 2017), namely, uninformative extractions, the difficulty in handling n-ary relations that are latent in the text, difficulties handling negations, and very large argument lengths. In general, these errors together point to several areas for further improvement including:

- deeper co-reference resolution either for variables in mathematical formula or for pronouns;
- improved handling of prepositional phrases;
- relaxing requirements for correct grammar within sentences;
- better handling of abbreviations.

9 Conclusion

The pace of change in the scientific literature means that interconnections and facts in the form of relations between entities are constantly being created. Open information extraction provides an important tool to keep up with that pace of change. We have provided evidence that unsupervised techniques are needed to be able to deal with the variety of relations present in text. The work presented here provides an independent evaluation of these tools in their use on scientific text. Past evaluations have focused on encyclopedic or news corpora which often have simpler structures. We have shown that existing OIE systems perform worse on scientific and medical content than on general audience content.

There are a range of avenues for future work. First, the application of Crowd Truth framework (Aroyo and Welty, 2013) in the analysis of these results might prove to be useful as we believe that the use of unanimous agreement tends to negatively impact the perceived performance of the OIE tools. Second, we think the application to n-ary relations and a deeper analysis of negative relations would be of interest. To do this kind of evaluation, an important area of future work is the development of guidelines and tasks for more complex analysis of sentences in a crowd sourcing environment. The ability, for example, to indicate argument boundaries or correct sentences can be expected of expert annotators but needs to implemented in a manner that is efficient and easy for the general crowd worker. Third, we would like to expand the evaluation dataset to an even larger numbers of sentences. Lastly, there are a number of core natural language processing components that might be useful for OIE in this setting, for example, the use of syntactic features as suggested by (Christensen et al., 2011). Furthermore, we think that coreference is a crucial missing component and we are actively investigating improved coreference resolution for scientific texts.

To conclude, we hope that this evaluation provides further insights for implementors of these extraction tools to deal with the complexity of scientific and medical text.

Abstract

Standard word embedding algorithms learn vector representations from large corpora of text documents in an unsupervised fashion. However, the quality of word embeddings learned from these algorithms is affected by the size of training data sets. Thus, applications of these algorithms in domains with only moderate amounts of available data is limited. In this paper we introduce an algorithm that learns word embeddings jointly with a classifier. Our algorithm is called SWESA (Supervised Word Embeddings for Sentiment Analysis). SWESA leverages document label information to learn vector representations of words from a modest corpus of text documents by solving an optimization problem that minimizes a cost function with respect to both word embeddings and the weight vector used for classification. Experiments on several real world data sets show that SWESA has superior performance on domains with limited data, when compared to previously suggested approaches to word embeddings and sentiment analysis tasks.

1 Introduction

Word embedding algorithms learn vector representations for words that are useful to quantify semantic relationships between words in a given text. Additionally, word embeddings are used to initialize several algorithms for sentiment analysis, sentence encoding etc. Currently popular embedding algorithms such as word2vec (Mikolov et al., 2013b; Le and Mikolov, 2014), GloVe (Pennington et al., 2014), are based off neural network methods and have achieved tremendous success in various word, sentence/document level evaluation tasks. These algorithms thrive on the large volumes of training data sets when learning high quality word embeddings. However, there is an increase in application domains where getting large amounts of data is not always possible. Furthermore, in some of these domains, representing words from off-the-shelf word embeddings such as ones obtained from training word2vec, GloVe on Wikipedia or common-crawl may not be efficient. This is because the sentiment expressed by a word in such datasets could be somewhat different from the sentiment expressed by the same word when it appears in Wikipedia, common-crawl. A concrete example of such domains is given in the next paragraph. *In such cases off-the-shelf word embeddings are not very useful and better techniques are required to learn word embeddings and classifiers for sentiment analysis.*

The goal of this paper is to build classification algorithms for sentiment analysis on small, domain specific data sets that are sentiment rich. Such an algorithm is not limited to sentiment classification and easily generalizes to other text classification problems as well. An example of a small sized and sentiment rich data set is the Substance Use Disorder (SUD) data set (Mohr et al., 2013), (Moore et al., 2011) obtained from digital health intervention treatments. These treatments aim to predict relapse risk by analyzing the content of participants' text messages. Though forum moderators can monitor and provide support when participants are struggling, considerable labor is involved in reviewing and deciding the risk level of each text message. Text data obtained from these discussion forums is rich in sentiments such as 'determination,' 'pleasure,' 'anger,' 'fear' and by analyzing discussion messages for

Proceedings of the 27th International Conference on Computational Linguistics, pages 3424–3435
Santa Fe, New Mexico, USA, August 20-26, 2018.

sentiments such as 'anger', 'fear' it is possible to develop efficient algorithms that can automatically tag if a message is positive (i.e. benign) or negative (indicative of relapse).

One approach to this problem would be to use off-the-shelf word embeddings to learn document embeddings and then run a classification algorithm on the obtained embeddings. While this approach does decently well it fails to capture and exploit the semantics of within domain words. For example, consider words such as 'alcohol,' 'holiday,' 'party.' Such words are typically neutral or positive sentiment in the Wikipedia corpus. However, with data sets such as SUD, these words are indicative of a moderate/strong negative sentiment. As a result using off-the-shelf word embeddings from GloVe, word2vec embeddings trained on Wikipedia corpus for building a sentiment analyzer will result in a sentiment analyzer that performs poorly. An alternative is to obtain word embeddings by training word2vec or GloVe on the target dataset, and then using the resultant embeddings for sentiment analysis. Unsurprisingly this approach succeeds only when one has the luxury of large datasets. However, in the SUD application, as mentioned above, the amount of data that is available is limited and hence this approach is not a successful alternative. In fact we argue that in the presence of limited, but sentiment rich data, it is better to learn word embeddings in a supervised manner. This way the resulting embeddings tend to be polarity-aware and are better suitable for downstream tasks such as sentiment analysis. Our contributions are as follows,

1. We introduce an algorithm (Section 3) that jointly learns word embeddings as well as a sentiment analyzer (classifier) by solving a bi-convex optimization problem. Our algorithm is called Supervised Word Embedding for Sentiment Analysis (SWESA) . This is an iterative algorithm that minimizes a cost function for both a classifier and word embeddings under unit norm constraint on the word vectors.

2. SWESA uses document labels for learning word embeddings. Using document labels within SWESA helps us overcomes the problem of small-size training data and allows learning of polarity-aware word embeddings. Via a thorough empirical evaluation (Section (4)) we show that our algorithm outperforms classifiers built by re-training off-the-shelf word embeddings such as word2vec, GloVe. We also compare SWESA against an algorithm that uses convolutional neural networks to represent sentences (Kim, 2014) for sentiment analysis, and a sentiment analysis algorithm based on recurrent neural networks (Socher et al., 2013). On the A-CHESS dataset where data is limited but rich in sentiment, SWESA outperforms all algorithms by at least 12% on the precision.

3. To demonstrate the fact that the word embeddings learned by SWESA are better than embeddings learned from unsupervised learning algorithms we investigate the polarity of various word embeddings. We show that the embeddings learned from SWESA perform well on antonym task. For example, 'Awful/Good' is the antonym pair returned via SWESA as opposed to 'Awful/Could' obtained via word2vec. SWESA learns such antonym pairs, using document polarities, and as a byproduct of our optimization based formulations, independent of an antonym pairs training data set.

2 Related Work

Modern embedding algorithms such as word2vec (Mikolov et al., 2013a) and GloVe (Pennington et al., 2014) are neural network based algorithms that learn word embeddings in an unsupervised fashion. These algorithms exploit word co-occurrence statistics in order to learn word embeddings. Due to this, typically these algorithms thrive on large training data sets in order to learn generic word embeddings. Also these models learn word embeddings in an unsupervised fashion. However, using labeled data can often help with learning sentiment-aware word embeddings more appropriate to the corpus at hand In their work (Maas et al., 2011) propose a probabilistic model that captures semantic similarities among words across documents. This model leverages document label information to improve word vectors to better capture sentiment of the contexts in which these words occur. While it may seem that this model is similar to SWESA, it is not so because in their model (Maas et al., 2011) first learn word embeddings and then fit a classifier in two different objective functions. On the other hand SWESA is a single bi-convex objective. The probabilistic model used by (Maas et al., 2011) is similar to that in Latent Dirichlet

Allocation (LDA) (Blei et al., 2003) in which each document is modeled as a mixture of latent topics. In (Maas et al., 2011), word probabilities in a document are modeled directly assuming a given topic. Yet another model that makes use of word co-occurence features in a supervised learning task is that of (Aga et al., 2016). In this model word co-occurences and context are used to learn word embeddings through matrix factorization algorithms. However, the classification task is independent of the process used to learn word embeddings.

(Tang et al., 2014) propose a supervised neural network based model to classify Twitter data. The proposed algorithm learns sentiment specific word vectors, from tweets making use of emoticons in text to guide sentiment of words used in the text instead of annotated sentiment labels. The Recursive Neural Tensor Network (RNTN) proposed by (Socher et al., 2013) classifies sentiment of text of varying length. To learn sentiment from long text, this model exploits compositionality in text by converting input text into the Sentiment Treebank format with annotated sentiment labels. The Sentiment Treebank is based on a data set introduced by Pang and Lee (Pang and Lee, 2005). This model performs particularly well on longer texts by exploiting compositionality as opposed to a regular bag of features approach. A popular algorithm for sentiment analysis is the CNN based approach proposed by (Kim, 2014). This algorithm takes as input word embedding and learns a CNN based sentence composition on which sentiment analysis is performed. Finally we would like to mention that in some domains, the vocabulary in the domain is manually labeled. For example, SentiStrength (Thelwall et al., 2010), LIWC (Pennebaker et al., 2001) projects provide manually labeled data. However, such efforts are not scalable and need considerable human expertise.

Notation: Throughout this paper we shall denote word vectors as $\mathbf{w}_j \in \mathbb{R}^k$, for $j = 1, \ldots, V$, where V indicates the size of the vocabulary. The matrix of word vectors is $\mathbf{W}$ where $\mathbf{W} = [\mathbf{w}_1, \mathbf{w}_2, \ldots, \mathbf{w}_V] \in \mathbb{R}^{k \times V}$. The classifier to be learned is represented by $\boldsymbol{\theta} \in \mathbb{R}^k$, weights of word vectors $\mathbf{w}_j$ in document i are contained in the vector $\boldsymbol{\phi}_i \in \mathbb{R}^V$, and the document label of the i^{th} document is indicated by y_i, document i is represented as $d_i = \mathbf{W}\,\boldsymbol{\phi}_i$. Let $\Phi = [\boldsymbol{\phi}_1, \boldsymbol{\phi}_2, \ldots, \boldsymbol{\phi}_N] \in \mathbb{R}^{V \times N}$ be the matrix containing weight vectors $\boldsymbol{\phi}_i$ and vector $\mathbf{y} = [y_1, y_2, ...y_N]$ be the vector containing document labels.

3 Supervised Word Vectors for Sentiment Analysis

Given a collection of documents $d_1, d_2, \ldots d_N$ with binary sentiments $y_1, y_2, \ldots, y_N$ respectively, the aim is to learn a classifier that when given a new, previously unseen document d can accurately estimate the sentiment of the document. There could be class imbalance in the training data and so the algorithm should explicitly account for such a class imbalance. We approach this problem by introducing a new algorithm called SWESA. SWESA simultaneously learns word vector embeddings and a classifier, by making use of document polarity/sentiment labels. Representation of documents within SWESA is motivated by the fact that in short texts like "I am sad", "I am happy", polarity of the sentence hinges on the words "sad" and "happy". As a result, by learning polarity aware word embeddings, good vector representations for documents can be achieved. For instance, in the above example, the distance between the vectors $(\mathbf{w}_I + \mathbf{w}_{am} + \mathbf{w}_{sad})$ and $(\mathbf{w}_I + \mathbf{w}_{am} + \mathbf{w}_{happy})$ would capture dissimilarities in sentiment of these two documents while at the same time reflecting similarities in sentence structure.

Text documents in this framework are represented as a weighted linear combination of words in a given vocabulary. Weights can be either the term frequencies (tf) of words within each document or term frequency-inverse document frequency (tf-idf). Weights provided as input to SWESA for experiments described in Section (4) are term frequencies. We choose this weighting scheme to mimic the concept of local context used in the word2vec family of algorithms. Global co-occurrence information can be leveraged by using tf-idf for weighting words in documents. Such an approach in not entirely unheard off in sentiment analysis tasks, where word embeddings are considered as features for a classification algorithm (Labutov and Lipson, 2013).

SWESA aims to find vector representations for words, which when combined using weights, in a bag-of-words framework provide us with embeddings for text documents. These embeddings should be such that applying a nonlinear transformation f to the product $(\theta^\top\, \mathbf{W}\, \boldsymbol{\phi})$ results in a binary label y indicating

the polarity of document. Mathematically we assume that,

$$\mathbb{P}[Y = 1|d = \mathbf{W}\,\boldsymbol{\phi}, \boldsymbol{\theta}] = f(\boldsymbol{\theta}^\top \mathbf{W}\,\boldsymbol{\phi}) \tag{1}$$

for some function f. In order to solve for $\boldsymbol{\theta}$ and $\mathbf{W}$, a regularized negative likelihood minimization problem is solved. This optimization problem is as (1) and can be solved as a minimization problem with objective function,

$$J(\boldsymbol{\theta}, \mathbf{W}) \stackrel{\text{def}}{=} \frac{-1}{N}\Big[\mathrm{C}_+ \sum_{y_i=+1} \log \mathbb{P}(Y = y_i|\,\mathbf{W}\,\boldsymbol{\phi}_i, \boldsymbol{\theta}) + \mathrm{C}_- \sum_{y_i=-1} \log \mathbb{P}(Y = y_i|\,\mathbf{W}\,\boldsymbol{\phi}_i, \boldsymbol{\theta})\Big] + \lambda_{\boldsymbol{\theta}}||\,\boldsymbol{\theta}\,||_2^2. \tag{2}$$

This optimization problem can now be written as

$$\begin{aligned} \min_{\substack{\boldsymbol{\theta}\in\mathbb{R}^k,\\ \mathbf{W}\in\mathbb{R}^{k\times V}}} \quad & J(\boldsymbol{\theta}, \mathbf{W}) \\ \text{s.t. } & ||\,\mathbf{w}_j\,||_2 = 1\ \forall j = 1, \ldots V. \end{aligned} \tag{3}$$

The vector $\boldsymbol{\phi}_i$ is a vector of weights, corresponding to the different words, for document d_i. As mentioned previously, for testing SWESA term frequencies of different words in a certain document i are used in $\boldsymbol{\phi}_i$. $\lambda_\theta > 0$ is the regularization parameter for the classifier θ, C_+ is the cost associated with misclassifying a document from the positive class and C_- is the cost associated with misclassifying a document from the negative class. Following the heuristic suggested by (Lin et al., 2002), $\mathrm{C}_+ = \frac{\mathrm{N}_-}{N}$ and $\mathrm{C}_- = \frac{\mathrm{N}_+}{N}$, where N_+ is the number of positive documents in the corpus and N_- is the number of negative documents in the corpus. This scheme is particularly useful when dealing with data sets with imbalanced classes. When using a balanced data set $\mathrm{C}_+ = \mathrm{C}_-$. Sentiment in a given document is captured by the document label y_i, which in this framework is a binary label that capture sentiments such as 'positive/negative' or 'threatening/benign' depending on the data set.

The unit norm constraint in the optimization problem shown in (3) is enforced on word embeddings to discourage degenerate solutions of $\mathbf{w}_j$. For example in the absence of this constraint, the optimal $\mathbf{w}_j^*$ is typically a vector of zeros. Note that this optimization problem is bi-convex, but it is not jointly convex in the optimization variables. Algorithm 1 shows the algorithm that we use to solve the optimization problem in (3). This algorithm is an alternating minimization procedure that initializes the word embedding matrix $\mathbf{W}$ with $\mathbf{W}_0$ and then alternates between minimizing the objective function w.r.t. the weight vector $\boldsymbol{\theta}$ and the word embeddings $\mathbf{W}$.

Algorithm 1 Supervised Word Embeddings for Sentiment Analysis (SWESA)

Require: $\mathbf{W}_0$, Φ, C_+, C_-, λ_θ, $0 < k < V$, Labels: $\mathbf{y} = [y_1, \ldots, y_N]$, Iterations: $T > 0$,

1: Initialize $\mathbf{W} = \mathbf{W}_0$.
2: **for** $t = 1, \ldots, T$ **do**
3: Solve $\boldsymbol{\theta}_t \leftarrow \arg\min_{\boldsymbol{\theta}} J(\boldsymbol{\theta}, \mathbf{W}_{t-1})$.
4: Solve $\mathbf{W}_t \leftarrow \arg\min_{\mathbf{W}} J(\boldsymbol{\theta}_t, \mathbf{W})$.
5: **end for**
6: Return $\boldsymbol{\theta}_T, \mathbf{W}_T$

3.1 Logistic regression model

The optimization problem in (2) assumes a certain probability model and minimizes the negative log-likelihood under norm constraints. While, the specific goal of the user might dictate an appropriate choice of probabilistic model, for a large class of classification tasks such as sentiment analysis, the logistic regression model is widely used. In this section we assume that the probability model of interest is the logistic model. Under this assumption the minimization problem in Step 3 of Algorithm 1 is a

standard logistic regression problem [1]. Many specialized solvers have been devised for this problem and in this implementation of SWESA, a standard off-the-shelf solver available in the scikit-learn package in Python is used. In order to solve the optimization problem in line 4 of Algorithm 1 a projected stochastic gradient descent (SGD) with suffix averaging (Rakhlin et al., 2011) is used. In suffix averaging the last few iterates obtained during stochastic gradient descent are averaged. Suffix averaging guarantees that the noise in the iterates is reduced and has been shown to achieve almost optimal rates of convergence for minimization of strongly convex functions. For experiments in Section 4 we set $\tau = 50$.

Gradient updates for $\mathbf{W}$ given $\boldsymbol{\theta}$ are of the form

$$\nabla J(\boldsymbol{\theta}, \mathbf{W}) = \frac{1}{N}\Big[\sum_{y_i=+1} \frac{-\,\mathrm{C}_+\, y_i\, \boldsymbol{\theta}\, \boldsymbol{\phi}_i^\top}{1 + e^{y_i(\boldsymbol{\theta}^\top \mathbf{W}\, \boldsymbol{\phi}_i)}} + \sum_{y_i=-1} \frac{-\,\mathrm{C}_-\, y_i\, \boldsymbol{\theta}\, \boldsymbol{\phi}_i^\top}{1 + e^{y_i(\boldsymbol{\theta}^\top \mathbf{W}\, \boldsymbol{\phi}_i)}}\Big]. \tag{4}$$

Algorithm 2 implements the SGD algorithm (with stochastic gradients instead of full gradients) for solving the optimization problem in step 4 of Algorithm 1.

Algorithm 2 Stochastic Gradient Descent for $\mathbf{W}$

Require: $\boldsymbol{\theta}, \gamma, \mathbf{W}_0$, Labels: $\mathbf{y} = [y_1, \ldots, y_N]$, Iterations: N, step size: $\eta > 0$, and suffix parameter: $0 < \tau \leq N$.

1: Randomly shuffle the dataset.
2: **for** $t = 1, \ldots, N$ **do**
3: Set $C_t = C_+$ if $y_t = +1$, $C_t = C_-$ if $y_t = -1$.
4: $\widetilde{\mathbf{W}}_{t+1} = \mathbf{W}_t - \frac{\eta C_t}{1+e^{y_i(\boldsymbol{\theta}^\top \mathbf{W}\, \boldsymbol{\phi}_i)}} \times (-y_i\, \boldsymbol{\theta}\, \boldsymbol{\phi}_i^\top)$
5: $\mathbf{W}_{t+1,j} = \mathbf{W}_{t+1,j} \,/ || \,\mathbf{W}_{t+1,j}\, ||_2 \; \forall j = 1, 2, \ldots, V$
6: $\eta \leftarrow \frac{\eta}{t}$
7: **end for**
8: Return $\mathbf{W} = \frac{1}{\tau} \sum_{t=N-\tau}^{N} \mathbf{W}_t$

Convergence of SWESA: At a high level, SWESA can be seen as a variation of the supervised dictionary learning problem (SDL). Within SDL (Mairal et al., 2009) given labeled data $(x_1, y_1), (x_2, y_2), \ldots, (x_n, y_n)$, and unlabeled part of the data that lies in a d dimensional space, the goal is to learn a dictionary D of size $d \times k$, $(k >> d)$ such that each $x_i = Dz_i$ where z_i is a sparse encoding of x_i w.r.t. dictionary D. Further, the label is generated by a linear classifier w.r.t z_i, i.e. $y_i = \mathbf{W}^\top z_i$. The learning problem is to estimate the dictionary, the codes of each data point and the classifier. SWESA can be roughly mapped to the SDL by considering dictionary D of size $k \times V$, where each column corresponds to a word embedding. However, there are significant differences between SWESA and SDL. Despite these differences, with suitable modifications convergence analysis for SWESA can be performed. Extensive literature on alternative minimization and their convergence guarantees for SDL and related problems such as matrix completion (Jain et al., 2013) exist. A full theoretical analysis is out of scope of this paper and is left for future work. A brief description of differences between SWESA and SDL can be found in Appendix A.

3.2 Initialization of W

Two different initialization procedures are used to obtain $\mathbf{W}_0$. The first method uses the Latent Semantic Analysis (Dumais, 2004) (LSA) procedure to form the matrix of word vectors $\mathbf{W}_0$ from the given corpus of text documents. The second method uses the word2vec (w2v) algorithm to form word vector matrix $\mathbf{W}_0$ from the corpus. Since word2vec is ideally trained on a dataset that is much larger in size than the test datasets in Section 4, it is expected that the initialization vectors obtained by retraining word2vec on the test data sets will not be as suitable as the LSA intialization. However, as expected SWESA improves the performance of any initial guess parameters.

[1] A bias term, γ can be trivially introduced in the logistic regression model.

4 Experimental Evaluation and Results

We now describe in brief the data sets and the algorithms that we use to evaluate SWESA.

4.1 Data Sets

We conduct our experiments on four small sized data sets out of which 3 are balanced and 1 is imbalanced. All four data sets are drawn from different domains and hence have different vocabularies and contexts. The four data sets are:

- **Yelp:** This data set consists of 1000 restaurant reviews labeled 'positive' or 'negative'. There are a total of 2049 distinct word tokens in this data set.
- **IMDB:** This data set consists of 1000 reviews of movies with labels 'positive' or 'negative'. There are a total of 3075 distinct word tokens.
- **Amazon:** This data set contains 1000 product reviews with labels 'positive' or 'negative'. This data set has 1865 distinct word tokens.
- **A-CHESS:** This is a proprietary data set[2] and is obtained from an intervention treatment aimed at alcohol disorder. Text is obtained via the discussion forums part of the A-CHESS mobile app. There are a total of 2500 messages with 8% of the messages indicating relapse risk or 'threat'. Typical messages from this data set are of the form, *"I've been clean for 7 months now, but I still feel I may not make it"*. Such a message is marked as 'threat'. Positive or 'benign' messages are of the form, *"30 days and sober! I feel great!!"*. This labeling is human moderated. The goal is to automate this process. After removing special characters, this data set consists of 3400 distinct word tokens.

The first three data sets are obtained from (Kotzias et al., 2015).

4.2 Baselines

We choose two types of baselines that cover both neural and non-neural network style algorithms.
Standard baselines:

1. **Two-Step (TS):** The TS algorithm is a family of algorithms where we perform two steps (i) First, word embeddings are trained in an unsupervised manner on the target dataset. These word embeddings are combined together with appropriate weights (as is done in SWESA) to obtain document embeddings. (ii) In the second step the document embeddings obtained from the first step are used in a logistic regression classifier to obtain a classification model. To implement our first step we use two types of word embeddings, namely LSA word embeddings, and word2vec (re-w2v) obtained by re-training LSA, and word2vec algorithms on our target datasets. We use an open source implementation in gensim[3] to get word2vec embeddings.
2. **Naive Bayes classifier:** The classic Naive Bayes classifier for sentiment classification based on the Bag-of-words features, optimized in NLTK toolkit in Python is used.

Neural network based baselines:

1. **Recursive Neural Tensor Network (RNTN):** RNTN is an RNN proposed by (Socher et al., 2013) that learns compositionality from text of varying length and performs classification in a supervised fashion with fine grained sentiment labels. Since SWESA is aimed at binary classification, RNTN is also used in a binary classification framework. RNTN has been shown to perform better than the previously proposed Recursive Auto Encoder (RAE) by (Socher et al., 2011) and hence we limit our comparisons to RNTN only.

[2]Center for Health Enhancement System Services at UW-Madison.
[3]`https://radimrehurek.com/gensim/models/word2vec.html`

2. **CNN based sentence classification:** (Kim, 2014) propose a Convolutional Neural Network (CNN) based architecture that takes as input word embeddings and uses a CNN based architecture to learn sentence embeddings. These sentence embeddings are then used for classification. This algorithm belongs to a large class of algorithms that take as input word embedding and learn sentence embeddings for other tasks. While it seems that SWESA is similar to these algorithms, the significant difference between the two lies in the application domain of SWESA. SWESA is geared towards small sized datasets, whereas neural network based algorithms are data intensive and can extract useful relationships from very large amounts of data.

Note that neural network based baselines are used in two modes,

- **Pre-trained (Pr-tr):** In this framework both RNTN and CNN-static (CNN-S), CNN-non static (CNN-NS) are initialized with word2vec embeddings (w2v) and are trained on the Pang and Lee data set (Pang and Lee, 2005). This data set consists of roughly 10k text documents and is roughly 10 times the size of the data sets considered in experiments in Section 4.4. Note that in these experiments, word embeddings used are obtained from word2vec trained on the Google news data set and do not make use of any labels from the test data sets considered.

- **Re-trained (Re-tr):** In this framework, RNTN is retrained on the data sets described in subsection 4.1. Further, CNN-static and non static are used in the following ways,

    1. CNN-static and CNN-non static are initialized with re-trained w2v (re-w2v) embeddings. The training set is still the Pang and Lee data set used by the authors (Kim, 2014). We expect the performance of this baseline to be poorer when compared to CNN-static and non static initialized with pre-trained word embeddings. This baseline is used to investigate the sensitivity of CNNs to initial input word embeddings.
    2. CNN-static and CNN-non static are initialized with pre-trained word2vec embeddings but trained on train/dev sets obtained from the data sets described in subsection 4.1. We expect this data set to be the least well performing data set due to the size of the training data. This baseline is used to illustrate the limitations of small sized training data sets on neural network algorithms.

4.3 Dimensionality of word embeddings and hyperparameters

Dimensions of word embeddings and other hyperparameters such as regularization on the logistic regression classifier are determined via 10 fold cross validation. Pre-trained RNTN[4] and CNN-static/non static[5] are used with the training sets and parameters as described by the authors of both works. Procedure for retraining RNTN as well as for fine tuning word embeddings for use in CNN-non static follow the methods described in (Socher et al., 2013) and (Kim, 2014) respectively.

4.4 Results from classification tasks

Performance metrics reported are average Precision and average AUC. AUC is only reported for model that provide prediction probabilities in addition to predicted label. For the A-CHESS data set the minor class, i.e 'threat' owing to the large imbalance is of more importance. This is because, the system can accept few false positives, but the risk of misclassifying a 'threat' message as 'benign' has a larger impact. Owing to this, on this data set, the best performing classifier will be one that achieves maximum precision. Note that the objective of these results is to show how well SWESA performs in applications with small sized data sets as compared to i) completely re-training a neural network with a smaller training set, ii) or initializing a neural network with word embeddings learned on small data sets and iii) against a neural network that uses pre-trained word embeddings and larger training sets.

SWESA against pre-trained neural nets initialized with pre-trained word embeddings: On the balanced Yelp, Amazon and IMDB data sets, pre-trained RNTN, CNN-static and non static perform the

[4] https://nlp.stanford.edu/sentiment/code.html
[5] https://github.com/yoonkim/CNN_sentence

best. From table 1, observe that the best performing baseline CNN-NS achieves an average precision of 87.98, 87.15 and 87.77 respectively on the three balanced data sets. This result is *not surprising*, given that the pre-trained RNTN and CNNS are i)initialized with pre-trained word embeddings and ii)trained on a data set with roughly 10 times more training data points than within SWESA. However, note that on the imbalanced A-CHESS data set RNTN fails to perform any classification. This can be attributed to the fact that RNTN is a dependency parser and on varying length text like within SWESA, it is very hard to capture dependencies. CNN-static and CNN-non static achieve poor precision owing to the class imbalance which is not accounted for when training them.

SWESA against re-trained neural nets: CNN-static (re-w2v) and CNN-non static (re-w2v) perform comparably well to SWESA on the balanced data sets. From table 1 notice that on the balanced Yelp, Amazon and IMDB data sets, SWESA achieves an average precision of 78.35, 80.36 and 77.27 respectively while CNN-non static (re-w2v) achieves an average precision of 78.10, 80.40 and 75.85 respectively. These results suggest that SWESA is a suitable alternative to neural network architectures that are sensitive to initializing word embeddings. This result is particularly useful for data sets that are not large enough to enable learning of high quality word embeddings. Note that on the A-CHESS data set CNN-static and non static perform poorly.

SWESA against neural nets initialized with re-trained word embeddings: re-trained RNTN performs very poorly on the three balanced data sets and fails to classify the A-CHESS test set. On the other hand while CNN-static (re-w2v) and CNN-non static (re-w2v) perform comparably well to SWESA on the balanced data sets, both algorithms perform poorly on the A-CHESS data set. CNN-static and non static achiever average precision of 15.62 and 18.98 respectively on the A-CHESS data set while SWESA achieves an average precision of 35.80. This is not a surprising result because the training data to RNTN and CNNs is much smaller than the Pang and Lee Data set.

Polarity of word embeddings. The objective of SWESA is to perform effective sentiment analysis by learning embeddings from text documents with sentiment labels. Since, word embeddings are learned via a joint optimization framework one can expect that the resulting word embeddings are polarity aware. To test our hypothesis, we investigate if one can predict the antonym of a word. That is, given a word v whose word embedding is $\mathbf{w}_v$ we determine the antonym to be that word a with word embedding $\mathbf{w}_a$ such that the cosine similarity between $\mathbf{w}_a, \mathbf{w}_v$ is minimized over all possible choices of a. Figure 1 shows a small sample of word embeddings learned on the Amazon data set by SWESA and word2vec. The cosine similarity (angle) between the most dissimilar words is calculated and owing to the assumptions on word embeddings, words are depicted as points on the unit circle.

From figure 1 it is evident that a supervised algorithm like SWESA projects document level polarity onto word level embeddings while an unsupervised algorithm like word2vec that learns embeddings of words via virtue of word co-occurrences will fail to embed polarity. It is important to notice that SWESA learns word polarities by using document polarities, and these word polarities are useful for antonym tasks. Unlike classical antonym tasks where examples of known antonym pairs are provided, in our setup no such pairs are provided, and yet SWESA was able to do a good job discovering antonym pairs. For example the most dissimilar word to given word 'Excellent' is 'Poor' when learned via SWESA as opposed to 'Work' when learned via word2vec. From these examples, the advantage of SWESA is particularly towards exploiting strong polarity differences in words such as 'Excellent' and 'Poor', however not much success is noted towards less polarized synonyms such as 'Wet' and 'Dry'. However, with finer grained sentiment labels we would expect subtler antonym pairs to be distinguished by SWESA. This will be actively pursed in future extensions of SWESA, particularly when used to perform multi-class classification tasks.

Thus, word antonym pairs (w_a, w) can be obtained by calculating cosine similarities. Since the aim of experiments in section 4 was to perform document level sentiment analysis and observations on word dissimilarities is a consequence of this task, extensive experiments validating word antonym pairs have not been performed. This is left for future work and only a qualitative analysis of learned word embeddings is discussed here.

Table 1: This table shows results from a standard sentiment classification task on all four data sets. Results from SWESA are in boldface and results from pre-trained models are in blue. No AUC values are reported for models where classification probabilities of classifiers is not available.

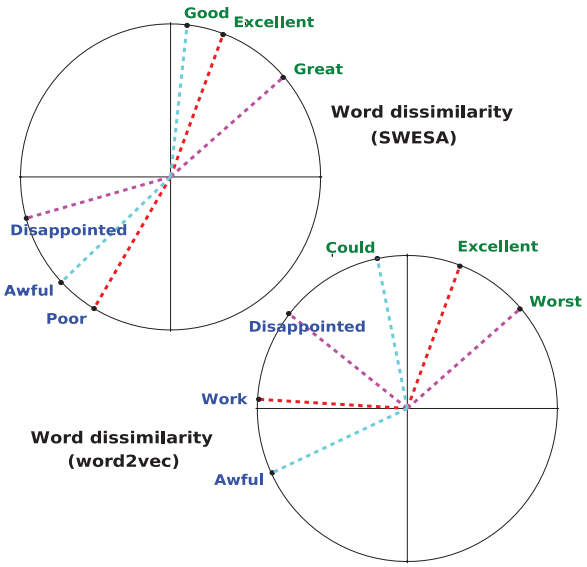

Figure 1: *This figure depicts word embeddings on a unit circle. Most dissimilar word pairs are plotted based on the cosine angle between the respective word embeddings learned via SWESA and word2vec.*

5 Discussions and Conclusions

In this paper we provide a simple optimization based framework, called SWESA that jointly learns word embeddings and a classifier for the task of sentiment analysis. Through extensive experimentation we show that SWESA outperforms both non-neural network algorithms (naive Bayes, LSA) as well as state-of-the-art neural network algorithms based on CNNs and RNNs. As a byproduct of our optimization formulation we show that the word embeddings learned by SWESA are polarity aware and perform very well on antonym tasks, even without being explicitly trained for such tasks. Particularly, strongly polarized word embeddings are easily distinguished. This results indicates that when using finer grained sentiment labels, word polarized along other scales such as dimension, etc can be determined. Our contributions strongly emphasize the point that on domains where data is limited, i.e few thousands of points, but sentiment rich, data size is not a handicap and simple algorithms can do a better task than more involved neural network based algorithm. In the future, we shall investigate modifications of our framework for tasks other than sentiment analysis.

Appendix A: Differences between SDL and SWESA.

The significant differences between SDL and SWESA are i) Input to SDL is a labeled dataset, with each data point already represented as a vector. This allows for a definition of reconstruction error within algorithms designed for SDL. In contrast, SWESA has labeled unstructured data without a direct vector

representation, and the aim is to learn vector representations for such data. As a result the notion of reconstruction error used in SDL does not apply to SWESA and hence the optimization formulation used is significantly different from the one used in SDL. ii) In SDL sparse encoding of each data point is to be learned, whereas in SWESA this sparse encoding is known and is proportional to the number of times a word appears in the document. (iii) Finally, in SDL the classifier is a high-dimensional vector that acts on the latent codes.

Word-Level Loss Extensions for Neural Temporal Relation Classification

Artuur Leeuwenberg and **Marie-Francine Moens**
Department of Computer Science
KU Leuven, Belgium
{*tuur.leeuwenberg, sien.moens*}*@cs.kuleuven.be*

Abstract

Unsupervised pre-trained word embeddings are used effectively for many tasks in natural language processing to leverage unlabeled textual data. Often these embeddings are either used as initializations or as fixed word representations for task-specific classification models. In this work, we extend our classification model's task loss with an unsupervised auxiliary loss on the word-embedding level of the model. This is to ensure that the learned word representations contain both task-specific features, learned from the supervised loss component, and more general features learned from the unsupervised loss component. We evaluate our approach on the task of temporal relation extraction, in particular, narrative containment relation extraction from clinical records, and show that continued training of the embeddings on the unsupervised objective together with the task objective gives better task-specific embeddings, and results in an improvement over the state of the art on the THYME dataset, using only a general-domain part-of-speech tagger as linguistic resource.

1 Introduction

Word representations in the form of continuous vectors are often pre-trained on large amounts of raw text to learn general word features, using unsupervised objectives. These representations are then used in supervised models for various classification tasks. However, such tasks sometimes require very specific features that may not have been captured by the unsupervised objective. In other domains such as computer vision, representations are often learned jointly from multiple resources for classification. In this work, we explore the possibility to exploit learning signals from both settings to construct better task-oriented word representations, and obtain a better relation classification model.

The main task in this work is the extraction of narrative containment relations (CR) from English clinical texts, as annotation of clinical data is costly and it is therefor crucial to fully exploit both the labeled as well as the unlabeled data that is available. The aim of CR extraction is to find if, given events A and B, event A is temporally contained in event B (i.e. if event A happens within the time span of event B). An example of such relation is given in Fig. 1, where the model should predict all containment edges given the entities (events and temporal expressions), by classifying each pair of entities as containment or no containment. Temporal relation classification in clinical text is a very important task in the secondary use of clinical data from electronic health records. The patient time-line is crucial for making a good patient prognosis and clinical decision support (Onisko et al., 2015). This task has already been addressed

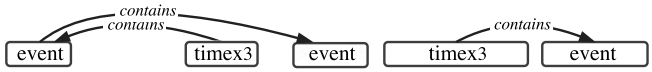

Figure 1: A sentence annotated with events, temporal expressions (Timex3), and containment relations.

Proceedings of the 27th International Conference on Computational Linguistics, pages 3436–3447
Santa Fe, New Mexico, USA, August 20-26, 2018.

in three iterations of the Clinical TempEval Shared Task (Bethard et al., 2016). Still there is a gap of more than 0.20 in F-measure between the state-of-the-art CR extraction systems and the inter-adjunctator agreement (indicating an upper bound for performance). This shows that this task is very challenging.

Following the current trend in NLP, the recent state-of-the-art models for extraction of CR are neural network models. These models all use pre-trained word embeddings as word representations (Tourille et al., 2017; Dligach et al., 2017; Lin et al., 2017).

Pre-training of the embeddings is done with an auxiliary task (a task where one is not interested in the final predictions, but in the trained model components), like the skip-gram task (Mikolov et al., 2013). When used for classification tasks in NLP, these pre-trained word representations are often either used as fixed inputs for the classification model, or as initialization for the word representations of the classification model (sometimes called fine-tuned embeddings).

A problem with pre-trained representations in classification models is that solving the main task often requires different information than the auxiliary task. Training word representations only on the auxiliary objective can result in loss of crucial information for the task, and afterwards fine-tuning on the task loss does not influence words that are not in the task's training data, losing generalization to those words.

In the current work, we propose a neural relation classification (RC) model that learns its word representations jointly on the main task (supervised, on labeled data) and on the auxiliary task (unsupervised, on unlabeled data) in a multi-task setting to overcome this problem, and ensure that the embeddings contain valuable information for our main task, while still leveraging the unlabeled data for more general feature learning. As auxiliary task we implement a skip-gram (SG) architecture, similar to Mikolov et al. (2013). Our proposed models use only unlabeled data and a general (news, out of domain) part-of-speech (POS) tagger as external resources, in contrast to the current state-of-the-art models, to ease extension to other languages for which specialized NLP tools for clinical texts might not be available. The main contributions of this work are that it:

- Shows that training the word-level representations jointly on its main task and an auxiliary objective results in better representations for classification, compared to using pre-trained variants.
- Shows that the method's increased performance and hyper-parameters are robust across different training set sizes, and that single-loss training settings act as lower bounds on performance.
- Constitutes a new state of the art for temporal relation extraction on the THYME dataset even without dedicated clinical preprocessing.

2 Related Work

The model we present draws inspiration from prior research on (temporal) relation classification and neural multi-task learning.

2.1 Clinical Temporal Relation Extraction

Temporal relation extraction from clinical texts is a widely studied area in NLP and has been explored through various shared tasks, such as the i2b2 shared task on clinical temporal information (Sun et al., 2013), and three iterations of Clinical TempEval (Bethard et al., 2015; Bethard et al., 2016; Bethard et al., 2017). Until recently, most of the top performing systems employed manually constructed linguistic feature sets (Lin et al., 2015; Lee et al., 2016; Leeuwenberg and Moens, 2017). In the last few years, there has been a shift towards using neural models, using LSTM (Tourille et al., 2017) and CNN models (Dligach et al., 2017; Lin et al., 2017) inspired by the work on relation classification in other domains (Zeng et al., 2014; Zhang and Wang, 2015; Zhou et al., 2016; Nguyen and Grishman, 2015). The top results in clinical temporal relation extraction are still achieved when enhancing the neural models with dedicated clinical NLP tools for preprocessing the clinical texts, often using the English cTAKES system (Savova et al., 2010), which contains tools for clinical POS tagging, named entity recognition, and a dependency parser all trained on clinical data. The main reason for using these dedicated clinical tools is that parsers trained on non-clinical texts perform significantly worse on clinical data (Jiang et al., 2015).

Dedicated clinical NLP tools are not available for most languages though, and retraining NLP tools on clinical data is quite resource intensive, because it requires extra annotation effort. Additionally, clinical data is often difficult to obtain or share publicly for patient privacy reasons. Hence, we keep resource intensive preprocessing to a minimum and employ only a general news domain POS tagger (Toutanova et al., 2003), providing important temporal relation extraction cues, such as tense shifts (Derczynski, 2017), and for which training data are available for many languages (Petrov et al., 2012).

2.2 Multi-task Learning

Our proposed model training can be seen as multi-task learning (MTL), where the aim is to improve model generalization by leveraging the information from training signals of different related tasks (Caruana, 1998). In earlier work, MTL has shown to be quite effective for different NLP tasks such as machine translation (Dong et al., 2015), sentiment analysis (Peng and Dredze, 2015; Yu and Jiang, 2016), sentence level name prediction (Cheng et al., 2015), semantic role labeling (Collobert and Weston, 2008), and many more. For example, Collobert and Weston (2008) used an auxiliary unsupervised objective for semantic role labeling (SRL). They alternately trained embeddings in a language model and a SRL model. In contrast to their work, we learn both tasks truly jointly, and optimize a single semi-supervised objective. Typically in neural MTL, one or more layers of the network are shared among different models. Two issues in MTL are (1) how to determine if the tasks are related enough to benefit from each other, and (2) what layers to share among the models. Baxter and others (2000) theoretically argue that tasks are related when they share an inductive bias. In our model, we expect that the skip-gram task (Mikolov et al., 2013) can act as a reasonable word-level inductive bias for our task, as it has already shown its effectiveness in SRL (Collobert and Weston, 2008) and sentiment analysis (Peng and Dredze, 2015) in MTL, and for many NLP classification tasks when using them as pre-trained embeddings. Hashimoto et al. (2017) showed that even when combining many tasks, considering the task hierarchy (simpler tasks lower in the network) allows them to benefit from each other. In most work on MTL the auxiliary tasks are supervised and specifically chosen for their relatedness to the main task (Ruder, 2017), whereas in our model we chose the unsupervised auxiliary skip-gram task, and share weights of the word embedding layer. This results in a new joint relation classification objective that is semi-supervised on the word-level and provides better generalization for the final classification model.

3 The Model

Our model consist of two components: (1) a relation classification component (RC), and (2) a skip-gram component (SG). A high-level schematic overview of our model's training setting is shown in Fig. 2.

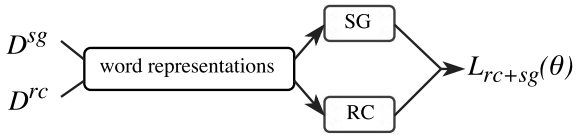

Figure 2: High-level overview of our model training setting. D^{rc} and D^{rc} indicate the dataset for the relation classification and skip-gram components respectively, and $L_{rc+sg}(\theta)$ the model's combined loss.

3.1 Relation Classification (RC)

To classify relations we employ a long short-term memory (LSTM) (Hochreiter and Schmidhuber, 1997) relation classification model (RC) (Zhang and Wang, 2015). We frame the task as a sequence classification problem, taking as an input: the textual candidate relation description, i.e. the arguments of the candidate relation (the entity pair), and the context words surrounding the arguments, all read as a sequence from left to right. A schematic overview of the RC model component is shown in Fig. 3.

Generation of candidate entity pairs is described later on in section 4.4. The locations of the arguments of each candidate relation are indicated by two types of features taken from the literature: (1) position indicators, which are XML tags added to the original input sequence indicating the start and end of the

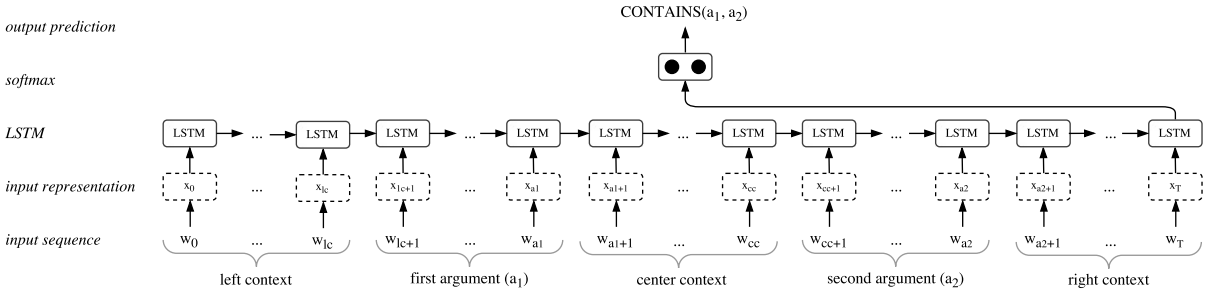

Figure 3: Schematic representation of the relation classification (RC) model component. Arrows represent sets of fully connected weights. The dashed box indicates a word input as shown in Fig. 4.

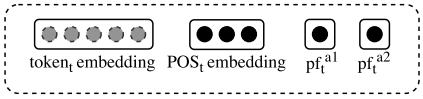

Figure 4: Each word input x_t of the RC model (at time step t) is a concatenation of a token embedding, a POS embedding, and two positional features (one for each argument).

arguments (Zhang and Wang, 2015), and (2) by position features, indicating the relative token-distance of each word to each argument (Zeng et al., 2014). Each word's total input x_t at time step $t \in \langle 0, 1, ..., T \rangle$ consists of the two argument locating features, pf_t^{a1} and pf_t^{a2}, together with a word embedding $x_t^{token} \cdot W_{em}^{token}$, and a POS embedding $x_t^{pos} \cdot W_{em}^{pos}$, where W_{em}^{token} and W_{em}^{pos} are the embedding matrices for tokens and POS respectively, and x_t^{token} and x_t^{pos} their one-hot representations. A schematic overview of the concatenated input x_t for each word to the LSTM unit is shown in Fig. 4.

The predicted class probabilities $\hat{p}_{rc}(x)$ are given by a softmax classifier placed on top of the LSTM output h at the last time step T (in Eq. 1).[1]

$$\hat{p}_{rc}(x) = \textit{softmax}(W_p h_T + b_p) \tag{1}$$

The RC model's loss function is cross-entropy loss, as shown in Eq. 2. D^{rc} indicates the supervised relation classification dataset, and θ^{rc} is the collection of all trainable parameters of the model.

$$L_{rc}(\theta^{rc}) = -\sum_{i=1}^{|D^{rc}|} y_i \log \hat{p}_{rc}(x_i) \tag{2}$$

3.2 Context Prediction (SG)

As the unsupervised auxiliary task, we implemented a feed-forward neural network for a word context prediction task, known as the continuous skip-gram (SG), following Mikolov et al. (2013). As input, the model takes a one-hot encoded input word w_j, which is projected to a word embedding, from which the probability distribution y over its surrounding context words $w_{j-c}, ..., w_{j-1}, w_{j+1}, ..., w_{j+c}$ is predicted, given a context window size c. The full model is given by Eq. 3.

$$\hat{p}_{sg}(w_j) = softmax(W_{p_{sg}}(w_j \cdot W_{em}^{token}) + b_{p_{sg}}) \tag{3}$$

Like the RC model, we use cross-entropy loss for our SG model, as shown in Eq. 4. D^{sg} indicates the unsupervised dataset, consisting of words and their contexts. θ^{sg} is the collection of all trainable parameters of our model.

$$L_{sg}(\theta^{sg}) = -\sum_{i=1}^{|D^{sg}|} y_i \log \hat{p}_{sg}(w_i) \tag{4}$$

[1]We also experimented with bidirectional LSTMs (Zhang et al., 2015) and adding attention (Zhou et al., 2016). In our experiments, this did not result in significant improvements.

3.2.1 Separate Left & Right Context (SGLR)

The skip-gram model is quite rough in its context description and does not take into account word order very well. However, for temporal relations we expect word order to be relevant. For this reason, we also experimented with a variation on the skip-gram model, separating the left and right context, following the intuition of Ling et al. (2015). The context separation is achieved by extending the context words by a 'left' or 'right' prefix depending on their location relative to the sampled word.

3.3 Combination (RC + SG)

We train our proposed model on a combination of both loss functions, each with their own dataset D^{rc}, and D^{sg} respectively. The combined loss, shown in Eq. 5, is a weighted sum of their cross-entropy losses, where λ_{sg} determines the importance of the SG loss.

$$L_{rc+sg}(\theta) = L_{rc}(\theta^{rc}) + \lambda_{sg} L_{sg}(\theta^{sg}) \tag{5}$$

A crucial part of our model is that although both models sample different types of inputs (the RC: sequences, the SG: single words) from different datasets, and have different classification weights, the word embeddings are shared, i.e. W_{em}^{token} ($\theta^{rc} \cap \theta^{sg} = W_{em}^{token}$), also illustrated in Fig. 2. So only the word embeddings are directly influenced by both losses. All other weights (from RC or SG) are only influenced indirectly, through the word embedding weights, as both models are trained simultaneously. Søgaard and Goldberg (2016) showed that, for NLP, sharing representations at the lower levels of the network is most effective: when lower level features are shared, there is room for the model to learn task specific abstractions in higher layers. For this reason we choose our model to share only the word embedding layer, as schematically illustrated in Fig. 5.

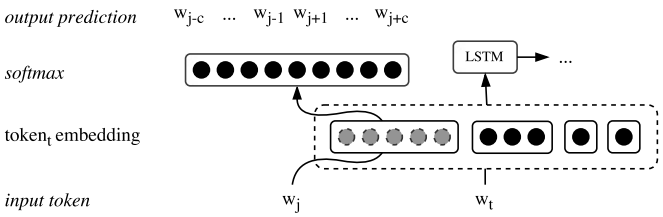

Figure 5: Schematic representation of how the SG model component extends the RC model when using the combined loss on input word $w_j \in D^{sg}$, and word w_t at time step t from input sequence $x_i \in D^{rc}$. The gray layer indicates the shared word embedding parameters. The dashed box represents the total word input x_t for RC, as in Fig. 3 and 4.

3.4 Training

We train all our models for at least 10 epochs, using Adam (Kingma and Ba, 2014) stochastic gradient descent, with the default parameters from the original paper (lr=0.001), and a batch size of 1024 on a Titan X GPU. As stopping criteria we employ early stopping (Morgan and Bourlard, 1990) with a patience of 20 epochs, based on F-measure on a small validation set of 3 documents (from Train). After each epoch on the main task, we shuffle the data and start the next one. During training we employ a dropout of 0.5 on the input, and on the second last layer (Srivastava et al., 2014).

For our semi-supervised setting, with the combined loss, we sample 1024 samples in our batch for each task from the corresponding dataset, and do a single weight update on the combined loss. A high-level schematic overview of our semi-supervised training setting is shown in Fig. 2.

4 Experimental Setup

4.1 Datasets

We conduct our experiments on the THYME corpus (Styler IV et al., 2014), a temporally annotated corpus of clinical notes in the colon cancer domain, also used in the Clinical TempEval Shared Tasks

(Bethard et al., 2015; Bethard et al., 2016). We use the provided Train, Dev and Test split so we can directly compare to other approaches from the literature. The Train section consists of 195 documents, with 11,2k annotated candidate relations, the Dev section of 98 documents and 6,2 annotated candidates, and the Test section contains 100 documents and 5,9k candidates. We now refer to this dataset as D^{rc}.

As data for the SG(LR) loss, we use the raw THYME train texts, extended with a MIMIC III (Johnson et al., 2016) section of 500 discharge summaries that contain the terms 'colon' and 'cancer' at least twice. We refer to this dataset as D^{sg} and it is used in all pre-training and joint training settings.

4.2 Training Settings

We compare five training settings for the model of which the first three settings act as baselines to compare with our proposed models (settings 4 and 5):

1. **RC (random initialization):** Uses random word embedding initializations (picked from [0.05, 0.05]) and trains on loss L_{rc}.
2. **RC (SG initialization):** Initializes the model with pre-trained SG embeddings, and trains on L_{rc}.
3. **RC (SG fixed):** Initializes the model with pre-trained SG embeddings, and trains the model on L_{rc}, while not updating the word embedding weights, keeping them as fixed features.
4. **RC + SG:** Initializes the model with pre-trained SG embeddings, and trains on L_{rc+sg}.
5. **RC + SGLR:** Initializes the model with pre-trained SG embeddings, and trains on $L_{rc+sglr}$.

4.3 Evaluation

As evaluation metrics we use precision, recall, and F-measure, calculated using the evaluation script provided by the Clinical TempEval organizers[2], which evaluates the CR under the temporal closure (UzZaman et al., 2012), taking into account transitivity properties of the temporal relations.

4.4 Preprocessing & Hyper-parameters

As preprocessing of the corpus, we employ very simple tokenization: splitting the text on spaces and considering punctuation[3] and newlines as individual tokens. Additionally, we lowercase the corpus, and conflate digits ($1992 \rightarrow 5555$). To extract POS we use the Stanford POS Tagger v3.7 (Toutanova et al., 2003), using the pre-trained (on WSJ) caseless left-3-words model. Finally, all 1-time occurring tokens in the training dataset are replaced by a <UNK>-token, to represent out-of-vocabulary words at test-time.

We employ the same candidate generation as Leeuwenberg and Moens (2017), considering all pairs of events (Event×Event, or EE) and events and temporal expressions (Timex3×Event, or TE) with a maximum token distance of 30 as candidate relations to be classified (ignoring sentence boundaries, as relations also occur across them). This candidate generation has a maximum recall of 0.87%, and gives a ratio between the positive and negative class of 1:36, also indicating the task's difficulty.

In our experiments, we tuned each model type within the same hyper-parameter search space on the Dev set. The number of LSTM units was chosen from $\{25, 50, 100\}$, and the word embedding dimension from $\{25, 50, 100\}$. This resulted in 100 LSTM units, and a word embedding size of 25. The loss weights λ_{sg} and λ_{sglr} were chosen from $\{0.01, 0.1, 1.0, 10, 100\}$, resulting in λ_{sg}=0.1 and λ_{sglr}=0.1. The context window size of the skip-gram was set to 2, chosen from $\{2, 4, 8\}$. The context size for the RC, and POS embedding dimension size were not tuned and set to 10 (left and right), and 40 respectively.

5 Results

5.1 Influence of Word-Level Loss

We looked at model performance when increasing the importance of the auxiliary word-level loss (λ_{sg} and λ_{sglr}). The results when changing these hyper-parameters are shown in Fig. 6.

[2] https://github.com/bethard/anaforatools

[3] , . / \ " ' = + − ; : ( ) ! ? < > % & $ * | [ ] { }

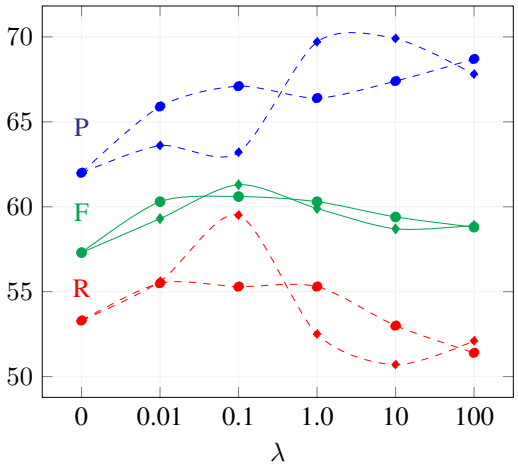

Figure 6: Precision (P), Recall (R) and F-measure (F) on the THYME Dev set for different values of λ_{sg} (○) and λ_{sglr} (◇).

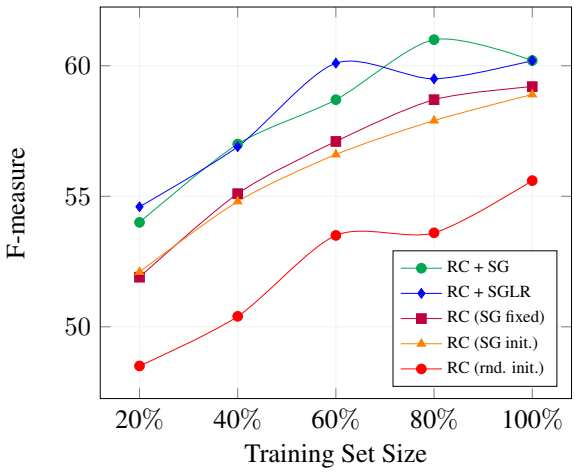

Figure 7: F-measure on the THYME Dev set for different training settings, over different training set sizes (in % of the full train set).

When choosing $\lambda = 0$ (λ_{sg} or λ_{sglr}) for our model, we obtain the same model as RC (SG init.), as the auxiliary objective has no influence. For very high values of λ, we hypothesize that the models converge towards RC (SG fixed), because when taking $\lambda \to \infty$, the word embeddings are solely optimized for the auxiliary loss, as the influence of the task loss is proportionally zero, i.e. $\lim_{\lambda \to \infty} \frac{1}{\lambda} = 0$. This property is interesting, as it shows these baseline models can act as lower bounds for our model performance when choosing a bad λ value. This can be observed in Fig. 6, where the F-measure is highest for a λ that balance both objectives, whereas for extremes F-measure decreases.

5.2 Comparison Across Training Set Size

We evaluated all model settings for different training set sizes. From Fig.7 we can see that the worst model is the one with random word embedding initializations. One improvement is to initialize the model with pre-trained SG embeddings. Fixing the pre-trained embeddings or continued training on the main task objective does not result in very different F-measure scores. However, continued training on the combined objective does seem to give a significant increase in F-measure, consistent over different training sizes for both the RC + SG as well as the RC + SGLR variant. Additionally, it should be noticed that parameters are not returned on each dataset size, but obtained from tuning on the full Dev set. Still the model ranking is consistent.

5.3 Evaluation on Subsets of Relations

To get a more detailed insight in what each model learns relative to the others, we evaluated our models on different subsets of the data. First, we split the containment relations based on their argument types and separately evaluated the 3.3k EE relations and the 2.7k TE relations. EE relations are generally found more difficult than TE relations (Lin et al., 2015; Lin et al., 2016; Dligach et al., 2017; Lin et al., 2017). In Table 1 we can see that also for our model, EE relations are harder to recognize than the TE relations, as all models achieve higher scores for TE compared to EE relations. What is interesting to see is that when training with the combined loss (SG or SGLR) we obtain a clear improvement on the more difficult EE relations, and perform slightly worse on TE relations compared to using pre-trained embeddings (the three upper settings). The reason could be that EE relations are more diverse in vocabulary, and are consequently more influenced by the quality of the embeddings.

We also analyzed the models w.r.t. total frequency in the training data ($D^{rc} + D^{sg}$) and made three subsets based on the average word frequency of the argument tokens in each relation. The three buckets of relations, 0-100, 100-500, and 500+, are of sizes 2.2k, 2.2k, and 1.8k respectively. What can be observed is that the RC+SG model performs best for low-frequency words, and RC+SGLR performs

Table 1: Evaluation on subsets of THYME Dev (in F-measure). The subsets of Event×Event (EE) and Timex3×Event (TE) relation pairs are of sizes 3.3k and 2.7k respectively. The intervals 0-100, 100-500 and 500+ are subsets reflecting average argument token frequency in the training data (of sizes 2.2k, 2.2k and 1.8k respectively).

Model	EE	TE	0-100	100-500	500+	All
RC (random initializations)	44.5	64.4	40.5	57.8	63.4	53.4
RC (SG initializations)	49.5	68.6	44.1	62.5	67.0	57.3
RC (SG fixed)	48.9	**68.7**	44.1	62.7	67.3	57.6
RC + SG	51.6	67.4	**46.4**	62.5	66.8	58.2
RC + SGLR	**51.7**	68.5	45.3	**63.0**	**68.1**	**58.4**

best for the higher frequency ranges. This can be explained by the fact that the SGLR separates left and right context words, creating sparser and more precise contexts compared to SG. Sparse context descriptions can hurt representations of low frequency words as there may not be enough words that share contexts. But, for more frequent words, more precise context descriptions as in SGLR help to prevents incorrect generalizations (such as cases where word order matters). When evaluating on the full Dev set, both combined loss settings outperform the baselines consistently.

5.4 Comparison to the State of the Art

We also compared our proposed models to various state-of-the-art systems from the literature:

The THYME system, by Lin et al. (2016), consist of separate models for EE relations and TE relations. They employ two feature rich support vector machines (SVM), using POS and dependency parse features from the cTAKES clinical pipeline (Savova et al., 2010) together with augmented training through extended UMLS entities. They later replaced the TE component by a token-based CNN model which improved their model (Lin et al., 2017; Dligach et al., 2017). Also replacing the EE component by a CNN model decreased model performance, showing that the CNN was not able to replace the feature rich SVM. Leeuwenberg and Moens (2017) used a feature rich structured perceptron, also using cTAKES POS and dependency parse features, jointly learning different relation types on the document level. Tourille et al. (2017) used two bidirectional LSTM models, one for inter-sentence and one for intra-sentence relations. They used fixed word embeddings pre-trained on the MIMIC III corpus, and also incorporated character level information. To obtain their top results they added ground truth event attribute features enhanced with entity information also obtained from cTAKES.

As can be noticed, all state-of-the-art baselines used dedicated clinical NLP tools to enhance their features in order to obtain their top results, in contrast to our model, which uses only the Stanford POS Tagger (trained on news texts).

Table 2 shows that initializing the model with the pre-trained embeddings gives a significant [4] 1.1 point increase in F-measure compared to random initialization, due to an increase in precision. Fixing the embeddings gives slightly better performance than using them as initialization, an increase of 0.9 point in F-measure, mostly due to higher recall. When extending the loss with the SGLR loss, we gain[6] 1.6 in F-measure compared to fixing the word embeddings, and also surpass the state of the art by 0.4 even without specialized resources. If we train our model using the SG loss extension we obtain the best results, and gain[6] 1.9 points in F-measure compared to using pre-trained fixed word embeddings. This setting also exceeds the state of the art (Lin et al., 2017) by 0.7 points in F-measure, due to a gain of 1.2 points in recall, again without using any specialized clinical NLP tools for feature engineering, in contrast to all state-of-the-art baselines.

5.5 Manual Error Analysis

Finally, we manually analyzed 50 false positives and 50 false negatives picked randomly from the test set predictions for different settings.

[4] $P < 0.0001$ for a document-level pairwise t-test

Table 2: THYME test set results, reporting precision (P), recall (R) and F-measure (F), macro-averaged over three runs. The standard deviation for F is also given.

Model	P	R	F
With specialized resources:			
Best Clinical TempEval (2016)	58.8	55.9	57.3
Lin et al. (2016)	66.9	53.4	59.4
Leeuwenberg et al. (2017)	-	-	60.8
Tourille et al. (2017)	65.7	57.5	61.3
Lin et al. (2017)	66.2	58.5	62.1
No specialized resources:			
RC (random initialization)	67.9	52.1	$58.9_{\pm 0.2}$
RC (SG initialization)	**71.2**	52.0	$60.0_{\pm 1.2}$
RC (SG fixed)	68.9	54.6	$60.9_{\pm 0.8}$
RC + SG	66.2	**59.7**	$\mathbf{62.8}_{\pm 0.2}$
RC + SGLR	68.7	57.5	$62.5_{\pm 0.3}$

From Table 3 we can see that all models have difficulties with distant relations that cross sentence or clause boundaries (CCR). This could be because class imbalance correlates with distance between the arguments of the temporal relations. Furthermore, arguments that are frequent in the supervised data (> 250) are a dominant error category. We suspect this is because frequent events often function both as container and as contained, whereas infrequent events are less ambiguous in their argument position. This hurts RC (SG fixed) most as its embeddings are not influenced by D^{rc}. Furthermore it can be noticed that RC+SG has less errors for infrequent arguments (< 10) in the supervised data. This could be because it leverages the few available instances from both the D^{rc} and D^{sg} data better than the single-loss models.

Table 3: Error analysis on 50 FP and 50 FN (random from test) for different settings. Clause boundaries are: newlines and sub-clause or sentence boundaries. Error categories are not mutually exclusive.

Error Type	RC + SG	RC (SG fixed)	RC (SG init.)
Cross-Clause Relations (CCR)	42	39	36
Infrequent Arguments (< 10)	11	15	26
Frequent Arguments (> 250)	37	50	40
Mistake in Ground-Truth	10	8	5
Other	21	15	28

6 Conclusions

In this work, we proposed a neural relation classification model for the extraction of narrative containment relations from clinical texts.[5]

The model trains word representations jointly on the supervised relation classification task and an unsupervised auxiliary skip-gram objective (with separate datasets) through weight sharing to more effectively exploit both the unlabeled and labeled data, as annotated clinical data is costly to create. We show that this word-level joint training results in significantly better generalizing classification models compared to using pre-trained word embeddings (either as initialization or fixed embeddings). Furthermore, we show that performance trends and good values for λ (balance between tasks) are robust over different training set sizes, and that even for (badly tuned) extreme values of λ the quality of the model's

[5]Code is available at: `http://liir.cs.kuleuven.be/software.html`

embeddings is naturally lower-bounded by their pre-trained variants. Additionally, our model sets a new state of the art for temporal relation extraction on the THYME dataset, without using extra dedicated clinical resources, in contrast to current state-of-the-art models.

As future work, it would be interesting to see how well the improvements caused by the word-level joint training generalize to other NLP tasks that typically use pre-trained word embeddings.

Acknowledgment

The authors would like to thank the reviewers for their constructive comments which helped us to improve the paper. Also, we would like to thank the Mayo Clinic for permission to use the THYME corpus. This work was funded by the KU Leuven C22/15/16 project "MAchine Reading of patient recordS (MARS)", and by the IWT-SBO 150056 project "ACquiring CrUcial Medical information Using LAnguage TEchnology" (ACCUMULATE).

Abstract

This paper describes a personalized text retrieval algorithm that helps language learners select the most suitable reading material in terms of vocabulary complexity. The user first rates their knowledge of a small set of words, chosen by a graph-based active learning model. The system trains a complex word identification model on this set, and then applies the model to find texts that contain the desired proportion of new, challenging, and familiar vocabulary. In an evaluation on learners of Chinese as a foreign language, we show that this algorithm is effective in identifying simpler texts for low-proficiency learners, and more challenging ones for high-proficiency learners.

1 Introduction

Since extensive reading is beneficial for learning a foreign language, students are encouraged to read a wide range of texts, beyond their textbooks and graded readers. Reading materials for language learning need to be carefully selected. On the one hand, if the text is too difficult, it would hinder comprehension and leave the student overwhelmed and discouraged. On the other hand, if the text is too easy, it would not serve to stretch the student's language skills. The best material should be challenging yet highly readable, containing just the right proportion of new, challenging, and familiar vocabulary. Graded readers created with specific language proficiency levels in mind alleviate this problem to some extent, but they provide only a limited amount of materials, and the grade levels are still coarse-grained. It often falls to language teachers to identify appropriate material, but they cannot do so for every individual student.

This paper describes a personalized text retrieval algorithm that helps language learners select the most suitable reading material in terms of vocabulary complexity. The user first rates their knowledge of a small set of words, chosen by a graph-based active learning model. The system trains a complex word identification model (CWI) on this set. Most current CWI approaches assume vocabulary knowledge to be a dichotomy, labeling each word either as "non-complex", if the user is familiar with the word, or as "complex", if the user is not familiar with it (Paetzold and Specia, 2016; Ehara et al., 2014). There are, however, many dimensions of vocabulary knowledge (Richards, 1976). As our first contribution, we take one step in this direction by attempting to identify not only known and unknown words, but also challenging words.

Further, we apply CWI to the text retrieval task, and measure its effect on the vocabulary complexity of retrieved texts from the perspective of a language learner. Specifically, the algorithm attempts to find texts with a minimum proportion of non-complex words and a maximum number of challenging words for the learner. As our second contribution, we show that the algorithm is effective in retrieving simpler texts for low-proficiency learners, and more difficult ones for high-proficiency learners.

The rest of this paper is organized as follows. The next section summarizes previous research in automatic CWI and text retrieval for language learners. Section 3 outlines our approach. Section 4 describes our dataset. Section 5 presents our experimental results. Section 6 concludes the paper.

2 Previous work

2.1 Complex word identification

The complex word identification (CWI) task aims to tag a word as "complex" if it is unfamiliar for a user, and "non-complex" otherwise. In the lexical simplification task, CWI is commonly used for identifying words that should be simplified to improve a user's understanding of a text while avoiding unnecessary simplification (Shardlow, 2013). CWI is also an important part in systems that aim to provide suitable reading material for users. Elhadad (2006), for example, built a system to predict terms in medical literature that were unlikely to be understood by layman readers and provide definitions. This work uses CWI to find texts suitable for learners of Chinese as a foreign language by estimating the proportion of complex, challenging, and non-complex words in a text.

Most previous research has focused on CWI for English as a foreign language. One approach for predicting vocabulary knowledge is by "word sampling" (Laufer and Nation, 1999). Using a ten-level proficiency scale, with 1000 words at each level, this approach samples a fixed number of words from each level and estimates the size of the learner's vocabulary from his/her knowledge of the sampled words.

Word frequencies were found to be the most reliable predictor of word complexity in the 2016 SemEval shared task for CWI in English (Paetzold and Specia, 2016). The best team, which combined various lexicon-based, threshold-based and machine learning voter subsystems, achieved a precision of 0.147 and recall of 0.769. This approach has yet to be evaluated on language learners at different levels of proficiency, since the entire test set was annotated by one learner.

Personalized models for CWI adjust their predictions based on user characteristics. Zeng et al. (2005) showed that demographic features can help improve CWI performance for individual users in the medical domain. Ehara et al. (2012; 2014) performed CWI for individual learners with a two-step approach. In the first step, an active learning approach selects the k most informative nodes, or words, to be annotated by the user (see Section 3.1 for details). The user rates their knowledge of these k words on a five-point scale (Table 1). In the second step, the system uses Local and Global Consistency (Zhou et al., 2004), a label propagation algorithm, to train an independent classifier for each user. The algorithm performs binary classification on the nodes to predict whether a user knows a word or not. The assumption behind this algorithm is that two nodes connected by a heavily weighted edge should have similar labels, and more heavily weighted edges should propagate more labels. The best model, where k=50, achieved 76.44% accuracy on a dataset of Japanese learners of English.

Score	Description	Label (Ehara)	Label (this study)
1	Never seen the word before	complex	complex
2	Probably seen the word before	complex	complex
3	Absolutely seen the word before but do not know its meaning, or tried to learn the word before but forgot its meaning	complex	complex
4	Probably know, or able to guess, the word's meaning	complex	challenging
5	Absolutely know the word's meaning	non-complex	non-complex

Table 1: Five-point scale for rating vocabulary knowledge, and the mapping to CWI labels used by Ehara et al. (2012; 2014) and in this study.

Recently, CWI for other languages has begun to receive more attention. The latest CWI shared task, for example, featured multilingual datasets, covering English, German, Spanish, and French (Yimam et al., 2018). To the best of our knowledge, there has so far been only one reported study on CWI for Chinese as a foreign language (CFL) (Lee and Yeung, 2018). They followed Ehara et al. (2012; 2014) in selecting 50 most informative words to be rated by CFL learners. They then used a support vector machine (SVM) classifier to train a CWI classifier for each individual learner based on his/her 50-word

training set. The classifier used features based on word difficulty levels in two assessment scales for CFL, namely the Test of Chinese as a Foreign Language (TOCFL) (Zeng, 2014) and the Hanyu Shuiping Kaoshi (HSK) (Hanban, 2014). Details on the features are provided in Section 3.2. On a dataset with seven CFL learners, this approach achieved 78% CWI accuracy, outperforming the label propagation method. In this study, we adopt this classification approach and extend it to three-way, so that we may use not just the proportion of complex and non-complex words, but also challenging words, as criteria for text retrieval.

2.2 Text retrieval for language learners

Past research has shown that the optimal reading material should fit the learner in terms of vocabulary and grammatical complexity, as well as personal interests (Heilman et al., 2007). In this study, we focus on the proportion of non-complex words in a text.

Several studies have been conducted to examine the proportion of words in a text that a learner needs to know to facilitate reading comprehension. There is no consensus on the "optimal" proportion of known words in a text. Laufer and Nation (1999), Liu and Nation (1985) and Hirsh et al. (1992) showed that a student could read and understand a text with ease if 95% to 98% of the words were known. If the goal is to stretch the student's vocabulary, the threshold can be made lower. Indeed, in the first 5 books of the *New Practical Chinese Reader*, a popular textbook series for Chinese as a foreign language (CFL), the proportion of difficult words ranges from 9% to 31% (Liang and Song, 2009).

3 Approach

We propose a text retrieval algorithm that aims to help language learners select the most suitable reading material in terms of vocabulary complexity. The algorithm has three components. First, it employs a graph-based active learning model to select a small set of words as training set (Section 3.1). After the user has rated his/her knowledge of these words, the system trains a complex word identification model on this set (Section 3.2). It then applies the model to find texts that contain the desired proportion of complex, challenging, and non-complex words (Section 3.3). We now provide details on each of these components.

3.1 Training set creation

The system performs graph-based active learning to select a small number of words to be included in the training set. The entire vocabulary is first organized as a multiple complete graph. Nodes correspond to words, and edge weights reflect the similarity between the frequency ranks of the words. The assumption is that words with similar frequency ranks are known to learners whose familiar words are similar to each other. Using Error Bound Minimization (Gu and Han, 2012), a non-interactive graph-based active learning algorithm, the system selects the k most informative nodes from the vocabulary graph in a non-interactive way. This algorithm selects nodes that are globally important, based on the number of edges. Further, the nodes must not be heavily connected to previously sampled nodes. Following previous work (Lee and Yeung, 2018; Ehara et al., 2014), we set k as 50. While a larger k can yield better performance, burdening users with a large amount of vocabulary annotation would be undesirable in practice.

3.2 Complex word identification

The CFL learners scored their knowledge on the 50 words in the training set with the five-point scale in Table 1. Following Ehara et al. (2014) and Lee and Yeung (2018), we asked the learners to score their knowledge of words in isolation, rather than in context such as in the CWI shared task.

The context of a word provides clues for learners to guess its meaning, and thus affects how they score their knowledge of a word. Even if the learner is able to guess a word in one context, the same is not guaranteed in another context since the content and the density of new words in each text is different. Since the CWI model in our system is intended for text selection, we did not wish to assume any one particular context when determining the learner's knowledge of a word. To more accurately judge the learners' ability to understand different reading materials, we asked them to consider each word in isolation.

For each individual user, we trained a classifier based on his/her annotation on the 50-word training set to perform CWI on all Chinese words. In a departure from previous CWI studies, we attempted three-way classification, labelling each word as "non-complex", "challenging" or "complex" (see Table 1). We experimented with a feature set similar to that of Lee and Yeung (2018):

- **WordList**: The difficulty level of the word (1, 2, 3, 4, 5, or 6), according to the HSK and TOCFL guidelines. HSK was used as the basis for this feature. For words not covered by HSK, we mapped their TOCFL level to HSK.
- **HSK-char-max**: A Chinese word may contain multiple characters. This feature takes the maximum level among the characters in the word (1, 2, 3, 4, 5, or 6), according to the HSK guidelines.
- **Freq**: The frequency of the word in Chinese Wikipedia.
- **LearnerFreq**: The frequency of the word in the *Jinan Corpus of Learner Chinese* (JCLC) (Wang et al., 2015).
- **LearnerFreq-char-min**: For each character in the word, we compute its frequency count in JCLC. This feature takes the minimum frequency.

3.3 Text retrieval

Our system allows the user to specify the minimum (estimated) proportion of words in the retrieved text that he/she should be able to understand. This parameter can be set to an arbitrary percentage between 0 and 100, but in consideration of the manual effort needed for evaluation, we set this parameter to 80% in our experiment.

Ehara et al. (2012) assumed that learners could only understand the words that received a score of 5 on the five-point scale in Table 1, and that they did not know any word with a score of 4 or below. The aim of our system, however, is to stretch the student's language skills. Taking lexical guessing in context into account, we consider both non-complex and challenging words, scored five and four on the five-point scale respectively, as words that the user should be able to understand.

To stretch the learner's language skills while maintaining a high level of comprehension, the system retrieves all documents that satisfy the minimum threshold of 80% non-complex words, and then ranks them from the highest proportion of challenging words to the lowest.

4 Datasets

4.1 Complex word identification

We used the same training set of 50 words and test set of 550 words as Lee and Yeung (2018). We retained the original annotations of the seven CFL learners, and included the annotations of an additional learner. The learners labelled each word in the datasets on a five-point scale (see Table 1). We considered a word to be "non-complex" if it was scored five, "challenging" if it was scored four, and "complex" otherwise.

The numbers of "non-complex", "challenging", and "complex" words of the test set and training set for each learner are shown in Table 2. We divided the eight learners into two groups. The four who knew less than 150 of the 550 words were designated as "Low-Proficiency", and the other four as "High-Proficiency".

4.2 Text retrieval

We compiled a collection of texts from Chinese Wikipedia, Chinese Internet Corpus (Sharoff, 2006), and *Duan Mei Wen*[1]. For each text, we extracted the first n sentences such that the total character count was between 200 to 225. A total of 38,881 texts were included as candidates for the text retrieval algorithms.

We evaluated three text retrieval methods. Our baseline method randomly selects texts. The other two methods use the two CWI models that achieved the best performance on low-proficiency learners and

User	Training Set			Test Set		
	non-complex	challenging	complex	non-complex	challenging	complex
1	11	2	37	68	25	457
2	7	9	34	78	91	381
3	22	10	18	296	38	216
4	14	8	28	113	114	323
5	17	8	25	217	116	217
6	13	15	22	188	109	253
7	14	8	28	146	75	329
8	20	13	17	268	135	147

Table 2: The numbers of non-complex, challenging, and complex words in the training sets and test sets.

high-proficiency learners (Table 3), respectively, coupled with the retrieval criteria described in Section 3.3. We retrieved the top five texts for each of these three methods.

We asked four of the eight learners — two low-proficiency learners and two high-proficiency learners — to annotate the fifteen retrieved texts with the same five-point scale used in the CWI experiment. They were asked to highlight the complex words in red and the challenging words in blue.

5 Experimental results

5.1 Complex word identification

Following Ehara et al. (2014) and Lee and Yeung (2018), we trained SVM classifiers and logistic regression (LR) classifiers. We used the implementation in scikit-learn (Pedregosa et al., 2011), and we tried all combinations of the features listed in Section 3.1. The results are shown in Table 3.

Features	Model	All	Low-proficiency	High-proficiency
WordList	SVM	64.18%	**70.96%**	57.41%
WordList	LR	63.66%	70.41%	56.91%
WordList + HSK-char-max	SVM	63.57%	69.68%	57.46%
WordList + HSK-char-max	LR	58.82%	65.46%	52.18%
Freq	SVM	40.52%	36.82%	44.23%
Freq	LR	56.23%	62.82%	49.64%
LearnerFreq	SVM	57.02%	64.50%	49.55%
LearnerFreq	LR	62.93%	70.09%	55.78%
LearnerFreq + Freq	SVM	51.11%	60.64%	41.59%
LearnerFreq + Freq	LR	60.64%	66.73%	54.55%
LearnerFreq + LearnerFreq-char-min	SVM	43.14%	50.46%	35.82%
LearnerFreq + LearnerFreq-char-min	LR	64.27%	69.87%	58.68%
LearnerFreq + LearnerFreq-char-min + WordList	SVM	54.61%	56.36%	52.86%
LearnerFreq + LearnerFreq-char-min + WordList	LR	**64.68%**	70.59%	**58.77%**

Table 3: The average accuracies of 3-way complex word identification for all eight learners, low-proficiency learners, and high-proficiency learners.

The LR model with LearnerFreq, LearnerFreq-char-min, and WordList features achieved the highest accuracy, at 64.68%. It slightly outperformed the LR model with LearnerFreq and LearnerFreq-char-min features, at 64.27%, and the SVM model with WordList features, at 64.18%. In general, CWI performance is better on low-proficiency learners than on high-proficiency learners.

The WordList features seem particularly useful for capturing the limited vocabulary of beginners, with the word lists covering most of the words that they know. This hypothesis is consistent with the fact that the SVM model with WordList features achieved the best performance for the low-proficiency learners, at 70.96%. For high-proficiency learners, however, the word lists are insufficient in modelling their larger vocabularies, and have to be augmented with frequency features in order to cover a wider range of words. The LR model with LearnerFreq, LearnerFreq-char-min, and WordList features achieved the highest accuracy for high-proficiency learners, at 58.77%.

5.2 Text retrieval

We evaluated three text retrieval methods:

- **WordList**: The SVM model with WordList features, which achieved the best CWI results for low-proficiency learners.
- **Learner + WordList**: The LR model with LearnerFreq, LearnerFreq-char-min, and WordList features, which achieved the best CWI results for high-proficiency learners,
- **Baseline**: Random selection.

Experimental results for high- and low-proficiency learners are shown in Tables 4 and 5, respectively. To prevent outliers from skewing the results, we removed the texts with the highest and the lowest proportion of non-complex words for each user.

Model	Non-complex words	Challenging words
WordList	**90.18%** (estimated: 85.06%)	7.84% (estimated: 18.13%)
Learner + WordList	**87.87%** (estimated: 84.62%)	6.13% (estimated: 23.39%)
Random selection	95.36%	4.82%

Table 4: The average proportion of non-complex and challenging words in text retrieved for high-proficiency learners.

Model	Non-complex words	Challenging words
WordList	**80.60%** (estimated: 82.66%)	5.91% (estimated: 38.24%)
Learner + WordList	**86.26%** (estimated: 83.91%)	3.76% (estimated: 20.45%)
Random selection	72.91%	6.09%

Table 5: The average proportion of non-complex and challenging words in text retrieved for low-proficiency learners.

For high-proficiency learners, randomly selected texts were relatively easy to read. This can be seen in the high proportion of non-complex words (95.36%) in texts returned by the baseline method. In comparison, the WordList model and Learner+WordList model both retrieved more difficult texts, with 90.18% and 87.87% of non-complex words, respectively. Thus, these models were able to find texts that presented more new vocabulary to advanced learners, while still exceeding the minimum comprehension rate of 80

For low-proficiency learners, experimental results showed the opposite effect. The baseline method retrieved rather difficult texts, in which only 72.91% of the words were non-complex, below the desired minimum rate of 80%. In contrast, the WordList model and Learner+WordList model retrieved texts with 80.60% and 86.26% of non-complex words, respectively. Thus, they succeeded in finding more readable texts, with above 80% comprehension rate, for the beginners.

For both the WordList model and the Learner+WordList model, the proportion of challenging words in the retrieved texts was lower than estimated. As shown in Table 6, among the words estimated to be challenging by the two best CWI models, most (63.11% and 75.15%, respectively) were scored as

non-complex by the learners. The discrepancy may be attributable to the fact that learners, with the benefit of context while reading a text, can better guess the meaning of a word that would otherwise be challenging. This phenomenon can be even more clearly seen by comparing the scores on the same words by the same learner in the CWI dataset (Section 4.1) and the text retrieval dataset (Section 4.2). Indeed, among the words that were annotated as challenging in isolation in the CWI dataset, 68% were annotated as non-complex in the text retrieval dataset by the same learners. Similarly, among the words that were annotated as complex in the CWI dataset, 36.67% were annotated as non-complex in the text retrieval dataset.

We conducted further analysis on the kinds of words that learners are more likely to find non-complex when reading a text. We found that "challenging" or "complex" single-character words (e.g. 以 *yǐ* (with), 称 *chēng* (named)) were more likely to be considered "non-complex" in context. Words related to the theme of the texts (e.g. 口音 *kǒu yīn* (accent) in a text about dialects and 政治 *zhèng zhì* (politic) in a text about democracy) were also more likely to be changed from "challenging" or "complex" to "non-complex".

Gold label	All	Low-proficiency	High-proficiency
WordList			
Complex	26.99%	32.16%	21.83%
Challenging	9.90%	6.04%	13.76%
Non-complex	63.11%	61.79%	64.42%
Learner + WordList			
Complex	17.44%	14.83%	20.06%
Challenging	7.41%	2.51%	12.30%
Non-complex	75.15%	82.67%	67.64%

Table 6: Gold label for words estimated to be challenging in the text retrieval dataset (Section 4.2).

6 Conclusion

Reading materials for language learning need to be carefully selected. The best material should be challenging yet highly readable, containing just the right proportion of new and challenging vocabulary. This paper describes a personalized text retrieval algorithm that aims to help language learners select the most suitable reading material in terms of vocabulary complexity.

The system first employs a graph-based active learning model to select a small set of informative words. Each user rates his/her knowledge of these words to create a training set for complex word identification (CWI). The system then trains a personalized CWI model, and applies it to find texts that contain the desired proportion of complex, challenging, and non-complex words. We evaluated this algorithm on learners of Chinese as a foreign language, and showed its effectiveness in identifying easier texts for low-proficiency learners, and more challenging ones for high-proficiency learners.

Abstract

In this paper, we describe experiments designed to explore and evaluate the impact of punctuation marks on the task of native language identification. Punctuation is specific to each language, and is part of the indicators that overtly represent the manner in which each language organizes and conveys information. Our experiments are organized in various set-ups: the usual multi-class classification for individual languages, also considering classification by language groups, across different proficiency levels, topics and even cross-corpus. The results support our hypothesis that punctuation marks are persistent and robust indicators of the native language of the author, which do not diminish in influence even when a high proficiency level in a non-native language is achieved.

1 Introduction

Native Language Identification (NLI) – identifying the native language (L1) of a person based on his/her writing in the second language (L2) – is useful for a variety of purposes, including security, marketing, and educational applications. The effect of native language phenomena seeping into texts produced in a different language is known as language transfer (Odlin, 1989). Numerous aspects of the language have been explored for NLI – character-level language models (Ionescu et al., 2014), lexical choice (Brooke and Hirst, 2012; Lahiri and Mihalcea, 2013), grammar (Nagata and Whittaker, 2013), spelling errors (Chen et al., 2017; Koppel et al., 2005), cognates (Nicolai et al., 2013), and general etymology (Nastase and Strapparava, 2017).

While punctuation has been included in some of these studies (e.g., in character-level models), its impact has not been studied. It is however an important, and often revealing, aspect of written language. For example, punctuation is a strong indicator of authorship, and has been used successfully in stylometric analysis for authorship attribution (Markov et al., 2017b; Grieve, 2007). More generally, from a linguistic point of view, punctuation has been disputed as following prosodic principles or as a clarifier of grammatical structure (Baron, 2001; Bruthiaux, 1993). Moore (2016) finds a common ground for these two views by observing that prosody and punctuation realize the same function – revealing/emphasizing the information structure of an utterance – in the spoken and respectively written modes of language. Since grammar and prosodic structure are language specific, indicators that reveal them would be language specific as well. As with other aspects of language, grammatical/prosodic influences from the native language may surface in the new language as particular punctuation choices. As an example, consider the following English sentence, written by a native German speaker[1]:

I think the biggest question is , how to defin an " enjoyed life " .

A native English speaker would not insert a comma between *is* and *how*, but it reflects correct punctuation usage in German:

[1]Extracted from one of the training essays in the data we work with (NLI: 10086.txt), with the author's misspelling of 'define'.

Proceedings of the 27th International Conference on Computational Linguistics, pages 3456–3466
Santa Fe, New Mexico, USA, August 20-26, 2018.

Ich denke, die größte Frage ist, wie man ein "glückliches Leben" definiert.

We propose the hypothesis that punctuation usage from the native language appears in a speaker's new language, and is distinctive enough to contribute to the native language identification task. To investigate this hypothesis we perform a series of experiments that measure the impact of punctuation on the NLI task, which we approach from a machine-learning perspective, as a multi-class classification problem of English (as L2) written documents, using two representations – word n-grams and part-of-speech (POS) tags – and analyze the performance of these feature sets when they include or not punctuation marks (PMs). We perform one-step classification – classify the L1 of the author directly – and also a two-step classification where in the first step we classify the language family/geographical group, and then the actual L1. This experiment shows that there are commonalities across language families, and also particularities that distinguish punctuation usage for specific languages within a family/group. We evaluate the use of punctuation within different proficiency levels, to test whether with better L2 skills, the speakers also adopt punctuation usage closer to a native speaker's. Surprisingly, the results indicate that punctuation usage remains influenced by L1 even for learners with high proficiency in L2.

In the previously mentioned experiments we focused on more abstract features (POS tags), which we combine with punctuation marks to capture a higher-level representation of punctuation usage. However, BoW/word n-gram features are the ones that lead to the best results on the task, even though they have been disputed as being useful (Brooke and Hirst, 2012), but potentially overfitting (Brooke and Hirst, 2011). To test whether punctuation marks are robust and can compensate some shortcomings of lexical features, we perform a final set of experiments in which we produce word and punctuation n-grams and test them in cross-dataset classification (training and testing on different datasets). The high drop in performance when using word n-gram features – consistent with the hypothesis that this representation leads to models that overfit the training data – is partly countered when punctuation marks are added to the mix.

The consistent and substantial improvement in native language identification brought by including punctuation marks in the different set-ups explored indicates that punctuation usage is a robust and persistent indicator of the native language of the author.

In a nutshell, the research questions addressed in this work are the following: (i) evaluate the contribution of PMs to NLI, (ii) examine how robust and persistent their contribution is with respect to levels of proficiency and topic/corpus variation.

2 Related Work

Numerous aspects of language, possibly all, can insinuate themselves from a language learner's native language to the targeted L2.

Numerous studies (Brooke and Hirst, 2012; Lahiri and Mihalcea, 2013; Tsur and Rappoport, 2007) show that the *lexical choices* of non-native speakers are strong indicators of their native language, and so are the spelling errors (Chen et al., 2017; Koppel et al., 2005). Lexical features and character n-grams (Ionescu et al., 2014) are considered the most indicative feature types for the NLI task. Nicolai et al. (2013) and Nastase and Strapparava (2017) find that lexical choice is partly influenced by cognates or more generally, by etymologically related ancestor languages.

Both Wong and Dras (2009) and Nagata and Whittaker (2013) investigate the influence of *grammar* as grammatical structures transfer from L1 to L2, whether they are legitimate patterns in L2 as well (Nagata and Whittaker, 2013), or are erroneous with respect to L2 (Wong and Dras, 2009).

The interest in the NLI task led to the organization of several NLI shared tasks (Tetreault et al., 2013; Malmasi et al., 2017), where participating teams used a variety of features: character n-grams of different types, n-grams of lexical features (words, lemmas, POS tags), grammatical information (parse tree rules, syntactic dependency-based n-grams), spelling errors, function words, among others. The top two teams in the recent edition of the NLI shared task (Cimino and Dell'Orletta, 2017; Markov et al., 2017a) used a combination of these features, achieving accuracy close to 90% for this task.

As linguistic studies show (Moore, 2016), punctuation is an important aspect of language. For the written mode of language, it serves to reveal/emphasize the information structure of a sentence, partly

	English proficiency

sharing the sentence structuring function of grammar. In this paper, we propose to investigate punctuation usage as a source of native language information, and understand to what degree it is reflected in writing in a new language. We do this through a suite of experiments described in Sections 4 and 5.

3 Data

3.1 Datasets

To investigate the impact of the punctuation usage on native language identification (NLI), we conducted experiments on two datasets commonly used in NLI research:

TOEFL11 (Blanchard et al., 2013): the ETS Corpus of Non-Native Written English (TOEFL11) contains 1,100 essays in English (with an average of 348 tokens per essay) for each of the following 11 native languages: Arabic, Chinese, French, German, Hindi, Italian, Japanese, Korean, Spanish, Telugu, and Turkish. The essays were written in response to eight different writing prompts/topics (P0–P7), all of which appear in all 11 L1 groups. The dataset also contains information regarding the proficiency level (low, medium, high) of the essay authors. Dataset statistics in terms of proficiency levels and writing prompts are presented in Tables 1 and 2, respectively.

ICLEv2 (Granger et al., 2009): the ICLEv2 dataset (henceforth, ICLE) consists of essays written by highly-proficient non-native college-level students of English. We used a 7-language subset of the corpus normalized for topic and character encoding (Tetreault et al., 2012; Ionescu et al., 2014)[2]. This subset contains 110 essays (with an average of 747 tokens per essay after tokenization and removal of metadata) for each of the 7 languages: Bulgarian, Chinese, Czech, French, Japanese, Russian, and Spanish.

[2]The authors express their gratitude to A. Cahill for providing the list of documents used in their paper.

3.2 Features

The suite of experiments we report were designed to investigate the impact of punctuation-based features on native language identification. The hypothesis we are testing is whether patterns of punctuation usage – possibly motivated by prosody or grammatical structure in the native language – are indicative of the native language of the author of written essays in English. Lexicalized representation of documents (through word/character n-grams of different sizes) have been criticized as overfitting the data (Brooke and Hirst, 2012). Because of this we use more abstract POS n-gram features to represent the documents (essays) in our data, to which we add punctuation marks to capture punctuation usage in the analyzed texts.

Part-of-speech (POS) tags POS features capture the morpho-syntactic patterns in a text. They are considered indicative features for NLI, especially when used in combination with other features, such as word and character n-grams (Cimino and Dell'Orletta, 2017; Markov et al., 2017a). POS tags were obtained with the TreeTagger software package (Schmid, 1999), which uses the Penn Treebank tagset (36 POS tags). We used POS n-grams with n = 1–3.

Punctuation marks usage (PM) Because linguistic theories propose that punctuation emphasizes the information structure of a sentence, and different languages structure information differently, the usage of punctuation for an author's L1 is distinct from norms of L2. To encode punctuation usage we incorporate them in the POS and word n-gram features. We use a set of 36 punctuation marks (only 31 of which appear in the ICLE dataset).[3]

3.3 Experiment setup

We used the tokenized version of the TOEFL11 dataset and performed tokenization of the ICLE dataset using the Natural Language Toolkit (NLTK)[4] tokenizer. We performed lowercasing and removed the text surrounded by $<\ldots>$ in the ICLE dataset, since it corresponds to the dataset metadata. Each essay was represented through the sets of features described above. We used term frequency (tf) weighting scheme and the liblinear scikit-learn (Pedregosa et al., 2011) implementation of Support Vector Machines (SVM) with OvR (one vs. the rest) multi-class strategy. The effectiveness of SVM has been proven by numerous experiments on text classification tasks. The results were measured in terms of classification accuracy. Where not otherwise specified, the experiments were carried out under 10-fold cross-validation.

4 Experiments

We have designed a suite of experiments to help clarify the role/impact of punctuation usage as indicators of the author's native language. We start with the usual multi-class classification setting, then investigate the punctuation usage within the represented language families/geographical groups, with respect to the levels of proficiency, and finally with respect to the topics represented in the data.

Multi-class classification This setting is the usual NLI task, where the L1 of the author of a document is predicted based on a specific representation of the document.

2-step classification We postulate that punctuation usage from the native language is reflected in the text produced in L2. Since native languages belong to specific families, it is natural to ask whether there are strong influences within the language families, as well as at individual language level. This experimental setting will investigate this issue, through a 2-step classification: (i) a coarse classification into language families/geographical grouping of languages, (ii) fine-grained classification within each language group.

[3] Punctuation marks used as separate features would not capture their usage and role in the sentence, which is what we aim to represent. For the curious reader, however, we can report that used in isolation, punctuation marks achieve 18.74% accuracy on the TOEFL11 dataset under 10-fold cross-validation and 33.25% on ICLE, which are twice as high as the baselines (which are included in Table 4).

[4] http://www.nltk.org

Based on the languages represented in each dataset, we group the languages either by language family or by geographical location[5]. The language grouping used is the following:

TOEFL11: Arabic; Asian = {Chinese, Korean, Japanese}; Romance = {French, Italian, Spanish}; German; Indian = {Hindi, Telugu}; Turkish.

ICLE: Slavic = {Bulgarian, Czech, Russian}; Asian = {Chinese, Japanese}; Romance = {French, Spanish}.

Proficiency-level classification As students master a language better and better, it would be expected that their usage of punctuation will get closer to a native's, and the influence of their native language to get weaker. To test whether this is indeed the case, we have built a balanced dataset (from the point of view of proficiency levels) as a subset of the TOEFL11 dataset. The distribution of English proficiency levels in the TOEFL11 dataset is quite imbalanced, as shown in Table 1. To produce a balanced subset, we extract the same number of essays within each proficiency level (equal to the minimum number of essays for each level for each L1, in italics in Table 1).

We use both the imbalanced and balanced subsets to perform multi-class classification based on the proficiency level using POS n-grams with and without PM features, to determine the impact the punctuation has within each proficiency level.

Cross-topic and cross-corpus classification Brooke and Hirst (2012) have criticized the datasets used for NLI because they represent different topics, and thus the performance of the n-gram-based classifiers is questionable as capturing topics rather than native language phenomena. To investigate the impact of punctuation features which are rather abstract, we perform cross-topic and cross-corpus classification:

cross-topic: the essays in the TOEFL11 dataset were written in response to eight different topics or prompts (P0–P7), and all eight prompts are represented in all 11 L1 groups. We split the dataset in two ways:

(1) We split the TOEFL dataset into folds based on the topics – a topic will be present in only one fold (8 topics $\rightarrow$ 8-fold cross-validation).

(2) We used 5,838 essays written on the first four prompts (P0–P3) for training and 6,262 essays written on the P4–P7 prompts for testing. To compare the result of this experiment with a mixed-topic scenario with approximately same number of essays for training and testing, we split the TOEFL11 dataset using half of the essays on each prompt for training (6,050 essays) and testing (6,050 essays). For example, there are 140 essays of Chinese learners on P0, so we used 70 for training and 70 for testing, etc.

cross-corpus: we extract subsets of our two datasets that represent the same languages. The TOEFL11 and the ICLE datasets have 7 common languages: Chinese, French, German, Italian, Japanese, Spanish, and Turkish. We extract the subsets corresponding to these languages from the two corpora. We use each in turn for training and testing, respectively. For this experiment, we did not balance the ICLE dataset and used all the essays for each of the selected languages. The number of essays per class in the ICLE dataset is shown in Table 3.

5 Results and Discussion

5.1 Multi-class classification

Table 4 shows the multi-class classification results (column *1-step*) in terms of accuracy (%) for POS n-grams (n = 1, 2, 3, and 1–3) with and without PMs. As a reference point we provide the random baseline (also used in the NLI shared tasks 2013 (Tetreault et al., 2013) and 2017 (Malmasi et al., 2017)): 9.09% for 11 classes in the TOEFL11 dataset and 14.29% for 7 classes in the ICLE dataset. We include

[5]While a grouping based on language family is more theoretically justifiable, the close results (and for some settings better) in terms of accuracy for the 2-step classification seem to support the geographical grouping of languages as well, which can be explained by shared prosody – and in the written mode, shared information organizational patterns (also evidenced by the results presented in Section 5).

Language	No. of essays
Chinese	982
French	347
German	437
Italian	392
Japanese	366
Spanish	251
Turkish	280
Total	3,055

Table 3: Number (No.) of essays per class in the ICLE dataset used for the cross-corpus experiment.

the improvement (as absolute percentage points) when using PM features over the setting when PMs are omitted. In this and further experiments, the number of features (No.) is provided; the improvements are shown in bold typeface.

Features	TOEFL11 dataset			ICLE dataset		
	1-step acc.	2-step acc.	No.	1-step acc.	2-step acc.	No.
Random baseline	9.09	9.09		14.29	14.29	
POS w/o PMs	12.72	15.67	35	32.34	34.68	35
POS w/ PMs	17.50	19.12	71	48.05	46.49	66
Improvement:	**4.78**	**3.45**		**15.71**	**11.81**	
POS 2-grams w/o PMs	32.40	32.43	923	52.34	51.04	826
POS 2-grams w/ PMs	43.11	41.93	2,262	67.14	65.32	1,678
Improvement:	**10.71**	**9.50**		**14.80**	**14.28**	
POS 3-grams w/o PMs	37.99	38.19	14,036	55.19	52.73	9,455
POS 3-grams w/ PMs	46.88	47.31	27,431	65.45	61.69	16,850
Improvement:	**8.89**	**9.12**		**10.26**	**8.96**	
POS 1–3-grams w/o PMs	38.88	39.08	14,993	59.87	51.04	10,316
POS 1–3-grams w/ PMs	48.83	48.43	29,763	69.48	65.19	18,594
Improvement:	**9.95**	**9.35**		**9.61**	**14.15**	

Table 4: 10-fold cross-validation results (accuracy, %); POS n-grams with and without PMs; 1- and 2-step approaches.

As the results from Table 4 show, the inclusion of PMs improves the results for all the considered settings. The improvement in results brought by including the punctuation marks in the representation shown in Table 4 and throughout this section are statistically significant (unless explicitly mentioned otherwise) according to McNemar's statistical significance test (McNemar, 1947) with an α value of 0.05.

5.2 2-step classification

As explained in Section 4, the 2-step classification set-up would be useful to determine whether there are commonalities in punctuation usage across languages within the same family/geographical group. This would be reflective of grammatical/prosody/information structuring in different language families or groups.

The improvement for the 2-step approach demonstrates that there are shared patterns of punctuation usage across the grouped languages and across the individual languages.

The analysis of the 10 top features according to their weights for each dataset revealed that PMs are present among the 10 top features for all of the classes. The most frequent punctuation marks in these highly ranked features (bigrams and trigrams) were commas and full stops. An ablation study conducted to reveal the most indicative PM-enriched features showed that the performance does not come from one pattern, but L1-specific combinations.

5.3 Proficiency-level classification

We investigate whether higher proficiency levels lead to punctuation usage closer to an L2 native speaker. Should that be the case, we should note lower performance in native language identification with higher

proficiency levels, and in particular lower improvement in performance when adding punctuation marks to the document representations.

The results for each proficiency level on the imbalanced and balanced subsets of the TOEFL11 dataset are shown in Tables 5 and 6, respectively. The results are provided for 1- and 2-step approaches. Here, and in further experiments, the impact of PMs is evaluated using POS 1–3-gram features with and without PMs.

Features	**1-step acc.**	**2-step acc.**	**No.**
Low proficiency			
POS 1–3-grams w/o PMs	41.47	39.32	8,681
POS 1–3-grams w/ PMs	46.71	45.49	13,311
Improvement:	**5.24**	**6.17**	
Medium proficiency			
POS 1–3-grams w/o PMs	42.60	42.48	13,259
POS 1–3-grams w/ PMs	51.34	51.51	24,800
Improvement:	**8.74**	**9.03**	
High proficiency			
POS 1–3-grams w/o PMs	32.39	33.58	12,480
POS 1–3-grams w/ PMs	42.05	43.93	23,006
Improvement:	**9.66**	**10.35**	

Table 5: *Imbalanced setting*: 10-fold cross-validation results (accuracy, %) for each proficiency level.

Features	**1-step acc.**	**2-step acc.**	**No.**
Low proficiency			
POS 1–3-grams w/o PMs	37.87	38.22	8,471
POS 1–3-grams w/ PMs	44.08	42.76	12,900
Improvement:	**6.21**	**4.54**	
Medium proficiency			
POS 1–3-grams w/o PMs	36.00	35.52	8,953
POS 1–3-grams w/ PMs	43.36	44.11	13,996
Improvement:	**7.36**	**8.59**	
High proficiency			
POS 1–3-grams w/o PMs	31.93	31.31	9,367
POS 1–3-grams w/ PMs	37.25	39.39	14,992
Improvement:	**5.32**	**8.08**	

Table 6: *Balanced setting*: 10-fold cross-validation results (accuracy, %) for each proficiency level.

It is interesting to note that while the L1 classification results based on POS n-grams go down for high proficiency levels, the impact of adding the punctuation marks is higher for each proficiency level compared to the lower ones. According to the study conduced by Hirvela et al. (2012), L2 English learners are confident about their use of punctuation. However, the high improvement for high-proficiency learners in both imbalanced and balanced settings suggests that learners keep their L1 punctuation style even when achieving high English proficiency.

5.4 Cross-topic experiments

The cross-topic and cross-corpus experiments were performed to show that the influence of punctuation from the native language transcends topics and corpora, through features that capture PM usage, can partly compensate for the loss in performance under cross-topic or cross-corpus conditions.

	TOEFL11 (10FCV)		**TOEFL11 (topic = fold)**	
Features	**Acc.**	**No.**	**Acc.**	**No.**
POS 1–3-grams w/o PMs	38.88	14,993	33.88	14,636
POS 1–3-grams w/ PMs	48.83	29,763	43.21	28,635
Improvement:	**9.95**		**9.33**	

Table 7: 10-fold cross-validation and one fold/topic setting results.

Features	TOEFL11 (mixed-topic) Acc.	No.	TOEFL11 (cross-topic) Acc.	No.
POS 1–3-grams w/o PMs	36.63	13,174	32.27	13,042
POS 1–3-grams w/ PMs	45.95	24,215	40.74	23,950
Improvement:	**9.32**		**8.47**	

Table 8: Mixed- and cross-topic settings results.

The results for cross-topic classification are presented in Tables 7–8. Separating the training and test data based on topics leads to a drop in performance of approx. 5 percentage points in both the cross-validation and train/test split conditions. But for both settings, adding the punctuation-based features leads to very similar increases in performance whether the topics are separated or mixed. This indicates that the punctuation-based features are robust and portable across topics.

5.5 Cross-corpus experiments

The cross-corpus experiments explore further the robustness of the punctuation-based features. An overfitting model would lead to lower scores when tested on a corpus different to the training corpus. We include here experiments done using word n-grams (n = 1–3), tf weighted just like our other features (as described in Section 3).

Training on TOEFL, testing on ICLE					
	10FCV		Test Set		
Features	**Acc.**	**F1**	**Acc.**	**F1**	**No.**
POS 1–3-grams w/o PMs	48.62	48.51	43.27	40.70	13,587
POS 1–3-grams w/ PMs	60.29	60.22	54.50	53.05	25,870
Improvement:	**11.67**	**11.71**	**11.23**	**12.35**	
Word 1–3-grams w/o PMs	80.91	80.87	73.81	71.27	1,904,839

Word 1–3-grams w/o PMs	92.47	90.85	43.66	42.41	1,706,554
Word 1–3-grams w/ PMs	94.11	93.04	47.19	45.26	1,644,978
Improvement:	**1.64**	**2.19**	**3.53**	**2.85**	

Table 9: Cross-corpus classification results for POS and word n-grams with and without PMs.

The results for cross-corpus experiments (training on TOEFL11 and testing on ICLE, and vice versa) are shown in Table 9. 10FCV stands for 10-fold cross-validation on the training data (accuracy, % and F1 macro, %). We note that despite the loss in performance suffered by the model based on POS and word n-gram features, the PM features are robust and lead to the same increase in performance on testing as they did on training. While the loss in performance when training on TOEFL, testing on ICLE is relatively small (5–7 percentage points for accuracy), training on ICLE and testing on TOEFL leads to much more dramatic drops (45 percentage points for accuracy). For the models based on word n-grams, their high results are harder to improve by the addition of PM features, but they contribute nonetheless, and when added to the model trained on ICLE their impact on the TOEFL data is higher than on ICLE.

In a detailed, per-language view, presented through the confusion matrices (Figure 1), we can note that the highest improvement when including PM features in this cross-corpus study was achieved for German. There is also a high improvement for Turkish and Italian. They indicate that these language have stronger, or maybe more consistent, punctuation styles that interfere in the production of L2. Personal

[6]This improvement is not statistically significant.

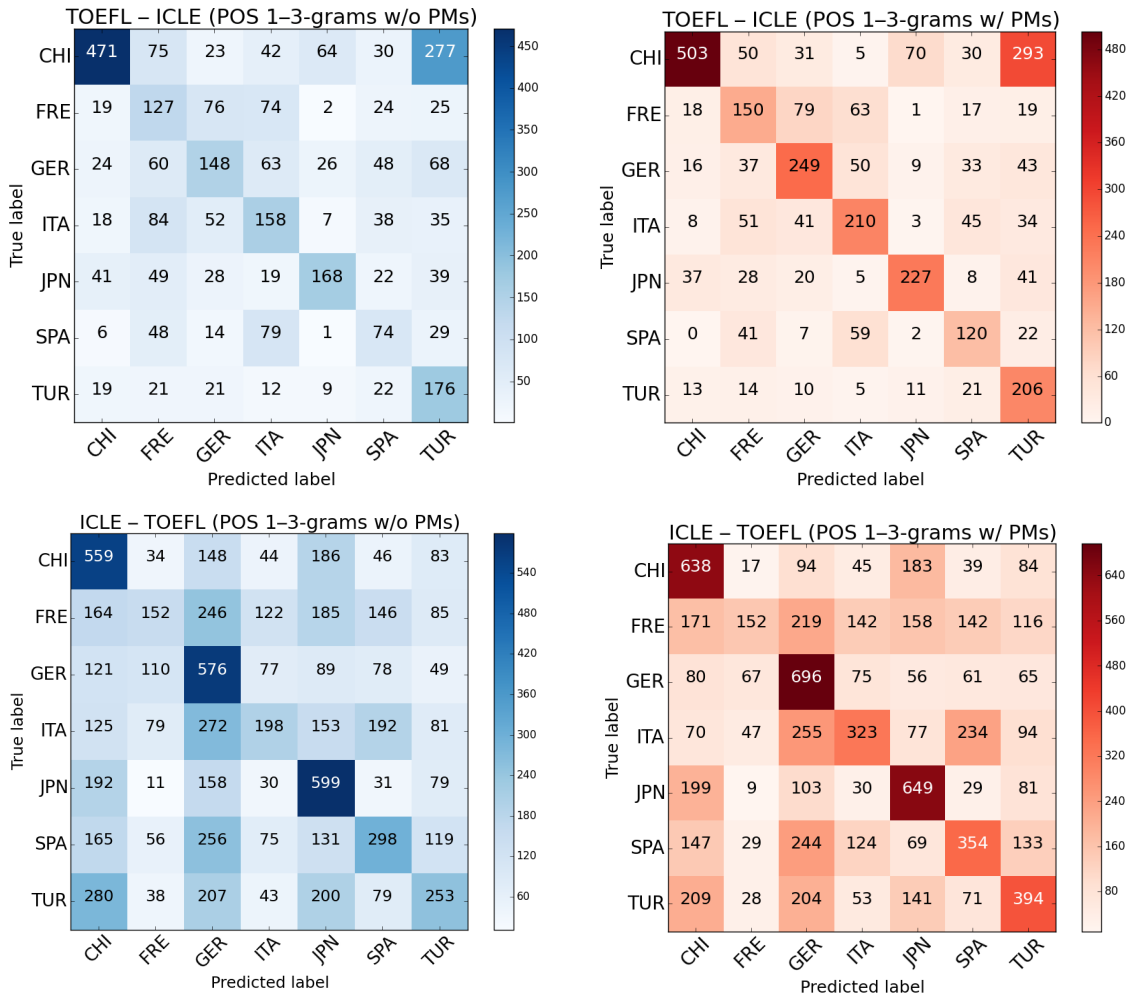

Figure 1: Training on TOEFL, testing on ICLE: POS 1–3-grams without (top left)/with PMs (top right). Training on ICLE, testing on TOEFL: POS 1–3-grams without (bottom left)/with PMs (bottom right).

experience with German and Italian punctuation confirms these findings, but our models could support deeper linguistic exploration into these phenomena.

6 Conclusions

While the role of punctuation is still disputed in linguistic theory – as a written indicator of prosody, or as grammatical features – punctuation is however linked to each language and the manner in which languages organize and convey information. We proposed the hypothesis that punctuation usage in L2 is indicative of an author's native language. We have conducted a series of experiments to investigate the impact of punctuation on native language identification. The experiments show that punctuation marks provide useful information, and when combined with POS and even word n-gram features – thus capturing their usage – lead to significant and substantial improvements. Their impact is positive for both coarse (family-language level) and fine-grained classification, indicating that there are patterns of punctuation usage that are common across language families, but also patterns specific to individual languages. Punctuation interference does not seem to decrease with the level of proficiency: while we would expect that as the proficiency level increases an author's usage of punctuation will be closer to English and thus the native language will be harder to detect, this is not the case. Finally, contrary to word n-grams which necessarily capture also topic-specific information and thus tend to overfit the training data, punctuation is more abstract and as such a more robust feature, as shown by the results of cross-topic and cross-corpus experiments.

Investigating Productive and Receptive Knowledge: A Profile for Second Language Learning

Abstract

The literature frequently addresses the differences in receptive and productive vocabulary, but grammar is often left unacknowledged in second language acquisition studies. In this paper, we used two corpora to investigate the divergences in the behavior of pedagogically relevant grammatical structures in reception and production texts. We further improved the divergence scores observed in this investigation by setting a polarity to them that indicates whether there is overuse or underuse of a grammatical structure by language learners. This led to the compilation of a language profile that was later combined with vocabulary and readability features for classifying reception and production texts in three classes: beginner, intermediate, and advanced. The results of the automatic classification task in both production (0.872 of F-measure) and reception (0.942 of F-measure) were comparable to the current state of the art. We also attempted to automatically attribute a score to texts produced by learners, and the correlation results were encouraging, but there is still a good amount of room for improvement in this task. The developed language profile will serve as input for a system that helps language learners to activate more of their passive knowledge in writing texts.

Title and Abstract in Portuguese

Investigação de Conhecimento Produtivo e Receptivo: Um perfil de aprendizado de segunda língua

A literatura de aquisição de segunda língua frequentemente aborda diferenças no vocabulário produtivo (que um aprendiz consegue utilizar em textos) e receptivo (que um aprendiz consegue entender em textos) de um aprendiz de língua, mas as estruturas gramaticais normalmente não são investigadas nesse nível. Neste trabalho, usamos dois corpora para investigar as divergências nas ocorrências de estruturas gramaticais pedagogicamente relevantes em textos de produção e recepção. Os valores de divergência observados foram incrementados com a atribuição de uma polaridade que indica um sobreuso ou subuso de uma estrutura gramatical por aprendizes de língua. Essa investigação levou à compilação de um perfil de linguagem voltado ao aprendizado de segunda língua que posteriormente foi combinado com informações lexicais e de legibilidade para uma classificação de textos de produção e recepção em três categorias: iniciante, intermediário e avançado. Os resultados da classificação automática tanto de textos de produção (medida F de 0,872) quanto de recepção (medida F de 0,942) foram comparáveis ao atual estado da arte. Também realizamos um experimento para atribuir automaticamente uma nota aos textos produzidos por aprendizes, e os resultados da correlação foram encorajadores, mas mostram que ainda há muitas lacunas a serem supridas e questões em aberto para a realização da tarefa, especialmente no que diz respeito à subjetividade envolvida na atribuição de notas. O perfil de linguagem apresentado servirá como base para um sistema de auxílio à ativação de conhecimento receptivo na escritura de textos.

1 Introduction

Second Language Acquisition (SLA) involves a series of different linguistic knowledge that a second language learner has to deal with, such as, but obviously not limited to, vocabulary and syntax of the second language. Besides the linguistic levels, another important topic for SLA is the knowledge activation capacity, i.e., how much from the learner's knowledge can be activated during a productive task. These are all aspects that help conform the SLA process, and are factors that get included in the evaluation of second language learners in terms of their capabilities of performance in a second language environment.

In the literature, it is possible to find many studies discussing how the passive/receptive vocabulary knowledge relates to the active/productive vocabulary knowledge, be it in a native or second language setting (e.g. Morgan and Oberdeck (1930), Meara (1990), Laufer (1998), Fan (2000), Schmitt (2008), Pignot-Shahov (2012)). In those studies, it is agreed that the passive vocabulary knowledge is larger than the active one. However, none of those studies devote some attention to grammar, so that it is not debated how grammar works in terms of productive and receptive knowledge.

In the case of second language learning, there is also the adherence to a commonly used framework, namely the Common European Framework of Reference for Languages (CEFR) (Verhelst et al., 2009), which divides and describes the communicative goals that should be achieved by an idealized second language learner, no matter in which language or from which native language, in each of the levels. The levels scale from A to C, and there are two sublevels each: A1, A2, B1, B2, C1, and C2. The CEFR also conceives the existence of a second subdivision, such as A1-, A1, and A1+, so that, if needed, the sublevels can be further specified. As such, if one intends to deal with SLA, there is a lot of ground to cover in terms of knowledge that is spread along all the different levels and subclassifications.

One of the ways of dealing with this spread knowledge is by organizing language profiles. The methods for characterizing a language profile use as basis the observation of different groups of people that use language in distinct ways, but that have some fundamental common traces when compared to other groups of speakers of the same language. The whole of these common traces can be called a language profile (Argamon et al., 2009). Two examples of profiles that deal with a specific linguistic level for language learning are the English Vocabulary Profile and the English Grammar Profile[1].

In this study, we are interested in the observation of receptive and productive knowledge present in second-language-related corpora to draw information about the differences between expected receptive and actual productive knowledge. We compare texts designed as input for SLA and the actual output of learners of English to see where the divergence between both of these types of tasks lies. Since vocabulary has already been studied in various works, here we will be using vocabulary as well, but we will deal especially with grammar, and we aim at automatically generating a language profile that can model the relationship between production and reception in SLA. We further hypothesize that, by adding grammatical information, we can improve the modeling of SLA in terms of productive and receptive knowledge.

The language profile developed in this study will also be used to help learners in the task of producing written texts that use the most from the learner's passive knowledge. For achieving this goal, we describe the relation between reception texts and production texts in terms of their divergence, and later we extrinsically evaluate our model, by applying the information drawn for our language profile to a text classification task. As an associated task, we also delve into the automatic evaluation of texts produced by language learners, by correlating scores generated by a classification algorithm to the actual scores given by professional evaluators.

This paper is divided as follows: in Section 2, we briefly contextualize the task addressed in this study and how we are going to deal with it; in Section 3, we describe the corpora that we used as representation of reception and production texts and their automatic annotation with pedagogically relevant grammatical information; we then explain the grammatical profiling that was carried out in Section 4; Sections 5 and 6 are dedicated to the experiments that we conducted using our language profile, these two sections present

[1] Both the EVP and the EGP are available at http://www.englishprofile.org/.

the methodology used for each experiment and also discuss their results; finally, we sum up our findings and report some future work in Section 7.

2 The Task at Hand

In this paper, we are dealing with the contrast between texts produced by learners and texts that are used as input for learners. Our main goal is to draw from this type of data a language profile that can be used to help language learners to produce texts that use the most of their passive knowledge. In this paper, we deal with texts written in English, but the methodology could be applied to other languages, provided there are similar resources.

The contrastive study of distributions was successfully used to identify characteristics that are relevant to text profiling (Biber, 1991). In a complementary manner, entropy-based approaches have been employed to identify similarities (and dissimilarities) among text sets (Dagan et al., 1997; Oakes, 2008) and to study vocabulary variation (Oakes and Farrow, 2007). In this respect, there are different divergence equations that can be employed for evaluating entropy, and one that stands out is the Kullback–Leibler divergence (Kullback and Leibler, 1951; Kullback, 1997), which is also called relative entropy. This divergence is defined in Equation 1, where P and Q are the probability distribution of two text sets. Despite its usefulness, it has a known problem: a lack of symmetry, which makes it hard to use in terms of a distance measure. In that sense, the Jensen-Shannon divergence (Endres and Schindelin, 2003; Österreicher and Vajda, 2003; Fuglede and Topsoe, 2004), presented in Equation 2, averages the divergence of the interchange of the distributions taking into account the average of the distribution P and Q, as shown in Equation 3. The Jensen-Shannon divergence solves the lack of symmetry, so that the result can be understood as a measure of distance, which allowed us to use it to observe the difference between reception and production.

$$D_{KL}\left(P||Q\right) = -\sum_{i} P(i) log\left(\frac{Q(i)}{P(i)}\right) \tag{1}$$

$$D_{JS}\left(P||Q\right) = \frac{1}{2} D_{KL}\left(P||M\right) + \frac{1}{2} D_{KL}\left(Q||M\right) \tag{2}$$

$$M = \frac{1}{2}\left(P + M\right) \tag{3}$$

For achieving the objectives described in this paper, we used two corpora: one made up of texts that are used as input in language learning tasks, and the other one composed of texts that were produced by language learners. Different parts of these corpora were used for deriving our language profile, which was based on a Jensen-Shannon Divergence model, and for extrinsically testing our profile in different tasks related to the evaluation of texts used in language learning.

By observing the divergence between production and reception and generating a language profile, we can also create a tool that guides language learners to potentially use more of their passive knowledge in written production tasks. The idea here is to match a learner's written text to the patterns found in reception texts, so that we can provide cues for the learner on how the text could be improved.

3 Corpora

In this study, we conducted several separate experiments that were related to the goal of developing a language profile that takes into account both sides of written language learning and applying this profile to classify and evaluate written texts in accordance to a given language level. The experiments had as basis two corpora: one corpus containing texts used as input for language learning, and another one containing texts that were produced by language learners. In the next two subsections, we describe the sources we used for both corpora. Since we used them differently in each of the experiments[2], here we provide only a general description, leaving the more fine details to be described together with the

[2]It is important to make it clear that we did not mix the texts used for creating the profile with those that were posteriorly used for extrinsically testing it.

experiments. At the end, we describe the automatic annotation that was applied to both corpora for the experiments.

3.1 Reception Corpus

For observing the type of linguistic information, in terms of vocabulary and grammar, that is present in the input for a language learning task, we combined texts from two different sources: the Breaking News English Lessons (BNE) (Banville, 2009), and Altissia's animation database for the English course[3].

The BNE corpus consists of texts written for learners of English that are distributed along the Common European Framework of Reference for Languages (CEFR) levels, albeit using a level classification from 0 to 7 (that covers the levels A2 to C2). It contains documents that range from 120 words on the easiest level to 250 words on the higher levels. Since the CEFR levels are mixed in some of the texts, what we did was to consider a division of the documents into a beginner class (for those addressing the A2 level), an intermediate class (for those addressing B1 and B2 levels), and an advanced class (for those addressing C1 and C2 levels). As such, levels 1 and 2 of the BNE were allocated to the beginner class; levels 4 and 5 composed the intermediate class; and levels 6 and 7 formed the advanced class. Level 3 was discarded for being a hybrid between the levels A2 and B1, and level 0 was discarded for balancing reasons. The final BNE corpus that we used contains 930 documents and 194,207 tokens.

Altissia's animation database is composed of transcribed texts from short animation sequences, comprising dialogs and narratives that are used as input for learners on an online language learning platform. The transcriptions are all classified according to the CEFR, so we put together texts from levels A1 and A2 (for the beginner class), B1 and B2 (for the intermediate class), and C1 and C2 (for the advanced class), in the same way as we did for the BNE corpus. This corpus amounts to 154 documents and 23,672 tokens, which conforms a rather small corpus, but we decided to add it to the BNE corpus for achieving more variation in terms of text genre.

3.2 Production Corpus

As our representative of the productive knowledge, we used the EF-Cambridge Open Language Database (EFCAMDAT) (Geertzen et al., 2013)[4]. This corpus is divided according to the CEFR (Verhelst et al., 2009), and contains a huge amount of documents written by learners, totaling more than 500 thousand documents with more than 33 million tokens. They were written by 83,385 learners from 137 nationalities, and each document has an evaluation score ranging from 0 to 100 and an associated topic (e.g. *introducing yourself by email*). The data from the corpus is organized following the CEFR classification, so that we just transposed the original division to our own three categories: beginner, intermediate, and advanced.

3.3 Corpus Annotation

Both the reception and the production corpora were automatically annotated with pedagogically relevant grammatical information. For this type of annotation, we used the features described in the SMILLE system (Zilio and Fairon, 2017; Zilio et al., 2017a; Zilio et al., 2017b), which can recognize 107 different grammatical (both morphosyntactic and syntactic) structures in English texts that are relevant for the learning of English as second language[5]. These grammatical structures are ranked according to the CEFR levels, from level A1 to C1, following the pedagogical organization of Altissia's English course. Large part of the information annotated by the SMILLE system is different from a simple parsing annotation, since it represents a combination of parser information with manually created rules that focus on a pedagogical approach to language learning. The annotation was done automatically, and previous work has shown that the overall precision of the system lies around 90.1% for syntactic structures in

[3] www.altissia.com.

[4] We used the EF-CAMDAT version 1 (https://corpus.mml.cam.ac.uk/efcamdat1/) in this paper, because version 2 (https://corpus.mml.cam.ac.uk/efcamdat2/public_html/) was not yet available at the beginning of the research.

[5] For a more complete description of these grammatical structures, please refer to Zilio et al. (2018). The annotated vectors of the EF-CAMDAT corpus can be downloaded from http://cental.uclouvain.be/resources/smalla_smille/sgate/.

the EF-CAMDAT corpus (Zilio et al., 2018) (and precision for morphologic structures is based on the Stanford Parser (Manning et al., 2014) performance)[6].

After the annotation process, each document in both corpora was represented as a vector with the normalized frequency of each of the annotated structures. The normalization of each of the syntactic features was done by dividing their absolute frequency in the document by the number of sentences in it. For the morphosyntactic features, the normalization was carried out by dividing the absolute frequency of the feature in the document by the number of tokens in it.

4 Grammar Profile: Production vs. Reception

The methodology that is generally applied to profiling consists in the use of a training corpus with annotated documents, which are then converted to vectors of features, and methods of classification based on machine learning. The creation of vectors normally takes into account the stylometry of the document. As an example of profiling, Argamon et al. (2009) employ a taxonomy of a specific grammatical class, combining it with other metrics for training a classification algorithm.

By using a corpus of input texts (texts that are used as a receptive means for language learning) and a corpus of output texts (texts that are produced by language learners), we could contrast the occurrences of pedagogically relevant grammatical structures in both of them. This enabled us to come up with a language profile oriented to language learning that considers both sides of the writing spectrum.

In this profiling task, while we used a random selection of 250 documents from each of the three classes (beginner, intermediate, and advanced) of the input corpus (totaling 750 documents), in terms of output, we randomly selected the same amount, but considering only those texts for which the evaluation score given by an expert was between 90 and 95. This ensured, at the same time, that our sample was not made up of texts that were above their level, which is a possible explanation for a maximum score, nor did it contained texts that were not so well formed from a linguistic point of view, because this could pose problems for the automatic annotation and, thus, for our profile.

The annotated corpora were analyzed in terms of the Jensen-Shannon divergence that exists in each of the three classes (beginner, intermediate and advanced) for each of the 107 annotated grammatical structures. As explained in Section 3.3, for a more balanced analysis, the structures were normalized in relation to the number of sentences (in the case of syntactic structures) and tokens (for morphosyntactic structures), and then, for applying the divergence score between both corpora, they were averaged in relation to the number of documents in each corpus. In this process, any structure with a relative frequency equal to zero, whether in the reception or the production corpus, was discarded. The divergence was calculated using ten different random samples for ensuring a better confidence in the data, and the results from the ten samples were afterwards averaged.

After the calculation of the divergence of each of the non-discarded grammatical structures, we had to select a cut-off point for making up our language profile. Since the divergence provides scores, but not a clear cut-off point, we deliberated that the structures classified at the upper quartile regarding the divergence distribution were a good choice to form our language profile. By the end of this process, we identified structures that could be considered problematic in terms of writing for a language learner in each of the three levels. However, the divergence score gave us only the magnitude of the divergence, but it did not account for where the divergence exactly lies, and, for our purposes, we deemed important to know the direction of the divergence, i.e., to know whether a structure is more prominent in the reception or the production. So we went further on the task and used a voting system based on normalized frequency to see which of the corpora presented more of a given structure. This voting system was used to attribute a polarity to the divergence score, representing cases of overproduction (positive scores), which are probably a sign of easier structures for the learners, but that are not that important in a more naturally written text, or cases of underproduction (negative scores), which are an indicator of structures that are more frequent in the input, but the learners may have some difficulties in producing them. For attributing a polarity to the grammatical structure, at least seven out of the ten random samples of the

[6]Further evaluation of more specific structures in different corpora can be found in Zilio et al. (2017a) and Zilio et al. (2017b).

output corpus had to point to overuse or underuse, if there was no side with seven votes or more, we filtered the grammatical structure out of the results, because it represented a case in which the use of the grammatical structures fluctuated too much in the samples.

Many of the highly divergent structures (upper quartile) were similar among the classes, but some of them showed an overuse in some levels and an underuse in others. Table 1 presents the structures that were divergent from input to output along all the levels, and the over- or underuse is expressed by plus or minus symbols, respectively. In the table, lines 1 to 9 represent structures that are divergent in all three classes, from beginner to advanced; lines 10 to 12 show structures that were divergent both in the beginner and intermediate classes; then lines 13 to 22 present structures that were divergent both in the beginner and advanced classes; and, finally, the remaining lines display structures that were divergent in only one of the classes (lines 23 to 26 for beginner, lines 27 and 28 for intermediate, and lines 29 to 34 for advanced). As we can see, the grammatical structures that present divergence go from more coarse-grained syntactic phenomena, such as passive voice and imperative, to more fine-grained ones, like the verb "to be" in different tenses and use of "would" to express hypothesis.

Before going to the other experiments, there are some interesting information presented by our profile that we would like to discuss. For instance: it seems that learners of English tend to overuse the present tense, while neglecting the past tense in relation to the texts that are considered fit for reception. There is also a constant trend to neglect the use of genitive, the present perfect tense and the use of direct complements. These structures that tend to be neglected throughout the levels may be clues for grammatical structures that pose a general problem for language learners. The divergence on the use of direct complements may be also a clue for the existence of a language use with emphasis on intransitive verbs. All these indications present a good basis for further linguistic investigation that would need to be directly assessed in the texts.

4.1 Applying the Grammar Profile

The grammar profile that we generated is intended to describe the behavior of grammatical structures in texts that are either input or output of a language learning task. So, we used it as a basis for other experiments that are important in helping a language learner to improve their writing skills but also that serve as an extrinsic evaluation of the profile.

For these experiments, that we describe and discuss in Sections 5 and 6, we used the grammatical structures that were present in the profile, which amounted to 26 for the beginner class, 14 for the intermediate class and 25 for the advanced class, in terms of their normalized frequency and of their significant difference in relation to the relative frequencies that were learnt in the samples used for generating the profile.

Following this principle, each of the documents in all of the following experiments were rendered as a vector with two scores per grammatical structure in the profile, according to the class to which it belongs: the first score is the normalized frequency observed in the document divided by the normalized frequency from the profile for the reception corpus; and the second score is the normalized frequency observed in the document divided by the normalized frequency from the profile for the production corpus. For both those scores, if there is no significant difference between the normalized frequencies, the score was set to 1.

Since a well-formed text is composed not only of grammar, but also of a series of linguistic information, including some that are not yet computationally verifiable (e.g., certain pragmatical and discursive aspects), we designed the experiments in the next sections in a way that they include not only our profile based on grammar, but also vocabulary and readability measures. By doing so, we are adding to our profile features that are well described in the literature and that may compensate for some of the extra linguistic information that is lacking in the profile. Even so, in each of the experiments, we also tested all of the feature sets separately. This allowed us to observe the possible contribution of others measures to the language profile that we propose here.

For the vocabulary features, we used as basis a frequency list that was extracted from the British National Corpus (BNC) (Aston and Burnard, 1998) and divided in five pedagogically distributed ranges

Table 1: Grammatical Structures: cases of overuse and underuse contrasting the productive with the receptive corpus

		Beginner	**Intermediate**	**Advanced**
1	*genitive*	-	-	-
2	*advanced modal verbs*	-	+	+
3	*past simple*	-	-	-
4	*present perfect*	-	-	-
5	*present simple*	+	+	+
6	*verb "to be" in the present simple*	+	+	+
7	*infinitive with "to" after a verb*	-	+	+
8	*number of direct complements*	-	-	-
9	*present participle*	+	+	-
10	*imperative*	+	+	
11	*number of main verbs*	-	-	
12	*number of subjects*	-	-	
13	*simple modal verbs*	-		+
14	*modal verbs with ellipsed main verb*	-		+
15	*passive voice*	-		-
16	*relative clauses*	-		-
17	*future with "will"*	-		+
18	*verb "to be" in the past simple*	-		-
19	*infinitive with "to" after an adjective*	-		+
20	*connectives of time*	-		+
21	*connectives of reason and result*	+		+
22	*connectives of purpose*	-		-
23	*use of articles*	-		
24	*use of plurals*	-		
25	*use of numbers*	+		
26	*present continuous*	+		
27	*use of present and present perfect after time connectives*		+	
28	*connectives of condition*		+	
29	*use of would to express hypothesis*			+
30	*prepositional verbs*			+
31	*infinitive with "to" after a noun*			+
32	*gerund after prepositions*			-
33	*connectives of alternative*			-
34	*connectives of example and explanation*			+

(Martinez, 2011; Cobb, 2013). Using this list we calculated the frequency of words from each range in each of the documents from our corpora. As a means of normalizing the frequency, we divided the sum of the frequency of words from each BNC range in the document by the total number of words from all ranges in the same document. Finally, for the readability measures, we used the Dale-Chall Score (Dale and Chall, 1948), the Flesch-Kincaid measure (Kincaid et al., 1975), and the Gunning Fog Index (Gunning, 1952), which are commonly used in the literature.

5 Text Classification: Production Corpus

Having a language profile at hand that emphasizes the divergence between reception and production in language learning, we used it to assess how good it is for classifying texts produced by language learners in the respective levels. This is an important task in the goal of helping learners to write texts that match their level, since the first step in evaluating a text is to attribute it to the correct level, so that it is possible

to further analyze its weaknesses and strengths.

For this test, we randomly selected documents from the production corpus that were not used to generate the divergences. For these random selection of documents, we used certain constraints, so that the documents must have been evaluated above 90%, so as to match the criteria employed by Wilkens et al. (2018), who use the same corpus, so that we would have a comparable basis. The corpus was divided in beginner, intermediate, and advanced classes, as explained in Section 3.2. The full sample contained 15,068 documents (6 thousand for beginner and intermediate, and 3,068 for advanced[7]). For the classification task, we used the Random Forest algorithm (Breiman, 2001) with a ten-fold cross-validation.

The results of this experiment are shown in Table 2 in terms of F-measure and standard deviation. For the beginner level, our best F-measure was 0.939, decreasing to 0.858 in the intermediate level and further to 0.822 for the advanced level. By averaging the three levels, we got a non-weighted result of 0.872 (0.882 if weighted). The best average result was achieved by mixing all three measures, and, with exception of the advanced level, which fared a bit better with only vocabulary features, the other levels also had better results using the combined approach. We can also see that the worst results were produced by readability measures, which scored consistently below the other features. Our best results in this experiment are consistent with the state of the art for document classification in levels, as can be seen in the description by Wilkens et al. (2018).

Table 2: F-measure and Standard Deviation for the Level Classification in the Production Corpus

	Profile	**Vocabulary**	**Readability**	**All**
Beginner	0.922 (0.024)	0.893 (0.020)	0.775 (0.030)	**0.939** (0.022)
Intermediate	0.819 (0.000)	0.811 (0.000)	0.589 (0.000)	**0.858** (0.000)
Advanced	0.747 (0.000)	**0.822** (0.000)	0.464 (0.000)	0.819 (0.000)
Average	0.830 (0.009)	0.842 (0.010)	0.609 (0.014)	**0.872** (0.009)

Values in bold reflect the best scores in each level and the average best score. All scores were significantly different from the best scores with a confidence of 99%.

5.1 Text Scoring

This experiment was conducted to observe if our language profile was good for evaluating texts produced by language learners in terms of score (the actual score attributed to a text by an evaluator regarding its well-formedness in relation to the given task). To do so, we randomly selected 70 texts from the production corpus per each ten score points[8] as input for the Random Forest algorithm in a three-fold cross-validation. As such, for each document received as input, the algorithm produced a score from zero to a hundred, in the same fashion as an expert would, for each of the EFCAMDAT documents in the sample. After that, we calculated the correlation of the scores produced by the algorithm with the actual scores that were given by the experts that evaluated the Cambridge Exams.

Using a total of 1,982 documents (734 documents for beginner, 700 for intermediate and 548 for advanced), we ran a three-fold cross-validation. The results in terms of Pearson's correlation and standard deviation are presented in Table 3. Again, as we saw for the classification experiment, the combined features yielded the best results for the beginner and intermediate levels, while the vocabulary alone was better to predict the scores of the advanced level, although this result was not significantly different from the one achieved by the combined features. Looking at the table and disconsidering the readability alone, which was a catastrophe, the correlations, especially for the advanced level, were not so bad, ranging from 0.509 to 0.685. However, by looking at the root mean squared error (RMSE), we see values ranging from 30.42 (advanced level) to 32.14 (beginner level), with a stop at 31.24 (intermediate

[7]This is the whole of EFCAMDAT for C1 and C2 combined for scores above 90% after excluding those that were used for calculating the divergence scores.

[8]We divided the whole corpus in eleven truncated ranges: from 0 to 9, 10 to 19 etc., up to 90-99, and 100 as a separate range, for each of the three classes (beginner, intermediate, and advanced). The EFCAMDAT contains lots of documents evaluated with higher notes, but not so many on the lower side. For some of the lower score ranges, there was not 70 documents, so we used all those available. None of these documents were present in the production corpus that was used for developing the language profile.

level). These values, which were not significantly different between each other in the levels for all setups, are far from good.

These results indicate that other factors need to be taken into consideration for the evaluation of a learner's text in terms of score, not only grammatical and/or vocabulary features, let alone readability measures. It is also important to consider that, for the scores, there is always a strong subjective impact based on the expert's opinion, which is beyond our actual capacity of modeling.

Table 3: Correlation and Standard Deviation for the Scoring Experiment

	Profile	**Vocabulary**	**Readability**	**All**
Beginner	0.457 (0.044)	0.445 (0.042)	0.253 (0.054)	**0.509** (0.034)
Intermediate	0.459 (0.044)	*0.512 (0.034)	0.242 (0.056)	**0.524** (0.037)
Advanced	0.624 (0.038)	**0.685** (0.047)	0.364 (0.055)	*0.674 (0.033)

Values in bold reflect the best scores in each level and the average best score. The values with a star (*) were not significantly different from the best scores with a confidence of 99%.

6 Text Classification: Reception Corpus

This last experiment was designed to test the capacity of our profile to classify texts that are used as input for language learning activities. Although this task does not directly relate to helping a learner in a writing activity, it does serve as an extrinsic test for evaluating the quality of our language profile, while also being an important task in language learning in general.

This experiment followed the exact methodology described in Section 5 for the production corpus, with the obvious difference that here we used the reception corpus as basis and, as such, we had a quite drastic reduction in the number of documents used for the classification, especially because we used only those documents that were not used for generating our language profile. So, to improve the corpus size, we sorted 10 random document samples from those that were not used in the profile. This process yielded a corpus of 1,892 documents[9]. We then used a ten-fold cross-validation with the Random Forest algorithm. Table 4 shows the results for this experiment.

Table 4: F-measure and Standard Deviation for the Level Classification in the Reception Corpus

	Profile	**Vocabulary**	**Readability**	**All**
Beginner	0.891 (0.053)	*0.903 (0.042)	0.878 (0.049)	**0.922** (0.039)
Intermediate	0.861 (0.000)	0.916 (0.000)	0.853 (0.000)	**0.921** (0.000)
Advanced	0.914 (0.000)	**0.984** (0.000)	0.932 (0.000)	0.982 (0.000)
Average	0.889 (0.033)	*0.934 (0.027)	0.888 (0.031)	**0.942** (0.026)

Values in bold reflect the best scores in each level and the average best score. The values with a star (*) were not significantly different from the best scores with a confidence of 99%.

The results of this experiment were not much different from the one that we carried out with the production corpus. We saw a general improvement of the scores, achieving a non-weighted average F-measure of 0.942 (0.940, if weighted). But here the vocabulary features excelled, presenting an average result similar to the combined model, and significantly exceeding the combined model for the advanced class. The language profile alone fared less well for the classification of reception texts, but still beat the readability features for the beginner and intermediate classes.

7 Conclusion

This study aimed at developing a language profile for second language acquisition that considers both productive and receptive knowledge, so that the information from the profile could be used as a helping tool for the learners to write a more naturally sounding text. We also hypothesized that, by adding

[9]Many of the documents in the corpus are duplicated due to the ten random samples that were selected.

grammatical information to already tested and proven vocabulary and readability features, we would achieve better results in terms of SLA-related tasks.

For achieving these goals, we used two corpora, one representing the productive knowledge and the other the receptive knowledge. We annotated both corpora with pedagogically relevant grammatical information and calculated a divergence score for each of the grammatical structures to find out which ones were different in the comparison of both corpora.

The results of the divergence score were further improved by an analysis of overuse or underuse of structures in the production corpus in relation to the production corpus. This improvement to the divergence score resulted in a grammatical profile that shows where and how the written texts from language learners differ from reception texts. The structures shown in Table 1 also present clues for grammatical structures that are possibly too easy or for those that remain a difficulty throughout the learning process.

By conceiving experiments for the classification of production and reception texts, we could observe that our profile can very well model the written texts, achieving results that are comparable to those of true and tested vocabulary and readability features. Regarding our hypothesis, the addition of grammar to lexical information did yield the best results in the production corpus, but the lexical information alone was enough to achieve the same result as the combined approach in the reception corpus.

It is important to emphasize that our results for the classification experiment in terms of the reception corpus are competitive with the state of the art. For instance, Xia et al. (2016), by means of a profound analysis of parameters, achieved an F-measure of 0.845 using readability features and a lexical distribution similar to our vocabulary features. The same is true for the classification experiment regarding the production corpus, since we achieved similar results to those presented by Wilkens et al. (2018).

In terms of the scoring experiment, we observed that scoring is a very challenging task and that there is still need for further study before we can get good results. Even so, we did get some encouraging results, reaching almost 0.7 correlation for the advanced class in a task that is known to present high discordance among evaluators.

As future work, we intend to increase the size of the reception corpus by including texts from didactic material that is used in second language classes. We are also going to develop a system for supporting the writing of texts that takes as basis our grammar profile, by detecting deviating behavior of grammatical structures in texts produced by the user.

iParaphrasing: Extracting Visually Grounded Paraphrases via an Image

Abstract

A paraphrase is a restatement of the meaning of a text in other words. Paraphrases have been studied to enhance the performance of many natural language processing tasks. In this paper, we propose a novel task *iParaphrasing* to extract *visually grounded paraphrases (VGPs)*, which are different phrasal expressions describing the same visual concept in an image. These extracted VGPs have the potential to improve language and image multimodal tasks such as visual question answering and image captioning. How to model the similarity between VGPs is the key of iParaphrasing. We apply various existing methods as well as propose a novel neural network-based method with image attention, and report the results of the first attempt toward iParaphrasing.

1 Introduction

A paraphrase is a restatement of the meaning of a word, phrase, or sentence within the context of a specific language (e.g., "a red jersey" and "a red uniform shirt" in Figure 1 are paraphrases) (Bhagat and Hovy, 2013). Paraphrases have been exploited for natural language understanding, and shown to be very effective for various natural language processing (NLP) tasks, including question answering (Riezler et al., 2007), summarization (Zhou et al., 2006), machine translation (Chu and Kurohashi, 2016), text normalization (Ling et al., 2013), textual entailment recognition (Androutsopoulos and Malakasiotis, 2010), and semantic parsing (Berant and Liang, 2014).

In this paper, we propose a novel task named, *iParaphrasing*, to extract *visually grounded paraphrases (VGPs)*. We define VGPs as different phrasal expressions that describe the same visual concept in an image. Nowadays, with the spread of the web and social media, it is easy to collect large amounts of images with their describing text. For example, different news sites release news with the same topic using the same image; photos with many comments are posted to social networking sites and blogs. As these describing texts are written by different people but about the same image, there are potentially large amounts of VGPs in the describing text (Figure 1). We aim to accurately extract these paraphrases using the image as a pivot to associate different phrases.

The extracted VGPs can be applied to various computer vision (CV) and NLP tasks, such as image captioning (Vinyals et al., 2015) and visual question answering (VQA) (Wu et al., 2017), for the better understanding of both images and languages. For example, a VQA system must understand queries of different expressions about the same visual concept (e.g., "a male" and "the pitcher" in Figure 1) in order to answer a question properly. VGPs can also be applied to the evaluation of image captioning systems in the similar way as paraphrases have been applied for machine translation evaluation (Snover et al., 2009).

As a pioneering study, we work on iParaphrasing on the Flickr30k entities dataset (Plummer et al., 2015). This dataset contains 30k images with 5 captions per image annotated via crowdsourcing, which can be seen as a very small subset of the data available in the web and social media. Figure 1 shows an example image together with its five captions taken from this dataset. In the Flickr30k entities dataset, entities (i.e., noun phrases) in the captions have been manually aligned to their corresponding image

Proceedings of the 27th International Conference on Computational Linguistics, pages 3479–3492
Santa Fe, New Mexico, USA, August 20-26, 2018.

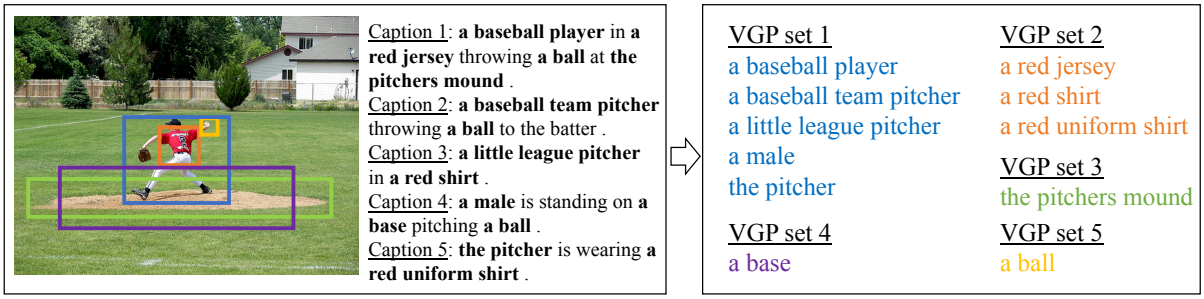

Figure 1: An example from the Flickr30k entities dataset, in which an image is described by five captions (entities in the captions are marked in bold). Our task is to extract the entities that describe the same visual concept (represented as an image region) in the image as VGPs. Note that the image regions are not given as input but are drawn here for comprehensibility.

regions (Plummer et al., 2015). Therefore, we can obtain a set of phrases annotated with the same image region. This set of phrases are used as the ground truth VGPs in our study. The goal of this work is to extract these VGPs.

We formulate our task as a clustering task (Section 3), where the similarity between each entity pair is crucial for the performance. We apply many different unsupervised similarity computation methods (Section 4) including phrase localization-based similarity (Plummer et al., 2017) (Section 4.1), translation probability-based similarity (Koehn et al., 2007) (Section 4.2), and embedding-based similarity (Mikolov et al., 2013; Klein et al., 2014; Plummer et al., 2015) (Section 4.3). In addition, we propose a supervised neural network (NN)-based method using both textual and visual features to explicitly model the similarity of an entity pair as VGPs (Section 5). Experiments show that our proposed NN-based method outperforms the other methods.[1]

2 Related Work

2.1 Paraphrase Extraction

Previous studies extract paraphrases from either monolingual corpora or bilingual parallel corpora. One major approach is to use the distributional similarity (Harris, 1954) with regular monolingual corpora (a large collection of text in a single language) (Lin and Pantel, 2001; Bhagat and Ravichandran, 2008; Marton et al., 2009), or monolingual comparable corpora (a set of monolingual corpora that describe roughly the same topic in the same language) (Barzilay and Lee, 2003; Chen and Dolan, 2011). Distributional similarity stems from the distributional hypothesis (Harris, 1954), stating that words/phrases that share similar meanings should appear in similar distributions. This approach sometimes suffers from noisy results, because the distributed similarity often maps antonyms to closer points. Some methods try to extract paraphrases from monolingual parallel corpora (a collection of sentence level paraphrases) (Arase and Tsujii, 2017; MacCartney et al., 2008), but such monolingual parallel corpora are rarely available.

Bilingual parallel corpora (a collection of sentence-aligned bilingual text) enjoys more availability than monolingual parallel corpora as they are mandatory for training machine translation systems. Bilingual parallel corpora can be used for paraphrase extraction, with bilingual pivoting (Bannard and Callison-Burch, 2005). This method assumes that two source phrases are a paraphrase pair if they are translated to the same target phrase. Bilingual pivoting has been further refined by using syntax information (Callison-Burch, 2008) or mutual information (Kajiwara et al., 2017). These methods have led to the construction of a multilingual paraphrase database (Ganitkevitch and Callison-Burch, 2014).

Note that our definition of paraphrases may look different from the studies mentioned above, as our paraphrases are a set of noun phrases that represent the same visual concept. Our idea to extract paraphrases under this definition is to use image captioning datasets (Young et al., 2014; Chen et al., 2015),

[1]Codes and data for reproducing the results reported in this paper are available at `https://github.com/ids-cv/coling_iparaphrasing`

which usually contain several captions for each image, and currently scale to sub-million images, instead of a bilingual parallel corpus with limited availability. To the best of our knowledge, this is the first study that aims to extract paraphrases from such multimodal datasets consisting of images and their captions.[2]

2.2 Coreference Resolution

Coreference resolution is a task to find the expressions that refer to the same entity in a text (Soon et al., 2001; Lee et al., 2017). Our task in this paper focuses on extracting entities that describe the same visual concept, making the formulation similar to coreference resolution. Our task differs from conventional coreference resolution that it requires visual grounding. In addition, the targets of coreference resolution are the entities in a sentence or a document, while our targets are the entities in the captions of an image that are quasi-paraphrases but are not related to each other in discourse level like sentences in a document. For coreference resolution, the context in a sentence or discourse information in a document are crucial, but discourse information does not exist in our task.[3] In the context of vision and language tasks, Konget al. (2014) used noun/pronoun coreference resolution in sentential descriptions of RGB-D scenes for improving 3D semantic parsing. The texts being handled in their work are either sentences or documents, and their targets are limited to noun words and pronouns but we extract noun phrases. Because our goal is not limited to entities but arbitrary phrases, we believe that comparing to coreference resolution, iParaphrasing is a more forethoughtful name to define our task for future research.

2.3 Phrase Localization

Phrase localization is a task to find an image region that corresponds to a given phrase in a caption, which is closely related to our VGP extraction task. Plummer et al. (2015) pioneered this work, in which they annotated phrase-region alignment in the Flickr30k image-caption dataset (Young et al., 2014) and released it as the Flickr30k entities dataset. They also proposed a method based on canonical correlation analysis (CCA) (Hardoon et al., 2004) that learns joint embeddings of phrases and image regions for associating them. Wang et al. (2016a) proposed joint embeddings using a two-branch NN. Fukui et al. (2016) used a multimodal compact bilinear pooling method to combine textual and visual embeddings. Rohrbach et al. (2016) proposed a convolutional NN (CNN)-recurrent NN (RNN)-based method for this task. They learn to detect a region for a given phrase and then reconstruct the phrase using the detected region. Wang et al. (2016b) noticed that the relationships between phrases should agree with their corresponding regions, and proposed a joint matching method, but their method only considers the "has-a" relationship that is explicitly indicated by possessive pronouns. Previous studies rely on region proposal to produce a number of region candidates for phrase localization, Yeh et al. (2017) proposed a unified framework that can search over all possible regions. Plummer et al. (2017) used spatial relationships between pairs of entities connected by verbs or prepositions, which achieved the state-of-the-art performance. In this paper, we use the current state-of-the-art phrase localization method of (Plummer et al., 2017) as a baseline for VGP extraction.

2.4 Other Vision and Language Tasks

Vision and language tasks have been a hot research area recently in both the CV and NLP communities. Various efforts have been made for many multimodal tasks such as image object/region referring expression grounding (Kazemzadeh et al., 2014; Mao et al., 2016; Hu et al., 2017; Cirik et al., 2018) visual captioning (Vinyals et al., 2015; Xu et al., 2015; Bernardi et al., 2016; Laokulrat et al., 2016), text-image retrieval (Otani et al., 2016), visual question answering (Wu et al., 2017), visual dialog (Das et al., 2017a; Das et al., 2017b) and video event detection (Phan et al., 2016). Some researchers also have employed images for improving NLP tasks, such as multimodal machine translation (Specia et al., 2016), cross-lingual document retrieval (Funaki and Nakayama, 2015), and textual entailment recognition (Han

[2] Although (Plummer et al., 2015) annotated the VGPs in the Filickr30k entities dataset, they did not propose any methods to extract them. (Regneri et al., 2013) collected sentence level paraphrases by aligning video scripts with the same time frame; these sentence level paraphrases are essentially similar to captions of an image.

[3] If we treat multiple captions as a document forcibly, we could apply a coreference resolution approach for our task.

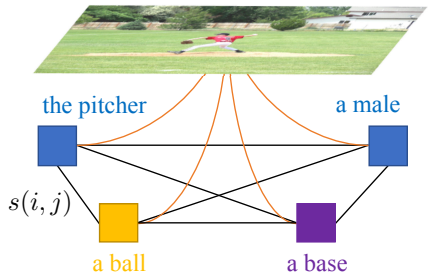

Figure 2: An overview of our VGP extraction formulation. We extract VGP via clustering, where the entity-entity similarity $s(i, j)$ is the key. We compare both unsupervised and supervised methods using entity-image and entity-entity associations for computing this similarity.

et al., 2017). iParaphrasing is a novel CV+NLP task, which to the best of our knowledge has not been studied before and can boost the performance of various multimodal and NLP tasks.

3 Paraphrase Extraction via Clustering

We formulate the paraphrase extraction from the Flickr30k entities dataset as a clustering task. Given an image and all the entities in the corresponding captions, the task is to cluster the entities[4] to its corresponding visual concepts represented as image regions. The number of clusters (i.e., the number of paraphrase sets in a set of an image and captions) is not explicitly given in our task. Therefore, we apply the affinity propagation algorithm (Frey and Dueck, 2007) to cluster entities, which can estimate the number of clusters as well.

Affinity propagation creates clusters by iteratively sending two types of messages between pairs of entities until convergence. The first type is the responsibility $r(i, j)$ sent from entity i to candidate representative entity j, indicating the strength that entity j should be the representative entity for entity i, which is defined as:

$$r(i,j) \leftarrow s(i,j) - \max_{\forall j' \neq j} \{a(i,j') + s(i,j')\} \tag{1}$$

where $s(i, j)$ is the similarity between entities i and j. The second type is the availability $a(i, j)$ sent from candidate representative entity j to entity i, indicating to what degree that candidate representative entity j is the cluster center for entity i, which is defined as:

$$a(i,j) \leftarrow \min\Big\{0, r(j,j) + \sum_{\forall i' \notin \{i,j\}} \max\{0, r(i',j)\}\Big\} \tag{2}$$

At the beginning, the values of $r(i, j)$ and $a(i, j)$ are set to zero, and they are updated in every iteration until convergence. We optimize the number of clusters on a validation split by adjusting the preference (i.e., self similarity $s(i, i)$) of affinity propagation.

Figure 2 shows an overview of our formulation, where the similarity between the entities is the key. We apply various unsupervised methods for computing this similarity, and propose a supervised NN-based model.

4 Unsupervised Similarity Methods

We apply phrase localization for modeling the entity-entity similarity based on entity-image association (Section 4.1). In addition, we apply various methods for modeling the entity-entity similarity directly (Sections 4.2, and 4.3).

[4]In this paper, we assume that entities are given. In the case that entities are not given, we can easily extract them by chunking the noun phrases.

4.1 Phrase Localization-Based Similarity

The similarity between entities i and j is defined as:

$$s(i,j) = \sum_{r_m \in R} p(i|r_m)p(j|r_m) \tag{3}$$

where R is a set of image regions that are aligned to both entities i and j obtained with the phrase localization method of (Plummer et al., 2017); $p(i|r_m)$ is the localization probability of r_m for i, defined as:

$$p(i|r_m) = \frac{l(i,r_m)}{\sum_{r_m \in R} l(i,r_m)} \tag{4}$$

where $l(i,r_m)$ is the localization score of region r_m for entity i obtained using the method of (Plummer et al., 2017).

4.2 Translation Probability-Based Similarity

The similarity between entities i and j is defined as:

$$s(i,j) = p(i|j)p(j|i) \tag{5}$$

where $p(i|j)$ and $p(j|i)$ are the direct and inverse translation probabilities of an entity pair i and j, which are calculated using a conventional statistical machine translation (SMT) (Koehn et al., 2007) method:

1. Generate a pseudo parallel corpus using the captions in the dataset, which treats the 5 captions for each image as monolingual parallel sentences and pair each of the sentences that leads to $\binom{5}{2} = 10$ sentence pairs per image.

2. Apply word alignment to the parallel corpus using IBM alignment models (Brown et al., 1993) in two directions with the grow-diag-final-and heuristic (Koehn et al., 2007) to align the words in each caption pair.

3. From the word-aligned parallel corpus, extract entity pairs such that the words inside an entity pair are aligned. Then $p(i|j)$ and $p(j|i)$ are calculated as follows:

$$p(i|j) = \frac{c(i,j)}{\sum_k c(i,k)}, \quad p(j|i) = \frac{c(i,j)}{\sum_k c(j,k)} \tag{6}$$

   where $c(i,j)$ is the number of co-occurrence of i and j in the word-aligned corpus.

4.3 Embedding-Based Similarity

In this method, the similarity between entities i and j is defined as:

$$s(i,j) = \frac{\mathbf{t}_i^\top \mathbf{t}_j}{\|\mathbf{t}_i\|\|\mathbf{t}_j\|} \tag{7}$$

where $\mathbf{t}_i$ and $\mathbf{t}_j$ are the phrase embeddings of i and j. We compare three different methods for phrase embeddings.

4.3.1 Word Embedding Average

We represent each word with a 300 dimensional word2vec (Mikolov et al., 2013) vector pre-trained on the Google News corpus.[5] We remove stop words in each entity, and calculate the representation of each entity using the average of all word embeddings.

[5] https://github.com/mmihaltz/word2vec-GoogleNews-vectors

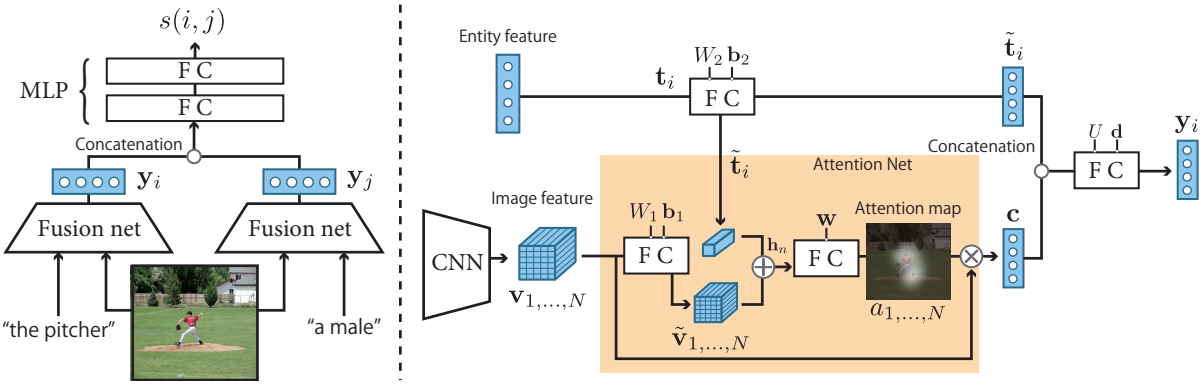

Figure 3: Our supervised NN with image attention-based similarity model (left) and its fusion sub-network (right).

4.3.2 Fisher Vector

Fisher vector is a pooling over word2vec vectors of individual words (Klein et al., 2014), which has been used in the phrase localization task for representing the entities (Plummer et al., 2015). To compute the Fisher vector for an entity, we represent the entity by the HGLMM Fisher vector encoding (Klein et al., 2014) of the word vectors, following (Plummer et al., 2015).[6]

4.3.3 Fisher Vector with CCA

Projecting the feature vectors of image regions and entities to a shared semantic space can provide strong associations between the image regions and entities, which has the potential to improve the performance of VGP extraction. Therefore, we learn a CCA projection on the Flickr30k entities dataset for the image region feature vectors and entity feature vectors with (Plummer et al., 2015), in which the normalized CCA formulation of (Gong et al., 2014) is used. The columns of the CCA projection matrices are scaled by the eigenvalues, and the feature vectors are projected by these matrices and normalized to the dimensionality of 4,096. The image region feature vectors are extracted using Faster R-CNN (Ren et al., 2015).[7] We use Fisher vectors for entity feature vectors.

5 Supervised Similarity Model Based on Neural Network with Image Attention

We propose a NN-based supervised model. This model computes the similarities of entity pairs as VGPs by explicitly modeling the associations between them and an image. Figure 3 illustrates our proposed NN model.[8] Given an entity pair and its corresponding image, we construct two separated *fusion nets* for each entity (Figure 3 (right)). Note that parameters of these two fusion net are shared. A fusion net represents an entity with a concatenation of its entity feature vector and visual context vector. The visual context vector is computed with an attention mechanism, indicating to which part of the image should be paid attention, in order to judge whether the entity pair is VGP or not. The outputs of the two fusion nets are then fed into a multilayer perceptron (MLP) to compute the similarity of the two entities.

Formally, let V be a 196×512 feature map[9] extracted from the `conv5_3` layer in the VGG-16 network (Simonyan and Zisserman, 2015) for an input image; $\mathbf{v}_n$ is a 512 dimensional vector at position n of V. Given an entity feature vector $\mathbf{t}_i$ and $\mathbf{v}_n$, we first transform them with fully connected (FC) layers whose unit sizes are 512:

$$\tilde{\mathbf{v}}_n = \mathrm{norm}_{\mathrm{L2}}(W_1\mathbf{v}_n + \mathbf{b}_1), \quad \tilde{\mathbf{t}}_i = \mathrm{norm}_{\mathrm{L2}}(W_2\mathbf{t}_i + \mathbf{b}_2) \tag{8}$$

[6]The Fisher vector is constructed with 30 centers of both first and second order information, which results in a very sparse vector whose dimensionality is $300 \times 30 \times 2 = 18000$. Therefore, we apply principal component analysis (PCA) to convert it to a lower dimensionality of 4,096.

[7]https://github.com/ShaoqingRen/faster_rcnn

[8](Yin et al., 2016) proposed a CNN network with attention for sentence level paraphrase identification; our model differs from theirs that we fuse both textual and visual information while theirs is a text only model.

[9]An image is split into $14 \times 14 = 196$ sub-images, and represented as a 196×512 feature map.

where $\mathrm{norm}_{\mathrm{L2}}(\cdot)$ indicates L2 normalization to an input vector. We then compute an attention value a_n for $\mathbf{v}_n$ as:

$$\mathbf{h}_n = \mathrm{relu}(\tilde{\mathbf{v}}_n + \tilde{\mathbf{t}}_i), \quad e_n = \mathbf{w}^\top \mathbf{h}_n, \quad a_n = \frac{\exp(e_n)}{\sum_{n=1}^{N} \exp(e_n)} \tag{9}$$

where $N = 196$. After obtaining a_n, we fuse a visual and an entity feature vector to $\mathbf{y}_i$ as:

$$\mathbf{c} = \sum_{n=1}^{N} a_n \mathbf{v}_n, \quad \mathbf{y}_i = U[\mathrm{norm}_{\mathrm{L2}}(\mathbf{c}), \tilde{\mathbf{t}}_i] + \mathbf{d} \tag{10}$$

where $[\cdot, \cdot]$ indicates the concatenation of two vectors, $\mathbf{c}$ is a visual context vector. We compute fusion feature vectors $\mathbf{y}_i$ and $\mathbf{y}_j$ with the corresponding image. Finally, we feed them to a two-layer MLP network with ReLU non-linearity, whose unit sizes are 128 and 1, respectively, to produce the similarity of the entity pair.

6 Experiments

6.1 Settings

We conducted experiments on the Flickr30k entities dataset (Plummer et al., 2015). This dataset contains 31,837 images, which is described with 5 captions annotated via crowdsourcing. We followed the 29,873 training, 1,000 validation, and 1,000 test image splits used in the phrase localization task (Plummer et al., 2015). Our task is to automatically cluster the entities in the captions that describe the same visual concept (i.e., region in the dataset) in the image as VGPs. Entities that share the same ID and group type (e.g., "a red jersey," "a red shirt" and "a red uniform shirt" in Figure 1 share the same entity ID and group type "/EN#19026/clothing") are treated as the ground truth VGP clusters in our evaluation.[10] As stop words should not be considered for computing the entity similarities, we preprocessed the entities in the dataset by removing stop words for all the methods.

We evaluated both clustering and pairwise performance.[11] The entity clustering performance for each image was measured with adjusted Rand index (ARI) (Hubert and Arabie, 1985). We used the implementation in the Scikit-learn machine learning toolkit (Thirion et al., 2011)[12] for computing ARI. We report the mean of ARI scores for all the images in the test split. To evaluate the performance for clustering, we optimized the number of clusters by adjusting the preference for affinity propagation on the validation split to maximize the ARI using the Bayesian optimization algorithm (Mockus, 1989) implemented in GPyOpt.[13] The pairwise performance was evaluated with precision, recall, and F-score, defined as:

$$\mathrm{precision} = \frac{\#\mathrm{predicted\_positive}}{\#\mathrm{predicted}}, \mathrm{recall} = \frac{\#\mathrm{predicted\_positive}}{\#\mathrm{true\_positive}}, \mathrm{F\text{-}score} = 2 \times \frac{\mathrm{precision} \times \mathrm{recall}}{\mathrm{precision} + \mathrm{recall}} \tag{11}$$

where an entity pair with a similarity higher than a threshold is treated as $predicted$, which is compared against the ground truth to judge whether it is $predicted\_positive$ or not. We report the performance using the similarity threshold tuned on the validation split that maximizes the F-score.

We used the affinity propagation implementation[14] in Scikit-learn for clustering. We compared the performance of the different similarity methods described in Sections 4 and 5, where the detailed settings for the methods were as follows:

[10] There is an entity type named "notvisual" in the dataset (e.g., "the batter" in Figure 1), which means this entity has no corresponding visual regions in the image. In our evaluation, we excluded this "notvisual" type, because all entities that are not visual are annotated with the same entity ID and thus ground truth VGPs for these "notvisual" entities are unavailable in the dataset. There are entity pairs in the dataset that are the same after removing the stop words (e.g., "a man" and "the man"), we treated them as one entity for evaluation. In addition, entities that do not have corresponding regions in the image were excluded from evaluation.

[11] We did not report phrase localization accuracies for our proposed NN-based supervised model, because attention is different from phrase localization. Instead of determining the best region corresponding to the given phrases, attention provides attention probabilities to the 196 sub-images, which cannot be used for evaluation directly. A soft-accuracy metric could be reported for discussion, but this metric is not directly comparable to previous phrase localization studies.

[12] http://scikit-learn.org/stable/modules/clustering.html#adjusted-rand-index

[13] https://github.com/SheffieldML/GPyOpt

[14] http://scikit-learn.org/stable/modules/generated/sklearn.cluster.AffinityPropagation.html

- Phrase localization (PL): we used the pl-clc toolkit,[15] which is an implementation of the localization method of (Plummer et al., 2017). For R in equation 3, we used the top 30 localization candidates for each entity. The localization scores for each entity and region pair obtained with (Plummer et al., 2017) were used to compute the similarity.

- Translation probability (TP): to get the entity translation probabilities, we first applied the GIZA++ toolkit[16] that is an implementation of the IBM alignment models (Brown et al., 1993) on the pseudo parallel corpus, and then a phrase table was extracted and the phrasal translation probabilities were calculated using state-of-the-art SMT toolkit Moses (Koehn et al., 2007).

- Word embedding average (WEA): see the detailed setting in Section 4.3.1.

- Fisher vector (FV): entity feature vectors were computed using the Fisher vector toolkit released by the authors,[17] following the settings described in Section 4.3.2.

- Fisher vector w/ CCA (FV+CCA): image region feature vectors and entity feature vectors were projected into a 4,096 dimensional space CCA trained on the training split of the Flickr30k entity dataset (Section 4.3.3).

- Supervised NN (SNN): to show the effectiveness of the fusion net (Section 5), we compared a supervised NN-based setting that only feeding the entity feature vectors to the MLP (Figure 3 (left)) for paraphrase similarity prediction. This setting only uses entity feature vectors as input for the NN. It was trained on the training split of the Flickr30k entity dataset. We used all the ground truth VGP pairs in the training split as positive instances. During training, we constructed mini-batches with 15% of positive instances and 85% of randomly sampled negative instances. We used Adam for optimization with a mini-batch size of 300 and weight decay of 0.0001. The learning rate was initialized to 0.01, which was halved at every epoch. We used sigmoid cross entropy loss. We terminated training after 5 epochs, where we observed the loss converged on the validation split. For the entity feature vectors, we compared three different settings described above namely: WEA, FV, and FV+CCA.

- SNN+image: this setting is for our proposed supervised NN-based method described in Section 5. We again compared the three different entity feature vectors. We used VGG-16 (Simonyan and Zisserman, 2015) for the image features. The model was trained with the same configuration as the SNN setting.

- Ensemble: the ensemble of the SNN and SNN+image models that takes the average similarity given by both models. The motivation of this setting is to complement these two models to each other.

6.2 Results

Table 1 shows the results of all the different methods. We report the performance based on the entity types to better understand the performance difference of each method, i.e., "all" evaluates on all entities, whereas "single" and "multi" only evaluate on entities with one single token and multiple tokens, respectively, after removing stop words. For the unsupervised methods, we can see that PL does not show good performance. This is due to the low performance of phrase localization.[18] TP shows a fairly high F-score, but a very low ARI score. The reason for this is that the translation probabilities are computed based on word alignment, leading to a similarity score of 0 to the unrelated entity pairs, which is not suitable for affinity propagation. WEA shows relatively good performance that is better than FV. This is because 45.84% of the entities in our task are single word type after removing the stop words, and converting the low dimensional word embedding to high dimensional and sparse Fisher vectors is harmful

Ensemble (FV+CCA)	**62.35** / 54.98 / 54.84	82.71 / 84.10 / 80.91	**85.67** / **83.50** / 87.06	**84.16** / **83.80** / **83.87**

Table 1: VGP extraction results ("all" evaluates on all entities, "single" and "multi" only evaluate on entities consist of one single token and multiple tokens after removing stop words, respectively; the methods above and below the double line are unsupervised and supervised, respectively).

for these single word entity pairs. However, for the performance of entities containing multiple words, the Fisher vector is better than word embedding average in the perspective of F-score. FV+CCA significantly outperforms FV. This is because it uses visual information in the training split that transforms the entity vectors and visual vectors into the semantic space that is helpful for detecting VGPs.

Regarding the supervised methods, NN-based methods using any entity feature vectors outperforms the methods that uses them in an unsupervised way. The reason for this is that it directly uses the paraphrase supervision in the training split, while the unsupervised methods do not. Using entity representation with better ARI and F-score for the SNN method can achieve better results. Our proposed method (SNN+image) that uses both textual and visual features shows better performance compared to SNN that uses textual features only, indicating that the usage of visual features is helpful for our VGP extraction task.[19] However, the performance improvements are not very large. We discuss the reason for this in detail in Section 6.3.1. The ensemble of SNN and SNN+image further improves the performance, which means that these two models complement each other.

6.3 Discussion

6.3.1 Neural Network w/ and w/o Images

We compared the SNN and SNN+image results, and found that image attention is helpful for identifying people-related paraphrases in about 50% cases, which are difficult to be determined based on the textual information only. In addition, the attention for these people-related paraphrases are well learned. We believe the reason for this is that many entities in the training split are people-related and thus they are well modeled. Figure 4a shows such an example, where the SNN (FV+CCA) model fails to identify these two entities "a group of order men" and "a group of people" as VGPs due to the diverse textual descriptions of the the same visual concept. Our proposed NN+image (FV+CCA) model correctly identifies these VGPs by paying attention to the image region of people in the image. In about 30% cases, the visual information is also helpful for the identification of other types of paraphrases, although the attention is not accurate. Figure 4b shows an example, where the SNN (FV+CCA) model could not identify two entities "a large display of artifacts" and "an art exhibit" as VGPs.

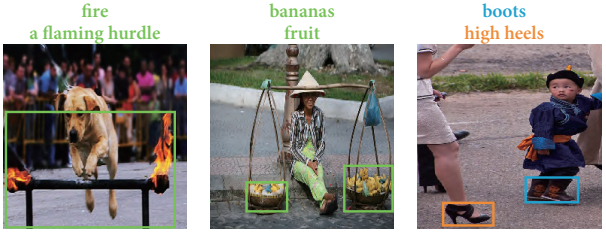
In about 20% cases, visual information could bring negative effects for paraphrase identification. Figure 4c shows an example that "the street window shops" and "a clothing store window" are mistakenly judged as a paraphrase after using the image information while using textual information judges correctly. Although, the attention for these entities refer to the same visual concept in the image, the entities actually refer to different concepts (i.e., "shop" and "window").

[19]The difference between SNN (FV+CCA) and SNN+image (FV+CCA) is whether using visual features for iParaphrasing explicitly or not. SNN (FV+CCA) uses image region features for learning entity features, but it does not use visual features explicitly for iParaphrasing.

(a) An improved example of people-related paraphrases.

(b) An improved example of scene-related paraphrases.

(c) A worsened example of scene-related paraphrases.



(d) Failed examples.

Figure 4: Examples comparing SNN (FV+CCA) with SNN+image (FV+CCA) ((a), (b), and (c); the leftmost images are the original ones, the images in the middle and on the right show attention of the entity pairs on the images, the degree of whiteness indicates the strength of attention, the identification results are shown under the images), and failed examples (d).

6.3.2 Failed Examples

Even the best method, namely Ensemble (FV+CCA), only achieves a ARI of 62.35 and a F-score of 84.16. We found that most false negative examples are sparse entity pairs that describe a image region in an image in a very diverse way, for example "fire" and "a flaming hurdle" (Figure 4d (left)), "bananas" and "fruit" (Figure 4d (middle)). These pairs are difficult not only for using textual features, but also for using image attentions. Most false positive examples are produced by the noisy phrase embedding method. For example, "boots" and "high heels" referring to the shoes on a boy and a lady, respectively, are identified as a paraphrase pair because of their closeness in the embedding space (Figure 4d (right)). Some of the false positive examples are caused by the noise introduced by the wrong attention in an image. For example, "a green snowman" and "his new toy" are attended to the similar image regions.

7 Conclusion

In this paper, we proposed iParaphrasing: a novel task to extract VGPs describing the same visual concept in an image. We not only applied various existing techniques for this task, but also proposed a NN-based method that uses both the textual and visual information to model the similarity between the VGPs. Experiments on the Flickr30k entities dataset showed that we achieved good performance.

For future work, we plan to study a multi task method for both VGP extraction and phrase localization to further improve the performance. We worked on the Flickr30k entities dataset, where noun phrases are given and VGP supervision is available, extracting VGP in an end-to-end manner without supervision in other datasets such as the Microsoft COCO caption dataset (Chen et al., 2015) is a more realistic scenario and could be more interesting. Extracting other types of paraphrases (e.g., prepositional and verb paraphrases) is another possible extension, which requires a much deeper understanding of the relation between phrases and image regions. We also plan to apply the VGPs for CV and NLP multimodal tasks, such as VQA.

Acknowledgement

This work was supported by ACT-I, JST and JSPS KAKENHI No. 18H03264. We are very appreciated to Prof. Kumiyo Nakakoji, Prof. Yuki Arase and Prof. Sadao Kurohashi for the helpful discussion of this paper. We also thank the anonymous reviewers for their insightful comments.

Abstract

In view of the differences between the annotations of micro and macro discourse relationships, this paper describes the relevant experiments on the construction of the Macro Chinese Discourse Treebank (MCDTB), a higher-level Chinese discourse corpus. Following RST (Rhetorical Structure Theory), we annotate the macro discourse information, including discourse structure, nuclearity and relationship, and the additional discourse information, including topic sentences, lead and abstract, to make the macro discourse annotation more objective and accurate. Finally, we annotated 720 articles with a Kappa value greater than 0.6. Preliminary experiments on this corpus verify the computability of MCDTB.

1 Introduction

In the field of natural language processing, discourse analysis is becoming increasingly important as the object of research gradually shifts from the word level to sentence, event and other semantic aspects. Discourse analysis primarily examines the text coherence and cohesion, including the analysis on structure, nuclearity and relationship. In discourse analysis, discourse refers to a series of continuous clauses, sentences or paragraphs of language as a whole; it not only includes text sequences but also the text structure and the logical relationship between text sequences.

Discourse analysis aims at studying the internal structure of texts and understanding the semantic relation between different text units. The granularity of this research can be clause, sentence, sentence group, paragraph and whole article. Commonly, discourse analysis is divided into microstructure and macrostructure analysis. The former is the study of intra-sentence or inter-sentence discourse relations, while the latter is discourse relation between sentence clusters, paragraphs and chapters (Van Dijk, 1976), which highlights a higher semantic level for text comprehension.

Example 1 is the content of the article chtb0155, which has a title (T) and five paragraphs (P1-P5), i.e., five discourse units. Figure 1 shows the example's macro discourse structure tree. The leaf nodes of the macro discourse structure tree refer to discourse units, and the internal nodes refer to relational nodes, which represent the larger discourse units of the relevant children. When connecting the parent and child nodes, the directed edge indicates that the child is an important discourse unit in the relationship, and the undirected edge indicates that the child is secondary in the relationship. Therefore, in Figure 1, there is an *Evaluation* relation between the discourse units P1 and P2, and they form a higher level unit (relational node) DU1-2. The discourse units P4 and P5 exhibit the *Purpose-Behaviour* relation and form a higher level unit DU4-5. Consequently, DU1-2 and P3 have the *Elaboration* relation and form a higher level unit DU1-3. Finally, DU4-5 is supplementary to DU1-3.

Based on the discourse structure tree shown in Figure 1, the article of Example 1 is easily understood. In the task of automatic summarization, for example, according to this discourse structure tree and the directed edges from the root node to the leaf nodes, the topic sentences of the leaf nodes can be used as the text summary. The summary of Example 1 is a combination of the first paragraph and the second paragraph's topic sentence, which is more appropriate than the simple use of the first paragraph as a summary of the full text.

Example 1: Content of chtb0155 (simplified version).

This paper uses the RST style to annotate macro discourse structure, nuclearity and relationship and constructs a Macro Chinese Discourse Treebank (MCDTB) including 720 articles. Compared with micro discourse annotation, macro discourse annotation has different characteristics. Macro discourse units are longer and fuzzier, and the relationship between discourse units is looser and less logical. To this end, we have formulated detailed annotation guidelines and quality assurance strategies. When marking macro discourse structure, nuclearity and relationship, we also annotate the annotation of the macro discourse information, such as topic sentences, lead and abstract, to make the annotation of macro discourse relations more objective and accurate.

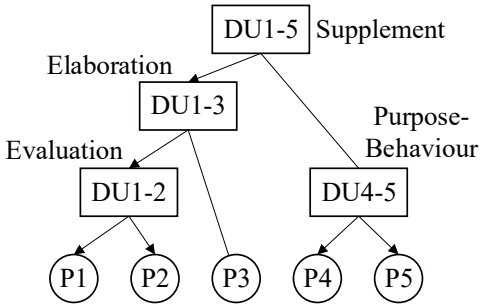

Figure 1: Macro discourse structure tree of chtb0155.

The rest of this paper is organized as follows. Section 2 overviews the related work. Section 3 describes the annotation system of MCDTB. Section 4 introduces our annotation process. Section 5 shows the corpus statistics on MCDTB. Section 6 provides a preliminary experiment. Finally, we present the study's conclusions and outline future work in Section 7.

2 Related Work

Discourse analysis is mainly divided into micro and macro discourse analysis. The theory of micro discourse primarily includes Hobbs model (Hobbs, 1985), rhetorical structure theory (RST) (Mann and Thompson, 1987; Mann et al., 1992), sentence group theory (Wu and Tian, 2000) and complex sentence theory (Fu, 2001), and the macro discourse theory has macro hyper-theme theory (Martin and Rose,

2003) and macro structure theory (Van Dijk, 1980). Under the guidance of these theories, various corpora have been developed accordingly.

In micro discourse analysis, the most popular corpora are RST-DT and PDTB. Based on RST, RST-DT (Marcu et al., 1999; Carlson et al., 2003) contained 385 articles from the Wall Street Journal annotated by 16 categories and 78 classes' rhetorical relations, to represent the relationship between two or more discourse units. Most of the elements of discourse units in RST-DT are phrases including partial clauses. To ensure the universality of the corpus, PDTB (Parsad et al., 2008) uses the LTAG (Lexicalized Tree-Adjoining Grammars) theory, and the annotation is entirely based on lexicalization. This approach primarily annotated the argument structure, including the conjunction and the semantic distinction information. The basic unit of argument is the event or state, and the specific form is the clause or sentence. The corpus is relatively large with 2,159 articles and approximately 1 million words.

Regarding Chinese micro discourse corpus, Zhou et al. (2015) used the PDTB annotation style to annotate 164 Chinese documents from CTB (Xue, 2005; Xue et al., 2005). The experiment demonstrated the transferability of the English discourse analysis theory in Chinese language. Lv et al. (2015) constructed a Chinese corpus of 496 news articles from People's Daily under the framework of the Chinese Framing Network (CFN) (Hao et al., 2007). Each news article annotated the discourse frame, structure and relationship. However, the discourse units are also smaller with a minimum of one sentence and a maximum of five sentences, and their research object is primarily at the word level. Li et al. (2014) integrated RST-DT and PDTB and used the representation method based on the connection dependence tree to annotate the Chinese Dependency Treebank (CDTB) containing 500 Chinese Xinhua news articles. However, this method only considered the discourse relationship annotation inside the paragraph and did not annotate the discourse relationship between paragraphs and the macro discourse information of the whole text.

Compared with the well-studied micro discourse analysis, macro discourse analysis is in the trial stage both in English and Chinese. In English, Sporleder and Lascarides (2004) attempted to perform an experiment on macro discourse analysis on RST-DT. However, RST-DT focuses on the micro discourse level, which is only tagging the relations on the sentence level and ignoring the relations on the paragraph level. Thus, it leads to some tailoring and correction when Sporleder carries out macro discourse analysis on the paragraph level. In Chinese, Chu et al. (2017) carried out relevant research on the nuclearity of macro discourse and made corresponding attempts to construct a macro discourse corpus.

In the field of Chinese discourse annotation, the number of relevant corpora is still relatively small, and its scale is also small. In addition, the existing micro discourse corpora still lack macro discourse information. For the task of analysis of macro discourse relationships, it is necessary to construct a macro discourse corpus, especially in Chinese.

3 Annotation System

3.1 Discourse Structure, Nuclearity and Relationship

Macro discourse analysis includes the analysis on discourse structure, nuclearity and relationship, similar to micro discourse analysis. However, macro discourse relationships are different from those of micro discourse. First, since the element of a macro discourse unit is a paragraph, macro discourse mainly considers the structure of paragraphs or its upper levels (e.g., DU1-2 in Figure 1). As shown in Figure 1, the annotation goal is to construct a discourse structure tree, where the leaf nodes are the element of the discourse units, i.e., paragraphs. Second, different from micro discourse relations, there are no connectives between the macro discourse units with lengths that are longer than those of micro discourse units. Consequently, it is difficult to grasp the theme of macro discourse units and the relationship between them. To ensure the correctness of macro discourse structure annotation, we first determine the theme of discourse units.

Category	Nuclearity
Mononuclear	Nucleus Ahead, Nucleus Behind
Multi-Nuclear	Multi-Nucleus

Table 1: Classification of discourse nuclearity.

In the annotation of discourse nuclearity, we are consistent with RST, which is divided into hypotactic ("Mononuclear") and paratactic ("Multi-Nuclear"). Specifically, it is divided into three categories: Nucleus Ahead, Nucleus Behind and Multi-Nucleus. Nucleus Ahead and Nucleus Behind belong to the Mononuclear, and Multi-Nucleus belongs to the Multi-Nuclear as Table 1.

Different from the discriminant method of micro discourse nuclearity, we not only compare importance among candidate macro discourse units but also consider which unit is more important with the full-text writing intention. In example 1, discourse units P1 and P2 have the *Evaluation* relation, where P1 tells the main story, and P2 is its evaluation. If the global information is not considered, P1 is more important than P2, and it should be annotated as *Nucleus Ahead*. However, given the full text, the title of which is "The Property Insurance Co. of PICC provides Shanghai with the largest amount of export credit insurance to date", P1 and P2 jointly form the subject of the full text such that P1 and P2 are equally salient; therefore, we annotated it by the relation *Multi-Nucleus*.

Following previous corpora on discourse analysis, we also construct a macro discourse corpus on news articles. In the annotation of macro discourse relationships, the theme of the paragraph as the element of the discourse unit is vaguer; the logic between discourse units is more insignificant. Considering the overall intentions of a news article, it is rare to have a *Transition* relation on the macro-level, and most of them have a *Contrast* relation. Therefore, based on the micro discourse relation representation that has 4 categories and 17 relations defined by CDTB, we delete the relations, such as *Transition*, *Concession* and other relations in the *Transition* category, and finally form the macro discourse relationship representation with 3 categories and 15 relations, as shown in Table 2.

Category	Relations
Coordination	Joint, Sequence, Progression, Contrast, Supplement
Causality	Cause-Result, Result-Cause, Background, Behaviour-Purpose, Purpose-Behaviour
Elaboration	Elaboration, Summary, Evaluation, Statement-Illustration, Illustration-Statement

Table 2: Classification of macro discourse relation.

3.2 Additional Macro Discourse Information

Van Djik (1980) notes that theme, gist, keystone and main points all belong to the overall macro discourse structure. The topic sentence of a paragraph, the lead and the abstract of a full text are related to the theme and key points of the text and are the overall structure of semantics, which also belong to the macro discourse structure. Therefore, in addition to the traditional annotation of micro discourse corpus, we also annotated the additional macro discourse information, including the topic sentence of a paragraph, the lead and the abstract of a full text. In addition, we automatically annotate the pragmatic functions of discourse elements.

The discourse structure tree can play a crucial role in building a natural language generation system (Carlson et al., 2003). A good macro discourse structure tree can preserve the semantic integrity of the text better (Liu and Zou, 2017). In discourse-level automated summarization tasks, a more natural and complete chapter summary can be generated in conjunction with annotated macro discourse information.

4 Annotation Process

Our annotation team consists of a doctoral candidate, two senior master degree candidates and three junior master degree candidates. All annotators are engaged in research on Natural Language Processing or Computational Linguistics and have a certain theoretical foundation of linguistics. Such an annotation team has increased professionalism and improved the efficiency of labelling. To ensure annotation quality, the entire annotation process has four phases:

1) Initialization phase. We annotated 10 articles per cycle. In each cycle, the doctoral candidate and two senior master degree candidates were annotating the same article at the same time, that is, triple tagging. At this stage, we had annotated 97 documents.
2) Revision phase. Different from the previous stage, the doctoral candidate double-tagged with two senior master degree candidates in each cycle, respectively. Finally, we annotated 147 documents.

3) Trial tagging. We annotated 20 articles per cycle. The tagging method is in line with the second stage, and we finally cumulatively tagged 305 documents. At the same time, three junior master degree candidates participated in the annotation.
4) Formal annotation phase. We annotated 30 articles per cycle. During each cycle, three senior annotators (one doctoral candidate and two senior master degree candidates) were matched with three junior master degree candidates, respectively, and formed three groups. After each cycle, we exchanged the partner between different groups. Finally, 720 articles have been tagged.

4.1 Annotation criteria

To ensure consistency and reliability of annotations in the macro discourse relationship labelling, the following annotation criteria are used in our annotations:

1) The annotation of nuclearity and relationship is independent of each other, and we do not consider the correlation between them. In Example 1, when judging the nuclearity of the two discourse units P1 and P2, we pay more attention to their relevance to the topic, not considering their relation Evaluation. Therefore, P1 and P2 are equally salient.
2) We annotate only one type of discourse relations to two discourse units. For example, both the *Sequence* and *Cause-Result* relations have the chronological order. When two discourse units have the chronological order, and there is a clear causal relation between them, they are annotated as *Cause-Result*; otherwise, it will be annotated as *Sequence*.
3) We adopt the way of majority voting. An article may have different discourse structure trees from the different perspectives. When these structures are all reasonable, we use a majority vote to choose a more widely accepted understanding to ensure the objectivity of annotation.
4) We adopt incremental annotation. At the time of macro discourse relationship tagging, our annotation strategy is to determine the topic sentence of each paragraph first. After grasping the intentions of each paragraph, we first divide the whole article into several independent regions from top to bottom and build sub-trees from bottom to top in each area. Next, we consider the structure of each region and eventually form a complete discourse structure tree. According to the complete discourse structure tree, we also annotate the lead and the abstract of an article. In example 1, when we read this article, if we can first find that P4 and P5 have the relationship of *Purpose-Behaviour*, we could directly connect them without considering the specific structure of P1 to P3.

4.2 Annotation sample

To facilitate labelling and accelerating the annotation speed, we have developed a platform for macro discourse annotation. In this platform, an article to be annotated should go through the following steps: data preprocessing, annotating paragraph topic sentence, annotating discourse structure, nuclearity and relationships, annotating lead and abstract, and automatically annotating pragmatic functions. The final generated annotation results of example 1 are shown in Table 3. An annotated document includes three parts: DISCOURSE, RELATION and TEXT. DISCOURSE refers to the abstract information of a document, including date (Dateline), topic (DiscourseTopic), lead (LEAD) and abstract (ABSTRACT). RELATION provides all discourse relationships in this document and its attributes include nuclearity and relation. TEXT shows all elementary discourse units (EDUs). The labels used in MCTDB are as follows.

- ID: the ID of the relation between two discourse units.
- Centre: the nucleairity relation (1-*Nucleus Ahead* / 2-*Nucleus Behind* / 3-*Multi-Nucleus*).
- ChildList: the ID list of its children relations (nodes). In this example, this relation has two children relations whose IDs are 2 and 3.
- Function: the pragmatic functions are derived from Van Dijk (1990)'s Hypothetical structure of the news schema and we modified them to suit the characteristics of Chinese macro discourse. Details of the labels are shown in Table 10.
- Layer: the layer in a macro discourse structure tree.
- ParagraphPosition: the positions of two discourse units which are split by "|". In this example, "1...3" indicates that the beginning paragraph and ending paragraph of the first discourse unit

are 1 and 3, respectively, while “4...5" indicates those of the second paragraph are 4 and 5, respectively.

```
<DOC>
<DISCOURSE Dateline="新华社上海三月六日电" DiscourseTopic="中保财险公司为上海提供迄今最大一笔出口信用保险">
<LEAD>中保财产保险有限公司……的最大一笔出口信用保险。</LEAD>
<ABSTRACT>中保财产保险有限公司……的目的。</ABSTRACT>
</DISCOURSE>
<RELATION>
<R ID="1" Center="1" ChildList="3|2" Function="NewsReport" Layer="1" ParagraphPosition="1...3|4...5" ParentId="-1" RelationType="Supplement" StructureType=" Hierarchical segmentation" />……
 <TEXT>
<P Function="Lead" ID="1" ParagraphTopic="中保财产保险有限公司……的出口信用保险。">中保财产保险有限公司…. . . 的出口信用保险。</P>……
<P Function="Behaviour" ID="5" ParagraphTopic="中国中央财政于一九八八年拨一亿美元专款作为风险准备金，用于中保集团公司开办出口信用保险业务。">为此，中国中央财政……四十多个。（完）</P>
</TEXT>
</DOC>
```

Table 3: Annotation format of chtb0155.

- ParentId: the ID of the relation’s parent.
- RelationType: the type of this relation, defined as RST, and details of the labels are shown in Table 2.
- StructureType: the annotation is divided into 2 categories: *Hierarchical segmentation* and *Parallel segmentation*. When the relationship is Mononuclear and has only two children, it is marked as *Hierarchical segmentation*. Otherwise, it will be marked as *Parallel segmentation* (usually the relation is *Joint*).
- ParagraphTopic: the topic sentence of the paragraph.

4.3 Quality Assurance

We guarantee the annotation quality of the corpus from two aspects. The first one is the tree verification, which is to ensure the correctness of corpus annotation. The second one is consistent assessment, which is designed to ensure the objectivity of corpus annotation.

In tree validation, we take two steps to verify the annotated corpus. First, the annotated corpus is imported to the macro discourse annotation platform to verify its correctness. Second, an automated pragmatic annotation tool is used to annotate the pragmatic functions of each discourse unit. Through pragmatic annotation rules, it can be used to calibrate the annotation of discourse relations and structures. When a problem occurs in the validation process, we manually verify the error type and then correct it. Compared with the traditional manual calibration, we use a double automatic verification method to improve the speed and ensure quality.

The evaluation of consistency can be used to measure the objectivity of corpus annotation. For evaluating the consistency of the discourse structure tree, tree consistency can more objectively reflect the quality of annotation. CDTB and PDTB only evaluated the consistency of certain indicators, such as discourse relation, and did not evaluate the tree consistency. RST-DT proposed a method of evaluating the complete consistency of a discourse tree, but it also had several shortcomings. The evaluation objects of RST-DT are the discourse structure, nuclearity and relationship annotated on the children nodes, while the evaluation object of the standard syntax tree (Black et al., 1991) is the annotations on the parent node. In this way, RST-DT will be at least double the standard syntax tree evaluation of the sample, and

because of the mutual constraint relationship between children nodes, the consistency of corpus annotation of RST-DT is objectively higher.

In the annotation of a macro discourse relationship, the leaf nodes are natural paragraphs and do not need to be manually divided. Therefore, unlike the assessment method of the RST-DT agreement, we do not use the leaf nodes as an example of a consistent assessment. In addition, we adopted the standard syntax tree method using the annotation on the parent node as the evaluation object. Although this may lead to a reduction in evaluation examples and a decline in the indicators of consistency, we believe that this evaluation method is more objective.

Indicators	Structure	Nuclearity	Relation
Agreement	86.24%	83.88%	80.46%
Kappa	0.68	0.66	0.61

Table 4: Consistency indicators of MCDTB.

To eliminate coincidental annotations, we also used the Kappa value (Siegel and Castellan, 1988) as an assessment of the consistency of annotations while using agreement rates. The average value of the agreement assessments of the 200 articles sampled served as the ultimate evaluation indicators of the corpus. As shown in Table 4, the corpus has an agreement rate of greater than 80% and a Kappa value greater than 0.6 in discourse structure, nuclearity and relationships. Krippendorff (1980) noted that the Kappa value of the annotation data is above 0.6, indicating that it has good annotation quality.

Confusing Relationships	Proportion
Elaboration and Supplement	21.90%
Elaboration and Joint	9.52%
Sequence and Joint	8.57%
Supplement and Joint	7.62%
Elaboration and Evaluation	5.71%
Elaboration and Sequence	5.71%

Table 5: Confusing Relationships in double-tagged.

To find the most confusion annotations among the annotators, we sampled 100 articles and obtained the double-tagged information (720 articles are double-tagged). The top six confusion relationships are shown in Table 5. Apart from the difference in the structure annotation, the primary confusing relationships are *Elaboration* and *Supplement*, accounting for 21.90%. Both of these relationships belong to the *Elaboration* category; therefore, it is easier to confuse them. The second confusing relationship is *Elaboration* and *Joint*, accounting for 9.52%. The confusion results from significant differences in the understanding of the article.

Confusing Nucleus	Proportion
Nucleus Ahead and Multi-Nucleus	89.19%
Nucleus Ahead and Nucleus Behind	8.11%
Nucleus Behind and Multi-Nucleus	2.70%

Table 6: Confusing Nucleus in double-tagged.

As shown in Table 6, the main confusion nucleus are primarily Nucleus Ahead and Multi-Nucleus, accounting 89.19%; this finding may be due to the confusion between *Elaboration* and *Joint* in the relationship. This result is also consistent with previous experimental results (Jiang et al., 2018), which show that humans and models are confused in the same place.

5 Statistics on MCDTB

Our macro discourse corpus MCDTB[1] annotated 720 news articles from CTB 8.0. As shown in Table 7, the entire annotated corpus has 3,981 paragraphs, and the average number of paragraph is 5.53 per document. Each article contains at most 22 paragraphs and at least 2 paragraphs.

#documents	720	#paragraphs	3,981
# paragraphs of the longest document	22	Average length (paragraphs /document)	5.53
# paragraphs of the shortest document	2	Average length (sentences/paragraph)	2.09

Table 7: MCDTB corpus details.

The distribution of document numbers on paragraph numbers in MCDTB is shown in Figure 2. 54.72% of the documents have 4 to 6 paragraphs, while this number is 92.08% when a document has 2 to 9 paragraphs, which indicates that news articles primarily focus on the middle passage.

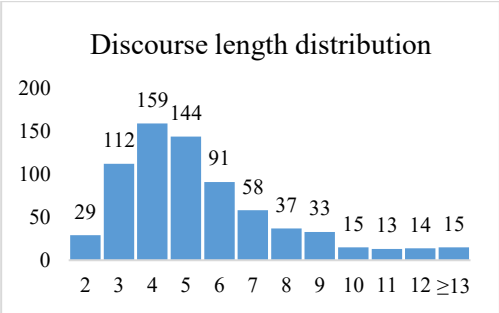

Figure 2: Discourse length distribution in MCDTB.

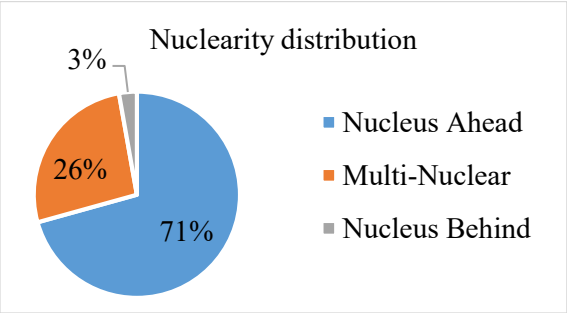

Figure 3: Nuclearity distribution in MCDTB.

The nuclearity distribution in MCDTB is shown in Figure 3. Among these numbers, the number of the *Nucleus Ahead* is 2,026, accounting for 70.69%. There are 760 *Multi-Nuclear* relations, accounting for 26.52%, while there are only 80 *Nucleus Behind*, accounting for only 2.79%. This finding shows that news articles tend to explain important events first, which is in line with the conclusion of linguistic statistics by Li and Liao (2001).

Relation	**Number**	**Proportion**	**Relation**	**Number**	**Proportion**
Elaboration	990	34.54%	Joint	634	22.12%
Supplement	493	17.20%	Background	237	8.27%
Evaluation	127	4.43%	Result-Cause	103	3.59%
Sequence	99	3.45%	Cause-Result	49	1.71%
Statement-Illustration	39	1.36%	Summary	23	0.80%
Illustration-Statement	20	0.70%	Contrast	17	0.59%
Behaviour-Purpose	14	0.49%	Purpose-Behaviour	11	0.38%
Progression	10	0.35%			

Table 8: Statistics on discourse relations.

As shown in Table 8, MCDTB contains 2,866 discourse relations, of which the top six relations are *Elaboration*, *Joint*, *Supplement*, *Background*, *Evaluation* and *Result-Cause*. These six types of relations accounted for 90.16% of the total number of relations.

[1] The Macro Chinese Discourse TreeBank is available at https://figshare.com/s/250474dba44e4161b040.

Furthermore, we analysed the correlation between the nuclearity and the relationship. The nuclearity distributions on different discourse relationships are shown in Table 9. This finding shows that most of the *Elaboration* and *Causality* relations are *Nucleus Ahead*, while those of the *Coordination* relations are more inclined to be equally salient in each discourse unit. The three relationships are about the same in *Nucleus Behind*.

Category	Nucleus Ahead	Nucleus Behind	Multi-Nucleus
Elaboration	1208	36	9
Causality	365	29	20
Coordination	453	15	731

Table 9: Nuclearity distribution of discourse relationships.

In particular, we analysed the distribution of pragmatic functions. MCDTB has a total of 6,847 pragmatic functions, including 3,981 annotations on the paragraph level, and 2,866 on the larger discourse unit level, as shown in Table 10. Apart from annotating the necessary pragmatic functions, such as *Situation* and *Story*, the annotations which are helpful to the automatic summarization and information extraction tasks, such as *Lead*, *Summary*, *Background*, *Comment*, *Cause* and *Result*, make up the majority.

Pragmatic function (in paragraph)	Number	Proportion	Pragmatic function (in discourse units)	Number	Proportion
Situation	1902	27.78%	Story	1437	20.99%
Supplement	439	6.41%	News Report	720	10.52%
Summary-Lead	354	5.17%	Summary	300	4.38%
Lead	284	4.15%	Sub-Summary	95	1.39%
Background	196	2.86%	Result	73	1.07%
Sub-Summary	193	2.82%	Cause	69	1.01%
Story-Situation	183	2.67%	Supplement	54	0.79%
Comment	117	1.71%	Background	41	0.60%
Cause	83	1.21%	Statement	22	0.32%
Result	79	1.15%	Behaviour	17	0.25%
Others	151	2.21%	Others	38	0.55%

Table 10: MCDTB pragmatic function statistics.

6 Preliminary Experiment

To demonstrate the computability of MCDTB, we conducted a preliminary experiment on the identification of macro discourse structures. Discourse structure identification is the first and most critical step in the related tasks of discourse analysis. We use a Conditional Random Field (CRF) model to experiment with the parameter C of 4, the feature window of 3, and the rest of the parameters as a default value. There were 8,863 samples in total, including 3,261 positive samples and 5,602 negative samples.

Because of the language differences between English and Chinese, as well as the microscopic and macroscopic differences in features, such as the absence of syntax trees and the absence of tense features, we select only several of the structural features of the previous study (Feng and Hirst, 2012) as our Feature Set 1 as follows:

- The position of the beginning and end of a discourse unit;
- The number of sentences and the number of paragraphs contained in a discourse unit;
- The comparison of the number of sentences in the discourse unit to the previous unit;
- The comparison of the number of paragraphs in the discourse unit to the previous unit.

Considering the process of constructing discourse structure trees, we may need some procedural characteristics. We regard whether the discourse unit is a leaf node or whether the discourse unit is merged in the previous round as organizational characteristics. In terms of semantic features, we use semantic similarity, the connectives, and their part-of-speech in the first sentence of the discourse unit. On the calculation of semantic similarity, we used the word2vec model to train on CTB8.0 and calculate the semantic similarity between the two discourse units according to the semantic similarity algorithm proposed by Xu (2009). In particular, we discretized the final semantic similarity into 10 levels. Finally, we use the semantic similarity, the conjunctions of the first sentence of the discourse unit with their part-of-speech, whether they are the leaf nodes and whether they were merged in the previous round as the characteristics of Feature Set 2 as follows:

- The semantic similarity between the discourse unit and the previous unit;
- The conjunction of the first sentence and its part of speech in the discourse unit;
- Whether the discourse unit is a leaf node;
- Whether the discourse unit was merged in the previous round.

Feature selection	Feature Set 1	Feature Set 2	Feature combination
Acc.	76.09%	77.01%	**77.56%**

Table 11: Comparison of the accuracy of the various models.

In addition, we use the most probabilistic way to fuse two feature sets, that is, we use two feature sets to model and finally select the predictive labels with the larger probability value as the final annotation result. In the five-fold cross-validation experiment of the MCDTB corpus, the performance of each model is shown in Table 11.

The experimental results show that the performance of the model using the structural features and semantic features is similar, and the best performance is obtained by using the joint model based on the maximum probability of the feature combination, which improves the accuracy by 1.47% and 0.55% over Feature Set 1 and Feature Set 2, respectively.

7 Conclusions

In this paper, we describe relevant experiments concerning the construction of a Macro Chinese Discourse Treebank (MCDTB). In view of the differences between the annotations of micro discourse relationships and macro discourse relationships, we annotate the corpus following RST and provide the higher level macro discourse information, such as topic sentences of paragraphs, lead and abstract of discourse, to make the macro discourse annotation more objective and accurate. To speed the annotation process and ensure the annotation quality, we formulated detailed annotation criteria and quality assurance strategies and developed a platform for macro discourse annotation. Finally, we annotated 720 Chinese news articles, and we achieved a better consistency of labelling with an improved Kappa value of greater than 0.6 based on the improved consistency assessment standard. Preliminary experiments on this corpus verify the computability of MCDTB. In future work, we will conduct research on identifying macro discourse structure, recognizing nuclearity and classifying relationship and eventually form a complete end-to-end macro discourse analyser.

Abstract

Enterprise content writers are engaged in writing textual content for various purposes. Often, the text being written may already be present in the enterprise corpus in the form of past articles and can be re-purposed for the current needs. In the absence of suitable tools, authors manually curate/create such content (sometimes from scratch) which reduces their productivity. To address this, we propose an automatic approach to generate an initial version of the author's intended text based on an input content snippet. Starting with a set of extracted textual fragments related to the snippet based on the query words in it, the proposed approach builds the desired text from these fragment by simultaneously optimizing the information coverage, relevance, diversity and coherence in the generated content. Evaluations on standard datasets shows improved performance against existing baselines on several metrics.

1 Introduction

Due to the increase in the number of channels and the need for more customized content for different audience segments, content authors need to produce content at a very rapid pace. On the other hand, a lot of such content has already been produced and is available in enterprise content repositories. Ideally, the author looks for such content and re-purposes them for her current need. Due to the tedium of this task, the author may resort to creating the content from scratch. Automating this task can greatly aid the author in improving their overall productivity.

Given an enterprise author's requirement in the form of a snippet describing the content she is trying to build, standard querying mechanisms can be utilized to fetch the right set of articles that can cater to her needs. However, constructing an initial piece of 'article' that can cater to her needs would still be a non-trivial task. Existing work in this direction focuses on generating content for standard platforms like Wikipedia (Banerjee and Mitra, 2016), where the target content is divided into different 'categories/section' and text is generated for each section. While this could be useful, the absence of a predefined structure in an enterprise setting makes the extension of such an approach challenging. This calls for an approach that can automatically build an author's content **covering various aspects** of the target article.

The content style in an enterprise corpus is fairly consistent. However, there could be multiple representations of the same information across the repository. This necessitates the content generation to **reduce the redundancy** in the constructed content and adding topical diversity to the article. Finally, the content generated should be coherent with a **cohesive flow** of information.

To address all these requirements, we propose an approach that automatically generates a *coherent* and *non-redundant* article based on an author's input snippet simultaneously optimizing the *relevance* of the generated text to the snippet, *coverage* of different aspects of the content and *diversity* in the information content. The acceptance criteria for such systems can be a reasonable draft instead of publishable content, given that the objective of such a system is not to replace the authors, but to provide them with a draft that can be polished quickly. Table 1 shows a sample article generated by the proposed algorithm based on an input snippet from DUC2007 data (Dang, 2007).

Proceedings of the 27th International Conference on Computational Linguistics, pages 3505–3515

Table 1: A sample snippet and the corresponding article generated by the proposed algorithm based on the DUC2007 data (Dang, 2007).

Input Snippet: Microsoft's antitrust problems and its alleged illegal behavior and antitrust proceedings against the company.
Generated article by CCC: a justice department spokesman confirmed thursday that we have an ongoing investigation and its continuing. microsoft based in redmond of washington has been the focus of antitrust investigations in the past years. microsoft corp is making a last minute offer to settle the charges. nbc news reported wednesday that the justice department and at least 19 states plan to file historic antitrust cases thursday against microsoft. if they proceed the suits could be among the biggest corporate challenges in history according to analysts. on monday in washington dc the federal government and 20 states kicked off the trial that accused microsoft of illegal activities including bullying competitors. back in seattle washington state where microsoft is based the company fired off five upbeat productoriented press releases and other announcements. its web site on monday carried two articles in favor of microsoft. it helps the atmospherics of the governments case but its not clear beyond that what the effect will be. meanwhile the antitrust trial is already well under way and judge thomas penfield jackson is expected to rule early next year. but sherlund noted the ruling does rein microsoft in and it clearly comes at an awkward time for the company given the antitrust case. antitrust experts said that most countries still investigating microsofts practices were taking a waitandsee stance toward the company pending the outcome of the major us antitrust case

Our algorithm takes author intent in the form of a short snippet (say a sentence) and finds relevant content from a repository to create a pool of content. It then identifies the most representative part of the content (factoring in relevance level) and generates multiple candidate sentences by compressing information from multiple related sentences to enrich the information content (and reduce redundancy). The compression algorithm leverages usage patterns in the repository to form sentences with good readability. Subsequent candidate sentence generations account for the already generated candidates to ensure diversity. We finally assemble the content in an appropriate order by solving an integer linear program that simultaneously optimizes the coherence with various linguistic quality measures to determine the best ordering. Thus, our system strives to generate a draft of content that is relevant to the author intent, diverse, information rich, cohesive and readable.

We present the results of performance evaluation of our system with DUC 2007 (Dang, 2007) and Australian Legal (Galgani et al., 2012) datasets. Our experiments show that our system produces drafts which are as good as state-of-art baselines for content generation in Rouge scores, diversity, readability and cohesiveness, and beat each of the baselines in at least one of these metrics.

2 Related Work

There is a significant body of work in the domain of **text summarization** (Nenkova and McKeown, 2011). The problem of corpus based content construction could be perceived as a summarization task once we have identified the required candidate content fragments from the corpus. In particular, the problem could be cast as a multi-document summarization or query-focused summarization. However, in our problem, there is no requirement to maintain the distribution of concepts/information between input document and output content, thus making it different from standard summarization problems.

There have been some efforts towards extending multi-document summarization for expanding a piece of content. Banerjee et al. (2015) use a sentence ranking and clustering formulation along with ILP based constraint optimization to create expanded documents. Bing et al. (2015) explore a more fine-grained setting, constructing sentences using noun/verb phrase level breakdown of input text. However, neither of these two approaches handle the document coherence problem at a granular level and rely on using the original sentence order as their notion of coherence.

Query-focused multi-document summarization approaches such as those of Li and Li (2014) and Wang et al. (2013) do not have an explicit model of coherence, in spite of using coherence as one of the evaluation criteria. In the proposed algorithm, we use an Integer Linear Program formulation to achieve a coherent generation despite not explicitly selecting contiguous content fragments.

Srinivasan et al. (2017) extend standard extractive summarization techniques to build article by combining different paragraphs in a corpus. However, they do not account for coherence or information redundancies in the generated content. Often, retaining an entire paragraph might not yield the best

information coverage. We explicitly account for these aspects in our proposed algorithm.

There are some recent efforts towards accounting for coherence in summarization by extending the transition probability based approach by Lapata and Barzilay (2005) and including coherence in their optimization frameworks. Parveen et al. (2016) use 'patterns' from a standard corpus to define the transition probability, while Nayeem and Chali (2017) and Wang et al. (2016) use information overlap based metric to define the transitions. Our framework also uses an approach similar to the latter to account for coherence in our text generation.

Knowledge enhancement: There have also been some efforts towards content elaboration in the context of knowledge enhancement. Schlaefer et al. (2011) aim to enhance question-answering by expanding a 'seed document' using web resources to construct the answer based on 'paragraph nuggets'. However, both lexical and semantic redundancies are undesirable for a content author. In our approach, we minimize the lexical and semantic redundancies based on a graph based sentence compression which jointly optimizes for relevance and diversity of the expanded content.

The work by Bairi et al. (2016) uses expansion of short documents to enhance the document representation for improved document classification. Their framework aims to improve performance for a task without using task-specific heuristics. However, since the objective is to maximize the classification performance, the algorithm proposed by Bairi et al. (2016) does not care about linguistic aspects of the elaborated content.

Taneva and Weikum (2013) identify relevant text snippets ('gems') by using an integer linear program to maximize relevance of selected words, and prefer the selection of contiguous content pieces since this maximizes the coherence of the content resulting in a lot of content being chosen from the same source. However, the information for a specific article can come from multiple sources and hence this will not achieve information coverage. We use this as one of the baselines for our comparisons and show improvements in the coverage of our proposed approach.

Wikipedia Generation: Mihalcea and Csomai (2007) identify key concepts in a document and link them to corresponding Wikipedia pages. While this helps to identify relevant Wikipedia areas for the document, it will not help in expanding the seed content from these sources. Sauper and Barzilay (2009) came up with the first complete version of such a system. Their work leverages the structure of Wikipedia articles of a category to produce a new article in the same category. Banerjee and Mitra (2016) extend these ideas to construct a Wikipedia article by learning the article structure from the structure of related articles, rather than relying on a single category. While this is closer to what we would like to achieve, the lack of structure in an enterprise article poses a unique challenge in our case. Further, if the corpus is huge, this can result in a lesser information coverage. We address this in our proposed algorithm via an iterative reward framework to maximize the information coverage of the generated article.

3 CCC: Corpus based Content Construction

We propose a **C**orpus-based **C**ontent **C**onstructor (CCC) that simultaneously optimizes for relevance to the input snippet, covers different information about the target content, avoids redundant sentences and improves the coherence of the final content. The algorithm involves 3 stages: extracting the intent of author from the snippet, identifying and **generating candidate content** towards the author's need and **assembling the generated content** in a coherent fashion.

We begin with extracting the top-k keywords in the snippet using the inverse document frequency (IDF) of the words in the corpus, thus capturing the most significant keywords in the snippet with respect to the corpus. A query q is then formulated by concatenating these 'k' keywords (Aula, 2003), where the choice of k determines the relevance and the amount of content that is available and fetched from the repository. A lower value of k results in the query under-representing the content and fetching articles that may not be very relevant. On the other hand, a higher value of k will result in a very specific query that might not fetch many results from the repository.

The retrieved fragments are broken into sentences. To select the appropriate content for construction, we create a graph and represent the sentences as nodes in the graph. The information content of the sentences is assigned as a "reward" to the corresponding nodes and their information overlap as the edge

weight. As explained later, the most "rewarding" part of the graph is identified and the sentences in that sub-graph are compressed to prepare candidates to be included in the final content. The sentence compression reduces the syntactic and lexical redundancies arising due to multiple manifestations of the same information in different parts of the corpus. Once the candidates are generated, the rewards of the nodes in the graph are adjusted to account for the information in the generated candidates. This allows for increased information coverage in the generated sentences by discounting the information covered by the previously extracted candidates.

The candidates are generated iteratively till the overall information relevant to the input snippet is exhausted in the graph. To select the final content, an Integer Linear Program (ILP) is formulated that maximizes the relevance to the snippet along with the information cohesion in the generated content. The optimization problem is also constrained to keep the constructed content to a certain budget (length) and avoid simultaneous selection of semantically very-similar sentences. The ILP outputs a set of compressed sentences along with their sequence to yield a cohesive content.

The candidate generation and coherent candidate organization are the key contributions of our algorithm and we describe the details below.

3.1 Candidate Generation via Sentence Compression:

The candidate set of fragments is broken into sentences and a graph $G(v, e)$ is constructed with every sentence as a node $v_i \in V$ in the graph. An initial "reward" r_i^0 for v_i is assigned based on its similarity to the query q. The edges $e \in E$ are constructed between every pair of fragment that contain a significant information overlap and the similarity between the sentences is assigned as its edge weight w_{ij}.

We iteratively select a sub-graph in G whose nodes can be used as candidates for compression. Each sub-graph consists of a node v_i along with its $1-$hop neighbors. The gain G_{v_i} of processing a node v_i (along with its $1-$hop neighbors) for sentence compression at round l is given by,

$$G^l_{v_i} = r_i^{l-1} + \sum_{v_j \in N_i} r_j^{l-1} \times w_{ij} \tag{1}$$

where N_i refers to the neighbors of node v_i. At step l, we select the v_i^* that has the maximum gain G_{v_i}. The sentence corresponding to the node selected v_i along with the sentences in its $1-$hop neighborhood is put into a set s_{v_i}, which is used for multi-sentence compression (Filippova, 2010) to remove the redundancy across the multiple sentences and generate candidates.

Multi-sentence compression constructs a (different) graph ($\hat{G}_c$) out of the candidates such that each word is a node, and each sentence represents a directed path in the graph. Specialized nodes serve as start-of-sentence and end-of-sentence nodes. A single node is used to represent all occurrences of a word with the same POS tag. The edges between nodes have weights representing the number of times the ordered combination of those node-words occurs across all sentences in s_{v_i}. The shortest paths (normalized by path length) are identified and the top-K generated sentences are used for further processing. For our purposes, we restrict the minimum number of words per generated sentence to 10 words and pick 1 sentence in every iteration.

A reward $r_{\hat{k}}$ is assigned to every compressed sentence based on its similarity to the query q. In order to factor the information captured by the compressed sentences for subsequent selections, the rewards of vertices v_i in the original graph ($G(v, e)$) whose information overlap ($w_{i\hat{k}}$, computed in the same way as the edge weights) with the compressed sentences is significant, is updated as as $r_i^{l+1} = r_i^l \times (1 - w_{i\hat{k}})$. This reduces the rewards for sentences which are covered by current set of compressed sentences thus reducing the chance of their inclusion in subsequent compression. This ensures that the information covered by the subsequent compression is different from already generated sentences while still relevant to the input query.

The candidate generation is stopped when there are no nodes left with significant reward (greater than a threshold) resulting in the same sub-graph being selected for successive compression.

3.2 Coherent Candidate Organization via ILP

The sentence compression yields candidates that cover the information space relevant to the input snippet. However, the compressed sentences might be grammatically incorrect and not ordered appropriately to be coherent. Therefore we select the right set of compressed sentences along with their order via an Interger Linear Program (ILP) formulation by extending the framework used by Deshpande et al. (2007) and Banerjee and Mitra (2016). The ILP objective is given by,

$$J = \sum_{i=1}^{K} w_i x_i + \lambda \sum_{i,j|coh_{ij}>\sigma} coh_{i,j} y_{i,j} \tag{2}$$

$$\text{such that: } \sum_{i=1}^{K} c_i x_i \leq B \tag{3}$$

$$y_{i,j} = 0 \text{ if } coh_{ij} < \sigma \text{ or } i = j \tag{4}$$

$$x_i + x_j \leq 1, \forall i, j | sim_{i,j} > 0.7 \tag{5}$$

$$\sum_i y_{s,i} = 1, \sum_i y_{i,e} = 1 \tag{6}$$

$$\sum_i y_{i,j} = \sum_i y_{j,i}, \sum_i y_{i,j} + \sum_i y_{j,i} = 2x_j \tag{7}$$

The binary variable x_i indicates the selection/non-selection of a compressed sentence i and the binary variable $y_{i,j}$ indicates a transition from a sentence x_i and x_j. Traversing the path of the sentences via $y_{i,j}$ would yield the final generated sentence. The w_i for each compressed sentence indicates a combination of the sentence's relevance to the snippet along with its overall linguistic quality. This ensures that the compressed sentence selected is not noisy and is relevant to what the author is looking to build. The second term in Eq. 2 maximizes the coherence of the selected flow of sentences. This follows from the work by Lapata and Barzilay (2005) which defines a model of coherence based on the topic overlap between successive sentences.

The constraint in Eq. 3 accounts for the length requirement of the author and limits the generated content to a target budget B. Eq. 4 prohibits a flow of content between lesser coherent sentences and avoids cycles in the arcs. Eq. 5 limits simultaneous selection two sentences with higher information overlap to produce less redundant content.

Similar to Banerjee and Mitra (2016), we constrain the optimization problem to also account for the overall quality of the generated content. The formulations to constrain the arcs is extended from WikiWrite (Banerjee and Mitra, 2016) by introducing dummy start s and end e nodes to the graph of sentences. An arc between two nodes exists if both the sentences are selected for the final content and are contiguous. The dummy nodes s and e are used to connect to the start and end sentences. Eq. 6 limits the number of starting and ending sentences to 1. Eq. 7 limit the number of incoming and outgoing arcs from a selected node to 1 each forcing a path via the arcs that indicate the flow in the selected content. Algorithm 1 summarizes the complete algorithm.

4 Evaluating different stages in CCC

In CCC, sentence compression (Filippova, 2010) is used to avoid redundant information in the constructed content by compressing information from multiple sentences into a single sentence. Further, the graph based candidate selection for compression enables covering diverse aspects around the target content. Finally, the ILP formulation facilitates coherence in the generated content.

To test if the different stages achieve the targeted goals, we test different parts of our algorithm on the DUC2007 Multi-document Summarization data (Dang, 2007). This data consists of a topic along with a set of documents related to the topic and reference summaries for the set of documents. For the sake of this experiment, we bypass the query construction stage. We use the topic associated with the document

Algorithm 1: Corpus-based Content Construction

Input: q: Snippet input by author, $\mathcal{F}$: Set of all fragments
Output: C: Generated Expanded Content
K $\leftarrow$ Top-k keywords from q based on IDF from $\mathcal{F}$;
F $\leftarrow$ query $\mathcal{F}$ with K;
$\mathcal{S} \leftarrow$ split F into sentences;
begin
  $\mathcal{G} \leftarrow$ graph($\mathcal{V}$, $\mathcal{E}$) where,
  $\mathcal{V} \leftarrow \mathcal{S}$, with reward $r_{v_i} \leftarrow$ info content of v_i
  $\mathcal{E} \leftarrow \{e_{ij} \mid$ weight $w_{ij} \leftarrow$ info overlap$(v_i, v_j)\}$
end
$\mathcal{S} \leftarrow \phi$;
repeat
  forall $v_i \in \mathcal{V}$ **do**
    $N_i \leftarrow$ neighbours of v_i;
    $G_{v_i} \leftarrow r_i + \sum_{v_j \in N_i} r_j \times w_{ij}$;
  end
  $v_{\mathcal{I}} \leftarrow$ node with maximum G_{v_i} ;
  $\Gamma \leftarrow$ subgraph of $\mathcal{G}$ with $v_{\mathcal{I}}$ and its 2-hop neighbourhood ;
  $S_{\mathcal{K}} \leftarrow$ top-$\mathcal{K}$ sentences after sentence compression on $v_i \in \Gamma$;
  $\mathcal{S} \leftarrow \mathcal{S} \cup S_{\mathcal{K}}$;
  forall $v_k \in \mathcal{V}$ **do**
    $r_k \leftarrow r_i \times (1 - w_{\mathcal{S}_{\mathcal{K}} k})$;
  end
until $\forall v_i$, $r_{v_i} \leq$ *threshold*;
C $\leftarrow$ ILP($\mathcal{S}$) ; // Integer Linear Program (Eqns. 2-7)
return *C*

as the 'author' content snippet and the set of documents as the input. Further, we considered the reference summaries as the articles that the author has constructed and is used as a basis for our quality evaluations. The average length of the reference articles is used as the desired length of the generated content.

In order to evaluate the generated content, we use the following **metrics** to measure different aspects of the generated content.

Rouge-N (Lin, 2004) scores measure the precision, recall and f-measure for the occurrence of n-grams in the generated summary with respect to the reference human generated summary. We compute the Rouge scores of the generated content against the reference article.

To compute the **coherence** of the generated content, we follow the definition of local coherence by (Lapata and Barzilay, 2005). Measuring local coherence is quantified by the the degree of semantic relatedness between consecutive sentences and is obtained by taking the mean of all individual transitions. Coherence is given by,

$$coherence(c_{\text{gen}}) = \frac{\sum_{i=1}^{n-1} sim(c_{\text{gen}}^{i}, c_{\text{gen}}^{i+1})}{n-1} \tag{8}$$

where $sim(c_{\text{gen}}^{i}, c_{\text{gen}}^{i+1})$ is a measure of semantic similarity between sentences c_{gen}^{i} and c_{gen}^{i+1}.

To measure the **relevance** of the generated content to the input snippet, we follow the formulation by (Srinivasan et al., 2017). Relevance is computed as a weighted average given by,

$$rel(c_{\text{ref}}, c_{\text{gen}}) = \sum_{i=1}^{M} \frac{\sum_{k=1}^{TopK(c_{\text{ref}}, c_{\text{gen}}^{i})} \gamma^{k} sim(c_{\text{gen}}^{i}, c_{\text{ref}}^{k})}{M \sum_{k=1}^{K} \gamma^{k}}, \tag{9}$$

where c_{ref} are the sentences in the reference and $c_{\text{gen}}^{1 \ldots M}$ are the sentences in the generated content. $TopK(c_{\text{ref}}, c_{\text{gen}}^{i})$ returns the top-K sentences in the reference content similar to c_{gen}^{i} (in the decreasing order of their similarly as computed by $sim(c_{\text{exp}}^{i}, c_{\text{inp}}^{k})$). The parameter γ, $(0 \leq \gamma \leq 1)$, penalizes the addition of a sentence that is similar to only a small set of the input sentence via a decayed-weighted-average.

Finally, to calculate the **information diversity** in the generated content, we again extend the formula-

tion by (Srinivasan et al., 2017) and compute a weighted average given by,

$$div(c_{\text{gen}}) = \sum_{i=1}^{N} \frac{\sum_{k=1}^{TopK(c_{\text{gen}}, c^i_{\text{gen}})} \gamma^k sim(c^i_{\text{gen}}, c^k_{\text{gen}})}{N \sum_{k=1}^{K} \gamma^k}. \quad (10)$$

4.1 Information Coverage and Diversity:

Picking content from a corpus to construct a text can yield redundant content because of multiple representations of the same information in the corpus. If the final content is budgeted, this can result not only in redundant content, but also in a lost opportunity to cover other aspects of the content. In order to address this, we extend the sentence compression (Filippova, 2010) to combine multiple such sentences to provide a compressed content.

However, performing the sentence compression on a larger set of sentences may result in the compression of totally different pieces of information and can often be detrimental to information quality. Our proposed graph formulation identifies similar sentences to be compressed. The iterative subgraph selection in our formulation also enables us to cover different aspects of the content that are required to be generated.

Fig. 1(a) shows the performance of the sentence-compressed content against the uncompressed content selected based on relevance maximization (Carbonell and Goldstein, 1998). We have used box-and-whiskers plots for our results in this paper. The box gives the boundaries of the first and third quartile, and the middle band shows the median value. The whiskers extending from the box boundaries on both sides show the minimum and maximum values, except for the outliers which are shown as points by themselves.

The Rouge scores are comparable across the 3 methods indicating similar quality of the different settings. Similarly, the relevance of the generated content is also comparable across the 3 methods. Since the graph based compression iteratively selects candidates to compress based on those previously generated, it produces content that is more diverse as indicated in Fig. 1(a). Since the plain sentence compression works on a large set of candidates, the diversity improvement is lower than that for the graph based compression. This validates our hypothesis that graph based compression yields diverse yet relevant content.

Finally, the graph based sentence compression improves the overall readability of the text based on the Flesch reading ease (Kincaid et al., 1975) suggesting that the improvements observed with relevance and diversity are not coming at the cost of the linguistic quality of the generated content.

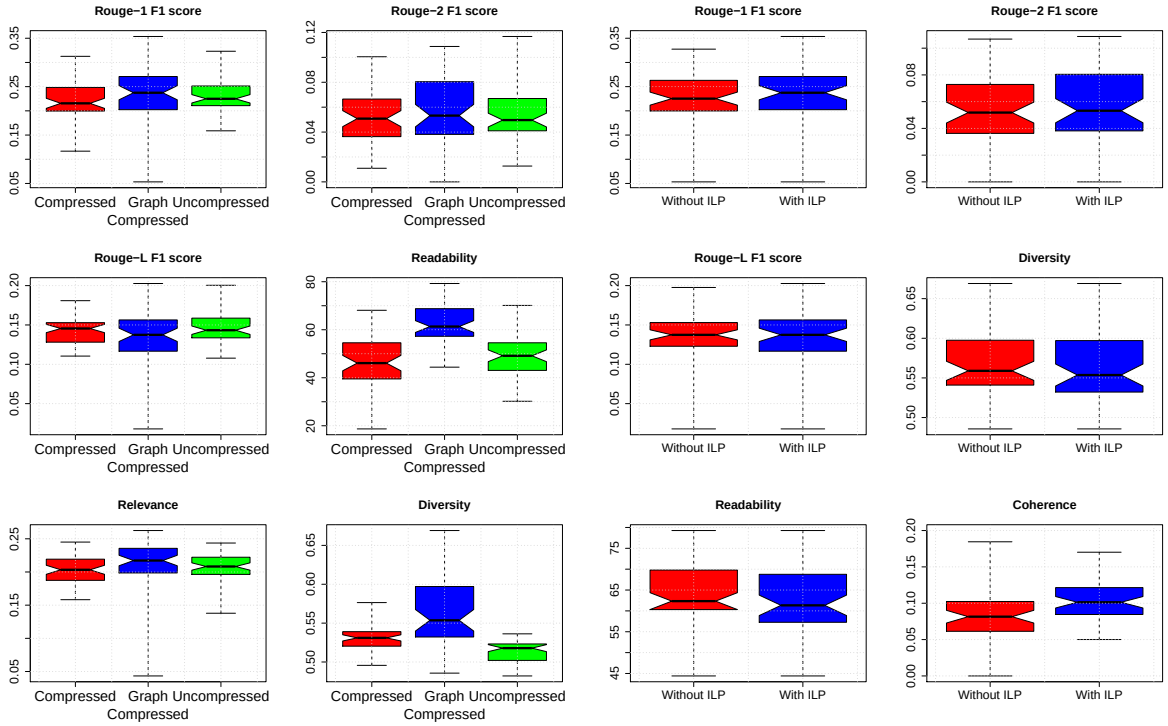
4.2 Coherence with ILP formulation:

The ILP formulation reorders the generated content in a way that improves the overall coherence of the content. Fig. 1(b) shows the performance of the generation with and without ILP. For the non-ILP version, candidates were selected from the compressed sentences via relevance maximization (Carbonell and Goldstein, 1998). It can be seen that the ILP formulation improves the overall coherence of the generated content while maintaining the other quality aspects.

5 Performance evaluation of CCC against baselines

To position our work against existing work, we use two state-of-the-art baseline systems. Our first baseline is GEMS, proposed by (Taneva and Weikum, 2013). GEMS is an extractive generation framework that uses an ILP formulation to extract a set of sentences towards the required content optimizing for the coherence by selecting contiguous sentence fragments. Our second baseline, WikiWrite (Banerjee and Mitra, 2016), has been used to generate Wikipedia articles in a coherent fashion. Similar to our approach, WikiWrite also uses a combination of sentence compression with ILP, however, the sentence compression does not account for the information covered by previously generated candidates, leading to lesser diversity.

Our goal is to obtain the best generation given a set of retrieved text. Alternative methods to modify *tf*idf* criteria (Lecorvé et al., 2008) could be used to increase the specificity of retrieved documents to



(a) Information Coverage & Diversity in the generated content (b) Coherence of the generated content with and without ILP with and without Sentence Compression

Figure 1: Impact of different stages of CCC on the various quality aspects of the generated content

the topics in the query. However, to prevent any bias in the quality of query search results, we ensure that the seed set of documents provided as input to each of the approaches is the same (specified in Section 3) without any such modifications.

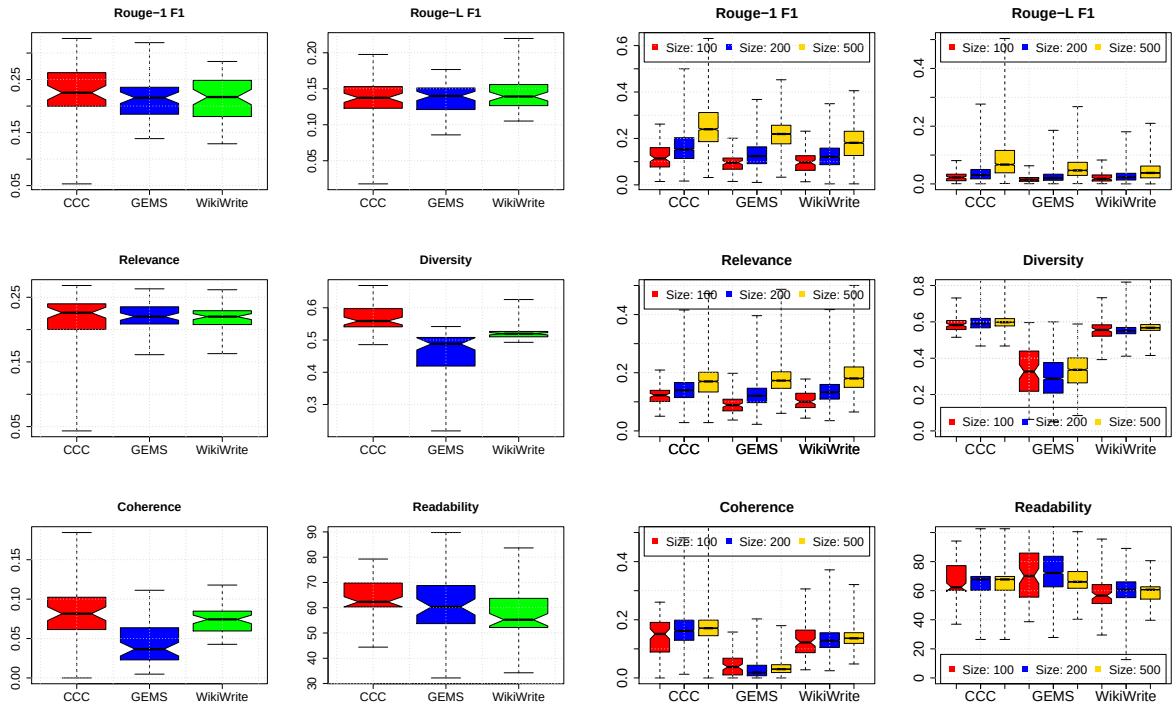
In the rest of this section, we present a comparison of CCC against the baselines. To check for statistical significance, we employ the Wilcoxon signed-ranked sum test (Wilcoxon, 1945), comparing the paired difference in values between the baseline and CCC. Test statistic and p-value indicated are from one sided tests, as indicated. The significance level is taken at $p = 0.05$. We also report the sum of ranks assigned to differences with positive sign (V) for each test.

Fig. 2(a) shows the Rouge scores for the generated content against the human generated content. At the entity level, the proposed generation has a significantly better performance against both the extractive (GEMS) ($V = 977$, $p = 0.042$) and abstractive (WikiWrite) ($V = 979, p = 0.040$) approaches. When compared beyond unigrams, the generation quality is comparable as indicated by the Rouge-L scores.

Since all the methods optimize for the relevance, the proposed approach has comparable relevance to the baselines. However, our proposed approach yields a higher information diversity and coverage as compared to the other approaches. As observed previously, sentence compression results in more information compressed into the content and hence both WikiWrite and our approach generate more diverse content. The diversity of our approach is more than that of WikiWrite due to the optimized sentence selection that precedes compression in our approach. This indicates that our approach yields an article much **more informative** than those generated by the baselines - GEMS ($V = 1540$, $p < 0.001$) and WikiWrite ($V = 1440$, $p < 0.001$).

GEMS is outperformed by both our approach ($V = 1440, p < 0.001$) and Wikiwrite ($V = 1398$, $p < 0.001$) at coherence, since both of these algorithms account for coherence explicitly. The coherence of our algorithm and Wikiwrite was found to be comparable.

Finally, we compute the Flesch reading ease (Kincaid et al., 1975) to quantify the readability of the generated content as its based on the Flesch reading ease. Since GEMS uses human generated sentences as-is from the input, it yields readable sentences. Unlike WikiWrite, our approach compresses only



(a) DUC 2007 Data

(b) Australian Legal Data

Figure 2: Generated content quality for CCC against GEMS ((Taneva and Weikum, 2013)) and WikiWrite ((Banerjee and Mitra, 2016)) on the Australian Legal Dataset (Galgani et al., 2012)

related sentences and thus does not result in unusually larger and less readable sentences, thus, our readability is higher ($V = 1380$, $p < 0.001$). The reading ease is comparable to GEMS despite not using the sentences as-is.

To conclude, we are able to achieve a performance which parallels that of the better of the two baselines in most aspects, while significantly outperforming them in other aspects.

Australian Legal Dataset: Although the performance of our proposed algorithm on the DUC2007 dataset is promising, the dataset is relatively small as compared to an enterprise content repository. In order to test the performance on a larger enterprise-like corpus, we evaluate the proposed approach on the Australian Legal Case Reports dataset[1] (Galgani et al., 2012), a collection of 3890 legal cases from the Federal Court of Australia (FCA) from 2006 to 2009. We used the gold standard summary for every case as the input snippet and the actual article as the reference. The legal articles were 6406-word long on an average, while the summaries were 65-word long on an average. Here, we also try to generate articles of different length - 100, 200 and 500 - to test the robustness of extraction. Fig. 2(b) shows the generation quality for our approach against the baselines. The trends observed in Fig. 2(a) for the DUC dataset carry over to Australian Legal Case Reports one as well. This validates the performance of our approach across corpora.

As the target size of generated content is increased, the algorithms' output becomes increasingly more relevant to the original article. The diversity of the proposed algorithm also increases with a minor dip in coherence. This can be attributed to the fact that the coherence measures inter-sentence topical overlap and with increased diversity, there is a minor dip in local coherence since the topic overlap will reduce.

6 Conclusion

We studied the problem of constructing a piece of text by picking content from an existing corpus and combining them by optimizing relevance, information coverage and coherence with reduced redundancy. Evaluations based on several metrics against state-of-the-art baselines shows superior performance of the proposed solution and hence demonstrates the feasibility of the approach. We believe that automated text generation will play a key role in smart authoring workflows for several domains in the near future.

Bridging resolution: Task definition, corpus resources and rule-based experiments

Ina Rösiger, Arndt Riester and Jonas Kuhn
Institute for Natural Language Processing
University of Stuttgart, Germany
{roesigia,arndt,jonas}@ims.uni-stuttgart.de

Abstract

Recent work on bridging resolution has so far been based on the corpus ISNotes (Markert et al., 2012), as this was the only corpus available with unrestricted bridging annotation. Hou et al.'s (2014) rule-based system currently achieves state-of-the-art performance on this corpus, as learning-based approaches suffer from the lack of available training data. Recently, a number of new corpora with bridging annotations have become available. To test the generalisability of the approach by Hou et al. (2014), we apply a slightly extended rule-based system to these corpora. Besides the expected out-of-domain effects, we also observe low performance on some of the in-domain corpora. Our analysis shows that this is the result of two very different phenomena being defined as bridging, which we call referential and lexical bridging. We also report that filtering out gold or predicted coreferent anaphors before applying the bridging resolution system helps improve bridging resolution.

1 Introduction

Bridging is an anaphoric phenomenon where the interpretation of a bridging anaphor, sometimes also called associative anaphor (Hawkins, 1978), is based on the non-identical associated antecedent. The corresponding NLP task of bridging resolution is about linking these anaphoric noun phrases and their antecedents, which do not refer to the same referent but are related in a way that is not explicitly stated. Bridging anaphors are thus discourse-new but dependent on previous context.

(1) Our correspondent in Egypt is reporting that **the opposition** is holding a rally against **the constitutional referendum**.[1]

One can think of bridging anaphors as expressions with an implicit argument, e.g. *the opposition (in Egypt)*. Compared to coreference resolution, which has become one of the standard NLP tasks, the progress in bridging resolution is much slower. The main issue for most researchers aiming to apply statistical algorithms to this task is the lack of training data, as well as the rather diverse bridging definitions and annotations. The resolution of bridging links is important because it can prove beneficial in tasks which use the concept of textual coherence, for example Barzilay and Lapata's (2008) entity grid or Hearst's (1994) text segmentation.

Note that while a benchmark dataset for bridging has not yet been established, most recent work is based on the ISNotes corpus (Markert et al., 2012), which contains Wall Street Journal articles. Full bridging resolution on this corpus has been investigated in Hou et al. (2014), following earlier experiments on the subtasks of bridging anaphor detection (Hou et al., 2013a) and antecedent selection (Hou et al., 2013b). Apart from this, there is some work on bridging detection as a subclass of information status classification, where bridging is typically a category with low annotator agreement and low detection accuracy (Markert et al., 2012; Rahman and Ng, 2012; Hou, 2016a). In the meantime, a few other corpora

[1] Anaphors are marked in bold face, their antecedents are underlined.

Proceedings of the 27th International Conference on Computational Linguistics, pages 3516–3528
Santa Fe, New Mexico, USA, August 20-26, 2018.

have been made available (some of the same domain as ISNotes, newspaper, some of other domains) which make it possible to assess how generalisable the rule-based approach is.

The focus of this paper lies on full bridging resolution but we also report numbers for anaphor detection. We start with a re-implementation of Hou et al. (2014),[2] which we extend with one new rule to find more general bridging cases, as we think that this contributes to the generalisability of the approach, before we apply the extended system to other corpora. We also include a couple of additional experiments, where we compare predicted and gold markables and investigate the effect of coreference information. We report that filtering out gold or even just predicted coreferent anaphors before bridging resolution significantly helps improve bridging resolution.

Besides the expected out-of-domain effects, we also observe low performance on some of the in-domain corpora. Our analysis shows that this is the result of two very different – though often co-occurring – phenomena being defined as bridging, namely *referential* and *lexical bridging*, which is why we have included a rather extensive review of bridging definitions in the next section.

2 Defining bridging

Bridging has been examined in many theoretical studies (Clark, 1975; Hawkins, 1978; Hobbs et al., 1993; Asher and Lascarides, 1998; Baumann and Riester, 2012) as well as in corpus and computational studies (Fraurud, 1990; Poesio et al., 1997; Vieira and Teufel, 1997; Poesio and Vieira, 1998; Poesio et al., 2004; Nissim et al., 2004; Nedoluzhko et al., 2009; Lassalle and Denis, 2011; Cahill and Riester, 2012; Markert et al., 2012; Hou et al., 2013b; Hou et al., 2013a; Hou, 2016b; Zikánová et al., 2015; Grishina, 2016; Roitberg and Nedoluzhko, 2016; Riester and Baumann, 2017).

Unlike in work on coreference resolution, these studies do not follow an agreed upon definition of bridging. On the contrary, many different phenomena have been described as bridging. While some of the issues have been controversial for a long time, e.g. the question of definiteness, the importance of the distinction between *referential* and *lexical* bridging, inspired by the two-level *RefLex* annotation scheme by Baumann and Riester (2012), became evident in our experiments. The two terms describe two different phenomena which are currently both defined and annotated as bridging.

2.1 Referential bridging

Referential bridging describes bridging at the level of referring expressions, i.e. we are considering noun phrases that are truly anaphoric, in the sense that they need an antecedent in order to be interpretable, like in (2). As such, (referential) bridging anaphors are non-coreferent, context-dependent expressions.

(2) The city is planning a new townhall and **the construction** will start next week.

Referential bridging is often a subclass of (referential) information status annotation. We claim that referential bridging anaphors can be seen as expressions which require for their interpretation the antecedent as an implicit argument, e.g. *the construction of the new townhall* in (2). When uttered out of context, their referent is unidentifiable. The two above-mentioned examples are captured by this linguistically motivated definition.

Referential bridging anaphors are typically short, definite expressions (*the construction, the door*), and several accounts explicitly restrict bridging to definites, e.g. Poesio and Vieira (1998), Nedoluzhko et al. (2009), Grishina (2016), Rösiger (2016) or Riester and Baumann (2017), while others also allow for indefinite bridging, e.g. Löbner (1998) or Markert et al. (2012), with the consequence that some studies have linked indefinites as bridging anaphors (e.g. in ISNotes and others). Although having held different views on this issue, we nowadays think that indefinite expressions can indeed – in some cases – be referential bridging anaphors, for example in (3) or (4), where the (partitive) expressions *one employee (of Starbucks)* or *leaves (of the old oak tree)* are introduced.

(3) Starbucks has a new take on the unicorn frappuccino. **One employee** accidentally leaked a picture of the secret new drink.

[2]The system will be made available here: `https://github.com/InaRoesiger/BridgingSystem`

(4) Standing under the old oak tree, she felt **leaves** tumbling down her shoulders.

However, while short, definite expressions signal identifiability and are thus either anaphoric expressions or familiar items, it is much harder to decide which indefinite expressions are bridging anaphors, since indefinite expressions are prototypically used to introduce new discourse referents and principally do not need an antecedent/argument in order to be interpretable. This is, for example, also reflected in the higher inter-annotator-agreement for definite than for indefinite bridging anaphors (Rösiger, 2018a).

Thus, despite the interpretational uncertainty surrounding indefinites, we take linguistic anaphoricity/context-dependence to be the defining criterion for referential bridging. Semantic relations like meronymy will be addressed in the next section under the notion *lexical bridging*. In this connection, it is important to concede, however, that the reason why certain definite or indefinite expressions function as bridging anaphors (while others do not) is typically due to some kind of semantic proximity between antecedent and anaphor. However, the specific relation we are dealing with may be rather abstract, vague and difficult to define, as the examples in (1)-(3) show.

2.2 Lexical bridging

Baumann and Riester (2012) use the term *lexical accessibility* to describe lexical semantic relations, such as meronymy or hyponymy, at the word or concept level (e.g. *house – door*). It is important to bring to mind that lexical relations are defined as part of the intrinsic meaning of a pair of concepts, thus, abstracting away from specific discourse referents: it is the words *house* and *door* which stand in a meronymic relation, not two actual physical objects or their mental images, although typically the referents of a holonym-meronym combination will, at the same time, stand in a physical whole-part relation. Since this physical relation has often been taken as one of the defining criteria for bridging, e.g. by Gardent et al. (2003), Nissim et al. (2004), Nedoluzhko et al. (2009) or Grishina (2016), we suggest to use the term *lexical* (or *lexically induced*) *bridging* for this phenomenon.

The referents of the proper nouns *Europe* and *Spain* are in a whole-part relation,[3] and the referring expressions can thus be considered a case of lexical bridging. However, the expression *Spain* is not anaphoric, since its interpretation does not depend on the "antecedent" *Europe*. Whole-part is probably the prototypical pre-defined relation, and it is a straightforward concept to annotate in the case of nouns denoting physical objects. However, it is less applicable in connection with abstract nouns, which is why many additional relations have been suggested, including, for instance *thematic role in an event, attribute of an object* (like *price*), *professional function in an organisation* (like *president*), *kinship* (like *mother*), *possessed entity* and so on. And yet, few schemes get by without an "other" category for the many examples which cannot be naturally classified into one of the assumed classes.

It should be noted that lexical and referential bridging are two different concepts with completely different properties: one deals with the question of pragmatic anaphoricity (or grammatical saturation) of an expression, the other with lexical proximity between two words and the relation between entities in the real world, although the two types of bridging often co-occur within one and the same pair of expressions, such as in (5), where we have a relation of meronymy between the content words *sea urchin(s)* and *spine(s)*, but also an anaphoric relation between the referring expressions *most sea urchins* and *the spines*, i.e. a case of referential bridging.

(5) In most sea urchins, touch elicits a prompt reaction from **the spines**.

The second release of the ARRAU corpus (Uryupina et al., to appear, first released in Poesio and Artstein, 2008), as used in the first shared task on bridging resolution, for example, contains instances of both referential and lexical bridging, with the majority of the bridging links being purely lexical bridging pairs, i.e. most expressions labeled as bridging are actually not context-dependent.

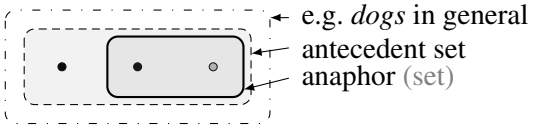
[3]Note that for proper nouns (names), like *Spain*, there is a one-to-one mapping between the word and its referent in the real world, which is not the case for common nouns, cf. Kripke (1972).

2.3 Subset relations and lexical givenness

Another relation often brought up in connection with (lexical) bridging is the *subset* or *element-of* relation, which is the most common relation in ARRAU. In principle, an expression referring to an element or a subset of a previously introduced group can be of the referential type of bridging, like in (6), where the anaphor is interpreted as *the small pug (from the prementioned group of dogs)*, but this is not always the case, as (7) shows.

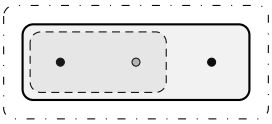
(6) I saw some dogs yesterday. **The small pug** was the cutest.

(7) Newsweek said it will introduce the Circulation Credit Plan, which awards space credits to advertisers on renewal advertising. The magazine will reward with page bonuses **advertisers who in 1990 meet or exceed their 1989 spending**, [. . .]



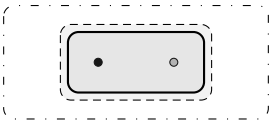
The subset relation can sometimes be reversed, as shown in (8).

(8) I saw a small pug yesterday. I like **many dogs**.



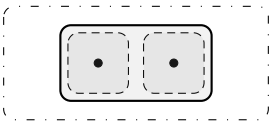
It should be noted, however, that subset/element-of pairs also have a lot in common with coreference pairs, since the lexical relation between their head nouns tends to be hypernymy, synonymy or plain word repetition (lexical relations which are summarised as *lexical givenness* in Baumann and Riester, 2012) or hyponymy (i.e. *lexical accessibility*). Note that, although the antecedent and anaphor expressions in (9) stand in a hypernym-hyponym relation (or reverse), their respective referent is the same. Hence, these cases do not exemplify bridging but coreference.

(9) a. I saw a dog yesterday. **The small pug** was very cute.
b. I saw small pugs yesterday. **The dogs** were very cute.



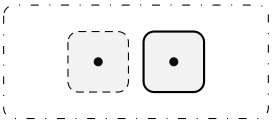
Note that *element-of* bridging is also conceptually very close to the phenomenon of aggregation/summation, in which the group entity follows a list of elements, and which also counts as a case of coreference.

(10) I saw a pug and a Yorkshire terrier. **The dogs** were very cute.



A final case, which is treated as a special class of information status in Markert et al. (2012) and annotated as a subclass of bridging in ARRAU, are so-called *comparative* or *other*-anaphors. The head noun of the anaphor must be lexically given (Riester and Piontek, 2015, 242f.) and the two expressions are marked as two contrastive elements from the same alternative set (Rooth, 1992). Comparative anaphors can be considered cases of referential bridging where the implicit argument is the implicit or explicit alternative set, i.e. *another dog (from a specific or unspecific set dogs)*.

(11) I saw a small pug two days ago and **another dog** yesterday.



2.4 Near-identity

While many approaches distinguish only between coreferent anaphors, which refer to the same referent as their antecedent, and bridging anaphors, which refer to a different referent, Recasens and Hovy (2010) and Recasens et al. (2012) have introduced a third concept, the concept of *near-identity* which has been picked up by others (e.g. Grishina, 2016). Near-identity is defined to hold between an anaphor and an antecedent whose referents are almost identical, but differ in one of four respects: name metonomy, meronymy, class or spatio-temporal functions.

(12) On homecoming night Postville feels like Hometown, USA, but a look around this town of 2,000 shows its become a miniature Ellis Island ... For those who prefer **the old Postville**, Mayor John Hyman has a simple answer.

We believe that the introduction of this additional category in between coreference and bridging introduces more uncertainty and, therefore, potentially makes the annotation process more difficult. Ex. (12), for instance, is structurally analogous to comparative anaphors.

3 Available corpus resources

Table 1 presents English corpora containing bridging annotations as well as their number of bridging pairs, limitations on the bridging anaphor, the type of bridging and the respective domain. Each corpus is quickly summarised below.

Corpus	# of pairs	Anaphor	Type	Domain
ISNotes	663	all	referential	news
ARRAU	5,512	all	mostly lexical, some referential	news, (narrative, dialogue)
BASHI	459	all	referential	news
SCiCorp	1366	only definite	referential	scientific text
CorefPro	188	only definite	referential	news, narrative, medicine
GUM	(growing)	all	referential, some lexical	dialogue, narrative, informative, instructional, ...

Table 1: Overview of available English corpora containing bridging annotations

There exist a few older corpora with bridging annotations which are not listed here because their annotations deviate from the ones presented here in one or several aspects. For example, in earlier experiments, "different-head-coreference", compare Ex. (9), was considered bridging (e.g. in Poesio and Vieira, 1998). As the bridging corpora are already rather diverse, we limit ourselves to the ones presented in Table 1.

ISNotes The ISNotes corpus (Markert et al., 2012), a corpus of newspaper text, contains bridging as a subclass of information status annotation, with 633 annotated bridging pairs. It contains definite and indefinite bridging anaphors, but no comparative anaphors, as these cases were considered a different information status category. To the best of our knowledge, the ISNotes corpus has been the only corpus on which recent results have been published, cf. Hou et al. (2013b; 2014).

ARRAU Recently, the first shared task on bridging resolution was announced. As a data basis, the second release of the ARRAU corpus was used, which contains 5,512 bridging pairs in three different domains: news text, dialogue and narrative text. This is, as far as we know, currently the largest corpus resource containing bridging pairs. However, only a small subset of the annotated pairs contains truly anaphoric bridging anaphors (cf. Section 2 for the distinction between referential and lexical bridging).

BASHI The BASHI corpus (Rösiger, 2018a) is a corpus of news text, which contains 459 bridging pairs, of which 114 are labeled as indefinite bridging anaphors and 70 as comparative anaphors.

SciCorp SCiCorp (Rösiger, 2016) is a corpus annotated with information status and bridging as a subclass. It contains scientific text of two disciplines, computational linguistics and genetics. 1366 bridging pairs were annotated. However, the bridging pairs contain pairs where possessive pre-modification was involved, as in (13).

(13) them ... **their interest**.

This is sometimes called *containing inferrable* (Prince, 1981) or *bridging-contained* (Baumann and Riester, 2012), as the antecedent is a syntactic argument within the markable. We filter out these cases, as we think that they should not be included in the category bridging proper, since anaphoricity is achieved by linking the pronoun *their* to its coreferential antecedent.

GUM The GUM corpus (Zeldes, 2017) is a corpus of (currently) 85,350 tokens The corpus is expanded every year by students as part of a curriculum at Georgetown University. As GUM contains bridging annotation as part of their information status classification, most bridging pairs are expected to be referential bridging. However, after a quick scan of the data, we also found some non-anaphoric, lexical bridging (or lexically given) pairs, e.g. in (14) or (15).

(14) However, there are four hotels in Hadibo – **Taj Socotra Hotel**, **Hafiji Hotel**, **Socotra Hotel** and **Summer land Hotel**.

(15) Name your language. This is the most fundamental property in **all languages**. You have many names to choose from [...] **most languages** [...]

GUM also contains a number of bridging-contained cases as well as some cases of aggregation, which we see as a special case of coreference, e.g. in (16).

(16) Mix .2 grams of luminon, 4 grams of sodium carbonate, .4 grams of copper sulfate [...] in a second bowl. Unfortunately, **these hazardous chemicals** will not float freely in mid-air like this graphic suggests.

CorefPro Grishina (2016) recently described a parallel corpus of German, English and Russian texts with 432 German bridging pairs that have been transferred to their English and Russian counterparts, resulting in 188 transferred English bridging pairs. The corpus has recently been made available.[4] In contrast to the other corpora, they apply a three-way classification: anaphors can be coreferent, bridging or of the category near-identity. Only definite anaphors were annotated.

4 Experimental setup

4.1 Corpora

ISNotes Hou et al. (2014) split the corpus into a development (10 documents) and test set (40 documents). The rules were optimised on the development set and the performance of the system reported on the test set. Unfortunately, the concrete development/test split is not specified. We report numbers for our own test-development-split[5] as well as for the whole corpus.

ARRAU The data was obtained from the LDC and consists of training, development and test sets for the three domains newspaper, narrative text and dialogue, with most of the text being news text. As the number of bridging anaphors in the narrative and dialogue part is quite small, we report numbers only on the test set of the news part (RST). This is also done in order to be compatible to the scores of the shared task associated with this data, which also focused on the RST domain.

BASHI The data was downloaded from the webpage.[6] As we simply apply our systems to this data, we report performance on the whole corpus.

SCiCorp The data was downloaded from the webpage.[7] Again, we report numbers on the whole corpus.

[7] http://www.ims.uni-stuttgart.de/forschung/ressourcen/korpora/scicorp.html

Rule	Example	Anaphor	Antecedent search	Window
1	A white woman's house ← The basement	building part	semantic connectivity	2
2	She ← Husband David Miller	relative	closest person NP	2
3	The UK ← The prime minister	GPE job title	most frequent GEO entity	-
4	IBM ← Chairman Baker	professional role	most frequent ORG NP	4
5	The firms ← Seventeen percent	percentage expression	modifying expression	2
6	Several problems ← One	number/indefinite pronoun	closest plural, subject/object NP	2
7	Damaged buildings ← Residents	head of modification	modifying expression	-
8	A conference ← Participants	arg-taking noun, subj pos.	semantic connectivity	2

Table 2: Overview of rules in Hou et al. (2014).

4.2 Evaluation metrics

The evaluation of bridging resolution is computed using the widely known precision and recall measures (and the harmonic mean between them, F1). The bridging anaphor is considered a mention, while the antecedent is considered an entity. This is taken into account by including gold coreference chains during the evaluation. If the predicted antecedent is one of the mentions in the coreference chain of the gold antecedent, the bridging pair is considered correct. The evaluation is rather strict, as overlapping markables are considered wrong. Furthermore, bridging anaphors with more than one link, e.g. comparative anaphora in the sense of (17), cannot be predicted with our system, as it is based on predicting just one antecedent.

(17) Canada, the US and **other countries**

It is also unclear how these multiple antecedents should be evaluated in case of partial correctness. In the current study, when the pair *the US* and *other countries* is suggested by the system, it is considered wrong. The same holds for antecedents with discontinuous or empty antecedents, which are contained in the ARRAU corpus.

5 Re-implementation of Hou et al. (2014)

As a basis for our experiments, we re-implement the rule-based system proposed by Hou et al. (2014).[8] For more details on the re-implementation, please refer to the supplementary material of this paper.[9]

The re-implementation comprises all three components of the original paper: pre-processing, rule adaptation and post-processing. During pre-processing, markables are extracted, which are then passed on to eight rules which predict bridging anaphor and antecedent pairs. These eight hand-crafted rules are based on linguistic intuitions about (referential) bridging. Most of the rules are rather specific, aiming at high precision, while some of the rules are designed to capture more general bridging cases, thus increasing the recall. Finally, the rules are applied in order of their precision. We extract NPs as our predicted markables. We also extract the markables of the information status annotation as our set of gold markables, where available. These form the initial set of anaphors and antecedents. We follow Hou et al.'s (2014) suggestion to exclude NPs whose head appeared before in the document, as these cases are typically involved in coreference chains. We also experiment with filtering out predicted and gold coreferent anaphors before applying the rules, described in Section 5.4.

5.1 Rules

Each rule is applied separately to the list of extracted markables and proposes pairs of bridging anaphors and antecedents. Table 2 gives an overview of the rules implemented. Two measures are computed independently of the actual bridging resolver and are needed as input for several rules, the semantic connectivity and the argument taking ratio. In order to find more general bridging cases, we have also implemented one additional rule, which is explained in Section 5.3.

[8]The re-implementation was necessary because the source code has not been made publicly available.

[9]Code and supplementary material: `https://github.com/InaRoesiger/BridgingSystem`

Computing the semantic connectivity The semantic connectivity between two words can be approximated by the number of times two words occur in a noun preposition noun pattern in a big corpus. This means that two nouns like *window* and *room* have a high semantic connectivity because they often occur as *windows in the room*, whereas other nouns do not appear often in such a construction and are therefore not highly semantically connected. Following Hou et al. (2014), we take the GigaWord corpus as the basis for the computation of the scores.

Computing the argument-taking ratio The argument taking ratio of a mention's head reflects how likely an NP is to take arguments (Hou et al., 2014), i.e. how *relational* an NP is. This can be used for bridging resolution as we assume the bridging anaphor to be lacking an implicit modifier in the form of the antecedent. If it has a low argument taking ratio, then the likeliness of an expression to be a bridging anaphor is also low. For example, the lemma *child* is often used without arguments, when we are generically speaking about *children*. *Brainchild*, however, seems to be an expression that is exclusively used with modification, e.g. in *the brainchild of* ... For details on the computation of the scores, please refer to the supplementary material.

5.2 Results

Setting	Corpus	Anaphor recognition			Full bridging		
		Precision	Recall	F1	Precision	Recall	F1
Hou (2014), gold markables	test set	61.7	18.3	28.2	42.9	11.9	18.6
Re-implementation with gold markables							
	test set	73.4	12.6	21.6	60.6	10.4	17.8
	whole corpus	65.9	14.1	23.2	57.7	10.1	17.2
Re-implementation with predicted markables							
	test set	69.3	12.2	20.7	57.7	10.1	17.2
	whole corpus	65.2	13.6	22.5	49.2	10.3	17.0
Extended re-implemenation (+new rule) using gold markables							
	test set	51.7	17.1	25.7	36.8	12.2	18.3
	whole corpus	45.9	18.3	26.2	32.0	12.8	18.3
Filtering out coreferent anaphors							
No coreference	whole corpus	45.9	18.3	26.2	32.0	12.8	18.3
Predicted coreference	whole corpus	68.6	18.3	28.9	47.9	12.8	20.2
Gold coreference	whole corpus	71.6	18.3	29.2	50.0	12.8	20.4

Table 3: Performance of the re-implementation of Hou et al. (2014), with different settings

Hou et al. (2014) state a precision of 42.9, a recall of 11.9 and an F1 score of 18.6 for full bridging resolution and a precision of 61.7, a recall of 18.3 and F1 score of 28.2 for anaphor detection. In both settings, they use gold markables but no coreference information. Table 3 contains the scores of the re-implementation for the test and the whole corpus when using gold or predicted markables. As mentioned above, we have defined a different test-development-split, which is why the results are not directly comparable. In general, however, we think that our re-implementation achieves comparable results, as our rules also achieve similar precision values and firing rates than in Hou (2016b), which are not shown here due to lack of space. As we have simply re-implemented the system from the original paper without any hand-tuning on the development set, we also report the numbers on the whole ISNotes corpus. Here, our re-implementation yields a precision of 57.7, a recall of 10.1 and an F1 score of 17.2 for full bridging resolution. Compared to the original numbers in Hou et al. (2014), we achieve higher precision, but lower recall, resulting in an overall lower F1 measure.

5.3 New rule and final performance

In order to include more general information and to increase recall, we apply the distributional (DS) classifier described in Shwartz and Dagan (2016) to distinguish certain semantic relations, e.g. hyponyms and meronyms. The classifiers input are word embeddings, taken from ConceptNet (Speer et al., 2017). As we expect the prototypical bridging relation to be the relation of meronymy (part-whole), we include this information in our bridging resolver, in the form of the following rule: the anaphor has to be a definite, unmodified expression in the form of *the N*. We search for an antecedent within the last three sentences

Corpus	Domain	Bridging type	Anaphor recognition			Full bridging		
			Prec.	Recall	F1	Prec.	Recall	F1
ISNotes (gold markables)	news	ref.	71.6	18.3	29.2	50.0	12.8	20.4

Table 4: Performance of the rule-based method on other corpora. We use gold markables for ARRAU in order to be compatible with the shared task results, and predicted mentions for BASHI and SciCorp as they do not contain gold markables.

for which the classifier has predicted the pair of antecedent-anaphor to be an instance of meronymy. Additionally, the constraint that the two pairs need to have a cosine similarity score over the threshold of 0.2 has increased results (this threshold has been optimised on the development set). The new rule decreases precision, but significantly increases recall[10], which is why we get a significant increase in F1 score. The final system performance is shown in Table 3. More details on our experiment on integrating predictions from neural-net relation classifiers can be found in Rösiger et al. (2018).

5.4 Filtering out coreferent anaphors: Gold vs. predicted

Bridging anaphors are difficult to distinguish from coreferent anaphors, as they both often are short, unmodified expressions which are either interpretable because they are coreferent with a previously mentioned entity or are bridging anaphors which require an antecedent for their interpretation. Thus, we think it may be beneficial for the precision of our system to filter out coreferent anaphors before applying the bridging system. We experiment with three settings: (i) no coreference information, (ii) predicted coreference information and (iii) gold annotated coreference information. For predicted coreference, we applied the IMSHotCoref system (Björkelund and Kuhn, 2014) with its default settings on the ISNotes corpus.[11] We report the change in performance on the whole corpus, as there was no optimisation involved in the filtering of the coreferent anaphors. In Table 3, it can be seen that both predicted and gold coreference significantly improve the precision of the system, as well as the final F1 score. Surprisingly, the difference between gold and predicted coreference is small, compared to having no coreference information at all. The same effect can be observed with predicted mentions. We use gold coreference for the remaining experiments of the paper, as it is available in all corpora on which we want to apply our system.

6 Application to other corpora

6.1 BASHI (in-domain)

We first apply our re-implementation to a corpus of the exact same domain, BASHI. As can be seen in Table 4, the F1 score for anaphor recognition is 28.7, which is comparable to the score on ISNotes, although we observe a much lower precision on BASHI. Lower precision is also the reason for the overall lower score on BASHI for full bridging resolution, which means that the performance for anaphor detection is about the same, while we are worse in finding the correct antecedent. Still, the system performs relatively well on this data.

6.2 ARRAU (in-domain)

We apply our system to the test set of the RST (news) part, without making any changes. As can be seen in Table 4, the performance is extremely poor. We carefully analysed the reasons for the huge difference in performance between ISNotes/BASHI and ARRAU, which both contain Wall Street Journal articles and can thus not be explained with domain effects. We soon realised that the annotations differ quite a lot with respect to the understanding of the category bridging. We noticed that besides predicting wrong

[10] We compute significance using the Wilcoxon signed rank test (Siegel and Castellan, 1988) at the 0.05 level.

[11] We made sure to exclude the ISNotes part of OntoNotes from the training data for the coreference system, of course.

pairs, the original system would suggest bridging pairs which are fine from a referential point of view on bridging, but are not annotated in the corpus, such as (18).

(18) As competition heats up in Spain's bank market, [...] **The government** directly owns...

Additionally, it would miss a lot of lexical bridging and subset/lexical givenness pairs, as these often involve mentions with matching heads, which are filtered out in the pre-processing step of the system, such as in (19).

(19) Her husband and older son [...] run a software company. Certainly life for her has changed considerably since the days in Kiev, when she lived with her parents, her husband and **her two sons** in a 2 1/2-room apartment. (*relation: element-inverse*).

This is why the performance is so poor: a lot of referential bridging pairs which are not annotated were predicted, while the system missed almost all cases of (pure) lexical bridging. With the modular approach of the rule-based system, however, one can define new rules to also capture lexical bridging. The rules have been developed on the training and development set of the RST domain of the corpus and include rather specific rules, to find e.g. locations *Hollywood – LA* or *Los Angeles – California*, as well as more general rules to find the predominant relations in the corpus, namely subset and element-of. For more details on the adapted rule-based system, please refer to Rösiger (2018b). The final performance of the adapted system (F-score of 19.5) is also given in Table 4.

6.3 SciCorp (out-of-domain)

In contrast to ARRAU, SciCorp is an out-of-domain corpus annotated with referential bridging. When applying our system, we observe that it really does not generalise well to completely different domains, as the F1 score for full bridging resolution drops to 1.46. SciCorp also differs from BASHI and ISNotes with respect to the definiteness criterion: all bridging anaphors are definite. Of course, rules designed for indefinite anaphors cannot work. While we expected some of the rules designed for news text to perform poorly (e.g. building parts, relatives, job titles etc.), the rules designed to find more general cases of bridging also do not seem to predict a lot of pairs in this domain. The reason for this might also lie in the coverage of the semantic connectivity and argument-taking ratio, which are applied in these general rules: only 32 percent of the nouns in SciCorp are represented in the argument-taking-ratio lists, and only 3.9 percent of the noun pairs are contained in the semantic connectivity scores. Adding some in-domain text (e.g. large PubMed/ACL corpora) to the general corpora used to create these resources would be necessary to improve performance for the general rules of the system to work. We are positive that doing some form of domain adaptation, i.e. designing specific rules for scientific text and combining them with the improved general rules would lead to better results.

7 Conclusion and future work

We have presented a re-implementation of Hou et al. (2014), the state-of-the-art system for bridging resolution (which will be made publicly available), and applied it to other corpora, to test the generalisability of the approach. Besides the expected out-of-domain effects, we also observe low performance on some of the in-domain corpora. Our analysis shows that the system generalises well to in-domain corpora, if they are of the same type of bridging, namely referential bridging. We think that the distinction between referential and lexical bridging is a valuable contribution towards the understanding of the phenomenon of bridging and that it can also help design computational approaches. We also report that filtering out gold or predicted coreferent anaphors before bridging resolution helps improve bridging resolution.

As the GUM and CorefPro corpus have in the meantime been made available, we are planning to analyse the bridging annotations in these corpora according to our categorisation as well as to test the rule-based system on it.

Abstract

While the disfluency detection has achieved notable success in the past years, it still severely suffers from the data scarcity. To tackle this problem, we propose a novel semi-supervised approach which can utilize large amounts of unlabelled data. In this work, a light-weight neural net is proposed to extract the hidden features based solely on self-attention without any Recurrent Neural Network (RNN) or Convolutional Neural Network (CNN). In addition, we use the unlabelled corpus to enhance the performance. Besides, the Generative Adversarial Network (GAN) training is applied to enforce the similar distribution between the labelled and unlabelled data. The experimental results show that our approach achieves significant improvements over strong baselines.

1 Introduction

A characteristic of spontaneous speech is different from written text, since it's usually accompanied by disfluencies. Identifying and removing these non-fluent factors would help to improve the spontaneous speech quality. It often plays a significant role in understanding the semantics of these sentences and it's vital for the downstream NLP tasks, such as question answering, machine translation, and information extraction.

$$\text{I want to flight [} \underbrace{\text{to Boston}}_{\text{RM}} + \{ \underbrace{\text{um}}_{\text{IM}} \} + \underbrace{\text{to Denver}}_{\text{RP}} \text{]}$$

Figure 1: Example of disfluency annotation style in Switchboard corpus.

Figure 1 shows a standard annotation of disfluency structure (Shriberg, 1994), which includes three types of annotations: RM (*reparandum*, words that are discarded, or corrected by the following words), RP (*repair*, the correct words), and IM (*interregnum*, such as filled pauses, discourse cue words, etc.) The interruption point (+) marks the end of the reparandum and an optional interregnum. Ignoring the interregnum, disfluencies can be further categorized into three types: repetition (when RP is same as RM), repair, and restart (when RP is empty). Table 1 gives a few examples. However, it is usually difficult to identify the reparandum non-fluent factors. The main challenge behind is that this type of structure is flexible, variable in length, able to occur anywhere in a sentence, and in many cases will be nested. Detecting the disfluency can work in arbitrary form.

Recently, a number of approaches based on deep neural networks have been proposed to address the problem of disfluency detection under the framework of sequence labeling or sequence to sequence(Hough and Schlangen, 2015; Zayats et al., 2016; Wang et al., 2016; Wang et al., 2017). For most of the approaches mentioned above, the researchers switch between the RNN and CNN. But the RNN/CNN shows less flexibility than the self-attention layer which has achieved great success in neural machine translation (Shen et al., 2015; Wu et al., 2016; Gehring et al., 2017) and language understanding

(Shen et al., 2017). In the framework of sequence to sequence mapping, the model of NMT has achieved great success. Therefore, it is natural for us to investigate how to apply the NMT system to the problem of disfluency detection. In this paper, we take the disfluency detection as the translation task and build our model following the architecture of newly emerged NMT system, i.e., Transformer(Vaswani et al., 2017). The Transformer has achieved state-of-the-art results on both WMT2014 English-German and English-French translation tasks. Inspired by the success of self-attention, we propose a RNN/CNN-free network for disfluency detection through multi-task learning, which is built only on the self-attention layers. In the proposed model, we apply the self-attention layers to extract the hidden features of the input sentence. And two softmax layers, namely the label softmax and word softmax, are applied to perform classifications. The label softmax is used to calculate the probability of the disfluency label, and the word softmax is applied to compute the probability of the word.

In addition, we leverage unlabelled data to improve the performance of the disfluency detection. Due to lack of tagging information, using the unlabelled corpora is very promising, since the unlabelled corpora is usually easy to be collected. To utilize the unlabelled data, we extend the traditional encoder-decoder model by leveraging two independent encoders but with some layers shared. Specifically, we share the weights of the last few layers of two encoders that are responsible for extracting high-level representations of input sentences. In the proposed model, one encoder is utilized to encode the unlabelled data and the other is applied for the labelled data. For the unlabelled data, the corresponding encoder and decoder perform an Auto-Encoder (AE), where the encoder generates the latent representations from the perturbed input sentences and the decoder reconstructs the sentences from the latent representations. We utilize the GAN to constrain the latent representations from the labelled and unlabelled corpus to subject to a similar distribution, whereby the encoders try to fool a discriminator which is simultaneously trained to distinguish whether the latent representation is from labelled or unlabelled data.

In summary, we mainly make the following contributions:

- We propose a novel semi-supervised approach for the problem of disfluency detection, which can utilize large amounts of unlabelled data.
- We firstly introduce the self-attention mechanism into the disfluency detection through multi-task learning . Without relying on the RNN/CNN, the proposed model has more flexibility in sequence length and allows for more parallelization, which makes great significance.
- We conduct extensive experiments to test the proposed model. Experimental results show that the proposed approach consistently achieves great success.

2 Related Work

One of the most common approaches to disfluency detection is taking the task as a sequence labeling problem, where each sentential word is assigned with a label. Many approaches had achieved good performance by using the Condition-based Random Field (CRF) as a classifier (Ostendorf and Hahn, 2013; Liu et al., 2006; Cho et al., 2013; Zayats et al., 2014). (Qian and Liu, 2013) proposed a detection model based on maximum interval Markov random field (M^3N), which outperformed CRF by using an f-score matching objective function. (Ferguson et al., 2015) proposed the Semi-Markov CRF model for

disfluency detection and achieved the best performance of linear statistical sequence labeling methods by integrating prosodic features. Sequence labeling methods mentioned above are not powerful enough to model long-range dependencies of complicated disfluencies. RNN has been widely used to disfluency detection (Zayats et al., 2016; Hough and Schlangen, 2015), since it can capture dependencies at any length in theory. However, these RNN methods still suffer from the defect of unable to model the linguistic structural integrity, since it does not model the transition between tags which is important in recognizing the repair phrases of multi-words. Recently, sequence-to-sequence methods based on deep neural networks are applied to disfluency detection. (Wang et al., 2016) proposed an attention-based detection model and achieved good performance. It can capture a global representation of the input sentence by RNN when encoding and model tag transition when decoding.

Another branch of researches adopt transition-based parsing model, which jointly perform dependency parsing and disfluency detection (Rasooli and Tetreault, 2013; Honnibal and Johnson, 2014; Wu et al., 2015). These syntax-based models are capable of capturing long-range dependencies by modeling the repair phrases on a syntax tree. However, their high requirements for training data reduce their practicality, since it is expensive to obtain training data containing both syntax trees and disfluency annotations. Furthermore, the performance of syntax parsing also restricts the performance of disfluency detection. (Wang et al., 2017) proposed a transition-based model for disfluency detection, which learned representation of both chunks and global contexts without using any syntax information. It achieved the state-of-the-art f-score on the commonly used English Switchboard test set.

Lack of large scale of labelled data is always a bottleneck for improving the performance of disfluency detection (Wang et al., 2016; Wang et al., 2017). Recently, the unsupervised and semi-supervised NMT have arose many interests in the research area. To improve the translation performance of NMT, they use the auto-encoder and back-translation to train the model(Saha et al., 2016; Cheng et al.,). Following the same idea, we firstly propose the semi-supervised training for disfluency detection.

3 The Approach

In this section, we will give more details about the design of our proposed semi-supervised disfluency detection model.

3.1 The Input and Output

Since we consider the problem of disfluency detection as a translation task, translating the non-fluent sequence into the fluent sequence, we prepare our input and output as the training examples of translation. In traditional translation, the training example consists of one source-side sequence and one target-side sequence. However, for the proposed model, the source-side input is the non-fluent sequence, the target side includes two output sequences, one is the fluent sequence, which is the real needed output of disfluency detection task, and the other is the label sequence, which is an auxiliary information sequence. Considering a sentence from the training data, the non-fluent input of source side is:

”I want to flight to Boston um to Denver”

The target-side fluent sequence is represented as:

”I want to flight E E E to Denver ”

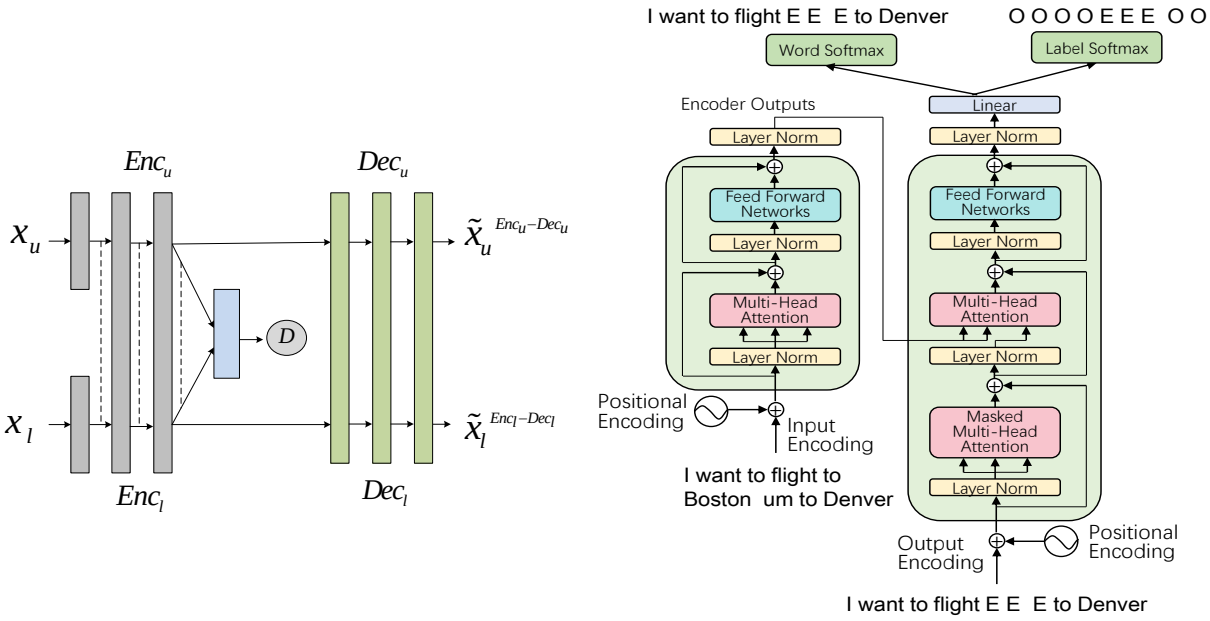
And the target-side label sequence can be represented as:

”O O O O E E E O O”

Where ’O’ indicates that the word at this time step is fluent, which should be copied from the source side to the fluent sequence, and ’E’ means the word at this time step is non-fluent, i.e., RM and IM words, which should be discarded. The length of the label sequence is the same as the input sequence. The motivation of the design of two output sequences will be elaborated in section 3.2.

3.2 The Model Architecture

Our proposed semi-supervised model is extended on traditional encoder-decoder framework. As illustrated in Figure 2(a), the model architecture is composed of four subnetworks: including two partially



(a) Weight sharing model with GAN

(b) Multi-task Transformer model

Figure 2: The framework of the proposed model. (a) is the whole architecture of our model, which contains two independent encoders with some weight sharing and the fully-shared decoder. (b) is the specific architecture of the proposed model which extends the Transformer into multi-task learning setting.

shared encoders Enc_l and Enc_u, one totally shared decoder Dec_l (Dec_u is the same as Dec_l), and a discriminator D, where subscript 'l' and 'u' represent labelled and unlabelled data, respectively. Each encoder consists of three identical layers, where each layer consists of a multi-head self-attention and a simple position-wise fully connected feed-forward network, which follows the powerful self-attention based model Transformer (Vaswani et al., 2017). Specifically, the encoder is composed of a stack of three identical layers. Symmetrically, the decoder is also a stack of three identical layers, and each layer also follows the Transformer. The key difference is the last output layer of the decoder, where we use two softmax layers to predict label sequence and word sequence separately (see Figure 2(b)). The decoding is constrained by the label prediction and word prediction at the same time, which is critical important for improving the disfluency detection performance.

To utilize unlabelled data x_u for training, the output of Enc_u should have similar distribution with the output of Enc_l. Therefore, we apply the weight sharing constraint to associate the two encoders by sharing the weights of the last few layers of two encoders that are responsible for extracting high-level representations of input sequences. Afterwards, a discriminator, implemented as a multilayer perceptron, is used to further constrain the latent representations from the labelled and unlabelled data to have similar distribution, whereby the encoder tries to fool the discriminator which is simultaneously trained to distinguish whether the latent representation is from the labelled or unlabelled data. As a matter of fact, the encoders and the discriminator constitute a GAN tactfully, where the encoders act as the cheater and the discriminator plays the role of police. The weight sharing and GAN training are pivotal strategies to make the semi-supervised training manner feasible.

To give more detailed interpretation of the weight sharing model, we piece together several roles by combining some subnetworks of the model, which are summarized in table 2. If only consider using labelled data x_l for training, it is enough to compose a complete model only with the encoder Enc_l and the decoder Dec_l, which will be back to a self-attention based Transformer model with multi-task learning. As for the unlabelled data, the encoder Enc_u generates the latent representation of the perturbed input sentence (such as adding random noises). And the corresponding decoder Dec_u reconstructs the

normal input sentence from the latent representation. Actually, Enc_u and Dec_u constitute an AE. The key information of these roles will be described in the following subsections successively.

Networks	Roles
$\{Enc_l, Dec_l\}$	Transformer for labelled data
$\{Enc_u, Dec_u\}$	AE for unlabelled data
$\{Enc_l, Enc_u\}$	Weight sharing of labelled and unlabelled data
$\{Enc_l, Enc_u, D\}$	GAN for discriminating data reality

Table 2: Interpretation of the roles for the subnetworks in the weight sharing model.

3.2.1 Multi-task Learning and Constrained Decoding

Our improvement on the Transformer model focuses on the last output layer of the decoder. Traditional output layer of Transformer is only one softmax layer. However, either the word sequence or the label sequence is incapable of handling the problem of disfluency detection independently. For the word sequence, it guides the model to treat each fluent word and disfluency word equally. However, in disfluency detection task, the model just needs to distinguish the non-fluent words from the fluent words in sentence. Too careful classification will detriment the classification performance. For the label sequence, it guides the model to output the fluent label or the non-fluent label. Nevertheless, it may cause overfitting during training since the fluent label 'O' and non-fluent label 'E' dominate in the training example. In other words, the word sequence needs a simple classification as the label sequence does, and the label sequence can benefit from the semantic information of the word sequence. Therefore, we fuse the disfluency detection sequence and the label sequence through multi-task learning to improve the performance.

Multi-task Learning

Given N such non-fluent source word sequences, target word sequences and label sequences. Our goal is to maximize the probability of observing the target word sequence y_n and minimize the label classification error rate of the label softmax, with regard to the model parameter θ. Different from the traditional end-to-end model in disfluency detection which only maximizes the probability of observing the target label sequence, the word error rate of the word softmax is also leveraged in the proposed model. From the multi-goal learning perspective, two different goals are used to dictate the parameters of the proposed model to converge to a better region. Formally, the objective function used in the joint punctuation model can be represented as:

$$\underset{\theta}{\operatorname{argmax}} \frac{1}{N} \sum_{n=1}^{N} (log_{p_\theta}(y_n|x_n) + \gamma * log_{p'_\theta}(z_n|x_n)) \tag{1}$$

Apart from the cross entropy loss used in the label neural network model, the error rate of the word neural network is also considered to train the proposed model.

$$J = J_w + \gamma * J_l \tag{2}$$

here J_w refers to the loss of the word, J_l denotes the loss of the label and γ is the hyper-parameter. We use the γ to balance the loss between the word softmax and label softmax.

Constrained Decoding

In the test decoding, we design a constrained decoding algorithm to adapt the proposed self-attention based network. In this algorithm, we need to judge the class of the label softmax to determine the decode sequence of the model. Specifically, if the label softmax outputs 'O', we copy the word from the source side and feed it into the model for the next time step. And if the output of the label softmax is 'E', we feed the generated 'E' into the model for the decoding in the next time step. The decoding process repeats until the "eos", i.e., the end of sentence token, is emerged and all the source words are copied. The constrained decoding algorithm could effectively avoid the inconsistency between the source word and the target word in a transduction model.

3.2.2 Denoising Auto-Encoding

In order to learn some knowledge from the unlabelled corpus to make up the scarcity of labelled data, an AE is utilized to train the unlabelled data via reconstructing their inputs. Specifically, the encoder is responsible for composing the high-level latent representation of the input and the decoder endeavors to decompose this representation into its corresponding input sequence. However, the AE usually fails to capture any internal structure of the involved sentences under unconstrained condition. Instead it just learns to copy every word one by one. To solve this problem, we employ the similar strategy of denoising AE (Vincent et al., 2008) and randomly add some noises to the input sentences (Hill et al., 2016; Artetxe et al., 2017).

To this end, for each sentence, we add two types of noises separately, one is repeating, the other is inserting. In repeating operation, we randomly choose one to three positions in sentence. And for each position, one to five words starting from selected position are repeated randomly, which is abide by the constraint that the repeat fragment does not overlap with the next selected position. In inserting operation, we still randomly choose one to three positions in sentence to add noises. Different from repeating operation which simply repeats words in the sentence, we insert words randomly selected from a top frequent dictionary, which is extracted from the corpus by keeping the top 10,000 most frequent 1-grams to 5-grams respectively beforehand. Thus, inserting operation can introduce more complicated noises. In this way, the system needs to learn some useful structure of the involved languages to be able to recover the correct word order.

3.2.3 Weight Sharing

To decrease even eliminate the distribution differences between the labelled and unlabelled corpora in some ways, a weight sharing constraint is applied to the two encoders according to the shared-latent space assumption. Different from (Cheng et al., 2016; Saha et al., 2016) which adopt the fully shared encoder, we share only partial weights for the encoders, considering that 1) The independent weights are devoted to encode the hidden features about the internal characteristics of each corpus, such as the terminology, style, and sentence structure; 2) The shared weights are concentrated on projecting those hidden features into the shared-latent space. Therefore, we share the weights of the last few layers of encoders Enc_l and Enc_u, which are committed to capture the high-level representations of the input sentences. A totally shared decoder is applied to decode those high-level representations that are vital for reconstructing the fluent sentences, since both for the labelled and unlabelled input sentences, they share the same decoding space and target.

3.2.4 Discriminator

For the weight sharing constraint based on the shared-latent space assumption, we would expect that the corresponding sentences in the labelled or unlabelled corpus will have the similar latent representations. However, the weight sharing constraint alone does not necessarily guarantee the same latent representations. To further enforce the shared-latent space, we train a discriminative neural network to classify whether the encoding representation is from the auto-encoded unlabelled or the labelled sentences.

The discriminator is implemented as a multi-layer perception with two hidden layers of size 256. The discriminator performs as a binary classifier and predicts whether the input is the labelled or unlabelled data.Given the encoding vector Enc(x), i.e., the output of the encoders either from the Enc_u or Enc_l, we build the perception layer as:

$$x_c = \rho(BN(W \times Enc(x) + b)) \tag{3}$$

where W and b is the learning parameters. ρ is a non-linear activation function which is implemented as ReLU. At last, we pass x_c into a softmax layer to generate the probability $p(f|Enc(x))$ as:

$$p(f|Enc(x)) = softmax(V * x_c) \tag{4}$$

where V is the transformation matrix and f is the data class, satisfying $f \in \{l, u\}$, where l means labelled data and u means unlabelled data. The discriminator is trained to predict the label probability

by minimizing the following cross-entropy loss:

$$L_D(\theta_D) = -\mathbb{E}_{x \in x_u}[\log p(f = u|Enc_u(x))] - \mathbb{E}_{x \in x_l}[\log p(f = l|Enc_l(x))] \quad (5)$$

here θ_D represents the discriminator parameters. The encoders are trained to fool the discriminator:

$$L_{Enc_u}(\theta_{Enc_u}) = -\mathbb{E}_{x \in x_u}[\log p(f = l|Enc_u(x))] \quad (6)$$

$$L_{Enc_l}(\theta_{Enc_l}) = -\mathbb{E}_{x \in x_l}[\log p(f = u|Enc_l(x))] \quad (7)$$

where θ_{Enc_u} and θ_{Enc_l} are the parameters of the two encoders.

4 Experiments

4.1 Datasets

To evaluate the effectiveness of utilizing unlabelled corpus on disfluency detection task, we firstly conduct an experiment solely on a labelled corpus named Switchboard. Then we expand the training data by introducing large-scale unlabelled corpus.

Switchboard is the largest available corpus for disfluency detection task, which is portion of the English Penn Treebank. Two annotation layers are provided in Switchboard corpus: one for syntactic bracketing (MRG files), the other for disfluencies (DPS files). Our proposed method only needs the DPS files. The disfluency annotation style of DPS files has been described in introduction. In our experiments, the word labelled with RM and IM would be tagged with 'E' and others would be tagged with 'O'. Some previous work has been done on this corpus. To keep the direct comparison possible, we follow the experiment settings in (Johnson and Charniak, 2004), taking directory 2 and directory 3 in subcorpus of PARSED/MRG/SWBD as training set, and splitting directory 4 into test and development sets. Table 3 shows the detailed scale of each dataset, where "total" means the total number of sentences and "non-fluent" means the number of non-fluent sentences among total.

Unlabelled corpus is randomly extracted from the source side of WMT2014 English-German corpus, consisting of English news. Noises, which make the unlabelled fluent sentence non-fluent, are added to the unlabelled datasets (named as WMT2014 English corpus) according to the description in subsection of denoising auto-encoding. The scale of training, development and test sets of WMT2014 English corpus is shown in Table 4.

Dataset	Total	Non-fluent
Training set	261,882	87,701
Dev set	2,000	1,455
Test set	2,000	1,425

Table 3: Scale of Switchboard corpus.

Dataset	Total	Non-fluent
Training set	1,000,000	1,000,000
Dev set	2,000	1,500
Test set	2,000	1,500

Table 4: Scale of WMT2014 English corpus.

4.2 Training Details

BPE Byte Pair Encoding (Sennrich et al., 2015) is a simple data compression technique, which is highly efficient to reduce the OOV quantity by iteratively replacing the most frequent pair of bytes in a sequence with a single unused byte. In our experiments, we set source number operations to 20,000 and the vocabulary size to 30,000.

Hyper-parameter The configuration of the hyper-parameter is critical to the performance of the proposed self-attention based model, since it directly affects the generalization and regression of the model. To balance the whole information from the word sequence and the label sequence, we introduce γ parameter. The hyper-parameter γ is designed to balance the loss from the label sequence and the word sequence. In order to highlight the word sequence loss, we set the γ value to 0.15 to weaken the influence of label sequence .

Metric Following previous works (Wang et al., 2016), token-based precision (P), recall (R), and F-score (F1) are used as the evaluation metrics.

Sharing layer	Switchboard			WMT2014		
	P	R	F1	P	R	F1
0	89.2	87.9	88.5	68.5	59.5	63.7
1	84.2	78.9	81.4	94.5	96.4	95.4
2	92.1	90.2	91.1	93.2	95.9	94.5
3	90.7	87.8	89.2	95.3	96.9	96.1

Table 5: Performance on Switchboard and unlabelled WMT2014 test set with different sharing layers.

4.3 Number of Weight-Sharing Layers

To investigate how the number of weight-sharing layers affects the translation performance, we vary the number of weight-sharing layers of the two encoders from 0 to 3. Table 5 shows the experimental results. It is observed that the number of weight-sharing layers has a significant impact on the performance of disfluency detection. When we set the number of weight-sharing layers to 0, resulting in two independent encoders, we get pool F-score on both test sets, especially on the WMT2014 test set. This is mainly because in testing phase, the unlabelled data will be encoded by encoder Enc_l and decoded by the totally shared decoder, while Enc_l could not encode the unlabelled data well under this condition since the encoder Enc_l could not learn any knowledge from the unlabeled data in training phase. Furthermore, the decoder needs to balance the two different kinds of input data, which leads to the small decline of performance on Switchboard corpus as well. From another perspective, it also indicates that without the weight sharing constraint, the GAN alone is insufficient to enforce the labelled data and unlabelled data to learn the similar latent representations, which results in a negative role. This confirms our intuition that the shared layers are crucial to project the labelled and unlabelled latent representations into a shared-latent space. At the opposite extreme, when all three layers of the two encoders are shared, resulting in a totally shared encoder, it is equal to feeding labelled and unlabelled data into a multi-task Transformer directly. In spite of a larger amount of training corpus, the F-score is better than the one of two independent encoders but still 1.8% lower than the one of two weight-sharing layers on Switchboard corpus. This verifies our conjecture that unlabelled data can enhance the generalization ability of model, but the shared encoder may also detrimental to the performance since it will weaken the unique characteristic of different corpora. Choosing proper number of weight-sharing layers makes much difference. We achieve best F-score of 91.1% on the commonly used Switchboard corpus test set when the two encoders share the last two layers. Under this condition, model can learn both the general characteristic and the internal characteristics such as the terminology and sentence structure of each corpus well.

Method	P	R	F1
Multi-task Transformer	91.5	87.1	89.2
Weight sharing	92.1	90.2	91.1
Transition-based (Wang et al., 2017)	91.1	84.1	87.5
Attention-based (Wang et al., 2016)	91.6	82.3	86.7
Bi-LSTM (Zayats et al., 2016)	91.6	80.3	85.9
semi-CRF (Ferguson et al., 2015)	90.0	81.2	85.4
UBT (Wu et al., 2015)	90.3	80.5	85.1
M^3N (Qian and Liu, 2013)	-	-	84.1

Table 6: Comparison with previous approaches on the test set of English Switchboard.

4.4 Results and Analysis

We compare our self-attention based models with six previous top performing systems. Table 6 shows the comparable results on English Switchboard test set. Our first model, named *multi-task Transformer*,

only utilizes the Switchboard corpus for training as other baselines. It is designed to assess the performance of self-attention based model directly. As it shown in Table 6, our multi-task Transformer achieves 89.2% F-score, outperforming the Transition-based method (Wang et al., 2017), which is the state-of-the-art, by 1.7 point improvements. Compared with the semi-CRF method (Ferguson et al., 2015), which gains the best performance of linear statistical sequence labeling methods, our multi-task Transformer achieves 3.8 point improvements without leveraging any prosodic features. The performance gab between our multi-task Transformer and UBT (Wu et al., 2015), the best syntax-based method for disfluency detection, is even larger. The F-score of multi-task Transformer increases by 5.1% than UBT. Furthermore, our second model focuses on how to take the advantage of unlabelled data, since labelled data is usually scarce. A weight sharing model (named *weight sharing* in Table 6) is introduced to tackle the training problem of mixed data. It improves the best F-score of our self-attention based models from 89.2% to 91.1%, which indicates that our novel proposed weight sharing model is capable of learning useful language knowledge from unlabelled noisy dataset automatically. As a result, our weight sharing semi-supervised model achieves 3.6% improvements than the previous state-of-the-art.

5 Conclusion

In this paper, we propose a novel semi-supervised model based on weight sharing mechanism and self-attention based multi-task learning scheme, which views the disfluency detection as a translation task. In the multi-task self-attention based network, the word sequence information and labelling information are incorporated into the model at the same time, and a constrained decoding method in testing phase is applied. Experimental results show that the proposed model achieves significant improvements than the strong baseline models. We are among the first endeavors to use the translation model to handle the disfluency detection task, which can be applied to any other sequence labelling task easily. In addition, we utilize the unlabelled corpus to enhance the performance by introducing the weight sharing strategy and the generative adversarial training to enforce the similar distribution between the labelled and unlabelled data. Experimental results show that the semi-supervised model can further improve the performance significantly.

ISO-Standard Domain-Independent Dialogue Act Tagging for Conversational Agents

Abstract

Dialogue Act (DA) tagging is crucial for spoken language understanding systems, as it provides a general representation of speakers' intents, not bound to a particular dialogue system. Unfortunately, publicly available data sets with DA annotation are all based on different annotation schemes and thus incompatible with each other. Moreover, their schemes often do not cover all aspects necessary for open-domain human-machine interaction. In this paper, we propose a methodology to map several publicly available corpora to a subset of the ISO standard, in order to create a large task-independent training corpus for DA classification. We show the feasibility of using this corpus to train a domain-independent DA tagger testing it on out-of-domain conversational data, and argue the importance of training on multiple corpora to achieve robustness across different DA categories.

1 Introduction

The correct interpretation of the intents behind a speaker's utterances plays an essential role in determining the success of a dialogue. Hence, the module responsible for intents classification lies at the very core of many dialogue systems, both in research and industry (e.g. Alexa, Siri). Moreover, although the task of intent recognition is traditionally linked to task-based systems, recently it has also proved crucial for non task-based conversational systems. According to the results of the Amazon Alexa Prize challenge (Ram et al., 2017), the most successful conversational systems in the competition relied on a strong spoken language understanding module, while more than 60% of the approaches explicitly used intents.

Nevertheless, automatic intent recognition is hard, since participants' intents in a dialogue are implicit. Intent classification has therefore been mostly modeled as a supervised machine learning problem (Gupta et al., 2006; Xu and Sarikaya, 2013; Yang et al., 2017), with the consequent definition of intents taxonomies. Over time this led to the creation of expensive annotated resources (Price, 1990; Henderson et al., 2014) with the related time-consuming design of multiple intent schemes. In most cases, however, intents taxonomies are defined specifically for a given application or a dataset and are not generalizable to other systems or tasks, making these resources difficult to reuse (e.g. the popular Air Travel Information Services (ATIS) corpus include heavily domain-dependent intents such as *Airfare* or *Ground Service*).

Dialogue Acts (DA), also known as speech or communicative acts, represent an attempt to create a formalized and generalized version of intents. As such, DAs have been investigated by the research community for many years (Stolcke et al., 2000) and have been applied successfully to many tasks. In particular, their aspiration to generality makes them an appealing option for non task-based application (e.g. more than 20% of the teams in Amazon Alexa Prize Challenge explicitly used DAs (Cervone et al., 2017; Bowden et al., 2017), including the winning team (Fang et al., 2017)). Also, in the case of DAs, over the years there have been several efforts to produce publicly available annotated resources (Godfrey et al., 1992; Carletta, 2006; Alexandersson et al., 1998) to train DA taggers. The DA taxonomies created

Proceedings of the 27th International Conference on Computational Linguistics, pages 3539–3551
Santa Fe, New Mexico, USA, August 20-26, 2018.

for these resources, albeit arguably more general compared to corpora like ATIS (for example utilizing categories such as *wh-questions*), are still dataset specific; since many of these schemes lack coverage of some crucial aspects of dialogic interaction. Furthermore, given that all these datasets utilize different schemes, these resources are hardly compatible.

The ISO 24617-2 (Bunt et al., 2010; Bunt et al., 2012), the international ISO standard for DA annotation, represents the first attempt to create a truly domain and task independent scheme. Given its holistic approach compared to previous schemes, ISO 24617-2 can be used as a lingua franca for cross-corpora DA mapping, as confirmed by successful attempts to remap single corpora to the standard (Chowdhury et al., 2016; Fang et al., 2012).

However, there is no reference training set for the standard, since the only public resource currently available with ISO 24617-2 annotation (DialogBank, (Bunt et al., 2016)) is too small to be used to train classifiers. Therefore, most DA tagging research still focuses on in-domain studies on large datasets with incompatible DA annotations (Stolcke et al., 2000; Ji et al., 2016). Moreover, most publicly available corpora are imbalanced with respect to the distribution of various DA dimensions such as *Information Transfer* (e.g. "What's your favourite book?") or *Action Discussion* (e.g. "Tell me the news."), which are required for successful open-domain conversational systems.

In this work, we show how to reuse and combine publicly available annotated resources to create a large training corpus for domain-independent DA tagging experiments. We map different corpora using an ISO standard compliant DA taxonomy, following the previous research on the topic (Fang et al., 2012; Petukhova et al., 2014b) and we share this resource with the research community.[1]

In order to investigate the soundness of our approach compared to in-domain models we further experiment with domain-independent DA tagging. As previously done in the literature we cast the Dialogue Act tagging task as a supervised multi-class classification problem using Support Vector Machines. The correctness of the approach is first tested on the de facto DA tagging standard – the Switchboard (SWDA) corpus (Godfrey et al., 1992), using the reference training and test sets and achieving performance comparable to the state-of-the-art approaches. Secondly, we experiment with domain-independent DA tagging following the same approach and using our combined resource as a training corpus. The DialogBank corpus, that represents a reference manual DA annotation for the ISO standard, is used for the evaluation of the tagger. To the best of our knowledge this is the first attempt to test automatic DA annotation on this corpus.

The domain-independence and suitability of the tagger for conversational systems trained on multiple resources is additionally evaluated on two other corpora annotated following our optimized taxonomy (human-machine conversations from the Amazon Alexa Prize Challenge). The performances achieved on these three datasets suggest that the training on multiple corpora represents a step forward for DA tagging of open-domain non task-based human-machine conversations. Finally, we present experiments to investigate the contribution of the different corpora to the performance of the classifiers. The results of our experiments show the importance of utilizing multiple resources to achieve a sound performance across different types of DA categories. The multi-domain DA tagger presented here was successfully employed in Roving Mind, our open-domain conversational system for the Alexa Prize (Cervone et al., 2017).

2 State of the Art

2.1 Dialogue Act Annotation Schemes

The notion of Dialogue Acts can be traced back to the one of illocutionary acts introduced by (Austin and Urmson, 1962). The illocutionary act represents a level of description of an utterance's meaning that goes beyond the purely semantic level ("Is the window open?") to encompass the intent of the speaker in producing that utterance ("Please, close the window.").

One of the first DA taxonomies was the one created for the task-based corpus MapTask (Anderson et al., 1991) in the early nineties. The MapTask scheme distinguishes between *initiating moves* – such

[1]The suite of scripts we wrote to map and combine publicly available corpora can be found at `https://github.com/ColingPaper2018/DialogueAct-Tagger`

as giving instructions, explaining, checking information or asking questions – and *response moves* – for example acknowledging instructions, answering questions and clarifying information. The corpus also makes a distinction regarding the grammatical and semantic structure of the interactions, classifying, for example *wh-questions*, *yn-questions* and *positive/negative answers*. Although pioneering at the time, the MapTask annotation scheme is very specific to the described scenario, and some of its DAs (e.g. *instruct*, *clarify*, *check*) do not scale well to generic, non task-based conversations. Moreover, its taxonomy was not designed to capture all human behaviours during conversations, and, as a consequence, its coverage for labelling a non task-based interaction is inadequate.

The first attempt to define a unified, non task-based standard for DA tagging was the Discourse Annotation and Markup System of Labeling (DAMSL) (Core and Allen, 1997) tag-set for the SWDA (Godfrey et al., 1992) corpus. This annotation scheme proposes a taxonomy of 42 tags, describing both semantic aspects of conversation (*opinion*, *non-opinion*, *preference*, etc.), syntactic aspects (*yn-questions*, *wh-questions*, *declarative questions*, etc.) and behaviours related to the dialogue (*conventional closing*, *hedge*, *backchanneling*, etc.). Nevertheless, the taxonomy still has some issues: tags are mutually exclusive (making it impossible to annotate, for example, a no answer which was also signaling non-understanding) and are organised in a flat taxonomy, which does not take into account similarities and differences between the tags.

Bunt (1999) introduced the Dynamic Interpretation Theory (DIT) for dialogues, setting the theoretical foundation for a domain-independent and task-independent DA taxonomy. The paper introduced some very important concepts like the idea of *multidimensionality* of DAs and the distinction between *Action-Discussion*, a macro-category of DAs encompassing cases in which interlocutors negotiate actions to be performed (e.g. requests like "Let's switch topic."), and *Information-Transfer* interactions, capturing the DAs through which speakers exchange information (e.g. sharing personal information like "My name is John."). The DIT++ taxonomy (Bunt, 2009) was then defined in 2009 with the aim of providing a unique and universally recognized standard for DA annotation based on the theoretical ideas introduced in the DIT scheme. Its fifth version was accepted as ISO 24617-2.

The core aspects of the ISO standard are its multidimensionality and its domain and task independence. The ISO scheme is multidimensional in the sense that it makes a clear distinction between *semantic dimensions* (i.e. the aspect of the communication which the DA describes) and *communicative functions* (i.e. the illocutionary act performed within that dimension). In this way, ambiguities between various aspects of the communication and overlapping between DAs are removed. Furthermore, the scheme contains a generic dimension and communicative functions, which is suitable for mapping virtually any kind of conversation, both task-based and non task-based. Moreover, its multidimensional aspect and hierarchical taxonomy make it extensible and potentially adaptable to specific conversational sets.

2.2 Dialogue Act Tagging

The automatic recognition of Dialogue Acts has been addressed by the literature using various machine learning techniques. In particular DA classification has been modeled both as a sequence labeling problem, using techniques such as HMM (Stolcke et al., 2000), neural networks (Ji et al., 2016; Kumar et al., 2017) or CRF (Quarteroni et al., 2011), and as a multi-class classification problem, using for example SVM (Quarteroni and Riccardi, 2010). Mentioning and comparing all DA classification approaches is difficult because of the differences in annotation schemes and datasets used. All approaches, however, are usually tested on in-domain data.

One of the most popular datasets for benchmarking is SWDA (Godfrey et al., 1992), a dataset of human-human open-domain telephone conversations. The state-of-the-art on SWDA (77.0% accuracy on 42 DA tags) was achieved by (Ji et al., 2016) using deep neural networks.

The ISO standard (Bunt et al., 2010) can be seen as a generalization of all these annotation schemes. However, there is no available training data for the ISO standard.

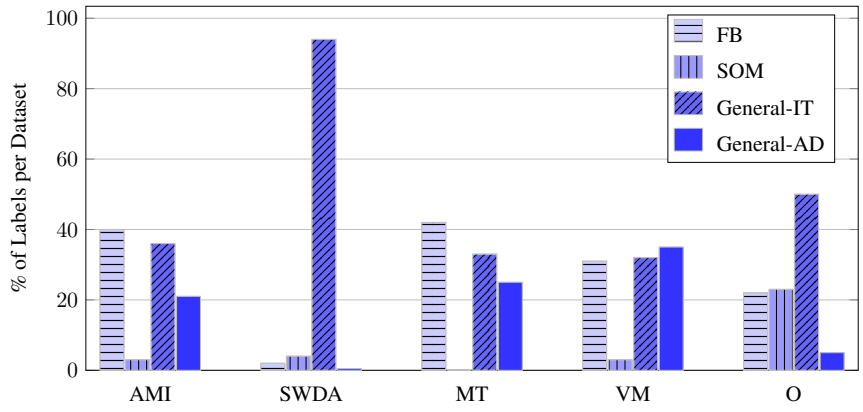

Figure 1: The distribution of dialogue act categories (after mapping to ISO standard) in various corpora – AMI, SWDA, MapTask (MT), VerbMobil (VM) and BT Oasis (O). The represented DA categories are Social Obligations Management (SOM) and Feedback dimension DAs, as well as *Action-Discussion* (AD) and *Information-Transfer* (IT) DAs from general dimension.

3 Data Sets

3.1 Training sets

The scarcity of resources of adequate size annotated with the ISO standard makes it difficult to train a DA tagger for this taxonomy. To the best of our knowledge, the DBOX corpus (Petukhova et al., 2014a) – the only resource manually annotated using the ISO standard – is not yet publicly available . The best possible approach given the current availability of data is to map existing corpora's DA schemes to the ISO scheme. Given the limited – and often domain-dependent – annotation scheme of these resources, it is impossible to map enough data to train a DA tagger for the full ISO taxonomy, since some of the ISO dialogue acts have no correspondence in any of the considered corpora. Therefore, we opted for a reduced version of the taxonomy, limiting our research to subsets of the General (Task), Social Obligation Management and Feedback dimensions. So far, we mapped the following five different corpora to our scheme:

SWDA: The Switchboard corpus (Godfrey et al., 1992) is a dataset of transcribed open-domain telephone conversations. The Switchboard Dialogue Act Corpus (SWDA) is a subset of the Switchboard corpus annotated with DAs. SWDA represents a logical choice when building a training set for a domain-independent DA tagger, as it is a large collection of open-domain, non task-based conversations, and therefore provides a natural similarity to the conversational domain of social bots. Moreover, there are already examples in literature of mappings from the Switchboard corpus to the ISO standard (Fang et al., 2012). As visible from Figure 3.1, drawbacks of the corpus with respect to the task include its unbalancedness (60% of utterances are *Information-providing*) and lack of *Action-Discussion* interactions (less than 1% of overall corpus).

AMI: This corpus contains transcriptions from 100 hours of meeting recordings of the European-funded AMI project (FP6-506811), a consortium dedicated to the research and development of technology (Carletta, 2006). This dataset presents a reasonably balanced collection of utterances and a taxonomy which shares some similarities with the ISO standard (e.g. distinction between *Action-discussion* and *Information-transfer*). Drawbacks of the corpus include the fact that there are multiple speakers (it is therefore more difficult to capture contextual information) and sometimes its scheme does not map to the leaves of the ISO tree.

MapTask: This is a task-based dialogue corpus collected by the HCRC at the University of Edinburgh (Anderson et al., 1991). Dialogues involve two participants, one with an empty map and one with a route-marked map which must instruct the other speaker to draw the same route. The corpus was chosen due to its abundance of *Action-discussion* interactions (more than 30% of the overall corpus), which are often lacking in other corpora.

VerbMobil: This is a collection of task-based dialogues released in 1997 (Burger et al., 2000). A subset of these dialogues is annotated with DAs (Alexandersson et al., 1998). The scenario involves two speakers, which play respectively the roles of a travel agent and of a client. The client usually provides a set of constraints and requests to be satisfied, while the traveling agent has to ask questions and provide information in order to satisfy the client's requests. Interactions happening within the VerbMobil 2 corpus closely resemble those usually seen with personal assistants, with a user looking for the fulfillment of a task and a serving agent interacting with the user to solve his/her issues making it an appealing addition to our training set.

BT Oasis: The BT Oasis corpus is a collection of task-based conversations involving personal assistance for clients of the British Telecom services (Leech and Weisser, 2003). The conversations are human-to-human, and usually involve a user who has a problem to solve and an assistant who helps the user solving his issues. The BT Oasis corpus was chosen as part of the training set for its interesting scheme, called SPAAC (Speech Act Annotation scheme for Corpora), which is easily mappable to the ISO standard due to its clear separation of grammatical and illocutionary act.

3.2 Test sets

DialogBank (DB): the DialogBank (Bunt et al., 2016) is a corpus[2] annotated with ISO 24617-2 which currently contains 15 English dialogues: 3 from MapTask and 3 from TRAINS (Traum, 1996) (both task-based), 5 from DBOX (games collected in a Wizard-of-Oz fashion) and 4 from Switchboard (open-domain human-human conversation). Overall there are 1,596 DAs. The corpus currently represents the only publicly available resource manually annotated using the ISO standard.

Common Alexa Prize Conversations (CAPC): The CAPC corpus (Ram et al., 2017) is a dataset of 3,764 anonymised individual user turns pooled from different users interacting with all socialbots participating in the Alexa Prize. We have extracted a balanced subset of 458 turns and have annotated it with DAs from our adapted version of the ISO standard by 3 annotators, with an inter-annotator agreement of $\kappa = 0.82$. CAPC exemplifies frequent user interaction data not biased by the interaction with one socialbot in particular. Another advantage of this dataset is that it is balanced across different DA categories. One drawback is that no interaction context (previous DA) is available for the individual turns.

Socialbot Logs (S-Logs): S-Logs is a dataset of 13 open-domain conversations that different native American English speakers had with one of the socialbots of the Alexa Prize Challenge 2017. Overall this dataset contains 310 machine DAs and 165 user DAs. Two annotators tagged this dataset with DAs from our adapted version of ISO 24617-2, with an inter-annotator agreement of $\kappa = 0.81$. While we have annotated both machine and user turns, we test only on the latter and exploit machine turns as features for our classification experiments.

4 Methodology

4.1 Preprocessing

Before mapping the DA schemes of the corpora to the ISO subset scheme, a series of preprocessing steps have been performed to obtain a uniform training resource with the same surface text features as the testing corpora, since in S-Logs data, user input is lowercased and the punctuation is limited to apostrophes. More specifically, the text has been lowercased (including any named entity appearing in the original transcription and excluding the 'I' pronoun), punctuation has been removed (except for the apostrophe character in contracted expressions like "let's" and "can't") and any special characters have been deleted from the utterances. Moreover, any information regarding prosody has been removed, since this feature is not available in our test sets.

For experiments on the SWDA DAMSL corpus we recreated the same setting described in (Stolcke et al., 2000), using the same train and test set and preprocessing the corpus in the same way following the WS97 manual annotator guidelines (Jurafsky, 1997).

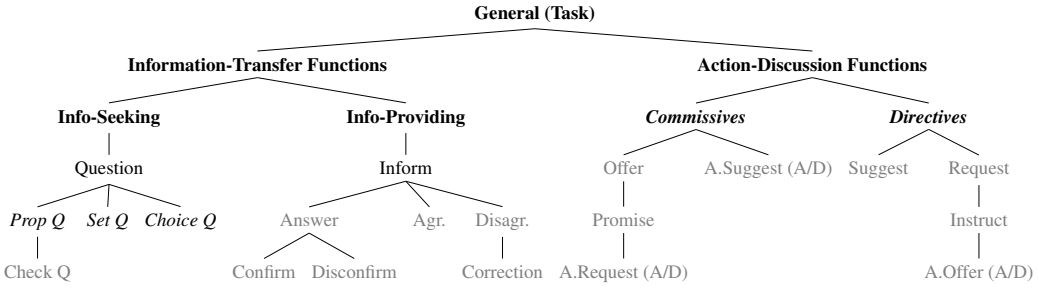

Figure 2: Communicative functions from ISO 24617-2 General purpose (Task) dimension. The nodes of the taxonomy that are not considered are grayed out.

Apology	Apology, Accept Apology
Thanking	Thanking, Accept Thanking
Feedback	
Feedback	Auto-Feedback (all), Allo-Feedback (all)

Table 1: Our scheme (S-scheme) compared to the corresponding ISO 24617-2 scheme for the SOM and Feedback dimensions

4.2 Dialogue Act scheme and mapping

The Socialbot scheme (S-scheme), the DA scheme used during the classification experiments, is a subset of the official ISO standard. Only three dimensions out of the official eight defined in the standard are considered (*Task*, *Social Obligation Management* and *Feedback*), and some of the communicative functions are generalized with an higher level of the tree.

Figure 4.2 shows the labeled subset of the ISO standard taxonomy for the General-purpose functions (i.e. functions independent from any given dimensions), while table 1 shows the correspondence for dimension-specific functions. The main difference between the DA scheme labeled in this work and the complete ISO taxonomy is the lack of further specification for the *Inform*, *Commissive* and *Directive* tags. This is due to the fact that most of the DA schemes used when building the training set do not provide contextual information detailed enough to label these tags accurately. Moreover, there is confusion and discrepancies about when these contextual DA should be used, even in the official ISO guidelines. Indeed, in (Fang et al., 2012), which provides the official mapping from Switchboard to the ISO standard, it is reported that some contextual DA tags (for example *other_answer*) do not have a direct mapping to the standard. This becomes even more problematic considering that among the training resources there are corpora like AMI, MapTask or VerbMobil, which label answers as Informs, which would make training data for this class extremely noisy. A similar argument can be raised on the lower leaves of the *Directive* and *Commissive* nodes, some of which are not labeled even in the very detailed SWDA taxonomy. Mapping of the available corpora to this scheme was done according to the available documentation in literature.

For the Switchboard corpus, a detailed mapping is provided in (Fang et al., 2012), which was followed exactly for the supported dimensions/communicative functions. For MapTask and AMI, there is already research highlighting similarities and differences between their schemes and the ISO standard one (Petukhova et al., 2014b). These results do not provide an exact mapping between the two schemes, which in some cases is impossible: for example the AMI *Elicit-inform* tag is the equivalent of ISO 24617-

Table 2: Dialogue Act category counts across the considered corpora for different levels of the taxonomy. *Percentages of corpora* indicate the percentage of data available for the particular level in the corpus.
$*$ It is frequently the case that DA tags do not map to any leaf-node, e.g. VerbMobil for Task dimension and AMI for Social Obligations Management.

2's *Question*, but will not map to any specific question type (*SetQ*, *PropQ*, *ChoiceQ*, etc.). Utterances whose tags cannot be directly mapped to the ISO scheme were dropped and do not appear in the training set.

Since there is no available literature on mapping the VerbMobil 2 and BT Oasis corpora to the ISO standard, a specific mapping was designed from scratch by drawing inspiration from the approaches available on other corpora.

Table 2 presents counts of the DAs after mapping to our scheme, across all training and testing corpora. As mentioned in the paper, the corpora present quite imbalanced distributions of DA categories.

5 Experiments and Results

Since, to the best of our knowledge, there is no established state of the art on DialogBank – the only corpus manually annotated following the ISO 24617-2 scheme – we first establish the tagging methodology on the SWDA corpus using the DAMSL 42 tag set and compare it to the state of the art (Ji et al., 2016). Then, the feature set and the parameters of the best performing models are used for the training of the DA tagger on the aggregate dataset, considering some of the semantic dimensions and the communicative functions of the ISO 24617-2 . The models are then evaluated on the DialogBank and open-domain human-machine data from Amazon Alexa Prize Challenge. McNemar's test (McNemar, 1947) for statistical significance has been used to analyze whether introduced features give a significant contribution to the overall performance.

5.1 Experiments on SWDA

Prior to training the classification models, the SWDA (Jurafsky, 1997) utterances are preprocessed following (Stolcke et al., 2000). The dataset is split into training (1,115 dialogues) and test set (19 dialogues) following the same paper, and the remaining 21 dialogues are used as development set to tune the C parameter of Support Vector Machines (SVM) (Vapnik, 1995). For the experiments, we used the SVM

Features	Acc.	Features	Acc.
BL: Majority	31.5		
HMM (Stolcke et al., 2000)	71.0	1-2-grams + PREV	74.6 *
SVM (Quarteroni and Riccardi, 2010)	72.4	1-2-grams + PREV + POS	74.6
DrLM (LSTM) (Ji et al., 2016)	77.0	1-2-grams + PREV + I-POS	76.2 *
1-grams	71.2	1-2-grams + PREV + I-POS + DEP	76.0
1-2-grams	71.7	1-2-grams + PREV + I-POS + I-DEP	76.1
1-2-3-grams	71.4	1-2-grams + PREV + I-POS + WE	**76.7** *

Table 3: Classification accuracy of the different feature combinations on the SWDA test set. The best results are highlighted in bold. The results that are significantly better are marked with *.

implementation of scikit-learn (Pedregosa et al., 2011) with linear kernel (i.e. its *liblinear* (Fan et al., 2008) wrapper).

The results of the experiments on SWDA are presented in Table 3. The performances are on the SWDA test set with the SVM C parameter set to 0.1, with respect to the best results on the development set. It is worth mentioning that tuning the C parameter boosts the performance on the development set by 2 points.[3] For comparison, the table also includes majority baseline, the results from (Stolcke et al., 2000), the SVM results from (Quarteroni and Riccardi, 2010), and the state-of-the-art results from (Ji et al., 2016) that were achieved using deep learning methods.

Following the previous studies on SWDA (Stolcke et al., 2000; Quarteroni and Riccardi, 2010), we experiment with n-grams (unigrams, bigrams, and trigrams) and previous DA tag features. We do not consider the unit length feature from (Quarteroni and Riccardi, 2010), since classification instances in the SWDA scheme and ISO 24617-2 are different (slash unit vs. functional unit). The results are reported in Table 3; since the results reported were obtained with SVM C parameter set to 0.1, they are higher than the ones reported in (Quarteroni and Riccardi, 2010): e.g. for 1-2-grams 70.0 vs. 71.7.

The first observation is that the addition of the previous DA significantly improves the performance. Addition of part-of-speech tags does not yield any improvement; however, when POS-tags are indexed with their positions in an utterance, accuracy is significantly improved and rises to 76.2. Addition of dependency relations (both with and without indexing with their position) does not improve the performance. Addition of the averaged pre-trained word-embedding vectors (from Google News) to the model with indexed POS-tags, however, rises the accuracy to 76.7. The model with word embeddings comes 0.3 short of the state-of-the-art results reported in (Ji et al., 2016).

5.2 Experiments on Aggregate ISO-standard Data

The methodology established on SWDA is applied to training the ISO 24617-2 subset models using the aggregate data set. Since in ISO 24617-2 annotation scheme DAs consist of semantic dimensions and communicative functions, the utterances are first classified into the considered semantic dimensions – general, social obligations management (SOM), and feedback. Then, we experiment with the Task dimension, reporting the results without error propagation from the previous step, in order to give the reader a clearer understanding of the current classification capabilities when restricting interactions with the system to general communicative functions.

5.2.1 Semantic Dimension Classification

The results of the binary dimension classification models on the test sets – DialogBank (DB), CAPC, and S-Logs – are reported in Table 4. The CAPC corpus consists of isolated utterances; consequently, the *Feedback* dimension is not present. On DB and S-Logs, on the other hand, the *Feedback* dimension yields the lowest accuracy in comparison to General and *SOM* dimension communicative functions. Low performances on the *Feedback* dimension could be explained by the fact that the training data mostly contains *Allo-feedback* and lacks *Auto-feedback* and *Feedback elicitations*, which are present in DB.

[3]From 73 ($C = 1.0$) to 75 ($C = 0.1$) for the model trained on unigrams, bigrams and previous DA-tag.

Dimension	DB	CAPC	S-Logs
General	73.3	83.0	80.2
SOM	78.1	90.7	86.6
Feedback	56.3	–	71.3
Overall	68.4	83.3	79.4

Table 4: Classification accuracies of the binary semantic dimension models: General, SOM and Feedback. The CAPC corpus does not contain Feedbacks, therefore results for this dimension are not reported.

Features	DB	CAPC	S-Logs	Features	DB	CAPC	S-Logs
BL: Majority	53.4	22.9	63.4				
1-2-grams	64.2	71.2	78.7	+ I-DEP	67.1*	74.3	82.3
+ PREV	64.3	70.7	81.6*	+ WE	65.2	74.8*	82.0
+ I-POS	65.8*	73.8*	82.2	+ I-DEP + WE	66.6	75.1	81.8

Table 5: Accuracies of the feature combinations on the general-purpose communicative functions on the test sets. The best results are marked in bold, and statistically significant differences with *.

5.2.2 Communicative Function Classification

The utterances are further classified into communicative functions of the General (Task) dimension, using the methodology established on SWDA, i.e. the same hyper-parameter settings ($C = 0.1$) and features. However, since models with dependency relations do not yield statistically significant differences, they are also considered. The results of the models on the test sets are reported in Table 5. The behavior of the models trained with various feature combinations is in-line with the SWDA experiments: the addition of the previous DA tags and part-of-speech tags indexed with their positions in a sentence improves the performance. Different from the SWDA, the addition of the indexed dependency relations improves the performance on the test sets. In the case of DialogBank and CAPC, their contribution is statistically significant. Additionally, unlike for SWDA, the addition of word embeddings with and without index dependency relation (I-DEP) does not produce significant improvements for all but CAPC. Consequently, the model trained on 1-2-grams, previous DA tags, indexed POS-tags and dependency relations is chosen for the ablation study.

5.2.3 Corpora Combinations

The aggregation of all the corpora mapped to our subset of ISO 24617-2 is not necessarily the best one, as the distributions of DA categories varies from corpus to corpus. Consequently, we also present results on the test sets for the models trained solely on SWDA and AMI; as well as perform an ablation experiment removing one corpus at a time. The best performing model from the previous subsection (1-2-grams, previous DA-tag, indexed POS-tags, and indexed dependency relations) is used for the study. The results of these experiments are reported in Table 6.

While the best results for Dialog Bank are achieved considering all the corpora, for CAPC the best results are achieved by removing MapTask. For S-Logs, on the other hand, the best performing corpora combination is all except VerbMobil. However, the performance differences from the models trained on all corpora are not statistically significant. Training DA taggers solely on SWDA and AMI – the largest and the most diverse corpora – yields performances inferior to the combination of all the corpora. From the table, we can also observe that these two corpora – SWDA and AMI – contribute most to the performance, as removing them affects the performance the most. On the other hand, removing the smaller datasets – BT Oasis, MapTask, and VerbMobil – affects the performance less.

6 Conclusions

We have presented an effective methodology for corpora aggregation for domain-independent Dialogue Act Tagging on a subset of the ISO 24617-2 annotation. We have also reported an accurate evaluation

Dataset	DB	CAPC	S-Logs	Dataset	DB	CAPC	S-Logs
ALL	**67.1**	74.3	82.3	- AMI	59.7	73.7	71.3
				- SWDA	60.2	68.3	77.5
SWDA only	57.9	71.3	53.5	- Oasis BT	66.1	74.2	81.8
AMI only	53.2	39.8	61.6	- MapTask	66.8	**74.6**	80.5
				- VerbMobil	66.5	74.0	**82.6**

Table 6: Accuracies of the corpora combinations on the test sets – Dialog Bank (DB), CAPC, and S-Logs.

of our approach on both in-domain and out-of-domain datasets, proving that the described DA tagging technique is indeed independent from the underlying scheme and task of the annotated corpora. Finally, the machine learning technique used for DA tagging was tested on a popular DA tagging task (the Switchboard corpus), obtaining very close to state-of-the-art results.

This work represents one of the first attempts to use an ISO compliant DA scheme for a real-life application, as well as one of the first structured approaches for evaluation of dialogue resources annotated with this taxonomy.

Research on available training resources is one of the first things to look forward to, since the current data proved to be effective, but also presented numerous drawbacks (lack of adequate coverage for the Feedback dimension, imbalanced DAs, lack of context-aware communicative functions). We plan to make our resource continue to grow in the future by adding and mapping additional corpora, such as the MRDA (Shriberg et al., 2004) corpus.

Arrows are the Verbs of Diagrams

Malihe Alikhani and Matthew Stone
Computer Science, Rutgers University
malihe.alikhani, matthew.stone@rutgers.edu

Abstract

Arrows are a key ingredient of schematic pictorial communication. This paper investigates the interpretation of arrows through linguistic, crowdsourcing and machine-learning methodology. Our work establishes a novel analogy between arrows and verbs: we advocate representing arrows in terms of qualitatively different structural and semantic frames, and resolving frames to specific interpretations using shallow world knowledge.

1 Introduction

Natural communication is multimodal—people get their ideas across not just through words but through gestures, diagrams, illustrations, and even practical activity. Research in discourse has found suggestive evidence for interpretative parallels across modalities; the challenge now is to substantiate these parallels at large scale, by developing broad-coverage cognitive models of multimodal communication.

This paper illustrates the promise of new data sets to further such a general understanding of visual communication. In particular, Kembhavi et al. (2016) have curated, annotated and released a sizeable corpus of scientific diagrams in diverse domains. We draw on formal analysis, crowdsourcing, and machine-learning experiments to carry out a systematic study of the interpretation of arrows in these diagrams. The central insight in our work is to give a novel account of arrows using existing *linguistic* concepts and methodology—specifically, ideas developed for explaining verb meaning in context.

We begin in Section 2 with a tour of work on multimodal communication, which has made a strong case for parsing diagrams to organize basic conventional elements into recursive structural relationships, and for interpreting such parses by combining compositional meaning with discourse-based inference. We use this framework in Section 3 to motivate a linguistically-inspired approach to the interpretation of arrows: we characterize arrows into four qualitatively different structures, analogous to verb subcategorization frames; we associate each structure with a meaning, analogous to verb frame semantics (Baker et al., 1998); and we describe the contextual supplementation some structures require, by analogy to the co-compositionality of generative lexicon theory (Pustejovsky, 1998, GLT).

The remainder of the paper offers empirical evidence in support of our approach. Our first experiments, presented in Section 4, assess our semantic frames for arrows in light of crowd workers' judgments about the Kembhavi et al. (2016) data set. People label our categories with high agreement, and the categories account for the overwhelming majority of items in the corpus. Moreover, we find that arrows are normally used in one sense per diagram, much as lexical items exhibit one sense per discourse (Gale et al., 1992).

Our next experiments, presented in Section 5, assess our approach to contextual interpretation: certain frames must be supplemented with a salient relationship. Assuming one sense per diagram, we train a machine-learning model that predicts this relationship from the textual content of the diagram. The performance of the method corroborates our hypothesis (analogous to GLT) that these relationships can and should be resolved based on relatively shallow encyclopedic knowledge.

Our contributions are primarily formal—to characterize the knowledge needed to model diagrams. Fundamental challenges remain to apply such ideas in practice. We conclude in Section 6 with an

appraisal of our contributions: we suspect many other abstract pictorial elements can be described using linguistic concepts, enabling more expressive systems for diagram understanding and generation.

2 Related Work

Schematic pictorial content abounds in everyday communication, from informal interactions around a whiteboard to figures in formal scientific and engineering documents. Consequently, diagrams have been studied from the standpoint of design, as in Horn (1998); psychology, as in Larkin and Simon (1987); computer graphics, as in Agrawala et al. (2003); computer vision, as in Alvarado and Davis (2004); and common-sense reasoning, as in Forbus et al. (2011)—as well as natural language (NL) technology.

Our work is most directly inspired by prototypes in mulitmodal communication that use NL techniques either to synthesize communicative presentations, as in André et al. (1993) and Feiner and McKeown (1993), or to interpret multimodal user input, as in Johnston (1998), Johnston and Bangalore (2005) and Bangalore and Johnston (2009). For example, Johnston (1998) argues for processing diagrams with a syntactic parser, so that systems can recognize their essential hierarchical relationships, and for using a constraint-based grammar formalism, so specific productions can inherit constraints from general rule schemas, as in HPSG (Pollard and Sag, 1994). The success of such efforts shows that NL architectures can effectively capture communicative acts across a diverse range of modalities and contexts. This leads us to ask how we might develop domain-general tools and methodologies that could support such multimodal architectures—perhaps following the successful application to text of wide-coverage grammars (Copestake and Flickinger, 2000, among others) and parsers (de Marneffe et al., 2006, among others).

To pursue this direction, we build on an emerging trend of applying the theory of NL semantics and discourse to multimodal communication, which includes work on the grammar of coreference, such as Schlenker and Chemla (2017) for gesture, and Abusch (2013) and Cohn (2013) for comics, and work on the grammar of coherence, such as Lascarides and Stone (2009) for gesture, and Bateman and Schmidt (2013) and Cumming et al. (2017) for film. Looking at arrows is a novel contribution to this literature.

Of course, we can find many loose parallels to our ideas in work on diagrams across many disciplines. For example, researchers from Alvarado and Davis (2004) to Tversky et al. (2000) have observed that diagrams are composed from a small taxonomy of abstract elements, including arrows, that are grouped together in hierarchical relationships. Researchers such as Alvarado and Davis (2004), Forbus et al. (2011), and Horn (1998) have argued that these elements take on diverse interpretations, which must be recovered in context using conceptual content from a specific domain. Researchers such as Agrawala et al. (2003) and Forbus et al. (2011) have emphasized that effective diagrams abstract cognitively essential information in consistent and recognizable ways.

Our findings are entirely compatible with such observations, but our contribution is to approach them using the tools and methods of NL research. Other ways of implementing the ideas include custom architectures based on cognitive design principles, as in Agrawala et al. (2003), or structured user interaction, as in Forbus et al. (2011), as well as general methods for visual recognition and grouping, as in Alvarado and Davis (2004) and Kembhavi et al. (2016). Such approaches may be effective, especially for purely

visual processing, but they make it difficult to compare and integrate the reasoning involved in interpreting text and diagrams in combination, as well as to develop models that can be used simultaneously for understanding, generation and mixed-initiative interaction—a key virtue of NL techniques.

Our work is made possible by Kembhavi et al. (2016). They have collected, annotated and distributed a data set of more than 5000 diagrams scraped from the web using science education key phrases as seeds for Google searches. We refer to this as the AI2D data set. Kembhavi et al. (2016) characterize diagram content by associating diagrams with high-level questions and answers. Meanwhile, their work formalizes the structure of diagrams using a graph-based representation that features a regimented set of elements and relationships. Their annotation protocol broke this process of building these representations down into a series of lightweight decisions that could be accomplished reliably by crowd workers on Amazon Mechanical Turk. This annotation scheme, while useful in describing the shallow organization and overall content of diagrams, says little about the semantic and pragmatic knowledge that connects form and content. Our work addresses one case of this open problem.

3 Towards a Formal Analysis of Arrows

We start by exploring how linguistically-inspired representations might capture the intuitive structure and interpretation of arrows. We draw on the AI2D examples in Figure 1, which are representative and diverse: Figure 1a maps areas of the human brain; Figure 1b shows part of the food chain of a northern forest; Figure 1c illustrates plate tectonics; and Figure 1d explains the seasons. Our observations about the form, meaning and interpretation of arrows in these diagrams lays the groundwork for the experiments we report in Sections 4 and 5 (and anticipates further formal investigations).

3.1 Formal Structure

An arrow consists of a head, a tail and a body.[1] The head and tail can each be structurally linked to another constituent in the diagram, to create a larger unit containing the arrow and its affiliates. Thus the arrows of Figure 1a link the text at the tail to the pictorial element at the head; the arrows of Figure 1b link two pictorial elements; and the arrows of Figure 1c are anchored into the scene rather than connected to elements at the head or tail. We assume this structure in giving examples in running text: ♘ → ♙. This schematizes an arrow with ♘ at the tail and ♙ at the head. Where arrows are not understood to depict spatial information, we will use these schemas to abstract away from details of layout and rendering (so ♙ ← ♘ would be equivalent).

Three classes of form are particularly important to our further investigations:

1. arrows with pictorial elements at both the head and tail, as in ♘ → ♙;
2. arrows with pictorial elements at the head and text at the tail, as in bishop → ♗; and
3. arrows with an empty head or tail area (and perhaps pictorial elements elsewhere), as in ♖ → or → .[2]

We see this structural variation as analogous to the syntactic subcategorization of verbs: the idiosyncratic character of verbal complementation motivates a fine-grained account of syntactic combination. For example, the verb *get* can take arguments of a range of different syntactic categories, involving noun phrases, predicates and full sentences: “I got flowers for my mother”, “Get well soon”, “I get that this is difficult”. In a similar way, arrows have optional argument positions (head and tail, comparable to subject and object) which may be filled by elements of formally different categories (for example, with textual or pictorial elements).

[1] We focus on simple arrows here of the form →, excluding double-headed arrows ↔ and pure line segments (—). Arrows can also differ in rendering attributes such as width, perspective and color, which sometimes provide further cues to the role of the arrow in the diagram.

[2] Arrows with pictorial elements at the tail and text at the head also occur: ♠ → oxygen. We hypothesize that these have analogous properties to purely pictorial arrows, but defer investigation to future work.

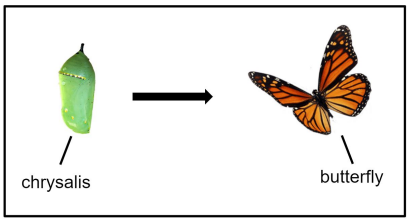

Figure 2: Part of a butterfly cycle of life diagram.

Just as with verbs, some structural possibilities for arrows seem not well-formed: it's odd, for example, to have text at the tail of an arrow and nothing at its head, as in # problem →.[3]

As noted by many researchers (Alvarado and Davis, 2004; Johnston, 1998; Tversky et al., 2000), diagrams are hierarchically organized. We hypothesize that arrows can contribute to the overall structure of a diagram in diverse ways, just as verbs contribute in diverse ways to the structure of sentences and discourse. Of course, an arrow can establish the overall structure of a diagram, as in Figure 2—just as the main verb projects the root of a sentence. Arrows in diagrams can also be modified, for example with labels and other annotations; we show a few such examples in Figures 3 and 4. In addition, many arrows seem to attach to and modify existing elements, just as verbs can anchor relative clauses, which adjoin in as modifiers to existing structure. For example, we might analyze the indication arrows of Figure 1a as modifiers that expand on the presentation of individual brain regions, with the head of the arrow playing a role analogous to an extracted argument in a subject or object relative clause—compare *the region we call the frontal lobe*. Similarly, the direction arrows of Figure 1c are similar to locative relative clauses—compare *a place things are pushed eastward*. Finally, the arrows of Figure 1b or 1d seem broadly analogous to the use of sentence-final appositives to carry the discourse forward (Koev, 2012)—compare *the prickly pear is eaten by the boar, which is eaten by the bear*. Note, however, that the two-dimensional structure of diagrams allows for new structural possibilities, such as the circular dependencies exhibited in Figure 1d. Formalisms for encoding diagram structure involve generalized notions of syntactic combination (Johnston, 1998). Integrating our account of arrow structure into such a generalized syntactic framework remains a topic for future work.

3.2 Meaning Frames

Arrows have qualitatively different meanings. One difference is whether the path has spatial meaning. For example, the arrows in Figure 1b indicate temporal or causal relationships with no spatial content. By contrast, the arrows of Figure 1c are rendered in perspective with the diagram's tectonic plates to depict the direction of action in an earthquake.

These qualitatively different interpretations are correlated with the structural description of an arrow. We see these constraints as analogous to the semantic frames assigned to verbs in databases like FrameNet (Baker et al., 1998). A semantic frame is a conceptual structure describing an event or a relation and the participants in it. For example, "Mary sold her car to John" and "John bought Mary's car" describe the same semantic frame. We interpret each structural option with an appropriate underlying conceptual representation, or frame, and assign each argument an appropriate role in the frame. Our frames for arrows are INDICATION, ACTION, DIRECTION, and MOTION.

- The INDICATION frame, for arrows like those in Figure 1a, involves a SUBJECT (prototypically, a pictorial element at the head), and a LABEL (text at the tail), as in bishop →  . In indication, the label represents the name, location or category of the subject.

- The ACTION frame, for arrows like those in Figure 1b, involves a SOURCE (prototypically, a pictorial element at the tail) and a TARGET (prototypically, a pictorial element at the head), which are

[3]The distinctive status of text means that arrows with text at the tail are often equivalent to line segments with text at one end. In fact, only 19.09% of the labeling relations in AI2D are drawn with arrows; the rest are line segments. Other arrows cannot be replaced by segments.

understood to stand in a contextually-specified telic or agentive RELATION, as in  . Such arrows may represent causation, change, consumption, or transfer of possession depending on the content of the diagram. Source and target may represent different objects or different states of the same object.

- The DIRECTION frame, for arrows like those in Figure 1c, involves the DIRECTION indicated by the rendering of the arrow. This direction gives a contextually-specified ATTRIBUTE of a SUBJECT, which may be an element linked to the arrow (as in ) but may also be whatever lies where the arrow sits (as in ). The implicit meaning of such arrows has to be recovered using context. For instance, direction arrows can show the direction of traffic in street signs, the direction of the wind in weather maps, and the flow of material in mechanical drawings.

- The MOTION frame, for arrows like those in Figure 1d, involves a MOVER, which is rendered *twice*, both at the head and at the tail of the arrow, as in  . The frame indicates a translation event in which the mover starts in the tail configuration and ends at the head configuration.

Minimal pairs underscore the qualitative distinctions among these interpretations, which must therefore rely on conventional knowledge, not just common sense. An element  probably indicates that graduation *amounts to* an accomplishment (the INDICATION frame), while the inverse element  probably means that graduation *leads to* accomplishment (the ACTION frame). The possibilities for ambiguity also support qualitative analyses of arrow meaning. For example, in some diagrams, the element  would represent an event in which a single ♘ moves through space (the MOTION frame); in others, it would represent one in which a first ♘ does something to a second (the ACTION frame). The experiments in Section 4 are focused at assessing whether (and how) people represent and resolve such ambiguities.

3.3 Resolving Interpretation

Designers like Horn (1998) enumerate the specific interpretations of arrows seen in Figure 1: the meaning *be eaten* of the arrows in Figure 1b, the meaning *driving force* of the arrows in Figure 1c, or the meaning *orbits* of the arrows in Figure 1d. Such alternatives cannot be listed in a wide-coverage approach; they have to be derived from the specific purpose and subject matter of the diagram. Work on verbs, such as the generative lexicon theory of Pustejovsky (1998), offers a suggestive model for how this derivation might go. Pustejovsky (1998) proposes that underspecified verbs (famously, *begin*) retrieve implicit actions via the *qualia structure*—the natural action associates—of their arguments. The broader lesson is that shallow associations can be a surprisingly good place to look for contextual interpretations. The experiments of Section 5 substantiate this suggestion by seeing what features are needed to recover the context-sensitive relation associated with the ACTION frame.

4 Distinguishing Semantic Categories

The linguistic approach of Section 3 raises empirical questions about qualitative ambiguities in diagrams. Do people distinguish between arrows that signal indication, action, direction and motion frames? Can we develop corpora that annotate our frame distinctions explicitly? AI2D annotations already distinguish indication arrows from other arrows, but do not encode our other distinctions, so we conducted a series of human-subjects experiments to address these questions. The studies were conducted with the approval of our human subjects review committee. The data is available electronically.[4]

4.1 Materials

The annotations in the AI2D dataset suggest that 2077 diagrams have arrows, but the annotations are not always accurate. We removed 196 diagrams that do not have arrows. Further, to focus on clear cases, we removed 232 diagrams: those whose action arrows involved words, question marks or letters at the

head rather than pictorial elements (as in our ♠ → oxygen example, the majority of exclusions); those whose illustrations were cropped and incomplete, and cases such as "flash cards" that involved multiple renderings (a small number of further cases). This left us with 1634 diagrams from the AI2D dataset.

4.2 Methods

In the first experiment, our goal was to look at the structural features of arrows, as well as the semantic distinction between the MOTION and ACTION frames. (In pilot studies, we found that offering subjects a broad range of options let them categorize arrows more reliably.) In each interaction, subjects saw a diagram and were asked to answer if any arrows in this diagram are:

1. between two different objects
2. between a label and an object
3. between two different locations of an object
4. between empty areas
5. none of the above

Option 1 is indicative of arrows in the ACTION frame (obj-obj). Option 2 corresponds to the INDICATION frame (txt-obj); Option 3, to the MOTION frame (two-loc); and Option 4, to the DIRECTION frame (empty). Subjects were able to choose more than one answer, as diagrams sometimes include multiple kinds of arrows. (See Figure 3.)

The goal of the second experiment was to see if people interpret empty arrows in line with the DIRECTION frame. In each interaction, subjects saw one of the 93 diagrams labeled as having empty arrows in Experiment 1, and answered whether any arrows in this diagram showed:

1. the direction of the movement of the objects
2. the different locations of the objects
3. none of the above

Option 1 and 2 explain the interpretation of the DIRECTION (dir) and MOTION (mov) frames respectively.

In all, we recruited 860 subjects through Amazon Mechanical Turk. subjects were all US citizens, high school graduates and had a computer to be able to participate in the experiments. Subjects gave written consent and received $0.10 for the first experiment and $0.30 for the second experiment for their participation in each human intelligence task (HIT), an estimated hourly rate of $15.00. Each HIT asked subjects to characterize all the arrows in three separate diagrams. Each diagram has one data point in the dataset; in addition, we collected additional data collecting multiple responses for a random subset of the data (544 diagrams in Experiment 1, 47 in Experiment 2) to assess reliability.

4.3 Results

We followed Chen et al. (2005) in measuring inter-rater agreement. Their method is a generalization of Kappa statistics for cases that multiple raters are involved in a multi categorization task. For the first experiment, the overall kappa is 0.9744. For the second experiment, the overall kappa is 0.8517. This

Group D	71	empty	91.57%

Table 3: Grouping diagrams by topic gives a strong indication of the structure and meaning of arrows.

indicates that subjects strongly agreed on their judgements, suggesting that the structural and interpretive distinctions that underwrite our semantic frames are clear to human interpreters.

This established, we can look at the distribution of annotations. Our first results appear in Table 1. Observe that only 38 diagrams seem to have an arrow classified in the "other" category; this suggests that our taxonomy has good coverage of frequent patterns. Further, the vast majority of the diagrams (1571 of 1634) feature exactly one kind of arrow; this is reminiscent of findings that words are used with one sense per discourse (Gale et al., 1992). This suggests that diagram understanding systems should be designed to look at a diagram holistically and prefer uniform interpretations for all the arrows.

Table 2 specifically focuses on the second experiment, which looked at whether DIRECTION is the appropriate semantic frame for empty arrows. The results are again consistent with our meaning frames. In particular, the 72 diagrams tagged as having just direction interpretations in Experiment 2 include 68 of the 70 diagrams tagged as having just empty arrows in Experiment 1. In addition, 12 out of 16 diagrams that were tagged with more than one option in Experiment 1 were reported to have multiple kinds of arrows in Experiment 2.

The AI2D dataset groups diagrams into different categories such as "Atom Structure" and "Moon Phase Equinox". We made four larger groups of diagrams categories for diagrams in AI2D: Group A includes diagram that map out scientific structures; Group B includes diagrams that present interactions between elements; Group C explains changing geometric configurations; and Group D highlights momentary spatial relationships.[5] These categories turn out to be highly correlated with a particular structure and interpretation of arrows: see Table 3. This provides further evidence that diagram interpretation should be guided holistically by general domain knowledge.

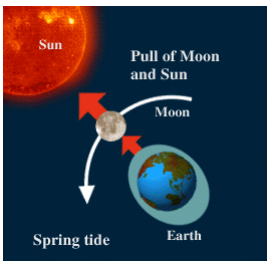
4.4 Exceptions

In an effort to understand the limitations of our taxonomy, we inspected the diagrams tagged as having multiple types of arrow and additional types of arrow.

We found that when designers use arrows to represent different meanings, they almost always render those arrows with different shapes or colors to represent different meanings. Each kind of arrow therefore has a consistent interpretation in the diagram after all. The left and the middle diagrams in Figure 3 show two examples of diagrams of this kind. The right diagram however is an example of the few that do not follow this principle.

We designed an experiment with the same terms and conditions as Experiment 2 to test the hypothesis that different kinds of arrows in complex diagrams have different appearances. We chose all diagrams that were tagged in Experiment 1 with more than one option (excluding diagrams that were tagged with "other") and asked participants to report how many different kinds of arrows with different appearances they see in each diagram. The result of the experiment shows that 21 out of 23 diagrams were reported to have more than one kind of arrow. This is in particular important in designing systems that can generate or understand diagrams. Such systems must allow each shape to get a different interpretation.

[5]Specifically, Group A is AI2D typesOf, partsOfA, atomStructure, partsOfTheEarth, circuits, solarSystem, rockStrata. Group B is Photosynthethis, lifeCycles, foodChainsWebs, waterCNPCycle, volcano, rockCycle. Group C is moonPhaseEquinox. Group D is faultsEarthquakes, eclipses.



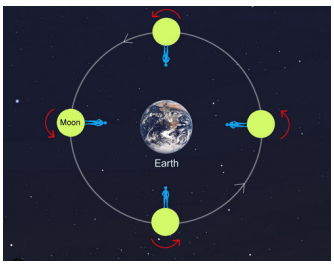


Figure 3: Authors typically render arrows with different interpretations differently. Left: thin circular arrows depict the moon's orbit (motion) while thick straight arrows depict the force of gravity (direction). Right: red arrows represent the direction of the movement of the moon where the white arrows are between two different locations of the moon.

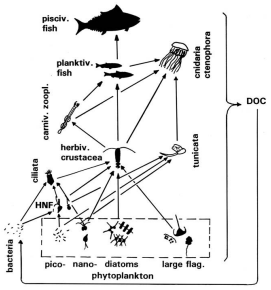

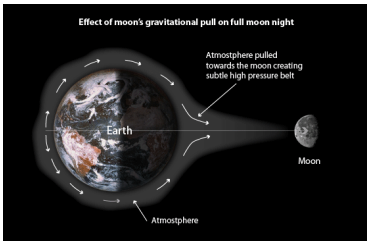

Figure 4: Examples of diagrams tagged as having other kinds of arrows.

Diagrams with arrows that were labelled as having additional kinds of arrows don't straightforwardly suggest omissions in our structural inventory. One case we might consider is arrows linked at their head to other arrows—a generalization of our INDICATION frame. The right diagram in Figure 4, includes such arrows. One arrow shows the direction of flow of the atmosphere; another arrow links that arrow to text explaining that the flow arises through the moon's gravity. A few other diagrams that come with arrows that are annotating another set of arrows were tagged other as well.

However, most of the "other" examples may simply have been difficult to understand. Some of these diagrams, like the left diagram in Figure 4, have arrows whose path are cutting each other. Similarly, some have labels that are not in proper places—for example very far from the tail of the arrow—or other unnecessary and distracting elements, such as mountains and clouds in a food chain diagram. These observations suggest that certain visual features can increase users' cognitive load in interpreting action diagrams. We suspect that viewers' cognitive limitations are an important constraint in diagram generation—a suggestion we return to in the conclusion.

4.5 Limitations

The experiments of Section 4 suggest that people agree on the structural organization of arrows in diagrams, and they also assign arrows consistently into semantic frames based on the identity of depicted objects and the broad significance of the arrow. While these results support a linguistic approach to diagram organization, they require substantial development to inform automatic diagram understanding. Automatic methods have trouble recognizing structural links between diagram elements (Kembhavi et al., 2016). Successful practical methods for diagram parsing rely on sketch stroke order (Johnston, 1998; Alvarado and Davis, 2004), which is not available in AI2D. Inferring coreference among schematic pictorial elements is also a challenging open problem, since current machine learning models of computer vision are notoriously bad at line art.

5 Interpretation of Action Arrows

The result of the experiments in section 4 showed that the specific import of arrows varies across contexts, but is typically consistent within a diagram and strongly contained by its subject matter. This means that once we know that an arrow falls into the direction, motion or indication category we have the interpretation of the arrow. However, in order to come up with the exact relation that explains the action arrows, we need to take a further step. In this section, we look specifically at how to predict the specific relation associated with an action arrow. Previous work has focused on resolving these interpretations using handcrafted knowledge bases describing specific domains (Alvarado and Davis, 2004; Forbus et al., 2011). Our analogy with verbs suggests that shallow methods based on element statistics and simple machine learning methods may provide more practical methods for inferring the domain-specific meaning of arrows in particular cases.

We carried out computational experiments to assess this hypothesis. Our machine learning classifier takes as input the verbal information in a diagram, such as label text and other annotations, and predicts the likely interpretation of all its action arrows.

5.1 Dataset and experimental setup

To link action arrows with their interpretations, we ran a pilot study on Mechanical Turk with 56 diagrams (5% of the diagrams that were tagged with action arrows in Experiment 1). Each subject saw a single diagram and responded to the prompt: "If you remove the arrows in this diagram, what words would you replace them with to convey the same meaning?" The results were consistent with the hypothesis that each diagram uses arrows to convey a single relation; unsurprisingly, however, the responses used diverse vocabulary (Furnas et al., 1987), so could not be used directly as training data for a classifier.[6] Instead, we associated diagrams with arrow meanings consistently based on AI2D categories: We used "turn into" for cycle of life and rock cycle diagrams; "eat/be eaten" for food chain web diagrams and "produce/receive" for photosynthesis diagrams.

AI2D includes multiple diagrams with similar content. We want to test whether we can learn general patterns for classifying arrows, not just memorize the features of individual examples. Thus, we organized our experiment in blocks using diagrams with different subject matter. We divided the data into three: we randomly split the receive class (it has only 93 datapoints), but we divide the two other groups, turn into and eats, based on three existing categories in AI2D (cycle of rocks, volcano, cycle of life) and three subcategories that we found in food web data (ocean, large birds, big cats). Since the number of blocks is small, we report cross-validation results leaving out one fold as test data.

5.2 Models

We used a bag of words (BoW) model with the SVM classifier as our baseline.

We compared the baseline to a convolutional neural network (CNN) with one convolution layer over pretrained word embeddings (Collobert et al., 2011; Kim, 2014). We used a max-over-time pooling operation and dropout regularization. See Table. 5. This setting enabled us to measure the effectiveness of considering distributional similarity in our classification task and thus the importance of generalizing based on shallow semantic knowledge.

To see how important it is to semantically understand the input by using sequential and structural information, we experiment with hierarchical attention RNNs (Yang et al., 2016). We made a look-up table for vocabulary, converted all words to integers and applied a one hot encoder. Next, we padded the input sequences, and fed them through Embedding, LSTM and Dense layers. Model Architectures are described in detail in Appendix A.

We trained the models to minimize binary cross entropy. Text was fed in left to right and top to bottom based on the position in the diagram.

[6] 44 responses consisted of a single verb (differing across subjects: turn into, metamorphose), and 5 included two verbs with similar meanings (develop, turn into), while 7 included nouns or short sentences.

	data size	CNN	RNN	SVM

Avg	train: 1187	0.842	0.708	0.553
	test: 262			

Table 4: Accuracy of predicting implicit RELATION for diagrams with ACTION arrows.

5.3 Results

Table 4 gives our experimental results. The CNN architecture works best. Its overall effectiveness corroborates our hypothesis that arrows pick up straightforward action associates of the objects they connect. The improvement over the SVM model suggests that distributional similarity is an effective proxy to the world knowledge needed to understand a diagram. The improvement over RNNs suggests that linguistic structure is not important for this task.

Error analysis revealed three major problems. The majority of the examples that our models failed to classify were the ones that contain labels that are shared between categories. For example, words such as "animal" and "plant" show up in both "turn into" and "eat" categories. We also had problems with diagrams labeled in languages other than English, and some diagrams with irrelevant labels, such as photosynthesis diagrams with "car" and "factory" labels.

Working with labels enable us to take into account the pictorial information that is available in a diagram without using a vision classifier. We can see that having a knowledge of the category of the diagram suffices for resolving the underspecification problems.

6 Conclusion

Arrows, we have argued, have a constrained form, meaning and interpretation, which can be theorized using linguistic concepts. This means, in particular, that we can ask subjects to report their interpretation of arrows in linguistic terms and use machine learning methods to resolve ambiguities in the interpretation of arrows in qualitative, linguistically-motivated ways. Vision researchers sometimes compare diagram understanding to scene understanding (Kembhavi et al., 2016). That may be right when it comes to grouping elements in diagrams together and recognizing pictorial elements—though much research on those topics is still needed. When it comes to organizing the content of a diagram as a whole, we think discourse modeling and other NL techniques also offer important tools.

Many of our findings echo designers' advice about effective diagrams (Tufte, 2001). They are simple. They have limited figurative content. Most of them have one kind of arrow that's easy to interpret based on general background knowledge. If they have multiple kinds the shape of the arrows are different so that the reader can distinguish between the two kinds of meanings that he has to infer. Our results therefore promise to help inform systems for diagram generation (Agrawala et al., 2003).

Our empirical work explores only a small number of the ways arrows vary—and diagrams include a wide range of other elements that we think can be studied with methods like ours. More generally, the minimal pairs we sketched in Section 3 suggest that we can operationalize interpretive constraints on multimodal communication with predictive, wide-coverage methods. We hope to contribute to such formalisms going forward.

Abstract

We use a broad coverage, linguistically precise English Resource Grammar (ERG) to detect negation scope in sentences taken from pathology reports. We show that incorporating this information in feature extraction has a positive effect on classification of the reports with respect to cancer laterality compared with NegEx, a commonly used tool for negation detection. We analyze the differences between NegEx and ERG results on our dataset and how these differences indicate some directions for future work.

Title and Abstract in Russian

К вопросу о применении формальных грамматик в посторении признаковых векторов для классификации отчетов о заключениях патологоанатомов

Мы предлагаем способ обогащения векторов признаков (*feature vectors*) лингвистичекой структурой. Для внешней оценки эксперимента (*extrinsic evaluation*) мы смотрим на результаты автоматической классификации отчетов о заключениях патологоанатомов (*pathology reports*, такие как заключение о результатах гистологического исследования и др.). В качестве лингвистической структуры мы выбрали сферу действия отрицания (*scope of negation*), так как известно, что отрицание в тексте может влиять на качество классификации медицинских заключений. В эксперименте мы используем имплементацию формальной грамматики английского языка (English Resource Grammar) для определения сферы действия отрицания на уровне предложения. Сначала текст отчета делится на предложения. Из каждого предложения при помощи базы данных UMLS мы выбираем слова и фразы – признаки. Те признаки, которые оказываются в сфере действия отрицания, мы заменяем на специальные признаки. Например, в предложении *No tumor in left breast*, если сфера отрицания определена достаточно широко, признак *left breast* будет заменен на признак *NEG:left breast*. Все признаки, полученные из одного отчета, собираются в один вектор (признаковый вектор данного отчета). Обогащенные таким образом признаковые векторы затем используются для классификации отчетов на группы по расположению первичного очага (в правой или левой части легкого или молочной железы). Мы сравниваем воздействие нашей системы построения признаковых векторов на точность классификации с популярной системой NegEx, которая использует для определения сферы действия отрицания ряд эвристик. Результаты и анализ ошибок позволяют увидеть, что формальная грамматика, основанная на глубоком синтаксическом анализе, действует точнее, чем система NegEx. Система NegEx может ошибочно предположить сферу действия отрицания в плохо структурированном тексте (например, в блоке текста, неправильно разбитом на предложения), а формальная грамматика в этом случае не выдаст никакого ответа и тем самым избежит ошибки. Мы делаем вывод, что использование формальных грамматик для подобных задач может быть целесообразно.

1 Introduction

Detecting negation scope remains a challenge in clinical notes information extraction (see e.g. Morante and Daelemans 2009 for an overview of existing approaches for negation detection and related issues). Perhaps the most extensively used negation detection tool is NegEx (Chapman et al., 2001), a regular expressions-based tool, with 696 citations on Google Scholar,[1] which is part of such well-known systems as cTAKES (Savova et al., 2010). One reason NegEx is so popular is that it is rule based and thus easily adapted to any English dataset. In general, rule based methods are important for domains where data cannot be easily shared and so there is no guarantee an existing machine learning approach can be successfully used, such as the clinical notes domain. That said, NegEx identifies negated tokens from surface strings using a set of domain-specific heuristics which it applies directly to the surface strings rather than to some syntactic or semantic representations of those strings. Such an approach is unlikely to capture the rules of English negation in their generality. In contrast, linguistically motivated implemented formal grammars[2] map surface strings to abstract syntactic and semantic representations and model language rules more accurately and robustly, in a domain-independent fashion.

For this paper, we classified a set of pathology reports diagnosing the cancer as located in the right or in the left part of the body, an important data element used in clinical operations and research for paired organ sites. The contribution of the paper is in incorporating precise negation scope information obtained with an implemented broad-coverage grammar of English into the feature extraction procedure. The experiment yielded incremental though consistent improvement when compared to NegEx, showing fairly clear evidence that incorporating robust domain-independent linguistic structure into feature extraction can be helpful for classification of this kind.

After summarizing related work (section 2), we present our experiment (section 3). The structure of the experiment is as follows. Each pathology report in the dataset (section 3.1) is represented by a feature vector constructed from a Unified Medical Language System (UMLS)-based feature set, which is obtained as described in section 3.2 and then augmented by what we call *negated features* (section 3.3). To help the reader, we introduce negated features right here first: In any sentence, a lexical feature which was selected as highly informative for the training dataset (e.g. *right*, or *malignancy*) could actually correspond to a negated concept. Assume the feature *malignancy* was selected by a feature selection algorithm and will now be used in a classification task on a test dataset. Compare two hypothetical single-sentence reports from this test dataset: *A malignancy was identified* and *No malignancy was identified*. For the second report, which contains the feature *malignancy* within the scope of negation, we want to exclude that feature when we turn this sentence into a vector. Otherwise, if we were to include *malignancy*, we might misclassify the report as positive.[3] Furthermore, a negated concept (which we will represent as *NEG:malignancy* in this case) may itself be an informative feature. We identify these negated features in the text of the reports using NegEx (as baseline) and the English Resource Grammar (ERG; Flickinger, 2000, 2011), as described in 3.3. Then we train a number of classifiers on the training portion of the dataset represented as feature vectors to discriminate between the classes *left* and *right*; we then evaluate on the test portion of the data. Since our dataset was not annotated for negation, we are performing an extrinsic evaluation of negation detection by showing the effect that using the grammar for feature extraction had on classification. This extrinsic evaluation can later be complemented by an intrinsic one.[4] We present the numeric results (section 4) which show small but consistent improvement of our approach over NegEx and conclude with a detailed analysis of the differences between the two systems, which helps us identify directions for future work.[5]

[1] Accessed June 5, 2018.

[2] Not to be confused with domain specific grammars, common in natural language processing.

[3] Admittedly if the training data contained lots of negated examples, the feature would not come up as one of the best for positive classification. However, negated and non-negated concepts may be unbalanced in the data, and furthermore, machine learning-based classification here is just one scenario.

[4] As discussed in the related work section, the effect of finding negation scope using a precision grammar of English has been examined by MacKinlay et al. (2012) on the sentence-level.

[5] To protect possible traces of sensitive data, the code will be available upon request.

2 Related Work

Both rule-based and machine learning approaches exist for detecting negation scope. Morante and Daelemans (2009) is an example of a machine learning approach. Their system consists of two classification tasks performed with supervised machine learning methods: finding negation tokens and classifying tokens as the first or last (or neither) token within the scope of negation. Morante and Daelemans (2009) report high scores on the BioScope dataset (Vincze et al., 2008). However, machine learning approaches like this one require sufficient annotated training data not always available for clinical tasks.

Sohn et al. (2012) use dependency parses in their rule-based system, noting that complex sentence structure is difficult to learn automatically. A similar approach is taken by Mehrabi et al. (2015). In both of these experiments, a set of rules was created specifically for the purposes of the project, and therefore the systems cannot necessarily be directly extended to work on other datasets. Furthermore, ad hoc rules are likely to be incomplete with respect to the variety of ways to express negation and the complexity of syntactic structures over which negation can scope.

Packard et al. (2014) used the English Resource Grammar (ERG; Flickinger, 2000, 2011) for negation scope detection in literary texts, to outperform the state-of-the-art at the time. In the biomedical domain, the ERG was used by MacKinlay et al. (2012). In one task described in their paper (Task 3), MacKinlay et al. (2012) constructed feature vectors for specific "events", which were already identified by annotations in their training data. They used the Minimal Recursion Semantics (MRS; Copestake et al., 2005) and Robust Minimal Recursion Semantics (RMRS; Copestake, 2003) representations produced by the ERG to identify speculation and negation over those events. Their results for negation performed best in the BIONLP 2009 shared task.

Our study differs from MacKinlay et al. (2012) in one key way: whereas they look only at events of interest (which they assume to be already identified in the data), we look at the entire text of a given pathology report, without relying on sentence-level annotation of any kind. In other words, we hypothesize that the usefulness of incorporating precise grammatical information about negation scope generalizes to the document level. Other differences include that MacKinlay et al. (2012) looked at scientific biomedical literature, while we use clinical reports as our data.

3 Experiment

The main contribution of the paper is the use of a broad coverage grammar (the ERG) for feature extraction on the level of a complete pathology report. We describe the dataset in section 3.1. The feature extraction technique is explained in detail in sections 3.3-3.5. To evaluate, we perform feature selection (section 3.2) and use four popular ensemble classifiers (section 4.1).

3.1 Data

The dataset (Table 1) comes from the Surveillance, Epidemiology and End Results (SEER) Program[6] and is a subset of 4000 randomly selected, de-identified annotated pathology reports, representing 4 registries and more than 70 pathology labs. This subset was used in a graduate level course[7] on Natural Language Processing in Cancer Informatics at the University of Washington .[8] It is annotated for a variety of things, including whether the primary tumor was found in the right or left part of the body (such as right vs. left breast or lung). It is not annotated for negation. A small number of reports were classified to have both right and left sites affected; we exclude them from the experiment in order to have a balanced dataset.

We relied primarily on the NLTK sentence tokenizer (Bird et al., 2009) to split pathology note sections into individual sentence tokens. Subtopic headers (identified by their line-ending colon punctuation) were extracted into separate sentence tokens, and mid-sentence line breaks were removed from sentence tokens. The dataset was divided into training and test randomly, using a 66% / 33% split (two thirds used for the training).

[6] https://seer.cancer.gov/

[7] LING575, Winter 2017

[8] Unfortunately, this particular dataset is not available for public use for reasons outside of authors' control. Applying the system to a public dataset remains part of future work.

	Total	LAT	RIGHT	LEFT
Training	581	446	234	212
Test	293	233	122	111

Table 1: Dataset size. LAT are reports gold-annotated for right or left laterality.

The dataset partially motivated the choice of right vs. left laterality as our target annotation: On the one hand, classifying documents for the location of the primary tumor is a useful task that could be performed by a machine; on the other, it was one of the gold annotations occurring most often in the reports. Filtering all reports for this annotation yielded a fairly large and balanced subset of documents (Table 1).

3.2 Features

We represented each report as a feature vector as follows. Features were extracted sentence by sentence and then aggregated into one set for the entire report. First we extracted all concepts for each report (as described in section 3.2.1), and then selected 44 features using recursive feature elimination with Random Forest[9] on 33% of the training dataset set and supplementing that set symmetrically, e.g. adding 'left upper lobe' where we only had 'right upper lobe'. The resulting features were: 'right breast', 'right lower lobe', 'right lung', 'right upper lobe','left breast', 'left lower lobe', 'left lung', 'left upper lobe', 'left', 'right', 'rul', 'lul', 'rll', 'lll', 'identified', 'carcinoma', 'adenocarcinoma', 'malignancy', 'malignant', 'tumor', 'in situ', 'invasive', 'infiltration', 'atypic', 'atypia', 'margin', 'rt breast', 'lt breast', 'rt lung', 'lt lung', 'rt upper lobe','lt upper lobe', 'rt lower lobe', 'lt lower lobe', 'metastasis', 'metastatic', 'found', 'suspicious', 'evidence', 'masses', 'tissue', 'specimen', 'determined', 'ruled out'. We supplement the set manually because one third of the training set used to select features was not sufficient to produce a list of features that robustly extended to the training set. For example, some of the training reports did not have the feature *right upper lobe* but we noticed that they have *left upper lobe* instead and decided to apply a symmetric manual extension to the feature set across the board. This way we hope to obtain informative features while not overfitting to the training dataset.

3.2.1 Basic Features

We constructed basic feature vectors for each report by using MetaMap Lite to recognize concepts from the UMLS term database (Aronson, 2001). Each sentence was parsed to find the longest matching UMLS concepts and phrases, using the default MetaMap Lite setting for both stop words and POS tagging. A report feature vector is the set of all the features listed above in section 3.2 that were extracted by MetaMap for each sentence in this report. We only count each feature once per report.

3.3 Negation Scope and Negated Features

We compare two different methods of extracting negated features and their effect on classification: NegEx (Chapman et al., 2001) which we consider our baseline, and the English Resource Grammar (ERG; Flickinger, 2000, 2011).[10] If a concept was marked as negated by the tool under consideration, we remove the original feature from the feature list extracted from the sentence and replace it with the negated feature (e.g. *NEG:tumor*, for a sentence like *No tumor identified*). Of course, if the same feature was detected but not marked as negated in a different sentence in the same report, the report will still have the non-negated version of the feature in its vector.

Table 2 shows the total number of feature tokens,[11] for all sentences in the dataset, and separately the number of feature tokens added by NegEx and the ERG. The ERG adds fewer features, which means it detects negation in fewer occurrences than NegEx. Later in the paper, we discuss that while sometimes

[9] We took all the top scoring features which looked meaningful, namely stopping once we saw the word 'Dr.'.

[10] Version 1214.

[11] We use the classic token/type distinction to talk about the features. For example, the sentence *Signs of malignancy in left upper lobe; no signs of malignancy in right upper lobe* contains two tokens of the feature type *lobe* and just one token of the feature type *right upper lobe*.

	total	+NegEx	+ERG
total	25159	3214	3002

Table 2: Feature tokens (features occurrences in each sentence).

it is detrimental to the evaluation results, other times features added by NegEx turn out to be noise, and skipping them is actually more precise and beneficial.

3.4 NegEx

NegEx (Chapman et al., 2001) takes text (assuming that the whole text is one sentence) as input and returns a list of concepts that it considers negated in that text. It attempts to determine what the scope of negation is, but sometimes makes mistakes. For example, in the sentence *No chest pain, no shortness of breath, and no abdominal pain*, the concept *chest pain* is affirmed (not negated) by NegEx.[12] (We will see a similar error hurting NegEx's performance in section 4.3.3.) While any specific error can be fixed, it can be difficult to fix such issues robustly and not cause regressions without relying on a general set of linguistically motivated language rules. When this method of negation detection was applied to feature extraction, the list of feature types was appended with *NEG:in-situ*, *NEG:left breast*, *NEG:left*, *NEG:identified*, *NEG:carcinoma*, *NEG:malignancy*, *NEG:margin*, *NEG:tumor*, *NEG:right*, *NEG:invasive*.

3.5 ERG

3.5.1 Overview

The English Resource Grammar (ERG; Flickinger, 2000, 2011) is a large, broad-coverage precision grammar of English.[13] The term 'precision' means that it encodes syntactic and lexical rules in a form that aims for linguistic adequacy and generality, in this case using the Head Driven Phrase Structure Grammar theory of syntax (HPSG; Pollard and Sag, 1994). The grammar maps surface strings to syntactic as well as semantic representations which are licensed by lexical and phrase structure rules. The ERG is supported by the DELPH-IN research consortium, along with a variety of tools for parsing, generation, and representing syntactic and semantic structures.[14] It is the largest HPSG-based grammar, but grammars of different sizes exist for other languages.[15]

3.5.2 Minimal Recursion Semantics

The ERG produces semantic representations compositionally in the format of Minimal Recursion Semantics (Copestake et al., 2005), which we then use to extract negated features. Figure 1 shows a syntactic structure (left) and an MRS (right) for the fragment sentence *No evidence of malignancy*. The syntactic representation is a familiar constituency tree. The flat MRS representation is a bag of quantifiers, relations, and predicates associated with handles (such as *h13*), which can be identified with each other or not, allowing for scope underspecification.[16] In this example, *evidence* is analyzed is being in the scope of the *no* quantifier. The word *malignancy* is analyzed as the first argument of *evidence* (through the indefinite quantifier, unexpressed on the surface level). The predicate of this sentence is *unknown*, reflecting that it is a fragment.

A dependency MRS for the sentence *A tumor was not identified* is shown in Figure 2. DMRS representations (Copestake, 2009; Copestake et al., 2016) are essentially a simplified version of MRS where variables and their relationships are expressed as links. DMRS representations consist of elementary predications (EPs) corresponding to surface tokens, such as the EP for negation, as well as abstract EPs contributed by grammatical rules. The EPs are connected by links, forming a semantic dependency

[12] We used the version downloaded from `https://github.com/chapmanbe/negex`.

[13] Demo: `http://erg.delph-in.net/logon`.

[14] To follow up on the earlier example of NegEx making a mistake with the sentence *No chest pain, no shortness of breath, and no abdominal pain*, we verified that the ERG returns a syntactic structure which has all three nouns in scope of negation.

[15] See e.g. `http://www.delph-in.net/wiki/index.php/Grammars`.

[16] See Copestake et al. (2005) for a discussion and examples of scope underspecification and other issues related to MRS.

graph.[17] DMRS representations are related to MRS (a DMRS can be created from an MRS deterministically) but are easier to look at and to work with, and for our experiment we used the DMRS representations.

One advantage of semantic representations like MRS or DMRS is that they abstract away from the syntactic notions of subjects and objects, normalizing active/passive pairs to the same representation. This is illustrated in Figure 2, where *tumor* is the ARG2 (the theme) of *identify*, despite being the grammatical subject of a passive sentence. Another advantage is a systematic treatment of scope, which is discussed in the next section.

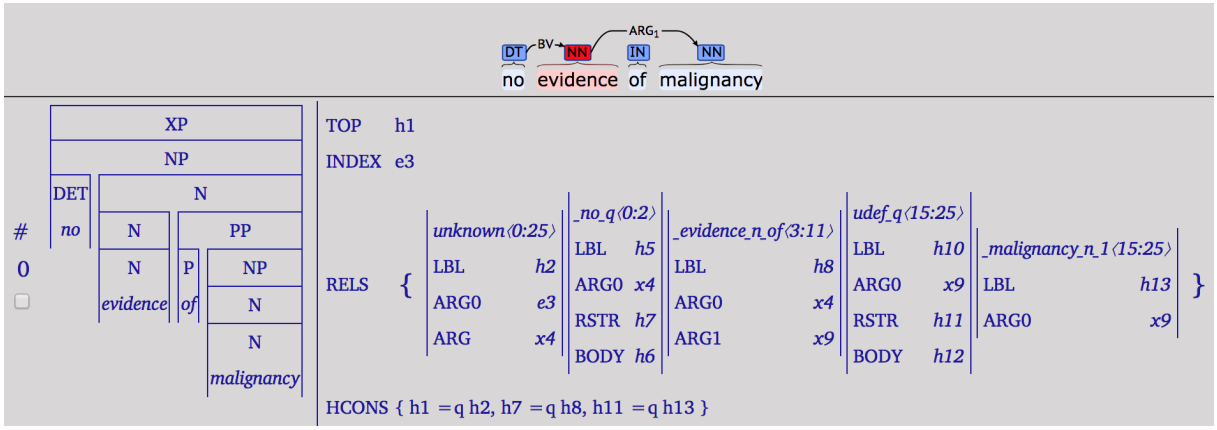

Figure 1: The ERG's syntactic parse and the MRS of the fragment sentence: *No evidence of malignancy*

3.5.3 Extracting Features with the ERG

We parsed every sentence in each report with the ERG loaded into the ACE parser (Crysmann and Packard, 2012).[18] ACE has a default parse ranking procedure trained on a treebank (Toutanova et al., 2005), and we selected the top ranked parse. The coverage of the parser was 22858/28788 sentences (79%). It is not surprising that not all sentences are parsed, given the highly fragmented nature of the reports, where newlines are often used to separate different parts of the same sentence. Statistical parsers always return a parse; however, we will show that when striving for precision, no parse can be better than a nonsensical parse.[19] Once we parsed each sentence using the ERG, we crawled the dependency (DMRS) representations to extract negated concepts. We extracted two types of negation: predicate negation (the negation of events) and quantifier negation (the negation of entities).

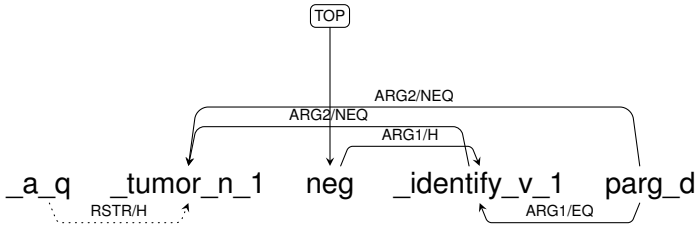

Figure 2: A semantic dependency graph (DMRS) produced by the ERG for: *A tumor was not identified.*

Predicate negation is represented with the EP *neg* (the semantic contribution of *not*) which scopes over the predications contributed by the verb (*neg*'s ARG1) and the verb's own arguments. From the DMRS we extract the verb as well as its argument labeled ARG2. This label refers to the argument receiving the action of the verb, or the semantic theme. For example, in *Skin: invasive carcinoma does not invade dermis or epidermis*, we extract the verb *invade* and its ARG2 which is the the coordinated

[17] The DMRS graphs were produced using `https://github.com/delph-in/delphin-viz`.

[18] Version 0.9.24.

[19] That said, a more sophisticated tokenization technique, which would reconstruct more full sentences, would improve ACE's coverage.

noun phrase *dermis or epidermis*.[20] Extracting the ARG2 yields the same result in passive sentences, such as *Additional distinct breast masses or lesions are not grossly identified*, where the 'things not identified' are the *additional distinct breast masses or lesions*.

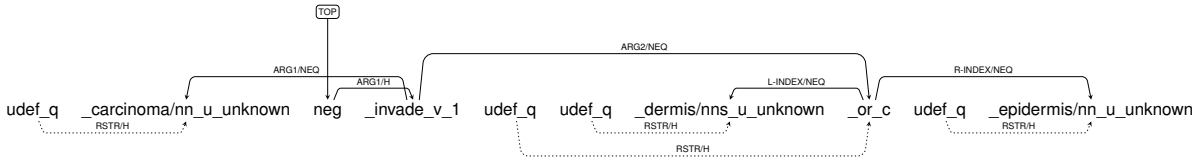

Figure 3: DMRS for the sentence *Carcinoma does not invade dermis or epidermis*

Quantifier negation is the negation of a noun phrase by the quantifier *no*, as in *There is no evidence of vasculitis, granulomatous inflammation, or neoplasm*. First we identify the predications restricted by the quantifier *no*. Here the restricted predication is the noun phrase headed by *evidence*, which itself contains a prepositional phrase with coordinated noun phrases. We identify each concept in the noun phrase and mark it as negated.

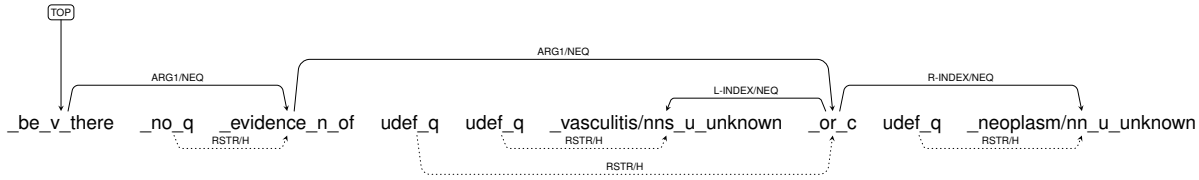

Figure 4: DMRS for the sentence *There is no evidence of vasculitis or neoplasm*

When this negation detection method is applied to feature extraction, the original list of features is appended by *NEG:tumor*, *NEG:identified*, *NEG:carcinoma*, *NEG:malignancy*, *NEG:margin*, *NEG:in situ*, *NEG:evidence*. Compared to NegEx, this is fewer feature types as well as fewer feature tokens added. As we will see, this may lead to higher precision in classification. On the other hand, the lack of highly informative concepts related directly to *left* and *right* (such as *left lung*) indicates we could get better results if we supplied the ERG with more data that it can successfully parse. There are certainly sentences in the data in which the concepts like this are within the scope of negation. As we will see, NegEx sometimes gets it right and other times it does not. The reason the ERG does not detect them is usually that it was not supplied a well-formed sentence due to tokenization issues.

4 Results and Error Analysis

4.1 Evaluation by Classification

To test our feature extraction technique, we used four popular ensemble algorithms which generally perform well on small datasets, taking advantage of the scikit-learn Python library (Pedregosa et al., 2011). The parameters were chosen by cross-validation on a small development set.

classifier	code	cite	# estimators	learn. rate	max. depth	other
AdaBoost	AB	Freund and Schapire (1995)	50	1	-	SAMME.R
Random Forest	RF	Breiman (2001)	100	-	20	-
Gradient Boost	GB	Friedman (2001)	100	0.1	1	-
Voting classifier	VC	Pedregosa et al. (2011)	-	-	-	hard, no weights

Table 3: Classifiers used for evaluation

4.2 Numeric Results

Table 4 shows the results. The first column is the ensemble classifier code (4.1); *right* and *left* are laterality classes. Incorporating information about negated concepts is beneficial in many cases; the

[20] An additional trivial step is required to extract *dermis* and *epidermins* as separate concepts

Table 4: Classification results with four different classification algorithms; NegEx vs. ERG.

improvement is small but fairly robust across different ensemble algorithms. The only algorithm where NegEx-detected negation was better than the ERG is Random Forest, and even for Random Forest, the precision is higher with the ERG for one of the classes and the recall is higher for the other.

4.3 Improvement and Error Analysis

Below we will look at specific improvements and regressions, per record. The record ID has been changed for anonymity concerns. We primarily see differences in classification with respect to 7 records; we will call them Records 1-7.

4.3.1 AdaBoost

Improvement: Records 1,2,3. The feature vectors for **Records 1 and 3** do not differ between the ERG and NegEx; Record 1 does not contain any negated features in either case, while Record 3 contains a feature negated by both the ERG and NegEx. This means the improvement is probably due to chance (a tie broken by the classifier in such a way that it shows as an improvement). **Record 2**, however, shows some differences. The features *identified* and *metastatic* were negated by NegEx but not by the ERG. These features and their negated counterparts may have a lot of weight and so an incorrect decision about negation can have impact. It turns out, NegEx uses a fairly big chunk of text with no sentence-final punctuation which happens to start from *Not indentified* to produce multiple negated features. The ERG is not able to parse that chunk of text as a sentence (since it really is not one). In this case, better precision leads to a better result.
Regression: None.

4.3.2 Random Forest

Improvement: Record 1, again can be attributed to chance.
Regression: Records 4, 5, 6. In **Record 4**, the feature *identified* is correctly negated by NegEx but not by the ERG. The source sentence has the form *No X or Y is identified*. The ERG only succeeds in negating X and Y but not the predicate *identified*. We discuss this issue in section 4.4. **Record 5** contains a phrase *negative for malignancy*, for which NegEx has a suitable heuristic. Our ERG algorithm is not sensitive to the word *negative*. We purposefully did not enhance our algorithm with any heuristics since we wanted our approach to be as domain-independent as possible. It makes sense that NegEx beats us here, however one direction for improvement is to map some of NegEx's heuristics to the ERG's semantic relations. NegEx negates multiple features in **Record 6**, including both *right* and *left*, *left breast*, (but not *right breast*) *identified*, *carcinoma*, *tumor*. The ERG does not negate any of them in this case. The correct label for this record's laterality is *right*, so NegEx probably wins by negating many of the features associated with *left*. However, it is hard to say why it chooses to do so; for example, it negates *left breast* in the sentence: *Left breast: According to the ultrasound core biopsy protocol data sheet, mammogram demonstrates a 2.0 cm irregular mass, and correlates as palpated.* This Record does not provide us with any insight with respect to the two systems' different behavior.

4.3.3 Gradient Boosting

Improvement: Record 7. For this record, the difference is that the ERG negates the features *evidence* and *tumor* while NegEx does not. In this case, this leads to a better result. The relevant text in the record is *no evidence of ductal carcinoma in situ*. NegEx detects negation for *ductal carcinoma in situ*, but not for *evidence*.

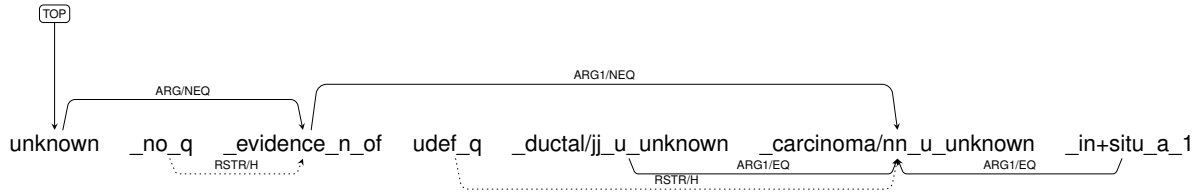

Figure 5: DMRS for *No evidence of ductal carcinoma in situ*

Regression: None.

4.3.4 Voting Classifier

Improvement: Records 1, 2, already analyzed for AdaBoost.
Regression: None.

4.4 Summary

The Improvement and error analysis revealed the following differences between the NegEx and the ERG approaches to feature extraction.

1. The two systems are not equally sensitive to **tokenization issues**. Clinical notes contain lots of tabs in place of sentence-final punctuation; that may lead to imprecise tokenization. NegEx does not care about whether its input actually is a sentence, while the ERG does; our ERG algorithm thus produces higher precision results in some cases where NegEx can negate a feature based on a trigger which does not actually belong to the sentence that contains this feature.

2. NegEx employs a variety of **domain-specific heuristics** while our ERG algorithm does not. We would like our approach to not include dataset or domain-specific heuristics, but some of the heuristics could be mapped to the ERG's existing semantic relations such as specific English quantifiers. We could take advantage of using a robust and precise domain-independent resource and apply a heuristic at a higher level, such as parse selection.

3. ACE **parse selection**. The treebanks used to train the ACE parse ranker are not necessarily representative of the data found in pathology reports. Therefore, it was possible for the desired parse to be produced by the ERG, but not be selected. In some cases, the top ranked parse did not exhibit the widest scope interpretation. For example, the top ranked parse for *no masses or previous biopsy sites are identified* only scoped *no* over *masses*, and not the entire coordinated phrase. We also find

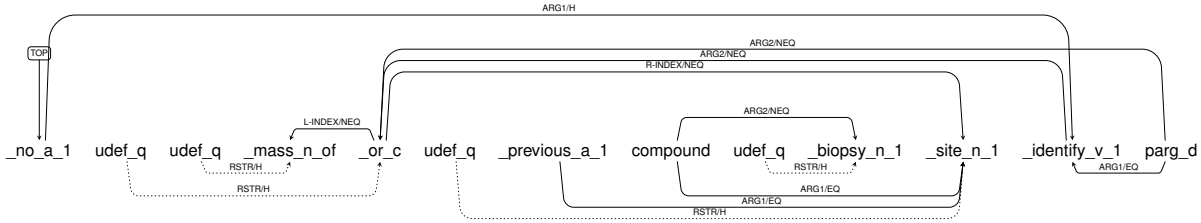

Figure 6: DMRS showing the desired negation scope for *No masses or previous biopsy sites are identified*; this DMRS was not the top-ranked parse

some inconsistency in the top ranked parse for constructions like *associated ductal carcinoma in situ: not identified*. This 'subject: adjective' construction was probably not common in the dataset used to train the parse selection model distributed with the ERG, version 1214, but is frequent in our dataset. In some sentences like the one above (illustrated also by Figure 8), *not* is parsed as a conjunction, or the phrase after the colon is treated as a modifier (effectively treating *identified* as a post-head adjective) rather than as a predicate (negated verb). In these cases, our algorithm, which looks for a *neg* predication and a verb with a theme, fails to negate *identified*. Customized parse

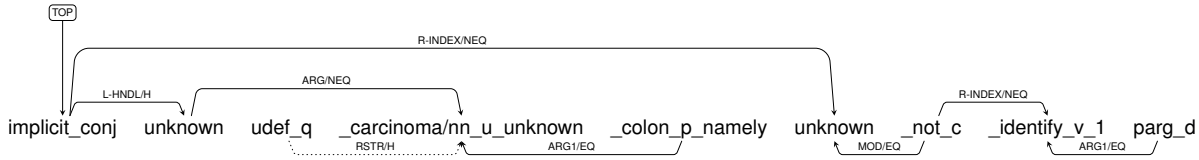

Figure 7: Abridged DMRS showing modifier analysis for *not* associated with some top-ranked parses

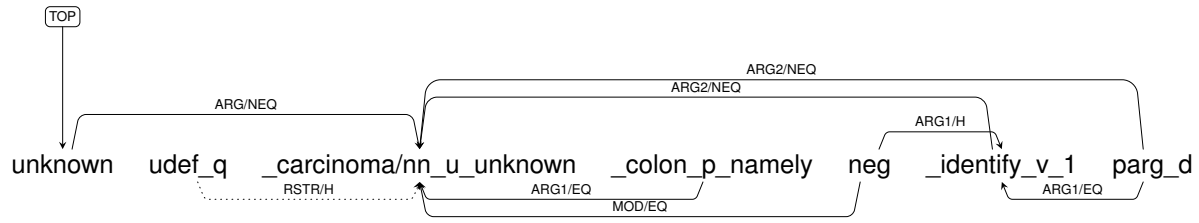

Figure 8: DMRS showing desired, predicate negation analysis for *not*

selection that prefers verbal predicates over modifiers and prefers the widest scope may help extract the features even better and further improve classification.

4. Finally, in some cases it is simply not clear why one approach wins over the other. This includes situations where there is a tie or when there is some difference between the feature vectors produced by the two approaches, but the difference seems to be due to a bug in NegEx (nonetheless leading to NegEx producing a better feature vector). We hope that we will gain more insight once we switch to a larger dataset.

5 Conclusion

We show as a proof of concept that a precision grammar can help extract potentially informative negated features for a pathology reports classification task, outperforming NegEx across several ensemble classification algorithms. Improvement and error analysis reveals that the ERG, being a *precision* grammar, tends to incorporate fewer noisy features compared to NegEx. Because it looks for a meaningful structure in what it expects to be a well-formed sentence, it will make fewer mistakes in terms of negation scope. At the same time, at this stage we did not go beyond simple predicate negation and did not customize parse selection, which causes our system to make some mistakes that NegEx, which includes multiple heuristics specialized for the domain, does not make. In future work, we will experiment with ways to customize parse selection so that it is better suited for the clinical notes domain, while not needing to change anything in the grammar itself. We will also explore which relations in the ERG may correspond to some of NegEx's heuristics, and this should give us further improvement. Furthermore, in any next stages we will be applying our system to a public dataset such as BioScope (Vincze et al., 2008).

Acknowledgements

This project would not be possible without Emily Silgard from Fred Hutch who provided us with the data and guidance for this project. We thank Michael W. Goodman and Ned Letcher for their delphin-viz tool that made it painless to include the DMRS representations.

Bridge Video and Text with Cascade Syntactic Structure

{xkp13, huang-k15, ysx15}@mails.tsinghua.edu.cn

Abstract

We present a video captioning approach that encodes features by progressively completing syntactic structure (*LSTM-CSS*). To construct basic syntactic structure (i.e., subject, predicate, and object), we use a Conditional Random Field to label semantic representations (i.e., motions, objects). We argue that in order to improve the comprehensiveness of the description, the local features within object regions can be used to generate complementary syntactic elements (e.g., attribute, adverbial). Inspired by redundancy of human receptors, we utilize a Region Proposal Network to focus on the object regions. To model the final temporal dynamics, Recurrent Neural Network with Path Embeddings is adopted. We demonstrate the effectiveness of *LSTM-CSS* on generating natural sentences: 42.3% and 28.5% in terms of BLEU@4 and METEOR. Superior performance when compared to state-of-the-art methods are reported on a large video description dataset (i.e., MSR-VTT-2016).

1 Introduction

Video has become a ubiquitous way of communication on the Internet, podcast channels, as well as mobile devices. Accelerated by the explosive spread of video data, automatic analysis of semantic video content remains a promising area. The advances of this task can provide comparatively favorable preconditions for subsequent tasks, such as video retrieval, human-perception analysis, keyframe recommendation(Chen et al., 2017). To encapsulate the informative dynamics in the video, researchers have started focusing on recognizing videos based on the predefined templates, such as (Kojima et al., 2002; Guadarrama et al., 2014). Rohrbach et al. (2013) learned a CRF to assemble between different components of the input video and generated descriptions for videos. Xu et al. (2015) utilized a unified framework that jointly models video and the corresponding text sentences.

Another line of work uses Recurrent Neural Network. In light of its success, the representations (e.g. key objects, locations, motions, and scenes) can be concatenated into an input sequence and then translated to a natural sentence (Donahue et al., 2015). Follow-up works investigate the modeling of not only video contents and their spatio-temporal relationships, but also the syntactical structure (Venugopalan et al., 2015). More recently, a visual-semantic embedding learning technique has been proposed to model video content and textual semantics as a regularizer in Long Short-Term Memory architecture (Pan et al., 2016). This was extended by (Hori et al., 2017) where they utilized a modality-dependent attention mechanism.

Over the past years, researchers have studied multiple strategies to effectively bridge the visual content and textual description based on some fresh ideas. (Pan et al., 2017) incorporated the transferred semantic attributes learned from images and videos into the *CNN plus RNN* framework. (Baraldi et al., 2017) proposed a novel LSTM cell which can modify the temporal connections of the encoding layer according to the identified discontinuity points among frames. (Kaufman et al., 2017) transferred the semantics of the selected reference clips to test clips, which keeps consistent and maintains temporal coherence. However, the existing methods fail to take advantage of the local constraints which can extract compressed features for generating complementary syntactic elements.

Input video:

Output Sentence:

- LSTM-CSS [ours]: a fashion show is going on the runway.
- Human: a woman is modelling clothes. / a fashion show with women walking. / fashion show runway walk involving several models.

Figure 1: Examples of video description generation

This paper proposes a novel deep architecture, named Cascade Syntactic Structure (CSS), which takes advantages of incorporating global representations and local object regions into sequence learning for video captioning. Take the given video in Figure 1 as an example, the object regions of interest can be extracted to depict primary objects with locations (e.g., "woman") while motions from global features convey the temporal dynamics (e.g., "walking", "showing"). As "fashion show" and "runway" are not in the motion and object candidate set, we believe it is the local features that convey this complementary information. This has facilitated video captioning to disentangle the global features (motions and objects) and local features (object regions) enabling independent specification of both within the generation process. Our exploration of object regions as a modality for video captioning complements recent advances. Concretely, we propose a hierarchical *CNN plus RNN* architecture to learn a low-dimensional joint embedding for global and local features. The Convolutional Neural Network (*CNN*) has two discriminatively trained streams, motion stream and object stream. The outputs of these two streams are motions and objects respectively, which are used by Conditional Random Field (*CRF*) (Lafferty et al., 2001) to formulate the basic syntactic structure. The Long Short-Term Memory Network, together with Path embeddings (i.e., *LSTM-PE*) is used to generate a final sentence with optimal semantic structure.

As the final performance of our description generation relies on the accuracy of motion classification and object detection, we argue that the two stream *CNN* needs to be discriminative enough to provide information for following sub-structures. Its output global representation (i.e., a triplet of motion and objects) is used to construct basic syntactic structure which determines the comprehensibility of a sentence. As actions in MSR-VTT-2016 dataset (Xu et al., 2016) have a small range of movement and 3D convolutional neural networks (*C3D*) (Tran et al., 2015) performs not well enough on these actions, we prefer to use Temporal Segment Networks (*TSN*) (Wang et al., 2016) to extract motion features with additional optical flows (Z. et al., 2017). A *CRF* model is then used to learn the optimal global representation which is sent to a Long Short-term Memory (*LSTM*) network. Inspired by object masks proposed by Mask R-CNN (He et al., 2017), we believe that local constraints (i.e. object regions) can contribute to generating more comprehensive information for the result. We apply region-based network to our object stream and the output local constraints will be directly sent to aforementioned *LSTM* for generating the final sentence. The path embeddings can model the relationship between word vectors and contribute to the prediction of next word. This will help our model to cope with some recursive structures (e.g., nested conjunctions). Its efficacy is analyzed in section 2. Given a video, our framework can generate a sentence invariant to recursive structures based on both global representations and local constraints extracted from the video.

Our main technical contributions are three-fold:

- We propose a multi-task convnet to learn local embedding and global embedding for objects, which outperforms, by a large margin, previous attempts that use deep convnets for learning only global features.

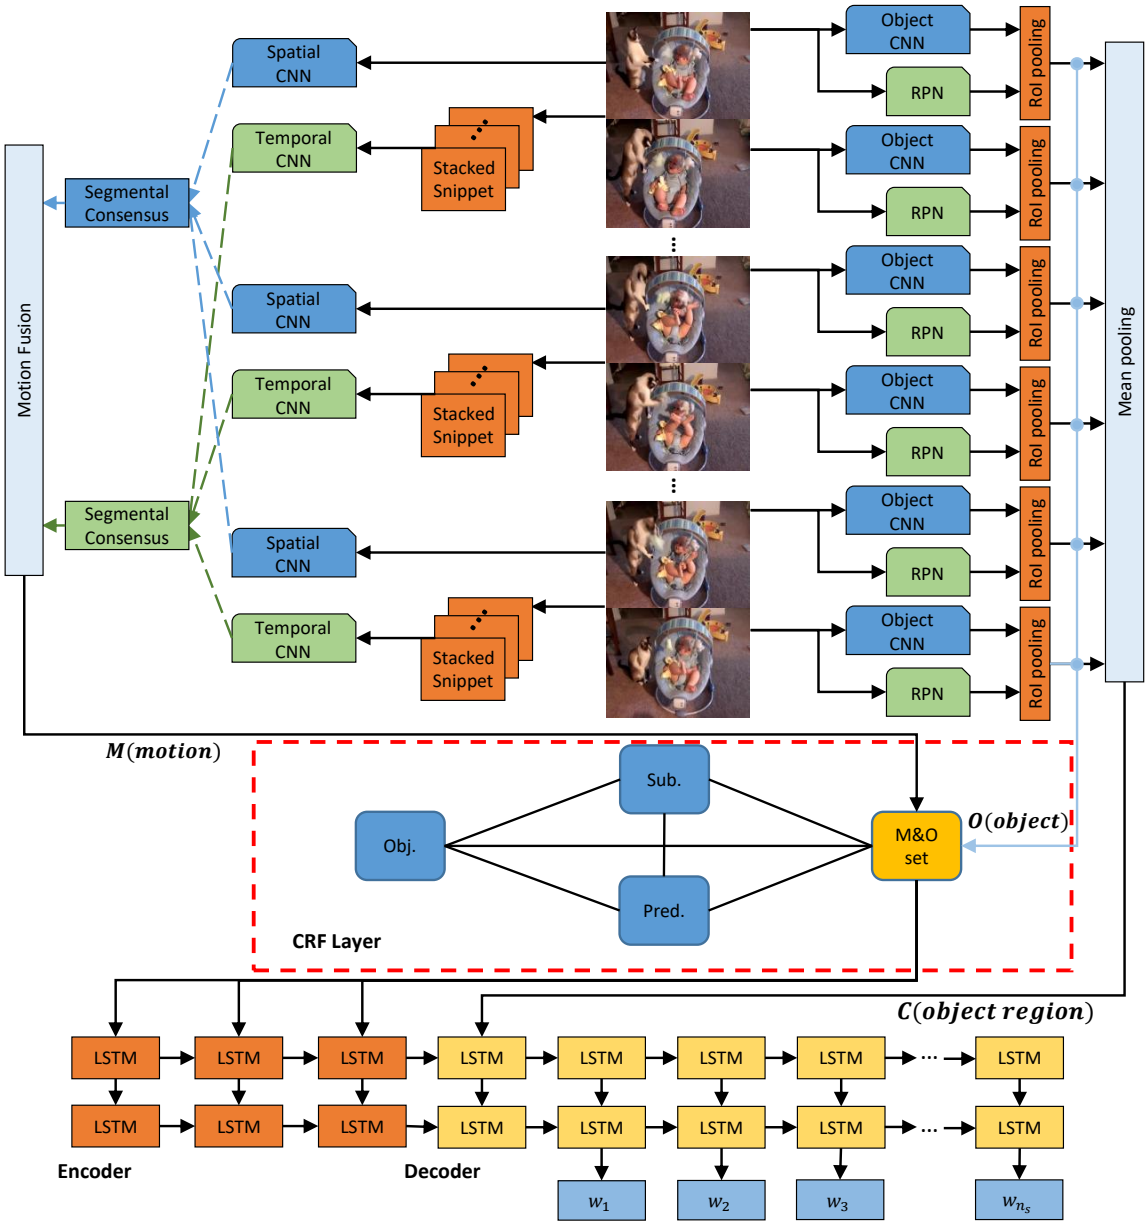

Figure 2: Hierarchical network combining global vectors (motions and objects) and local constraints (object regions) to generate video description with CRF and LSTM. Each sub-structure is trained independently (Section 2). M&O set denotes the semantic representation of motions and objects. Sub, Pred, and Obj denotes subject, predicate, and Object respectively in CRF.

- We empirically show the advantage of our unified video description generation framework whereby local constraints can be used to generate complementary syntactic elements, which can in turn improve the comprehensiveness of the description.
- We show that giving too much information to *LSTM* decoder could lead to chaos in the final structure. Hence, our method also input path embeddings to the decoder as context.

2 Video Captioning with Cascade Syntactic Structure

The goal of our network is to generate a sentence that describes the contents and their relationships. The problem is formulated as follows: given a video $\mathbf{V}$ with n_v segmented clips, our objective is to describe it by a textual sentence $\mathbf{S}$ with n_s words noted as $\mathbf{S} = \{\mathbf{w}_1, \cdots, \mathbf{w}_{n_s}\}$ with each word in it as

its column vector. $\mathbf{M} = \{\mathbf{m}_1, \cdots, \mathbf{m}_{n_m}\}$ and $\mathbf{O} = \{\mathbf{o}_1, \cdots, \mathbf{o}_{n_o}\}$ respectively denote the candidate of motions (resp. objects). $\mathbf{m}_i$ and $\mathbf{o}_i$ are represented by a one-hot vector. n_m and n_o refer to the size of the candidates. The local constraints $\mathbf{C}$ are D_c-dimensional local features, which are the mean pooling of selected frames in a video.

In the remaining of this section, we describe our network architecture and training methodology for generating a description for a specific video with local constraints. We first present two sub-structures of our architecture (Figure 2): 1) Feature extraction network (Section 2.1), which unify two discriminatively trained network streams that independently learn a motion (resp. object) feature embedding for a video; 2) Sentence generation network (Section 2.2), which uses CRF to learn optimal semantic representation and LSTM to generate the final description.

2.1 Feature extraction network

2.1.1 Motion stream

For each clip, the motion stream incorporates a Spatial CNN accepting a frame of RGB image and a Temporal CNN accepting a short snippet with 10 optical flow fields (5 for x directions and 5 for y directions) stacked in channel dimension extracted by warped TVL1 (Wang and Schmid, 2014). The frame sent to the Spatial CNN is randomly selected from a specific segment. The optical flow fields sent to the Temporal CNN are randomly selected from those computed for arbitrary two consecutive frames in each segment. Owing to the uncertain range of optical flow displacement, normalization is applied to constraint the displacements in $[0, 255]$ which is same as gray image. Thus, an optical flow field can be regarded as an image with 10 channels in the motion stream. The output of the motion stream, motion embedding $\mathbf{M}$, is averaged over all segments.

2.1.2 Object stream with local constraints

In conventional methods (Venugopalan et al., 2015), only embedding of motions and objects are extracted for LSTM. We believe that if visual features are sent to the LSTM, it is more generative to learn sentences for videos. In the human retina, visual features which represent natural signals formed by the peripheral receptors are very high-dimensional. However, we argue that the receptors to discover where and what objects only occupy a small fraction of the space of all possible receptor activation due to the statistical regularity and redundancy (Burton and Moorhead, 1987). We choose **ROI pooling** (Girshick, 2015) to extract local features specifically for the object regions as our local constraints.

As the object stream is the main sub-structure in our model, a careful training protocol is required to ensure convergence. For each clip, two images are randomly selected. For each input image, we train a network with aforementioned local constraints. The Object CNN can use many networks with the output discrete probability distribution $p = (p_0, \cdots, p_k, \cdots, p_{K-1})$, indexed by k. It is computed by a softmax layer over K object classes. The RPN network is a stack of convolutional filters of different sizes. Its outputs are the offsets of object regions, $r^k = (r^k_x, r^k_y, r^k_w, r^k_h)$, for the kth object class. The network can be described with a function $f(\cdot)$ minimising:

$$L = m + \sum_i L_{cls} + \lambda \sum_i L_{loc} \tag{1}$$

where m is a margin promoting convergence and i is the index of object region. The confidence loss L_{cls} is log loss for true class for each region. The location loss L_{loc} is the Smooth L1 loss (Girshick, 2015) between the predicted region and the ground truth region. Local constraint $\mathbf{C}$ (features in regions) and object embedding $\mathbf{O}$ are the output of object stream. Use of local Constraints is later shown to yield significant performance gain (Section 3.4.1).

2.2 Sentence generation

2.2.1 CRF: basic syntactic structure

The sentence generation network comprises two parts: CRF and LSTM. For CRF model, given $\mathbf{z} = \mathbf{M} \cup \mathbf{O}$ as input, let $\mathbf{y} = \{y_1, \cdots, y_{n_g}\}, n_g = n_m + n_s$ represents the label sequence of them, use the

following standard energy formulation:

$$E(\mathbf{y}, \mathbf{z}) = \sum_{i=1}^{n_g} E^u(y_i; \mathbf{z}) + \sum_{i,j} E^p(y_i, y_j) \tag{2}$$

where the first term defines the sum of quadratic unary terms and the second term describes the relationship between pairs of (y_i, y_j) (Hu et al., 2016).

Corresponding to our predicted $\mathbf{y}^*$, we rearrange $\mathbf{z}$ for optimal semantic representation $\mathbf{z}^*$. It is sent to the following LSTM model as well as local constraints $\mathbf{C}$. The LSTM model is based on an encoder-decoder framework (Sutskever et al., 2014). The encoder computes a intermediate representation $\mathbf{e}$ for the input semantic representation $\mathbf{z}^*$. Based on encoded intermediate representation, the decoder generates a translation, one target word at a time. The $\mathbf{S}$ is the output of the decoder. The log conditional probability is as follows:

$$\log\ p(\mathbf{S}|\mathbf{z}^*) = \sum_{t=1}^{n_s} \log\ p(\mathbf{w}_t|\mathbf{w}_{<t}, \mathbf{e}) \tag{3}$$

The objective is formulated as:

$$L = \sum_{(\mathbf{z}^*, \mathbf{S}) \in \mathbb{D}} -\log\ p(\mathbf{S}|\mathbf{z}^*) \tag{4}$$

where $\mathbb{D}$ refers to the parallel training corpus of source and target representation pairs $(\mathbf{z}^*, \mathbf{S})$.

2.2.2 LSTM-PE: final syntactic structure

The encoder and decoder share a common LSTM network with similar forward and backpropagation process. The difference is the decoder starts from the intermediate representation rather than zero states. In addition to the intermediate representation, the local constraints $\mathbf{C}$ are injected at the initial time of the decoder to inform the whole memory cells in LSTM. For timestep t, $\mathbf{x}_t$, $\mathbf{y}_t$ and $\mathbf{h}_t$ are the input vector, output vector, and hidden state respectively.

$$\begin{aligned}
&\mathbf{g}_t = \phi(\mathbf{U}_g\mathbf{x}_t + \mathbf{W}_g\mathbf{h}_{t-1} + \mathbf{b}_g), \mathbf{i}_t = \sigma(\mathbf{U}_i\mathbf{x}_t + \mathbf{W}_i\mathbf{h}_{t-1} + \mathbf{b}_i),\\
&\mathbf{f}_t = \sigma(\mathbf{U}_f\mathbf{x}_t + \mathbf{W}_f\mathbf{h}_{t-1} + \mathbf{b}_f), \mathbf{c}_t = \mathbf{g}_t \odot \mathbf{i}_t + \mathbf{c}_{t-1} \odot \mathbf{f}_t,\\
&\mathbf{o}_t = \sigma(\mathbf{U}_o\mathbf{x}_t + \mathbf{W}_o\mathbf{h}_{t-1} + \mathbf{b}_o), \mathbf{h}_t = \phi(\mathbf{c}_t) \odot \mathbf{o}_t,
\end{aligned} \tag{5}$$

where $\mathbf{g}_t$, $\mathbf{i}_t$, $\mathbf{f}_t$, $\mathbf{c}_t$, $\mathbf{o}_t$, and $\mathbf{h}_t$ are cell input, input gate, forget gate, cell state, output gate, and cell output of the LSTM. σ is the element-wise sigmoid function and $\odot$ is the element-wise product. $\mathbf{U}$ are the weight matrices of different gates for input $\mathbf{x}_t$, $\mathbf{W}$ are the recurrent weight matrices for hidden state $\mathbf{h}_t$, and $\mathbf{b}$ are bias vectors.

To make full use of aforementioned optimal label sequence $\mathbf{y}^*$, we learn the path embeddings from sequences (Chen and Manning, 2014) and use them as context (Jiang Guo and Xu, 2016) for decoder. We pre-train path embeddings together with word embeddings. At the initial time, the path embeddings stand for generic dependencies between labels (i.e., subject, predicate, and object). The path embeddings are then enlarged and refined during the learning phase. Let $\mathbf{P}_t$ denote the path embeddings, which is the concatenation of vectors representing labels:

$$\begin{aligned}
&\mathbf{p}_{-1} = [\mathbf{y}^*],\\
&\mathbf{p}_t = [\mathbf{p}_{t-1}\mathbf{y}_{t-1}],
\end{aligned} \tag{6}$$

The LSTM updating procedure of decoder is as:

$$\begin{aligned}
&\mathbf{x}_{-1} = \mathbf{U}_C\mathbf{C},\\
&\mathbf{x}_t = \mathbf{U}_s\mathbf{e},\\
&\mathbf{h}_t = f(\mathbf{W}_i\mathbf{x}_t + \mathbf{W}_h\mathbf{h}_{t-1} + \mathbf{W}_p\mathbf{P}_t),\\
&\mathbf{y}_t = softmax(\mathbf{W}_o\mathbf{h}_t),
\end{aligned} \tag{7}$$

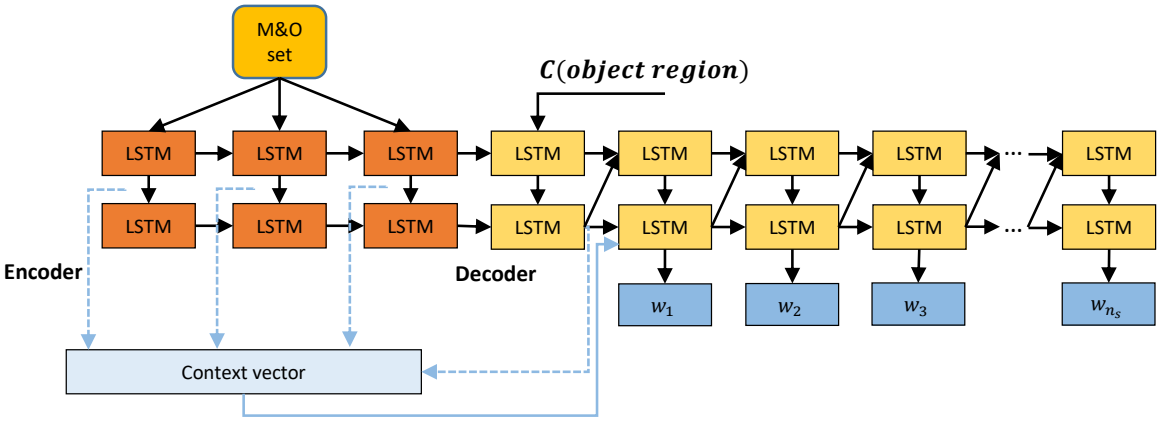

Figure 3: Detail architecture of LSTM-PE (The input of encoders is from M&O set, Local constraints $\mathbf{C}$ are input to initialize decoder as complementary information, $\mathbf{p}_t$ goes from the output layer to the input layer).

Figure 4: Examples of generated captions on MSR-VTT. GT1 and GT2 are ground truth captions.

where $\mathbf{U}_C$ and $\mathbf{U}_s$ are the transformation matrices for local constraints and intermediate representation respectively. $\mathbf{W}_i$, $\mathbf{W}_h$, $\mathbf{W}_p$, $\mathbf{W}_o$ are the weight matrices. f is the updating function within LSTM unit. We also apply an attention mechanism proposed by (Bahdanau et al., 2015) to LSTM units. The details can be illustrated in Figure 3. The output of LSTM is the final sentence $\mathbf{S}$ generated for video $\mathbf{V}$.

3 EXPERIMENTS AND DISCUSSION

We evaluate and compare our proposed LSTM-CSS with state-of-the-art approaches (Section 3.3) and analyze the effect of local constraints (Section 3.4.1). We also qualitatively analyze the effect of path embeddings (Section 3.4.2).

3.1 Datasets and settings

Dataset. We use MSR-VTT-2016 (Xu et al., 2016) which contains 10,000 web-collected video clips. There are roughly 20 available descriptions per video. In our experiment, our video captioning models are trained, hyperparameter selected, and evaluated using the official partitioned training, validation, and test set with 65%:5%:30% corresponding to 6,513, 497, 2,990 video clips, respectively.

Network detail. The motion stream is a reproduced model of TSN, fine-tuned over MSR-VTT-2016. For a single CNN, it closely resembles BN Inception network (Ioffe and Szegedy, 2015). We take the output of softmax layer from the combination of multiple CNNs as the motion representation $\mathbf{M}$. The object

Model	BLEU@4	METEOR	ROUGE-L	CIDEr-D

LSTM-CSS-E	42.0	27.0	60.2	46.7
LSTM-CSS	42.3	28.5	61.2	46.5

Table 2: Captioning accuracy of LSTM-CSS, LSTM-SR, LSTM-CSS-E, LSTM-CSS-N, and LSTM-CSS-E-N on MSR-VTT-2016 test set

stream is trained from scratch, using an COCO (Lin et al., 2014) to evenly detect objects $\mathbf{O}$ belonging to 90 classes and extract local features. In each video, 5 frames are selected and local constraints $\mathbf{C}$ are the average of local features extracted from these frames. We take the output of softmax layer and output of 4096-way fc6 layer from the Resnet-50 (He et al., 2016) as $\mathbf{O}$ and $\mathbf{C}$ respectively. The margin m in Equation 1 is set to 1. The dimension of the input and hidden layers in LSTM are both set to 512. In test stage, we set the beam size to 4 in beam search.

Evaluation metric. We adopt four common metrics in video captioning task for quantitative evaluation of our proposed model: BLEU@4, METEOR, CIDEr-D, and ROUGE-L (from MS-COCO evaluation server (Chen et al., 2015)).

3.2 Compared methods

We compare our LSTM-CSS model with the following methods to evaluate the efficacy of our model.

SA (**S**oft-**A**ttention) (Yao et al., 2015): utilizes a weighted attention mechanism to dynamically attend to specific temporal segments of the video with the input of both frame representation (2-D CNN) and video clip representation (3-D CNN). In the test, the frame representation is extracted from the same feature, while the video clip representation is extracted from a C3D network.

S2VT (**S**equence to **S**equence - **V**ideo to **T**ext) (Venugopalan et al., 2015): incorporates both RGB and optical flow inputs. The encoding and decoding of inputs and word representations are jointly learned. In the test, the RGB and optical flows are extracted from same structure with ours.

MTLM (**M**ulti-**T**ask **L**earning **M**ethod) (Pasunuru and Bansal, 2017): improves video captioning by utilizing sharing representations with a temporally-directed unsupervised video prediction task to learn richer context-aware video encoder representations, and a logically-directed language entailment generation task to learn better caption decoder. In the test, the representation is extracted from same structure with ours.

WS (**W**eakly **S**upervised) (Shen et al., 2017): links video regions with lexical labels by utilizing lexical fully convolutional neural networks with weakly supervised learning. It also trains a sequence-to-sequence language model with the weakly supervised information. In the test, the CNN model is trained starting from the same structure with ours.

We also compare the baseline criterion and top-3 rank (i.e. v2t_navigator, Aalto, and VideoLAB) results proposed by (Xu et al., 2016).

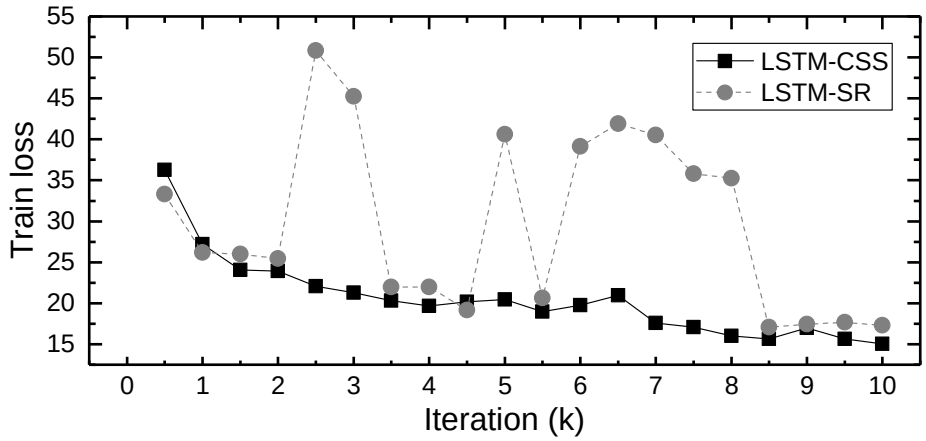

Figure 5: Train loss of LSTM-CSS and LSTM-SR

3.3 Performance comparison

Table 1 shows our primary results on MSR-VTT-2016 dataset. Overall, our proposed LSTM-CSS outperforms the other methods. Specifically, it reaches 42.3% BLEU@4, which makes the relative improvement over the two state-of-the-art methods S2VT by 20.1% and MTLM by 3.7%, respectively. We are also the new Rank1 on the MSR-VTT-2016 leaderboard, based on their ranking criteria. Figure 4 shows several example captions generated by our approach for MSR-VTT-2016 videos. The result indicates the utilizing of local constraints can contribute to the generation of comprehensive sentences.

In terms of BLEU scores, our method obtains bigger gains than others. Since the preference of longer captions tend to obtain lower BLEU scores, we argue that our method can generate comprehensive but concise captions. In terms of METEOR scores, our method does not perform best. From the aforementioned example, we can see that the subject of our caption is "fashion show" and the adverbial is "on the runway". In this example, there are no reference captions that have same syntactic structure with our caption. This may influence our recall rate and further affect the METEOR score.

3.4 Ablation study

3.4.1 Effect of Complementary syntactic elements

Our model **LSTM-CSS** depicted in Figure 2 uses local constraints to construct the final syntactic structure with complementary elements. To perform the ablation studies for our local constraints, we also test degraded versions of our model as follows: 1) **LSTM-SR**: the input of LSTM are semantic representation of motions and objects. Only global features are included; 2) **LSTM-CSS-E**: the local constraints are added as another input modal of LSTM and they are input to the encoder; 3) **LSTM-CSS-N**: the network without attention mechanism; 4) **LSTM-CSS-E-N**: the network remove attention mechanism from **LSTM-CSS-E**; 5) **LSTM-CSS w/o PE**: the network remove path embeddings from **LSTM-CSS**.

Figure 5 shows that LSTM-CSS achieves better training loss than LSTM-SR, which shows the training stability of LSTM-CSS. We can draw a conclusion that the local constraints can contribute to ensuring the convergence rate and alleviate the fluctuation of training loss. Table 2 summarizes the results on the MSR-VTT-2016 test set. As can be seen, in all the cases, LSTM-SR performs worse than the models with local features. Base on these results, the validation of local constraints is certificated. From the comparison of LSTM-CSS-E-N and LSTM-CSS-N, we can conclude that without attention mechanism, modeling global and local information at the same level will weaken the ability of local constraints. We can also find that LSTM-CSS and LSTM-CSS-E nearly perform equally. Therefore, we believe that attention mechanism can make the LSTM translation network focus on relevant content and alleviate the influence of the places where local constraints are input.

LSTM-CSS: a woman is talking on a show.
LSTM-CSS w/o PE: a woman is talking.

LSTM-CSS: a man is talking about a man who in black.
LSTM-CSS w/o PE: a man is talking about.

Figure 6: Examples with recursive syntactic structure

3.4.2 Qualitative analysis of path embeddings

As we can see, in the MSR-VTT-2016 dataset, some videos are about news, products, slides. In fact, people appearing in these videos are not the subject. Through visual analyzing, existing video caption algorithms can tell people are talking but not understand the content they talking about. Though some advanced methods can find both introducers and their contents, they are hard to model the relationship and organize sentences. In cases like 'someone is talking about something', our method can generate a completed sentence as shown in Figure 6. We can also see that in sentences generated by LSTM-CSS w/o PE, the content people shows are not included.

4 Conclusions

Inspired by the human receptors for object detection, we propose a hierarchical model for video captioning. Our model not only precisely captures motions and objects in videos but also learns a sentence constrained by cascade syntactic structure (*CRF* for the basic structure and *LSTM-PE* for the complementary elements). The experimental results demonstrate that our model performs on par with state-of-the-art methods on a large video description dataset in terms of accuracy.

However, the structure of generated sentence is relatively fixed for all videos. It should be better to improve the diversity of the sentences considering different object locations and make the syntactic structure more logical. We will address this issue in our future work.

Abstract

This paper is an initial study on multi-task and multi-lingual joint learning for lexical utterance classification. A major problem in constructing lexical utterance classification modules for spoken dialogue systems is that individual data resources are often limited or unbalanced among tasks and/or languages. Various studies have examined joint learning using neural-network-based shared modeling; however, previous joint learning studies focused on either cross-task or cross-lingual knowledge transfer. In order to simultaneously support both multi-task and multi-lingual joint learning, our idea is to explicitly divide state-of-the-art neural lexical utterance classification into language-specific components that can be shared between different tasks and task-specific components that can be shared between different languages. In addition, in order to effectively transfer knowledge between different task data sets and different language data sets, this paper proposes a partially-shared modeling method that possesses both shared components and components specific to individual data sets. We demonstrate the effectiveness of the proposed adversarial training using Japanese and English data sets with three different lexical utterance classification tasks.

1 Introduction

Modern spoken dialogue systems use multiple lexical utterance classification modules that can detect dialogue act (Stolcke et al., 2000; Khanpour et al., 2016), intent (Tur et al., 2011), domain (Xu and Sarikaya, 2014), question type (Wu et al., 2005), etc. to properly understand natural languages. The modules are typically trained using the machine learning technologies developed for individual language-specific systems (Higashinaka et al., 2014). A common issue is that the data resources for such individual training are often limited or unbalanced among different tasks and/or different languages.

For modeling lexical utterance classification, various modeling methods have been examined. Recently, neural lexical utterance classification, which is a fully neural-network-based modeling method, has demonstrated substantial performance without the use of manual feature engineering. The networks include long short-term memory recurrent neural networks (LSTM-RNNs) (Ravuri and Stolcke, 2015b; Ravuri and Stolcke, 2015a; Ravuri and Stolcke, 2016), convolution neural networks (Kim, 2014), and more advanced networks (Zhou et al., 2016a; Yang et al., 2016; Sawada et al., 2017).

In addition, neural networks are suitable for performing joint learning; the paucity of data is tackled by transferring knowledge between different tasks or different languages. Various joint learning methods have been examined for leveraging different tasks or different language data sets in the natural language processing field. Multi-task joint learning can transfer knowledge between tasks by sharing task-invariant layers (Collobert and Weston, 2008; Liu et al., 2015; Liu et al., 2016c; Zhang and Weng, 2016). In lexical utterance classification, multi-task joint learning has been shown to effectively improve individual tasks (Liu et al., 2016b; Liu et al., 2016a; Liu et al., 2017). In addition, multi-lingual joint learning can transfer knowledge between languages, mainly from the resource-rich language to the resource-poor language. The knowledge transfer is achieved by learning common semantic representations for different

Proceedings of the 27th International Conference on Computational Linguistics, pages 3586–3596
Santa Fe, New Mexico, USA, August 20-26, 2018.

languages. Usually, word-aligned or sentence-aligned parallel data sets are employed for joint learning (Guo et al., 2016; Duong et al., 2016)

However, most existing joint learning approaches focus only on cross-tasks or cross-lingual knowledge transfer. In fact, task-aligned multi-lingual data sets have been rarely utilized for joint learning (Mogadala and Rettinger, 2016; Pappas and Popescu-Belis, 2017). We can expect to enhance lexical utterance classification performance by achieving effective knowledge transfer among both different tasks and different languages.

In this paper, we propose multi-task and multi-lingual joint learning; it can enhance neural lexical utterance classification by flexibly transferring knowledge among both different tasks and different languages. The proposed method is closely related to multi-task sequence-to-sequence learning (Luong et al., 2016) including many-to-many neural machine translation (Firat et al., 2016; Firat et al., 2017; Schwenk and Douze, 2017). While input and output components are easily distinguished in sequence-to-sequence models, neural lexical utterance classification methods are not explicitly divided into input and output components. Our idea is to divide the neural lexical utterance classification into two components. The language-specific components converts words to hidden representations while task-specific components convert the hidden representations into prediction probabilities. The former can be shared between different tasks and the latter can be shared between different languages.

In addition, in order to perform effective joint learning by simultaneously using multi-task and multi-lingual data sets, this paper examines two joint modeling strategies. The fully-shared modeling strategy is often used in various joint learning methods. Fully-shared modeling can share knowledge between tasks or languages based on task-invariant components and language-invariant components, however, classification performance in some data sets is deteriorated. Therefore, this paper proposes the partially-shared modeling strategy; it introduces not only shared components between tasks or languages but also exclusive components that handle task-language combinations. It can be expected that the latter are suitable for multi-task and multi-lingual joint learning since they allow us to accumulate just shareable knowledge.

Main contributions are summarized as follows.

- This paper proposes multi-task and multi-lingual joint learning of neural lexical utterance classification. For neural lexical utterance classification, we introduce a state-of-the-art model structure based on bidirectional LSTM-RNNs with a self-attention mechanism. We demonstrate the superiority of multi-task and multi-lingual joint learning over multi-task joint learning and multi-lingual joint learning.

- This paper proposes partially-shared modeling for multi-task and multi-lingual joint learning. Partially-shared modeling can be utilized for various neural network based joint learning schemes. We demonstrate the superiority of partially-shared modeling over fully-shared modeling. In addition, we reveal the properties of partially-shared modeling.

- This paper introduces a new corpus for evaluating multi-task and multi-lingual lexical utterance classification methods. The corpus includes Japanese and English data sets with three different lexical utterance classification tasks. The tasks are dialogue act classification, extended named entity classification (Sekine and Nobata, 2004; Higashinaka et al., 2012), and question type classification.

2 Neural Lexical Utterance Classification

This section details neural lexical utterance classification. Lexical utterance classification is the problem of determining the correct label $l \in \{l_1, \cdots, l_K\}$ of given utterance $\mathcal{W} = \{w_1, \cdots, w_T\}$. In neural lexical utterance classification, conditional probabilities for each label given utterance, $P(l|\mathcal{W}, \mathbf{\Theta})$, can be modeled by neural networks in an end-to-end manner where $\mathbf{\Theta}$ is the model parameter. Various model structures can be used for neural lexical utterance classification. In this work, we use bidirectional LSTM-RNNs (BLSTM-RNNs) with a self-attention mechanism (Yang et al., 2016; Zhou et al., 2016b).

2.1 Modeling

In our neural lexical utterance classification, each word in input utterance $\mathcal{W}$ is first converted into a continuous representation. The continuous representation of the t-th word is defined as:

$$\boldsymbol{w}_t = \texttt{EMBED}(w_t; \boldsymbol{\theta}_{\texttt{w}}), \tag{1}$$

where $\texttt{EMBED}()$ is a linear transformational function to embed a word into a continuous vector and $\boldsymbol{\theta}_{\texttt{w}}$ is the trainable parameter. Next, each word representation is converted into a hidden representation that takes neighboring word context information into consideration. The hidden representation for the t-th word is calculated as:

$$\boldsymbol{h}_t = \texttt{BLSTM}(\{\boldsymbol{w}_1, \cdots, \boldsymbol{w}_T\}, t; \boldsymbol{\theta}_{\texttt{h}}), \tag{2}$$

where $\texttt{BLSTM}()$ is a function of the BLSTM-RNN layer and $\boldsymbol{\theta}_{\texttt{h}}$ is the trainable parameter.

The hidden representations are summarized as a sentence representation by using a self-attention mechanism that can consider the importance of individual hidden representations. The sentence continuous representation $\boldsymbol{s}$ is calculated as:

$$\boldsymbol{z}_t = \texttt{tanh}(\boldsymbol{h}_t; \boldsymbol{\theta}_{\texttt{z}}), \tag{3}$$

$$\boldsymbol{s} = \sum_{t=1}^{T} \frac{\exp(\boldsymbol{z}_t^\top \bar{\boldsymbol{z}})}{\Sigma_{j=1}^{T} \exp(\boldsymbol{z}_j^\top \bar{\boldsymbol{z}})} \boldsymbol{h}_t, \tag{4}$$

where $\texttt{tanh}()$ is a non-linear transformational function with tanh activation, $\boldsymbol{\theta}_{\texttt{z}}$ is the trainable parameter, and $\bar{\boldsymbol{z}}$ is a trainable context vector, which is used for measuring the importance of individual hidden representations. The output layer produces predicted probabilities $\boldsymbol{O}$ by:

$$\boldsymbol{o} = \texttt{LINEAR}(\boldsymbol{s}; \boldsymbol{\theta}_{\texttt{o}}), \tag{5}$$

$$\boldsymbol{O} = \texttt{SOFTMAX}(\boldsymbol{o}), \tag{6}$$

where $\texttt{LINEAR}()$ is a linear transformational function and $\boldsymbol{\theta}_{\texttt{o}}$ is the trainable parameter. $\texttt{SOFTMAX}()$ is a softmax activation to convert $\boldsymbol{o}$ into predicted probabilities. The k-th dimension in $\boldsymbol{O}$ corresponds to $P(l_k|\mathcal{W}, \boldsymbol{\Theta})$, and $\boldsymbol{\Theta}$ corresponds to $\{\boldsymbol{\theta}_{\texttt{w}}, \boldsymbol{\theta}_{\texttt{h}}, \boldsymbol{\theta}_{\texttt{z}}, \bar{\boldsymbol{z}}, \boldsymbol{\theta}_{\texttt{o}}\}$.

2.2 Optimization

The parameter can be optimized by minimizing the cross entropy between reference and estimated probabilities:

$$\hat{\boldsymbol{\Theta}} = \operatorname*{argmin}_{\boldsymbol{\Theta}} - \sum_{\mathcal{W} \in \mathcal{D}} \sum_{k=1}^{K} \hat{\boldsymbol{O}}_{\mathcal{W}}^{l_k} \log \boldsymbol{O}_{\mathcal{W}}^{l_k}, \tag{7}$$

where $\hat{\boldsymbol{O}}_{\mathcal{W}}^{l_k}$ and $\boldsymbol{O}_{\mathcal{W}}^{l_k}$ are, respectively, the reference probability and the estimated probability of label l_k for $\mathcal{W}$. $\mathcal{D}$ denotes the training data set.

3 Multi-task and Multi-lingual Neural Lexical Utterance Classification

This section presents multi-task and multi-lingual joint learning of neural lexical utterance classification. We split neural lexical utterance classification by considering two types of components: language-specific components and task-specific components.

Language-specific components can be shared between tasks, where words in an utterance are converted into hidden representations. The language-specific components can be simplified as:

$$\boldsymbol{h}_t = \texttt{W2H}(\mathcal{W}, t; \boldsymbol{\Theta}_{\texttt{W2H}}), \tag{8}$$

where $\texttt{W2H}()$ is a function that compiles Eqs. (1) and (2). $\boldsymbol{\Theta}_{\texttt{W2H}}$ corresponds to $\{\boldsymbol{\theta}_{\texttt{w}}, \boldsymbol{\theta}_{\texttt{h}}\}$.

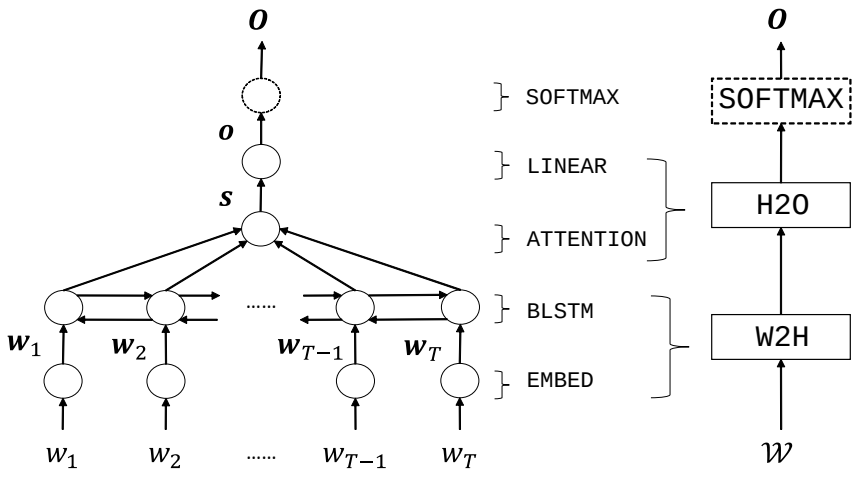

Figure 1: Neural lexical utterance classification and its simplified model structure.

Task-specific components can be shared between languages, where hidden representations are converted into predicted probabilities. The task-specific components can be simplified as:

$$\boldsymbol{o} = \texttt{H2O}(\{\boldsymbol{h}_1, \cdots, \boldsymbol{h}_T\}; \boldsymbol{\Theta}_{\texttt{H2O}}), \tag{9}$$

where $\texttt{H2O}()$ is a function that compiles Eqs. (3) to (5) and $\boldsymbol{\Theta}_{\texttt{H2O}}$ represents $\{\boldsymbol{\theta}_{\texttt{z}}, \bar{\boldsymbol{z}}, \boldsymbol{\theta}_{\texttt{o}}\}$.

Figure 1 shows a detailed model structure and a simplified model structure of BLSTM-RNN with the attention mechanism. Both the dotted line square and a dotted line circle represent softmax activation. White squares are simplified components in the neural lexical utterance classification.

3.1 Fully-shared Modeling

Fully-shared modeling forms universal hidden representations that are completely invariant to differences in tasks or languages. In this case, language-specific components are fully-shared between the same language data sets and task-specific components are fully-shared between the same task data sets. The t-th universal hidden representation is calculated as:

$$\boldsymbol{h}_t = \texttt{W2H}(\mathcal{W}^{(i)}, t; \boldsymbol{\Theta}^{(i)}_{\texttt{W2H}}), \tag{10}$$

where $\boldsymbol{\Theta}^{(i)}_{\texttt{W2H}}$ is the shared parameter that handles the i-th language and $\mathcal{W}^{(i)}$ denotes the input utterance in the i-th language. The universal hidden representation can be input to any task-specific component. The predicted probabilities for the j-th task, denoted as $\boldsymbol{O}^{(j)}$, are calculated as:

$$\boldsymbol{o}^{(j)} = \texttt{H2O}(\{\boldsymbol{h}_1, \cdots, \boldsymbol{h}_T\}; \boldsymbol{\Theta}^{(j)}_{\texttt{H2O}}), \tag{11}$$

$$\boldsymbol{O}^{(j)} = \texttt{SOFTMAX}(\boldsymbol{o}^{(j)}), \tag{12}$$

where $\boldsymbol{\Theta}^{(j)}_{\texttt{H2O}}$ is the task-specific shared parameter that handles the j-th task.

Figure 2 shows the model structure of multi-task fully-shared modeling for a language and two tasks. Figure 3 shows the model structure of multi-lingual fully-shared modeling for two languages and a task. Figure 4 shows the model structure of multi-task and multi-lingual fully-shared modeling for two tasks and two languages. Gray squares are shared components between languages or between tasks, and white squares are non-shared components.

3.2 Partially-shared Modeling

Partially-shared modeling introduces not only shared components between tasks or languages but also exclusive components that handle task-language combinations. Therefore, our hidden representations

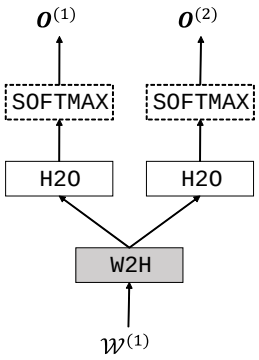

Figure 2: Multi-task fully-shared modeling.

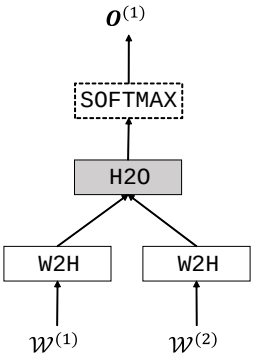

Figure 3: Multi-lingual fully-shared modeling.

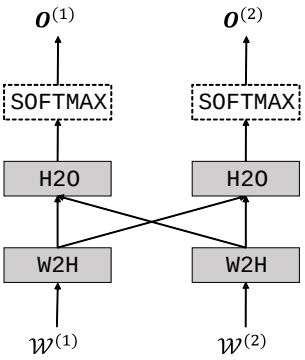

Figure 4: Multi-task and multi-lingual fully-shared modeling.

are designed to support such combinations. The t-th hidden representation for the combination of the i-th language and the j-th task, denoted as $\boldsymbol{h}_t^{(i,j)}$, is calculated as:

$$\bar{\boldsymbol{h}}_t^{(i,j)} = \texttt{W2H}(\mathcal{W}^{(i,j)}, t; \boldsymbol{\Theta}_{\texttt{W2H}}^{(i,j)}), \tag{13}$$

$$\bar{\boldsymbol{h}}_t^{(i)} = \texttt{W2H}(\mathcal{W}^{(i,j)}, t; \boldsymbol{\Theta}_{\texttt{W2H}}^{(i)}), \tag{14}$$

$$\boldsymbol{h}_t^{(i,j)} = \bar{\boldsymbol{h}}_t^{(i,j)} + \bar{\boldsymbol{h}}_t^{(i)}, \tag{15}$$

where $\boldsymbol{\Theta}_{\texttt{W2H}}^{(i,j)}$ is the exclusive parameter specific to the combination of the i-th language and the j-th task, and $\boldsymbol{\Theta}_{\texttt{W2H}}^{(i)}$ is the shared parameter that handles the i-th language. The predicted probabilities for the combination of the i-th language and j-th task, denoted as $\boldsymbol{O}^{(i,j)}$, are calculated as:

$$\bar{\boldsymbol{o}}^{(i,j)} = \texttt{H2O}(\{\boldsymbol{h}_1^{(i,j)}, \cdots, \boldsymbol{h}_T^{(i,j)}\}; \boldsymbol{\Theta}_{\texttt{H2O}}^{(i,j)}), \tag{16}$$

$$\bar{\boldsymbol{o}}^{(j)} = \texttt{H2O}(\{\boldsymbol{h}_1^{(i,j)}, \cdots, \boldsymbol{h}_T^{(i,j)}\}; \boldsymbol{\Theta}_{\texttt{H2O}}^{(j)}), \tag{17}$$

$$\boldsymbol{O}^{(i,j)} = \texttt{SOFTMAX}(\bar{\boldsymbol{o}}^{(i,j)} + \bar{\boldsymbol{o}}^{(j)}), \tag{18}$$

where $\boldsymbol{\Theta}_{\texttt{H2O}}^{(i,j)}$ is the exclusive parameter specific to the combination of the i-th language and the j-th task, and $\boldsymbol{\Theta}_{\texttt{H2O}}^{(j)}$ is the shared parameter that handles the j-th task.

Figure 5 shows the model structure of multi-task partially-shared modeling for a language and two tasks. Figure 6 shows the model structure of multi-lingual partially-shared modeling for two tasks and a language. Figure 7 shows the model structure of multi-task and multi-lingual partially-shared modeling for two tasks and two languages. Note that Figures 5-7 correspond to Figures 2-4.

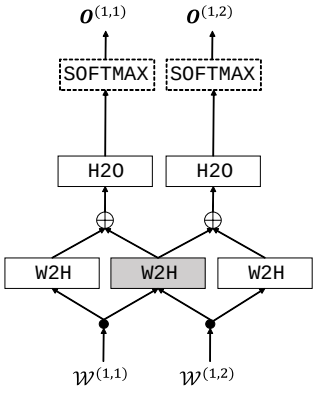

Figure 5: Multi-task partially-shared modeling.

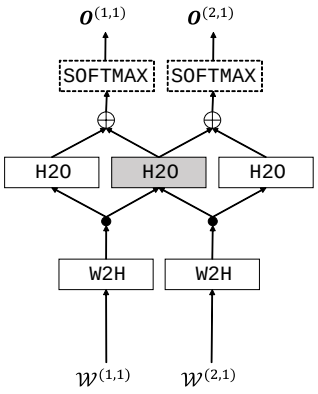

Figure 6: Multi-lingual partially-shared modeling.

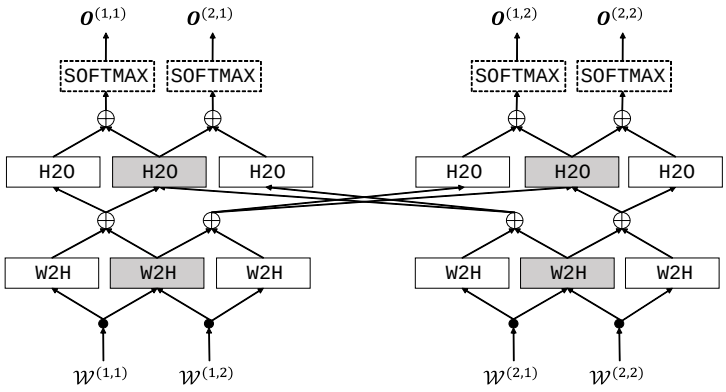

Figure 7: Multi-task and multi-lingual partially-shared modeling.

3.3 Joint Optimization

In multi-task and multi-lingual joint leaning, all parameters, denoted as $\mathbf{\Theta}$, can be jointly optimized by using all data sets. Given I languages and J tasks, joint optimization of the model parameter $\mathbf{\Theta}$ follows:

$$\hat{\mathbf{\Theta}} = \underset{\mathbf{\Theta}}{\operatorname{argmin}} - \sum_{i=1}^{I} \sum_{j=1}^{J} \sum_{\mathcal{W} \in \mathcal{D}^{(i,j)}} \sum_{k=1}^{K^{(j)}} \hat{\boldsymbol{O}}_{\mathcal{W}}^{l_k} \log \boldsymbol{O}_{\mathcal{W}}^{l_k}, \tag{19}$$

where $\mathcal{D}^{(i,j)}$ denotes the training data set for the combination of the i-th language and the j-th task, and $|\mathcal{D}^{(i,j)}|$ means the number of utterances. $K^{(j)}$ represents the number of labels in the j-th task.

Basically, $\mathbf{\Theta}$ can be gradually updated by repeating mini-batch training using individual data sets. In this case, an optimizer with a learning rate is prepared for individual data sets and individual learning rates fall when the cross entropy loss for a target validation data set increases. The training epoch is stopped when the averaged loss for all validation data sets is not improved. Details of the joint optimization procedure are shown in **Algorithm 1**.

4 Experiments

4.1 Data

Our experiments employed Japanese (Ja) and English (En) data sets created for three different lexical utterance classification tasks. The tasks were dialogue act (DA) classification, extended named entity (ENE) classification (Sekine and Nobata, 2004; Higashinaka et al., 2012), and question type (QT) classification; natural language texts were used for the lexical utterances and individual label sets were unified

Algorithm 1 :Joint Optimization procedure of multi-task and multi-lingual joint leaning.

Input: Training data sets $\mathcal{D}^{(1,1)}, \cdots, \mathcal{D}^{(1,J)}, \cdots, \mathcal{D}^{(I,1)}, \cdots, \mathcal{D}^{(I,J)}$
Validation data sets $\bar{\mathcal{D}}^{(1,1)}, \cdots, \bar{\mathcal{D}}^{(1,J)}, \cdots, \bar{\mathcal{D}}^{(I,1)}, \cdots, \bar{\mathcal{D}}^{(I,J)}$
Output: Model parameter $\mathbf{\Theta}$

end while
return $\mathbf{\Theta}$

Table 1: Number of utterances in individual data sets.

Language	Task	#labels	Train	Valid	Test
Japanese	DA	28	201,092	4,190	4,190
	ENE	168	40,350	4,036	4,036
	QT	15	55,328	4,257	4,257
English	DA	28	25,171	3,147	3,147
	ENE	168	25,005	3,230	3,230
	QT	15	22,213	2,777	2,777

between Japanese and English. For example, the task of English ENE classification is to obtain the requested ENE type for a question. Each of the data sets were divided into training (Train), validation (Valid), and test (Test) sets. Table 1 shows the number of utterances in individual data sets where #labels represents the number of labels. Table 2 shows English utterances and label examples for individual tasks.

4.2 Setups

We evaluated non-shared modeling, fully-shared modeling, and partially-shared modeling. For the shared modeling methods, multi-task joint learning, multi-lingual joint learning, multi-task and multi-lingual joint learning were examined. The multi-task joint learning used three classification tasks for optimizing each language. The multi-lingual joint learning used both Japanese and English data sets for optimizing each task. The multi-task and multi-lingual joint learning used all data sets. Several modeling parameters were unified. Word representation size was set to 128, LSTM-RNN unit size was set to 200, and context vector size in the attention mechanism was set to 200. Dropout was used for `EMBED`() and `BLSTM`(), and the dropout rate was set to 0.5. In these setups, words that appeared once or less in

Table 2: English utterances and label examples in individual tasks.

Task	Utterance	Label
DA	Hello, how are you today?	GREETING
	I am so sorry to hear of your son's accident.	SYMPATHY/AGREE
	Lets go to school an hour early today.	PROPOSAL
ENE	What is the highest mountain in the world?	MOUNTAIN
	Who is president of the united states?	PERSON
	What is the name of the most recent Star Wars movie?	MOVIE
QT	Do you like egg salad?	TRUE/FALSE
	How do you correct a hook in a golf swing?	EXPLANATION:METHOD
	Why is blood red?	EXPLANATION:CAUSE

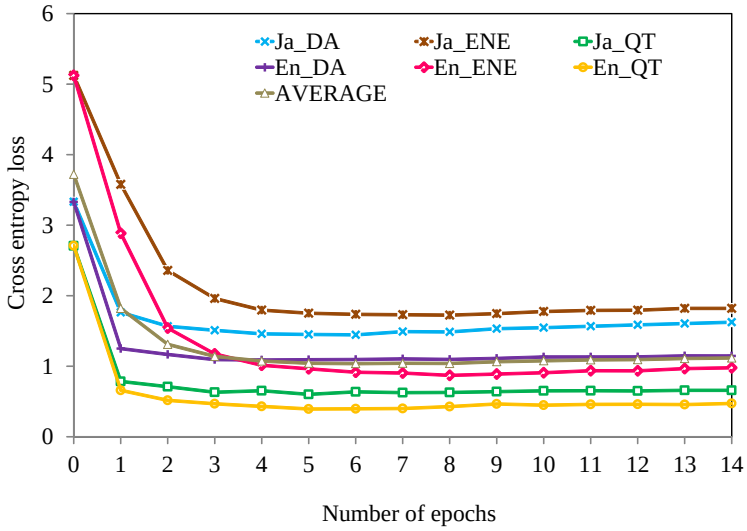

Figure 8: Cross entropy loss for validation sets.

the training data sets were treated as unknown words. For joint learning, mini-batch stochastic gradient descent was used for the individual optimizers. Initial learning rate for individual data sets was set to 0.1. The cutoff threshold for gradient clipping was set to 1.0. Training was stopped when the averaged validation loss was not improved in 5 consecutive iterations.

4.3 Results

Figure 8 demonstrates the change in cross entropy validation loss for individual validation sets when performing multi-task and multi-lingual joint learning based on partially-shared modeling. As epoch number increased, both cross entropy validation losses for individual data sets and averaged validation loss for all data sets (AVERAGE) decreased. This indicates that joint optimization procedure used in algorithm 1 worked well.

Table 2 shows the experimental results in terms of utterance classification accuracy for test sets. For each setup, we constructed five models by varying the initial parameters and evaluated the average accuracy.

First, (a) demonstrates the results of non-shared modeling trained using only an individual data set. These results are the baseline of this evaluation. In fully-shared modeling, (b) to (d), the classification performance deteriorated in some cases, while performance improvements were achieved in other cases. In English QT, multi-task and multi-lingual joint learning was inferior to multi-task joint learning or multi-lingual joint learning. This indicates that fully-shared modeling, which learns universal hidden representations, are not suitable for supporting both cross-lingual and cross-task knowledge transfer.

Table 2: Experimental results: utterance classification accuracy (%) for individual test sets.

		Joint learning		Japanese			English		
		task	language	DA	ENE	QT	DA	ENE	QT
(a).	Non-shared modeling	-	-	66.5	79.1	87.7	61.8	64.7	83.5
(b).	Fully-shared modeling	√	-	66.5	79.6	89.3	60.6	64.4	83.7
(c).		-	√	66.7	78.7	87.2	61.4	64.3	83.0
(d).		√	√	66.5	79.7	89.3	60.5	65.4	82.6
(e).	Partially-shared modeling	√	-	66.6	80.9	89.4	62.0	64.8	83.7
(f).		-	√	**66.9**	79.7	88.0	61.9	65.0	83.8
(g).		√	√	**66.9**	**81.8**	**89.7**	**62.3**	**65.8**	**84.0**

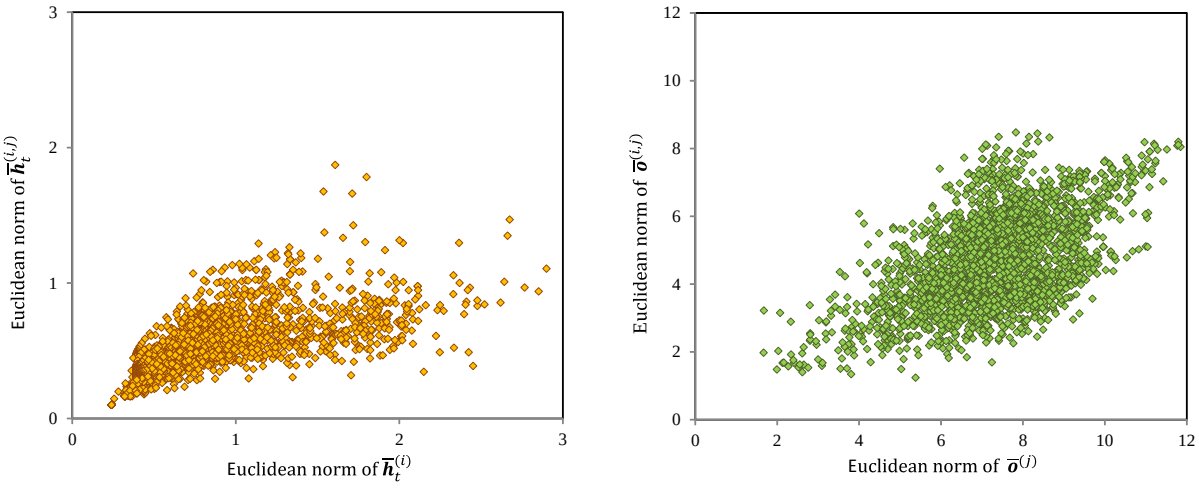

Figure 9: Euclidean norm results in partially-shared modeling.

On the other hand, partially-shared modeling, (e) to (g), improved the classification performance in all data sets compared to (a). In addition, multi-task and multi-lingual joint learning outperformed multi-task joint learning and multi-lingual joint learning. These results confirm that partially-shared modeling can effectively transfer knowledge between different data sets. We conducted sign test for verifying the effectiveness of multi-task and multi-lingual joint learning based on partially-shared modeling. In Japanese ENE classification, Japanese QT classification, and English ENE classification, statistically significant performance improvements ($p < 0.05$) were achieved by (g) compared to (a). Furthermore, in Japanese ENE classification, English DA classification, and English QT classification, significant performance improvements ($p < 0.05$) were also achieved by (g) compared to (d).

We investigated how shared components and exclusive components worked in partially-shared modeling. The left side of Figure 9 presents the Euclidean norm of both $\bar{\boldsymbol{h}}_t^{(i,j)}$ and $\bar{\boldsymbol{h}}_t^{(i)}$, while the right side presents the Euclidean norm of both $\bar{\boldsymbol{o}}^{(i,j)}$ and $\bar{\boldsymbol{o}}^{(j)}$ when classifying English question type validation data sets. These results show that shared components are more influential than exclusive components. This indicates that the shared components accumulate shareable knowledge, while exclusive components were utilized to offset the small differences between tasks or between languages.

5 Conclusions

This paper proposed multi-task and multi-lingual joint learning of neural lexical utterance classification for effectively leveraging data sets of different tasks and different language. For neural lexical utterance classification, we proposed BLSTM-RNN; it uses a self-attention mechanism and introduces language-specific and task-specific components. Each component can be effectively trained by partially-shared

modeling. Experiments on Japanese and English data sets created for three different tasks showed that the proposed multi-task and multi-lingual joint learning based on partially-shared modeling can transfer knowledge more effectively than multi-task or multi-lingual joint learning based on fully-shared modeling.

Abstract

To deploy a spoken language understanding (SLU) model to a new language, language transferring is desired to avoid the trouble of acquiring and labeling a new big SLU corpus. Translating the original SLU corpus into the target language is an attractive strategy. However, SLU corpora consist of plenty of semantic labels (slots), which general-purpose translators cannot handle well, not to mention additional culture differences. This paper focuses on the language transferring task given a tiny in-domain parallel SLU corpus. The in-domain parallel corpus can be used as the first adaptation on the general translator. But more importantly, we show how to use reinforcement learning (RL) to further finetune the adapted translator, where translated sentences with more proper slot tags receive higher rewards. We evaluate our approach on Chinese to English language transferring for SLU systems. The experimental results show that the generated English SLU corpus via adaptation and reinforcement learning gives us over 97% in the slot F1 score and over 84% accuracy in domain classification. It demonstrates the effectiveness of the proposed language transferring method. Compared with naive translation, our proposed method improves domain classification accuracy by relatively 22%, and the slot filling F1 score by relatively more than 71%.

1 Introduction

Spoken language understanding (SLU) is a key technique in today's conversational systems such as Apple Siri, Amazon Alexa and Microsoft Cortana. To make these conversational systems support multiple languages over different markets, collecting and annotating a large SLU training corpus per language are tedious and costly, and thus hinders the scalability of these systems. It would be greatly helpful if the efforts taken to develop one SLU system could be reused for other languages.

For such a purpose, much work has been reported to explore language transferring of SLU systems or multilingual SLU systems (García et al., 2012; Calvo et al., 2013; Calvo et al., 2016; Jabaian et al., 2016). These systems can be grouped into two categories: test-on-source-model vs. train-on-target-language. Test-on-source-model is to translate the test sentence in the 2nd language (referred to as L2 from now on) into the first SLU system's language (as L1), and then process it with the L1 SLU system. Train-on-target-language is to translate the L1 training corpus into L2, and then train an SLU system in L2. The train-on-target-language strategy allows tuning and adaptation of the models in the target language directly, and it avoids an overhead of machine translation during real-time execution. The test-on-source-model implies that the final search engine has to deal with L1 while the target answer database might be still in L2. Either the slot value needs to be translated again back to L2, or the database needs to be pre-translated into L1. Hence train-on-target-language is our preferred approach.

Each sample of the SLU training corpus consists of a query and its semantic annotation, for example,"Play <song>Sorry</song> in <album>They Don't Know</album>". In the L1 SLU training corpus, both query and its semantic annotation need to be transferred properly to the target language. Literally sending the annotated sentence to general-purpose machine translator or web translator may

Proceedings of the 27th International Conference on Computational Linguistics, pages 3597–3607
Santa Fe, New Mexico, USA, August 20-26, 2018.

lose or screw up the annotation information. Two schemes (Jabaian et al., 2013) have been proposed to solve this problem: transferring source language annotation indirectly through word alignment, vs. adapting the translation model so that it learns how to translate text with slot labels. Each scheme has its own limitations. The first scheme is weak for distant language pairs (e.g. Chinese and English) and the errors are accumulative after translation and word alignment. The second scheme needs extra data for adapting the translation model. In addition, some previous works (Servan et al., 2010; Misu et al., 2012; Jabaian et al., 2013) only focused on transferring slot labels but ignored the fact that the slot values should be adjusted properly to the target culture. For example, people in London will probably say "call a taxi to Tower of London" rather than "call a taxi to Forbidden City". It's better to make some adaptations on such culture difference for the L2 SLU corpus. In this paper, we will address culture adaptation when we transfer Chinese corpora to English and we will demonstrate its importance via experimental results. Given that neural machine translation (NMT) is the state-of-the-art translator, NMT model is applied in this paper for language transferring.

The main contribution of this paper is the proposal of using reinforcement learning to improve translation for language transferring. We name it source-critical reinforcement translation (SCRT). We first define the slot keeping ratio (SKR) as a metric for evaluating the performance of slot transferring. SCRT adapts NMT models via rewarding those translation candidates with higher SKR. By doing so, we can obtain target language translations which maintain both the semantics and slot information of the SLU labeled sentences in the source language. We evaluate our method on domain classification and slot filling tasks. The results show that our RL method improves the slot F1 score from 93% to 97% and domain accuracy from 82% to 84%, on top of an already adapted NMT.

2 Related Work

Language transferring for SLU systems has been an active research topic in recent years and much work has been reported on both the test-on-source-model and train-on-target-language two strategies. In Jabaian et al. (2013), different approaches based on test-on-source-model and train-on-target-language strategies are compared.

The simplest way for the test-on-source-model scheme is to translate L2 target sentences with a web translator into L1, and process these translations with the L1 SLU system. In He et al. (2013) the Microsoft Bing translator is used for this purpose. This approach provides translations of the user input at a very low economic and time cost. Moreover, Stepanov et al. (2013) have demonstrated that application of language-style and domain adaptation techniques to the "off-the-shelf and out-of-domain" SMT system could yield improved translation and thus obtain better SLU performance. For adapting MT, Garcıa et al. (2014) translated the L1 SLU training corpus into L2, with multiple web translators to obtain a large parallel dataset, and then trained their own L2-to-L1 SMT model to reduce translation errors. Calvo et al. (2013; 2016) proposed to build graphs of words from different translations and then to parse the translation graph with the SLU model.

The train-on-target-language approach relies on the accurate transferring of semantic annotations from L1 to L2. García et al. (2012) translates each segment within one slot separately with a web translator, and then joins these pieces together into a sentence. This method doesn't need additional procedures to transfer slot labels. However, this method misses the context information that is crucial to translation quality. Moreover, it's difficult to determine the ordering of the translated segments. Misu et al. (2012) trains an SMT model using conversational in-domain parallel data, and then translates the entire L1 SLU training corpus to L2. However, bilingual in-domain data is scarce and costly, making it difficult to deliver both quality and low cost. Jabaian et al. (2010; 2013) propose two language transferring schemes. One is transferring source language annotation indirectly through word alignment. The other one is forcing the SMT model to translate the segmentation and slot labels simultaneously. The authors report that the indirect alignment gives the best performance. However, they also point out that distant language pairs suffer severely in word alignment. Finally rather than relying on automatic machine translation, Stepanov et al. (2014) prefer using human professional translation services. In Stepanov et al. (2017), they extend their work via crowdsourcing for semantic annotation.

Methods	Source input	Translation result
Naive Translation	我想打个电话给白晓霞	I would like to make a call to telephone number of white sunshine
Token-added Translation	我想打个电话给（a 白晓霞）	I would like to make a call to (a white sunshine) 's telephone number please
Class-based / SCRT	我想打个电话给 $contact_name	I would love to make a call to $contact_name 's number please

Table 1: Translation examples by different translation systems.

3 Translation Systems

This section describes all the translation systems conducted in our experiments. Each system has its own approach of transferring slot labels to the target sentence. They all start from the same general-purpose NMT, trained on a huge L1:L2 parallel corpus without SLU annotation. Hence the general translator usually doesn't do well with input containing slot labels.

3.1 Naive Translation

The naive translation system uses the given well-trained general-purpose translator as it is. The slot labels in the L1 SLU corpus are stripped off before entering the general translator. We then align the words between the source sentence and the translated sentence, in order to add back slot labels into the translated sentence. This is an indirect slot transferring approach.

Some limitations of the naive translation approach come from both translation and alignment. There are plenty of slot values like song names and contact names in the original SLU corpus. Many of these words are out-of-vocabulary (OOV) for the translation model. Although the translation model can handle these OOV words with sub-word modeling techniques (Sennrich et al., 2016), there are still many slot values remain to be OOV or mistranslated. For example, the Chinese name "白晓霞" in Table 1 is literally translated to "white sunshine". Furthermore, wrong translations might also result in wrong alignments, which will yield inaccurate positions for slot labels.

3.2 Token-added Translation

To make the translator be aware of slots, we then propose a token-added translation approach. This approach uses some special tokens to mark the segmentation boundary for the slot value in the source sentence. These special tokens are common in both the source vocabulary and target vocabulary of the general translator and their translation is unique and easy to spot. For example, parentheses and double quotes are good candidates as the special tokens. Enclosing slot values in source sentences by these special tokens can help identify slot boundaries in the translation outputs. In our example in Table 1, the special tokens we choose is a pair of parentheses, where the beginning parenthesis is followed by a single character "a", representing the slot label (in this case contact_name). We choose a single English letter for Chinese-to-English transfer because we are almost certain that the English letter will be carried to the target side as it is. After translation, the slot values can then be easily identified.

In token-added translation, no additional word alignment process is required. However such approach relies heavily on the NMT general training data where the special tokens (e.g. parentheses or double quotation marks) are kept in both source and target data. For different language pairs, different special tokens might be chosen for the best translation quality. Empirically we find that parentheses with a single English character are highly effective for Chinese to English translation.

3.3 Class-based Translation

To better translate the slots, we further propose a class-based translation approach. It is to use a class symbol to replace both the slot label and its slot value in the source sentence, for example, "Play $song in $album". In other words, we generalize the source sentence into a pattern sentence.

The class symbol represents the slot label, but without any specific value, as shown in the last row in Table 1. Representing each slot segment with a single symbol has a great advantage of avoiding a multi-word segment to be translated into several non-consecutive segments and not enclosed by the correct slot-label pairs. In order to help the general translator understand these new words (class symbols), we need some new parallel sentences with class symbols to adapt the general translator. Then for each sentence in the L1 SLU corpus, we first transform it to use class symbols and then translate it with the adapted general translator. The translated sentence will contain class symbols as well. We then replace these class symbols with slot values appropriate to the target culture.

Therefore unlike the first two systems, the class-based translation model is an adapted translator. It requires a small parallel annotated SLU corpus for adaptation.

3.4 Source-Critical Reinforcement Translation

The performance of class-based model relies on whether parallel annotated SLU data is enough or not to translate class symbols correctly. In other words, slots will be missed or mistranslated without enough parallel data. However, in-domain SLU parallel data is scarce. It's best if we can take advantage of the existing L1 SLU corpus to solve the slots missing or mistranslated problem of class-based method. Assume the general translator has been adapted into a class-based translation model, we now propose another adaptation algorithm based on reinforcement learning that depends on monolingual instead of bilingual SLU corpora. Hence we name it source-critical reinforcement translation (SCRT).

Before formally introducing SCRT, it is necessary to first define SKR, a metric named slot keeping ratio for evaluating the slot transferring performance of translation models. For each (Chinese) sentence c_i, its SKR is defined as the number of slots in the translated (English) sentence, e_i, divided by the number of slots in c_i:

$$\text{SKR}(c_i, e_i) = \frac{\sum_s \min(g(c_i, s), g(e_i, s))}{\sum_s g(c_i, s)} \times 100\%$$

The function $g(c_i, s)$ is used to count the occurrences of slot s in sentence c_i. Minimum is taken at the numerator to avoid SKR to be over 100%.

It's easy to see that a high SKR is a critical condition for generating a high-quality training corpus for L2 SLU models. Our SCRT algorithm directly optimizes the SKR for each source sentence, and learns how to translate specific words according to specific rules. In this task, specific words are those class symbols, and specific rules are the correspondence of each class symbol in the two languages. This is inspired by Ranzato et al. (2015) and Rennie et al. (2017). Instead of promoting sequence-level training performance via directly optimizing BLEU scores that require ground truth target sentences, our algorithm focuses on the performance of specific words only, and therefore ground-truth target sentences are not required. The architecture of this model is depicted in Figure 1.

Since SCRT is based on REINFORCE algorithm (Williams, 1992; Zaremba and Sutskever, 2015), we first describe reinforcement learning from the perspective of sequence generation.

3.4.1 REINFORCE

In order to directly maximize SKR, we can cast our problem in the reinforcement learning framework (Sutton and Barto, 1998) as in Ranzato et al. (2015). Our NMT model can be viewed as an *agent* that interacts with an external *environment* (words). The parameters of neural network, θ, defines a *policy* p_θ, whose execution results in an *action*. The *action* is the prediction of the next word in the sequence at each time step. After taking an action, our agent will update its internal *state* (attention weights). Once our agent generates the end-of-sequence (EOS) token, the agent will observe a *reward*. We can choose different reward functions for various purposes. Here, we use the SKR value as the reward r.

During training, the agent chooses an action according to the current policy and observes a reward only when the end token is generated. This reward is computed according to the generated sentence and the input sentence. The goal of training is to maximize the expected reward, and therefore the loss function (negative of reward) for the encoder-decoder given an input source sentence, $x = x_1, x_2, ...$, is

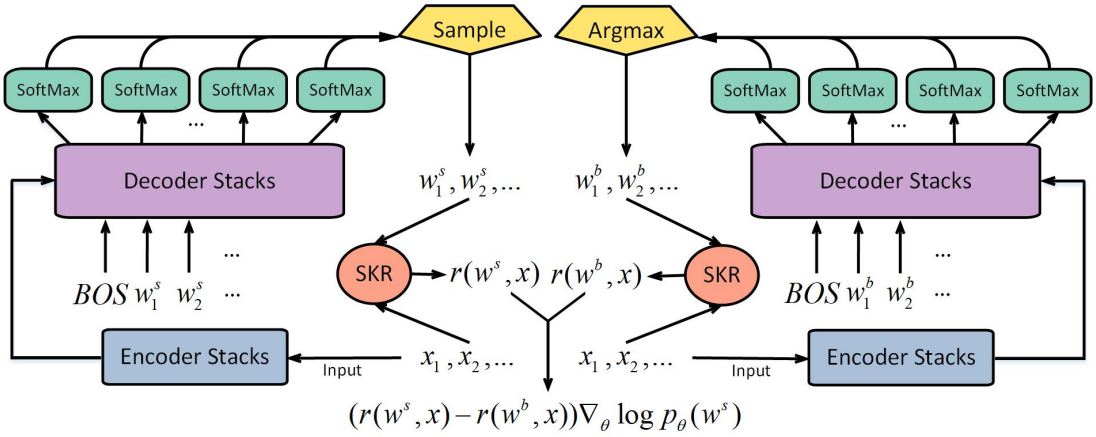

Figure 1: Architecture of Source-Critical Reinforcement Translation. $x_1, x_2, ...$ is the source input of the NMT model and $(r(w^s, x) - r(w^b, x))\nabla_\theta \log p_\theta(w^s)$ is the final gradient to optimize with policy gradient method. The encoder and decoder stacks represent inner layers of the Transformer general translator.

defined as:

$$\begin{aligned} L(\theta) &= -\sum_{w_1^g,\ldots,w_T^g} p_\theta(w_1^g, ..., w_T^g|x)\, r(w_1^g, ..., w_T^g, x) \\ &= -\mathbb{E}_{w^g \sim p(\theta)} r(w^g, x) \end{aligned} \tag{1}$$

where $w^g = (w_1^g, ..., w_T^g)$ is the generated sentence of length T. Notice the length of x is not necessarily T. The notion $w^g \sim p(\theta)$ means the generated sentence follows the distribution of the decoder softmax output $p(\theta)$.

The gradient of $L(\theta)$ can be computed as follow:

$$\nabla_\theta L(\theta) = -\mathbb{E}_{w^g \sim p(\theta)} r(w^g, x) \nabla_\theta \log p_\theta(w^g) \tag{2}$$

We approximate this expectation with Monte Carlo based sampling and a baseline b is used to reduce the variance in the Monte Carlo estimator of the gradient, following Weaver and Tao (2001):

$$\begin{aligned} \nabla_\theta L(\theta) &= -\mathbb{E}_{w^s \sim p(\theta)} (r(w^s, x) - b) \nabla_\theta \log p_\theta(w^s) \\ &\approx -(r(w^s, x) - b) \nabla_\theta \log p_\theta(w^s) \end{aligned} \tag{3}$$

where w^s is the sampled sentence. We use a single sample to approximate the expectation in the above formula. Using the chain rule of gradient computation, we have:

$$\nabla_\theta L(\theta) = \sum_t \frac{\partial L_\theta}{\partial y_t} \frac{\partial y_t}{\partial \theta} \tag{4}$$

where y_t is the input to the decoder softmax function at time stamp t. Following Zaremba's prior work, the gradient of loss $L(\theta)$ with respect to y_t is given by:

$$\frac{\partial L_\theta}{\partial y_t} = (r(w^s, x) - b)(p_\theta(w_t|h_t) - 1(w_t^s)) \tag{5}$$

where h_t is the input vector to the fully-connected layer before softmax, and $1(w_t^s)$ is the one hot vector for w_t^s. Notice y_t, $p_\theta(w_t|h_t)$, $1(w_t^s)$ are all vectors of length V, where V is the number of output units from the decoder.

3.4.2 Self-Critical and Source-Critical

The baseline reward b is obtained by the current model using the inference algorithm at test time (Rennie et al., 2017). This is called self-critical training. In this work, we choose greedy decoding at test time. That is, the most likely word from the decoder output $p(\theta)$ at each time stamp is selected as the baseline output, as shown on the right-hand side of Figure 1. The greedy translation sentence is denoted as w^b.

The above gradient can now be written as:

$$\frac{\partial L_\theta}{\partial y_t} = (r(w^s, x) - r(w^b, x))(p_\theta(w_t|h_t) - 1(w_t^s)) \tag{6}$$

Since the reward is based on SKR exclusively, no ground truth target sentence is needed. We call this source-critical learning.

3.4.3 Optimization

Equation (6) says that the sampled sentence w^s acts like a surrogate target for our output distribution, $p_\theta(w_t|h_t)$, at time t. Once the sampled sentence achieves a higher SKR than greedy decoding, a positive reward is used for parameter updating; otherwise, a negative reward is used.

The SKR criterion itself does not impose constraints on translation quality. Therefore it needs a well-trained general-purpose NMT system as the initial model. In this paper, we initialize the SCRT model with parameters from the adapted class-based model described in Section 3.3, which also offers good embedding features for the class symbols. Otherwise, the model would be difficult to converge, as the sampling space or action space is enormous.

After initialization, we then use policy gradient methods to find parameters that lead to a large expected reward. As our SCRT only optimizes the SKR score with monolingual data, the curriculum learning (Bengio et al., 2009) strategy is employed in which we begin with the class-based model, and gradually increase the number of SCRT training steps.

4 Experiments

4.1 Experimental Setup

We conduct experiments on Chinese to English language transferring task and evaluate the quality of the translated corpus via domain classification and slot filling tasks.

We annotated 3000 (over time this should be a very big number) Chinese dialogue sentences as the L1 SLU corpus and 1500 English dialogue sentences as the test set for the target language. Our goal is to transfer these 3000 Chinese sentences to English, and then train an English SLU model to handle these 1500 English test sentences.

Next we annotated additional 1500 pairs of parallel sentences for adapting the general translator into the class-based MT. This small parallel SLU corpus is called the adaptation corpus in this section. Finally, the Chinese side of the 3000 sentences of the L1 SLU corpus, together with the Chinese side of the 1500 sentences of the adaptation corpus is used in SCRT training, on top of the adapted class-based MT.

4.1.1 SLU model

The SLU annotated data are collected from communication, navigation and music three domains. It includes seven slots: contact name, contact type, address type, song name, album, feature and artist. As "others" domain is necessary for domain classification in practical applications, we collect additional 40,000 sentences from other scenarios as the fourth domain. For domain classification models, we use the SVM linear classifier with public toolkit LIBLINEAR (Fan et al., 2008). Stop words are removed from the training corpus. Simple N-gram features with a cut-off of 10 are used in domain classification. For slot filling experiments, the CRF++ toolkit (Kudo, 2005) is used. The slot labeling follows the IOB format.

Trans.	Culture A.	SKR	Slot_F1	Dom_Acc
Naive	No	57.13%	45.39	45.87%
Naive	Yes	57.13%	69.78	78.93%
TA	No	60.82%	24.87	55.07%
TA	Yes	60.82%	34.14	81.4%

Table 2: Slot F1 scores and domain accuracy, with naive translation vs. token-added (TA) translation using an unadapted general translator. The second column indicates whether culture adaptation is applied.

4.1.2 The general translator

We choose Transformer (Vaswani et al., 2017) as the general machine translation model. And for naive translation, we use Fast-Aligner (FA-IBM 2) (Dyer et al., 2013) to locate the slot labels for the translated queries. The architecture of our NMT model is the same as Vaswani et al. (2017).

Our training corpus is from AI Challenger: The English-Chinese Machine Translation track[1]. This competition provides over 10 million parallel English-Chinese sentences which were collected from English learning websites and movie subtitles. In our experiments, we extract nearly 8 million pairs of sentences from this corpus to train the baseline machine translation model. After sub-word (Sennrich et al., 2016) preprocessing, the source vocabulary size is 83,000 and the target part is 78,000. Our training batch size is 3,072 and we train the baseline model for a total of 300,000 steps with Adam optimizer (Kingma and Ba, 2014) on two GPUs. All decodings are conducted with a beam size of 4, and the top one translation is taken as the final translation output.

4.1.3 Culture adaptation

In our experiments, we select the culture-dependent slots such as contact name, song name, album and artist for target culture adaptation. We first collect thousands of English names, artists, song names and albums to build a database. The slot values in the test data are removed from the database. In the translated target queries, the corresponding slots are filled by randomly selected slot values from the database. The same random seed is used for all approaches.

4.2 Results

4.2.1 Without parallel adaptation corpus

We first compare the performance without the parallel adaptation data. Table 2 shows that the performance of naive translation method and token-added translation method. Note that the class-based model and the SCRT trained model are not included in this table, because the class-based translator needs the adaptation data to learn the translation of class symbols, and SCRT training is built on top of the class-based model.

In Table 2, compared with naive translation method, the token-added approach achieves a higher SKR score. However, keeping more slots doesn't yield good performance in the slot filling task. More mistranslations may happen in the token-added approach due to the fact that the added special tokens actually change the context of the original query and introduce noisy information. On the other hand, the token-added approach has a slightly better domain accuracy than the naive translation. This is probably because slot labels carry a certain degree of domain information.

In Table 2, the contribution of cultural adaptation is obvious. After filling the corresponding slots with culture appropriate slot values, substantial improvements are observed in this table. Adding culture adaptation gives naive translation method more than 50% relative improvement over slot filling F1 score and domain classification accuracy. The similar trend also holds for token-added translation.

4.2.2 With parallel adaptation corpus

In this section, we first compare different methods that use the adaptation corpus that consists of 1500 in-domain annotated sentences in communication, navigation and music domains. In the adaptation

corpus, 1200 sentences are randomly selected for training and the rest as the validation data to terminate training. Although 1200 sentences are tiny for model training, we also conduct the same experiments with a much small amount of data, 90 parallel sentence pairs which are also randomly selected from the 1500 in-domain annotated sentences, to test the performance of different methods under different condition.

In Table 3, comparing the naive translation with the token-added translation, we can find that the token-added method benefits more from adapting general purpose translator with in-domain parallel data. The SKR of naive translation barely increased, even using the adapted translator. It is obvious that the main limitation of naive translation is alignment rather than translation. The class-based model achieves 97.03% SKR after the convergence of supervised training with parallel adaptation data. Finally, SCRT training with 4500 monolingual annotated data is further applied to the adapted class-based translator. The SKR is increased to 98.08%. The F1 score of slot filling and accuracy of domain classification also jump significantly, which undoubtedly proves that our SCRT can generate better SLU training corpus for other languages, with the aid of monolingual annotated data exclusively.

In Table 4, the SCRT achieves the highest F1 score of slot filling and the slot transferring or SKR still benefits from monolingual data with SCRT incremental training. This result shows that our proposed method is very competitive even with an extremely small amount of parallel in-domain data. But the naive translation method with culture adaptation show a better performance on domain classification. This is because, with an extremely small amount of parallel training data, it is hard to achieve a high quality of translation for SCRT and class-based method, which is crucial for domain classification. Besides, the naive translation always benefits more from the culture adaptation in domain classification, as those mis-aligned segments will be replaced with correct slots, which makes such sentences more distinguish from the other.

4.2.3 Analysis of SCRT

In order to evaluate how much the proposed SCRT contributes to the class-based model, we analyze the systems at different iterations of training with 1200 in-domain parallel sentences. In the experiments, we find that the class-based model begins to converge after 800 steps with a batch size of 32 when adapted on the 1200 in-domain parallel sentence pairs. So this model at step 800 is chosen as a baseline and is labeled as SL800 in Figure 2. Based on such a baseline, we use the 4500 sentences of monolingual data to conduct 30 steps (SL800+RL30) and 60 steps (SL800+RL60) SCRT RL training. As shown in Figure 2, the SKR increases nearly one percent and the F1 score increases by over 7 percents for both models.

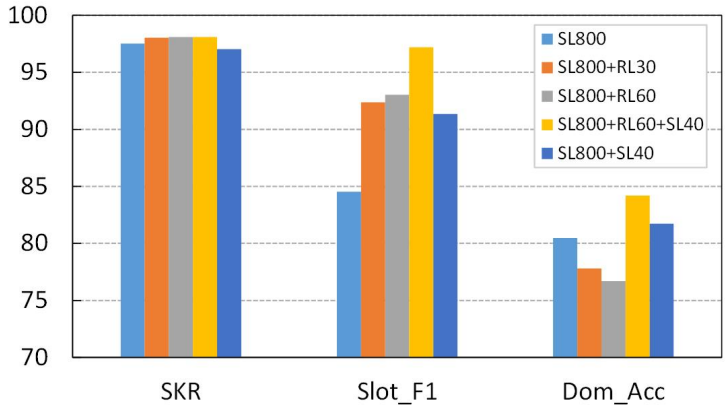

Figure 2: Performance on SKR, slot filling and domain classification, using translation models trained at different steps of supervised learning (SL) and reinforcement learning (RL).

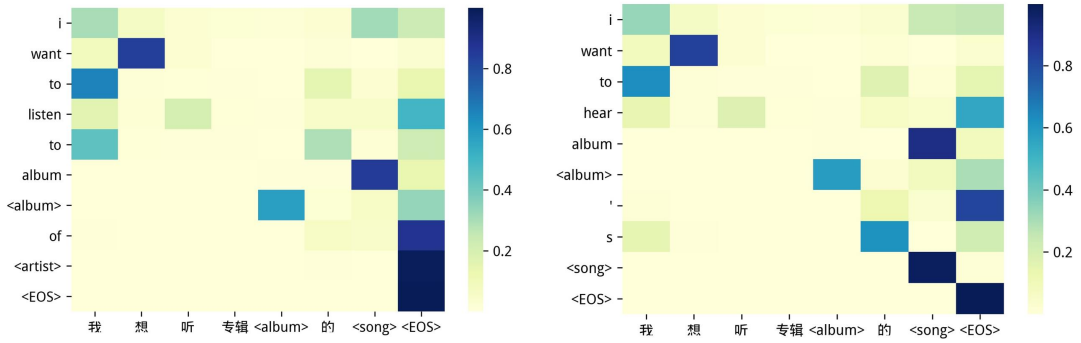

(a) Class-based (b) SCRT

Figure 3: Two heat maps of attention vectors between encoder and decoder in the translation model. The x-axis and y-axis of each plot correspond to the words in the source sentence (Chinese) and the generated translation (English), respectively.

However, we note that the accuracy of domain classification drops. This is because SKR imposes no constraints for general machine translation quality that is crucial for domain classification. The translation quality can be improved by additional steps of supervised training using in-domain parallel training data. For model SL800+RL60+SL40, another 40 steps of supervised training are conducted on top of SL800+RL60.

As we can see from Figure 2, SL800+RL60+SL40 achieves the highest scores on both slot filling and domain classification among all these models. The last model, SL800+SL40, is used for comparison with SL800+RL60+SL40. Although these two models are trained with the same steps of supervised learning, the model with SCRT achieves higher scores on all metrics. This result indicates the potential contribution of the monolingual data and the effectiveness of our proposed SCRT algorithm for language transferring. Furthermore, comparing SL800 and SL800+SL40, we can find that although the accuracy and F1 score goes up, the SKR goes down after additional training with parallel data. This is the shortcoming of maximum-likelihood estimation objective function for our task: treating all words equally without emphasizing important words like slot labels.

The proposed approach SCRT provides an intuitive way to guide the parameter updating for slots transferring with monolingual data. We visualize the attention weights between encoder and decoder of the translation model in Figure 3. The left plot corresponds to the model SL800 mentioned above and the right one is the model SL800+RL60. From the heat maps, we can see which positions in the source sentence were considered more important when generating the target word. Figure 3(a) shows that class-based model mistranslated the slot $song into $artist, and was corrected after additional SCRT

training in Figure 3(b).

5 Conclusions

Our work is motivated by the practical demand in language transferring for SLU systems: the lack of large annotated in-domain parallel data, and the requirement of high-quality SLU corpus in the target language. To address this problem, we applied an adapted Neural Machine Translator to translate the SLU copora to other languages. A small in-domain parallel data is used to adapt the general purpose NMT firstly. Based on the adapted NMT, we proposed a reinforcement learning approach with a source-critical mechanism to do further adaptation using monolingual data exclusively. Our proposed method optimizes the slot keeping ratio directly and adapts slot values accordingly based on the target culture. The experiments showed that comparing with naive translation, the proposed method could improve domain classification accuracy by relatively 22%, and the slot filling F1 score by more than 71%.

Abstract

Generative dialog models usually adopt beam search as the inference method to generate responses. However, small-width beam search only focuses on the limited current optima. This deficiency called myopic bias ultimately suppresses the diversity and probability of generated responses. Although increasing the beam width mitigates the myopic bias, it also proportionally slows down the inference . To alleviate the myopic bias in small-width beam search, this paper proposes a Prospective-Performance Network (PPN) to predict the future reward of the given partially-generated response, and the future reward is defined by the expectation of the partial response appearing in the top-ranked responses given by a larger-width beam search. Enhanced by PPN, the decoder can promote the results with great potential during the beam search phase. The experimental results on both Chinese and English corpora show that our method is capable of increasing the quality and diversity of generated responses, with inference efficiency well maintained.

1 Introduction

In recent years, Neural Response Generation (NRG) (Vinyals and Le, 2015; Shang et al., 2015) with sequence-to-sequence (Seq2Seq) structures (Sutskever et al., 2014a; Bahdanau et al., 2015) has been widely studied and adopted in open-domain dialog systems such as XiaoIce (Shum et al., 2018). Many studies have been done to generate target responses meeting desirable proprieties including emotion (Zhou et al., 2017), diversity (Li et al., 2016), etc., or to explore issues in decoding step such as exposure bias, loss-evaluation mismatch (Ranzato et al., 2016) and label bias (Wiseman and Rush, 2016).

Most NRG systems adopt the beam search algorithm to generate responses given queries. In brief, beam search explores the possible responses by storing only top-ranked ones as candidates at each time step. Though it is a useful prediction strategy, depending on beam width, beam search more or less suffers from its nature of focusing solely on current optimal results. Consequently, beam search tends to ignore some partial sequences which might lead to better future outcomes, especially if its beam width is too small. This deficiency is called the *myopic bias* (He et al., 2017). Recently, He et al. (2017) and Li et al. (2017) proposed methods that take account of future BLEU of partial sequences as the future reward during beam search, to alleviate the myopic bias in Neural Machine Translation (NMT). Their experiments show that such methods are capable of improving the BLEU scores of generated translations.

However, several studies point out that BLEU is weakly correlated with human judgments in response generation tasks (Liu et al., 2016; Mou et al., 2016). Unlike in machine translation, where the semantic

beam width = 10	0.2831	0.4277	-9.2474	0.7500
beam width = 50 (top10)	**0.4151**	**0.5536**	**-7.4490**	**1.0934**

Table 1: Evaluation results of beam search with width 10 and 50

distribution of appropriate translations given a source sentence is narrow, in response generation tasks, the semantic information of possible responses for one query can be highly diverse. Therefore it is inappropriate to use BLEU, which only takes responses in the training dataset as ground truth, as future reward to solve the myopic bias on response generation. Otherwise, the diversity of generated results might be suppressed.

In this paper, we introduce a new perspective for reducing the myopic bias in response generation. In NRG, the degree of myopic bias for beam search is negatively correlated with its beam width: a greedy search (beam width = 1) myopically stores only the top candidate at each time step; while a larger-width beam search is capable of storing more candidates with potentially higher future probability. Therefore, in this work, for a partial response generated from a small-width beam search, we define its future reward as if it will present in the top responses generated from a beam search with a larger width in future time steps. This presence indicates the potential probability one partial response's successors can reach in the future time steps, therefore taking it as future reward captures the future probability of one generated partial sequence from beam search.

Furthermore, given a query, we design a simple but effective neural network to estimate the future reward for a partial response. Based on this prediction, we re-rank the generated partial responses at each time step, so that we encourage beam search to consider the future probability information of each partial response and generate final results similar to those from a larger width beam search, without proportionally increasing the time cost.

2 Beam Width Analysis

2.1 Beam Search Overview

Given a query $\mathbf{x}$, a K-width beam search stores K candidates denoted as $C_t^K = \{\mathbf{y}_t^k |\ k \in [1, K]\}$ at time step t. At next time step $t+1$, it expands each candidate by words w from vocabulary V. The size of vocabulary V is denoted as $|V|$, so that we have in total $K \times |V|$ potential candidates written as $\{[\mathbf{y}_t^k, w] \mid k \in [1, K], w \in V\}$, with corresponding scores:

$$\text{score}(\mathbf{y}_t^k, w|\mathbf{x}) = \text{score}(\mathbf{y}_t^k|\mathbf{x}) + \log p(w|\mathbf{x}, \mathbf{y}_t^k)\ , k \in [1, K], w \in V \tag{1}$$

The top-K potential candidates are then selected as the candidates in time step $t+1$.

2.2 Influence of Beam Width on Generated Responses

The size of beam width affects results returned from a beam search significantly. Let us assume that there are two beam searches, one with a small beam width K_s and the other with a large beam width K_l. At each time step t, we have two sets of candidates $C_t^{K_s} = \{\mathbf{s}_t^{k_s} |\ k_s \in [1, K_s]\}$ and $C_t^{K_l} = \{\mathbf{l}_t^{k_l} |\ k_l \in [1, K_l]\}$ from corresponding two beam searches. The top-K_s results from the K_l-width beam search tend to benefit from the following properties:

- Higher Probability: For a $\mathbf{l}_t^{k_l}$ ranked lower than K_s in $C_t^{K_l}$, its successors might be ranked above top-K_s in the future time steps, as long as one of its future transition probabilities $p(w|\mathbf{l}_t^{k_l}, \mathbf{x})$ is high enough. Such responses, unfortunately can not be retrieved by the small-width beam search due to its limited beam width. Consequently, for those top-K_s responses from a large-width beam search, their probabilities are more likely to be higher in average. Since in Seq2Seq model, the ideal output given a query x is the response y with the maximum $p(y|x)$, a response with higher probability indicates that it is closer to the optimal result.

- Higher Diversity: In the small-width beam search, many responses in $C_{t+1}^{K_s}$ are generated from a same $\mathbf{s}_t^{k_s}$, because of a dominate score of $\mathbf{s}_t^{k_s}$ compared to other candidates. By contrast, in the large-width beam search, we have a higher chance to observe more top-K_s of $C_{t+1}^{K_l}$ generated from different $\mathbf{l}_t^{k_l}$, since there exist more potential candidates $\mathbf{l}_t^{k_l}$ with high future probabilities $p(w|\mathbf{l}_t^{k_l}, \mathbf{x})$. Therefore the larger beam width leads to a higher diversity in generated sequences generally.

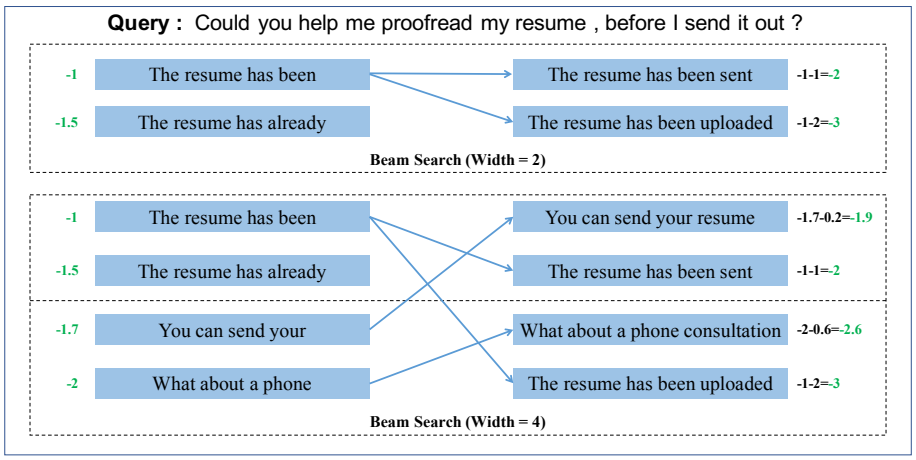

Figure 1: An example of partial responses generated from beam searches with width 2 and 4. The values in green are the corresponding log-probabilities of partial responses.

Figure 1 shows an example where larger beam width helps to generate more diversified results with higher probabilities. Benefited from the more stored candidates, the top-2 generated results from beam search (width =4) are more diversified and have higher probabilities.

To analyze the impact of the beam width on generated responses quantitatively, we employ evaluation methods including distinct, log probability and human evaluation to evaluate the top-10 responses generated by a Seq2Seq model with beam width 10 and 50 respectively. Distinct defined in Li et al. (2016) captures the level of diversity within the generated responses, log-probability is the probability computed by Seq2Seq model during inference after logarithm transformation. The details of above metrics and model training are further described in Section 4.4. The evaluation results in Table 1 show that the top-10 responses from beam width = 50 have higher diversities and probabilities, and are ranked higher by annotators, which is consistent with our hypothesis of beam width.

3 Prospective-Performance Network for NRG

Although a large-width beam search generates responses with higher probability and diversity, increasing beam width proportionally slows down the inference process. Therefore, to retrieve better responses and meanwhile maintain the inference efficiency, we propose Prospective-Performance Network to estimate the future rewards of partial responses in the inference procedure of NRG. The estimated future rewards is then incorporated in the small-width beam search to simulate the performance of a large-width beam search.

3.1 Future Reward

Given a K_l-width beam search we want to simulate, at time step t it generates a set of partial responses $C_t^{K_l} = \{\mathbf{y}_t^{k_l}, k_l \in [1, K_l]\}$. For one partial response $\mathbf{y}_t$, its future reward with regard to beam width of K_l is defined as

$$v(\mathbf{y}_t|\mathbf{x}, K, K_l) = \begin{cases} 1 & \text{if } \mathbf{y}_t \text{ in the top-}K \text{ responses (truncated at } t) \text{ from } C_{t+n}^{K_l} \\ 0 & \text{otherwise} \end{cases} \quad (2)$$

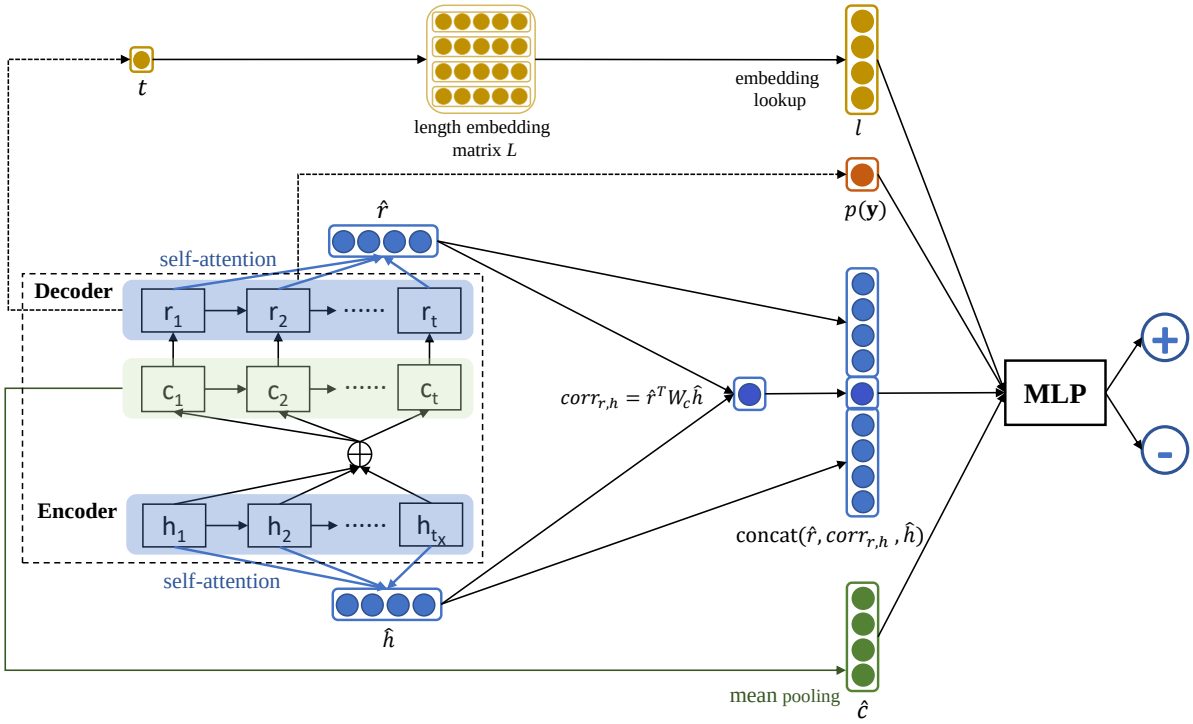

Figure 2: Structure of Prospective-Performance Network

In other words, if a partial response presents in the top-K responses from the given K_l-width beam search ($K < K_l$) at future time steps, we assign it with a positive future reward. The lookahead factor n indicates the prospective level of system.

For the example in Figure 1 where K=2, K_l=4, t=4 and n=1, at time step 4, partial responses "You can send your" and "The resume has been" are attributed with future rewards of 1, because their successors "You can send your resume" and "The resume has been sent" are the top-2 results at the next time step; while "The resume has already" and "What about a phone" are attributed with future rewards of 0. We expect that after reranking the results using future rewards, "You can send your" and "The resume has been" can be ranked at top-2 at time step 4, so that their successors, which have a higher probability at time step 5, can be retrieved through a beam search with beam width of only 2.

3.2 Prospective-Performance Network Structure

In practice, given one partial response and its query, its future reward is unknown without results from a large-width beam search as references. Therefore, we propose Prospective Performance Network (PPN) as a future reward estimator. To fully exploit the information from Seq2Seq encoder-decoder framework in decoding process, PPN is designed with the following four components:

- *Semantic Component:* The Semantic Component captures the semantic information of queries and partial responses. Firstly, to extract most semantics from queries and partial responses, it adopts self-attention mechanism to project encoder hidden states $[h_1, h_2, \ldots, h_{T_x}]$ and decoder hidden states $[r_1, r_2, \ldots, r_t]$ into $\hat{h}$ and $\hat{r}$, specifically:

$$
\begin{aligned}
u_i^h &= tanh(W_a^h h_i + b_a^h) \\
a_i^h &= \frac{\exp((u_i^h)^T u_w^h)}{\sum_{i=1}^{T_x} \exp((u_i^h)^T u_w^h)} \\
\hat{h} &= \sum_{i=1}^{T_x} a_i^h h_i
\end{aligned}
\qquad \text{and} \qquad
\begin{aligned}
u_i^r &= tanh(W_a^r h_i + b_a^r) \\
a_i^r &= \frac{\exp((u_i^r)^T u_w^r)}{\sum_{i=1}^{t} \exp((u_i^r)^T u_w^r)} \\
\hat{r} &= \sum_{i=1}^{t} a_i^r r_i
\end{aligned}
\tag{3}
$$

where W_a^h ,W_a^r, b_a^h, b_a^r, u_w^h and u_w^r are the self-attention parameters. In addition, bilinear transformation is used to further catch the correlation between $\hat{h}$ and $\hat{r}$, such that $corr_{r,h} = \hat{r}^T W_c \hat{h}$. Then the Semantic Component concatenates $\hat{h}$, $corr_{r,h}$ and $\hat{r}$ as a semantic information representation s.

- *Attention Component:* In the Attention Component, mean pooling is used to transfer the context $[c_1, c_2, \ldots, c_t]$ into context representation $\hat{c} = \frac{1}{t}\sum_{i=1}^{t} c_i$. This representation extracts the attention context from the Seq2Seq model.
- *Length Component:* In general, the information provided by short and long partial responses is significantly different from each other. Thus the Length Component is created to summarize the length information of partial responses, it transfers the response length into a length vector l by a length embedding matrix L, different for each time step.
- *Probability Component:* The probability of one partial response $\mathbf{y}$ largely determines the generative probabilities of its successors, therefore Probability Component is employed to extract the current probability $p(\mathbf{y})$ of each input partial response. It adds the log-probability scores for the current partial response, as an singe floating point number.

Finally, PPN concatenates all representations s, $\hat{c}$, l and $p(\mathbf{y})$ as the input of a multilayer perceptron, to estimate the future reward of a partial response $\mathbf{y}$. The whole procedure can be formulated as follows:

$$u = [l,\ p(\mathbf{y}),\ s,\ \hat{c}] \tag{4}$$

$$\hat{v}(\mathbf{y}|\mathbf{x}, K, K_l) = \sigma(W_{mlp}u + b_{mlp}) \tag{5}$$

The estimated future reward $\hat{v}(\mathbf{y}|\mathbf{x}, K, K_l)$ is used as part of the ranking scores in beam search (see details in Subsection 3.4).

3.3 Training Data Generation

Since we aim to generate the top-K_s responses from K_l-width beam search using a smaller search space of K_s, PPN is trained using samples generated from the K_l-width beam search, so that it can be used to estimate the partial responses' future rewards with regard to beam width of K_l. As mentioned in section 2.2, top-K_s responses from K_l-width beam search benefit from properties of higher probability and diversity. Therefore K here is set as K_s, so that a partial response with positive future reward is also associated with above desirable properties. The process of training data generation for PPN is shown in Algorithm 1.

Algorithm 1 Generate PNN training data

Input Small beam width K_s, large beam width K_l, maximum search depth L, candidates in every time step in large beam search $C_t = \{\mathbf{y}_t^1, \mathbf{y}_t^2, \cdots, \mathbf{y}_t^{K_l}\}$, lookahead factor n.

1: **Initialization:** Set $Pset = \emptyset$ as positive samples set, Set $Nset = \emptyset$ as negative samples set, $C_{pre} = \emptyset$ as predecessors set, $t = 0$ as initial time step.
2: **repeat**
3: $\quad t = t + 1$
4: $\quad C_{pre} \leftarrow \{\mathbf{y}[1:t] \mid \mathbf{y} \in C_{t+n}\}$
5: $\quad Pset \leftarrow C_t \cap C_{pre}[1 : K_s]$
6: $\quad Nset \leftarrow C_t \cap C_{pre}[K_s : K_l]$
7: **until** $t + n = L$
8: **Output:** $Pset, Nset$

After training data generation, samples from positive samples set are labeled as 1, while those from negative samples set are labeled as 0. The sum of cross-entropy loss is taken as the loss function to optimize PPN.

3.4 Inference using PPN

The output of PPN provides information related to the future performance of a partial response in the K_l-width beam search, therefore integrating it into the decoding step of a K_s-width beam search helps to alleviate the myopic bias.

For a partial response generated from a K_s-width beam search, its generative probability $P(\mathbf{y}|\mathbf{x})$ is combined with its future reward $\hat{v}(\mathbf{y}|\mathbf{x}, K_s, K_l)$ estimated by PPN. For efficiency, we only compute future rewards on K_l candidates with the highest probabilities at each time step. Among these K_l candidates, those top-K_s responses with the highest combined scores:

$$score(\mathbf{y}|\mathbf{x}) = \log P(\mathbf{y}|\mathbf{x}) + \alpha \times \log \hat{v}(\mathbf{y}|\mathbf{x}, K_s, K_l) \tag{6}$$

are chosen as the candidates after re-ranking. The detailed inference process is shown in Algorithm 2.

Algorithm 2 Beam search with PPN

Input Input query $\mathbf{x}$, Seq2Seq model $P(\mathbf{y}|\mathbf{x})$, vocabulary V, small beam width K_s, large beam width K_l, PNN model $\hat{v}(\mathbf{y}|\mathbf{x}, K_s, K_l)$, maximum search depth L, hyperparameter α.

Initialization: Set $S = \emptyset$ as output set, $C = \emptyset$ as candidate sets, $t = 0$ as time step.
repeat
  $t = t + 1$
  $C_{expand} \leftarrow \{\mathbf{y}_i + [w] \mid \mathbf{y}_i \in C, w \in V\}$
  $C_{K_l} \leftarrow \{\text{top } K_l \text{ candidates that maximize } \log P(\mathbf{y}|\mathbf{x}) \mid \mathbf{y} \in C_{expand}\}$
  $C \leftarrow \{\text{top } (K_s - |S|) \text{ candidates that maximize } \log P(\mathbf{y}|\mathbf{x}) + \alpha \times \log \hat{v}(\mathbf{y}|\mathbf{x}, K_s, K_l) | \mathbf{y} \in C_{K_l}\}$
  $C_{complete} \leftarrow \{\mathbf{y} \mid \mathbf{y} \in C, \mathbf{y}[-1] = EOS\}$
  $C \leftarrow C \backslash C_{complete}$
  $S \leftarrow S \cup C_{complete}$
until $|S| = K_s$ *or* $t = L$
Output: $\mathbf{y} = argmax_{\mathbf{y} \in S \cup C} \log P(\mathbf{y}|\mathbf{x})$

3.5 Time Analysis

In the decoding step of Seq2Seq, its time complexity is dominated by the vocabulary size $|V|$, because of the large-scale computation in the operation of probability distribution projection; while the time complexity of implementing PPN is much smaller than that of decoding, with the help of the simple structure of PPN. Therefore, the time complexity of incorporating PPN in K_s-width beam search is on the same scale as that of the vanilla K_s-width beam search, which means incorporating PPN into beam search preserves the inference efficiency.

4 Experiment

4.1 Dataset

To evaluate our approach, we conduct experiment on a Chinese SNS corpus, which contains single-turn dialogue sessions crawled from a Chinese social network service (SNS)[1]. The preprocessing strategy applied on this dataset is following that of Wu et al. (2017). To further evaluate the effect of our method, we also implement experiment on the large-scaled OpenSubtitles Dataset[2] (Lison and Tiedemann, 2016). After that, we obtain approximately 3,000,000 and 50,000 query-response pairs from the Chinese SNS dataset, 15,000,000 and 50,000 query-response pairs from the OpenSubtitles datasets for training and validating respectively.

[1]The Chinese SNS corpus is confidential in the working organization of the authors.
[2]http://www.opensubtitles.org/

4.2 Hyperparameters

4.2.1 Seq2Seq Model

The parameters settings of the two Seq2Seq models trained using the Chinese SNS and OpenSubtitles datasets are mostly the same: the word embedding size and attention size are both set as 512, both the encoder and decoder are composed of single Long-Short-Term-Memory (LSTM) of hidden size = 512. Seq2Seq models are optimized using Adam with learning rate 0.001 and trained for 10 epochs with batch size 512. The vocabulary sizes for Chinese SNS and OpenSubtitles dataset are set to 50,000 and 40,000 respectively, and all the out-of-vocabulary words are replaced with the *"<UNK>"* token. The maximum sentence lengths at inference step are set to 15 and 30 for the Chinese SNS and OpenSubtitles dataset respectively.

4.2.2 PPN Model

The parameters of Seq2Seq structure in PPN models are retained from pre-trained Seq2Seq models and set as untrainable. In this experiment, we set K_s as 10 and K_l as 50, and α in the inference step is set as 0.5. By setting the beam width as 50, and taking 1 million randomly sampled queries from the training samples of the two datasets as inputs, we obtain a group of responses from Seq2Seq outputs, which are then used to generate the training samples following Algorithm 1. In total 12,000,000 (11,000,000) PPN training samples and 10,000 (10,000) validation samples are generated from the Chinese SNS (OpenSubtitles) dataset, with positive/negative ratio of roughly 1. Adam with learning rate 0.001 is used to optimize the PPN model, the batch size is set as 256 and the models are trained for 3 epochs. The self-attention size and position-embedding size in PPN are set as 256 and 128 respectively.

In addition, the lookahead factor n is set as 1 for performance reason. In our previous experiment, the performance of PPN when n=2 is slightly lower than the case when n=1, and drops significantly when n$>$2.

4.3 Baselines

The following models are used as the comparisons with our proposed PPN:

- *Basic Seq2Seq model* with encoder-decoder structure and vanilla beam searches (Luong et al., 2015) is constructed as the standard baseline.
- *Value Network (VN)* introduced in (He et al., 2017) takes the $\hat{v}(\mathbf{y}|\mathbf{x}, K, K_l)$ defined in Section 3.1 as the future reward instead of future BLEU proposed in the original paper. VN and PPN are trained using the same samples and adopted the same loss function.

  In VN, due to its semantic matching module and context coverage module, it contains two more fully connected layers than PPN. Therefore under the same hyperparameter scale, VN is slower at inferencing step than PPN because of its more complicated network structure.
- *Maximum Mutual Information (MMI)* (Li et al., 2016) is a popular diversity-promoting method which takes maximum mutual information as the objective function. Since the PPN is expected to promote the diversity of generated responses, MMI is included to compare with it on diversity-promoting.

  The MMI variant used in our experiment is the MMI-antiLM.

The training and inference process for all models in our experiments are carried out under the same computational environment: a single Nvidia K80 GPU.

4.4 Evaluation Metrics

The proposed PPN, together with other baselines, are automatically evaluated in terms of the **similarity** toward large-width beam search, **diversity** and **efficiency**.

- **Similarity**: We measure the successfulness of one model with a small beam width K_s (denoted as *model-bw-K_s*) on approximating a standard large-width K_l beam search (*Seq2Seq-bw-K_l*) using

	Similarity		Diversity		Efficiency
	Coverage	**Log-prob**	**Distinct-1**	**Distinct-2**	**Time Cost**
Seq2Seq-bw50-top10	-	-7.4490	0.4151	0.5536	1.9496
Seq2Seq-bw10	0.4009	-9.2474	0.2831	0.4272	**0.4399**
MMI-bw10	0.4166	-8.9286	0.2858	0.4323	0.6233
VN-bw10	0.5030	-8.3672	0.3183	0.4715	0.6027
PPN-bw10	**0.5515**	**-8.0738**	**0.3555**	**0.5107**	0.5667

Table 2: Automatic evaluation results on the Chinese SNS dataset.

	Similarity		Diversity		Efficiency
	Coverage	**Log-prob**	**Distinct-1**	**Distinct-2**	**Time Cost**
Seq2Seq-bw50-top10	-	-5.0762	0.4338	0.4585	2.2996
Seq2Seq-bw10	0.4103	-6.9216	0.3341	0.4295	**0.4131**
MMI-bw10	0.4363	-6.8118	0.3240	0.4184	0.6089
VN-bw10	0.4880	-6.4787	0.3550	0.4449	0.7058
PPN-bw10	**0.5980**	**-5.8012**	**0.3711**	**0.4613**	0.5827

Table 3: Automatic evaluation results on the OpenSubtitles dataset.

coverage and **log-probability**. Coverage of *model-bw-*K_s is defined as the ratio of its generated responses presented in top-K_s responses from *Seq2Seq-bw-*K_l. A model with a higher coverage indicates it generates more responses ranked top by the compared large beam search. Log-probability is the mean probability of generated top-K_s responses after logarithm transformation ($log(p(\mathbf{y}|x))$) during inference. Generally speaking, a model with a closer log-probability compared to *Seq2Seq-bw-*K_l is more desirable.

- **Diversity**: Diversity of generated responses from each model is measured by the **distinct-1** and **distinct-2**, which are calculated respectively by the number of distinct unigrams and bigrams in the set of generated responses divided by the total number of generated tokens (Li et al., 2016).
- **Efficiency**: To evaluate the inference efficiency of each model, we also compare the **time cost** in seconds on generating the responses set given one query.

Besides automatic evaluations, the qualities of generated responses from each model are manually evaluated in terms of **relevance** and **grammar correctness**. In total, 300 query-response pairs generated from each model trained using the Chinese SNS dataset are randomly sampled. For each query-response pair, 3 annotators are invited to evaluate its grammatical correctness as 0 (grammatically incorrect) or 1 (grammatically correct), and relevance as 0 (irrelevant), 1 (acceptable) or 2 (great).

5 Results

5.1 Automatic Evaluation

Table 2 and 3 show the automatic evaluation results on the Chinese SNS and OpenSubtitles datasets. Here *Seq2Seq-bw10* and *Seq2Seq-bw50-top10* stand for two basic Seq2Seq models with beam width of 10 and 50 respectively. In addition, only top-10 ranked responses in *Seq2Seq-bw50-top10* are taken into account when evaluating. *MMI-bw10*, *VN-bw10* and *PPN-bw10* refer to the MMI, VN and PPN model respectively, and their beam widths are also set as 10.

It can be observed that *PPN-bw10* obtains the highest coverage and closest log-probability compared to *Seq2Seq-bw50-top10* on both datasets, which indicates that our proposed PPN is capable of simulating a larger-width beam search. In addition, with the help of more explicit method to capture semantics along with the length and probability information from corresponding components, the proposed PPN model is more effective on capturing the future reward than the VN, reflected by the higher coverage of *PPN-bw10* compared to *VN-bw10*.

	Grammar	Relevance
Seq2Seq-bw50-top10	0.8709	1.0934
Seq2Seq-bw10	0.6236	0.7500
MMI-bw10	0.6280	0.7680
VN-bw10	0.7135	0.8567
PPN-bw10	**0.8022**	**0.9505**

Table 4: Human evaluation results on the Chinese SNS dataset. The scores are means over 300 samples.

In terms of diversity, PPN also significantly improves the distinct-1 and distinct-2 compared to the vanilla beam search. It is worth noting that the distinct-1 and distinct-2 of *PPN-bw10* are higher than those of *MMI-bw10*. The PPN exploits the nature of high-diversity in large-width beam search to promote the diversity of responses, and the experiment results show some evidence that such method is more effective than MMI on diversity promotion.

As expected, the time cost of *Seq2Seq-bw50-top10* is approximately 5 times longer than that of *Seq2Seq-bw10*, while *PPN-bw10* only raises the inference time by around 10% meanwhile achieves a significant improvement on quality of responses compared to *Seq2Seq-bw10*. It proves the feasibility of our proposed PPN in practice.

The p-values of PPN against three baseline models on coverage, log-probability, distincts are all smaller than 5e-6, which indicates that the improvements of performance from PPN are significant.

5.2 Human Evaluation

The human evaluation result is shown in Table 4. The responses from *Seq2Seq-bw50-top10* and *PPN-bw10* are annotated with the highest and the second highest grammatical correctness and relevance. The result further reinforces our deduction that a larger beam width improves the quality of generated responses, and the PPN is capable of approximating a large beam width search. In addition, we test the consistency of the human evaluation using Fleiss' kappa (Fleiss and Cohen, 1973). For grammatical correctness and relevance, their Fleiss' kappa on all models are around 0.6 and 0.4 respectively, which can be both considered as "moderate agreement". The p-values of PPN against three baseline models on grammar and relevance scores are all below 0.05.

5.3 Further Analysis

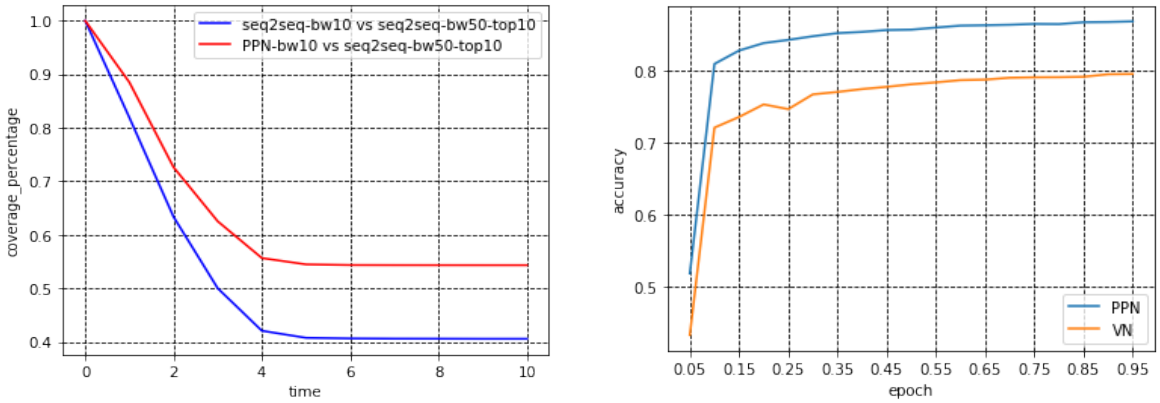

Figure 3: Left: Coverage evolution between PPN and vanilla Seq2Seq over time step. Right: Accuracy evolution on validation set during training of PPN and VN, Chinese SNS dataset.

To analyze the performance of PPN in detail, two plots regarded to the comparisons of coverage and prediction accuracy between PPN and other baseline models are shown in Figure 3. It can be observed in the left plot of Figure 3 that the coverages of *PPN-bw10* are always higher than those of *Seq2Seq-bw10*,

which indicates that PPN generates more top responses from large-width beam search consistently over time. Moreover, the right plot in Figure 3 shows the accuracy of PPN on classifying the samples in validation dataset throughout the training of PPN and VN. The higher accuracies of PPN further prove that PPN is more effective on estimating the future reward than VN.

6 Related Work

Inspired by the success of the Seq2Seq framework on NMT (Cho et al., 2014; Sutskever et al., 2014b; Bahdanau et al., 2015), this framework has been adopted for response generation (Vinyals and Le, 2015; Shang et al., 2015) and is proved to be effective on generating responses based on given queries (Sordoni et al., 2015; Li et al., 2016; Serban et al., 2016; Xu et al., 2017).

Most NMT and NRG systems generate outputs using the beam search algorithm, which unfortunately suffers from the myopic bias. To solve the myopic bias, He et al. (2017) and Li et al. (2017) both propose method to take the future BLEU of decoder partial outputs into account in beam search. Another study indirectly related to our work is Wiseman and Rush (2016), it treats the target sequences in training set as the gold sequences, and directly training the beam search to select word instead of probability. Although these methods are proved to be effective on NMT, it might be inappropriate to directly apply them on NRG, since appropriate responses for one query are highly diverse in terms of semantics. By contrast, the proposed method exploits the nature of beam search width to alleviate the myopic bias.

7 Conclusions

In this paper, we have described our attempt on reducing the myopia in beam search for NRG. In detail, we have: 1) verified the effectiveness of increasing the beam width on relieving the myopic bias; 2) proposed a future reward to alleviate the myopic bias of canonical Seq2Seq-based NRG model, and specially designed a perspective-performance network to quantify the future reward reasonably; 3) presented a new decoding strategy on the basis of the perspective-performance network to generate top-ranked responses given by a large-width beam search. The experiment results show the effectiveness and efficiency of our method. The proposed method is especially useful on online conversational agents, where the speed of response generation is of great importance. In the future, to better estimate the future reward, we will explore different model structures and new training data generation strategies.

Adaptive Multi-Task Transfer Learning for Chinese Word Segmentation in Medical Text

Junjie Xing **Kenny Q. Zhu** **Shaodian Zhang**
Shanghai Jiao Tong University
{jjxing@,kzhu@cs.,shaodian@apex.}sjtu.edu.cn

Abstract

Chinese word segmentation (CWS) trained from open source corpus faces dramatic performance drop when dealing with domain text, especially for a domain with lots of special terms and diverse writing styles, such as the biomedical domain. However, building domain-specific CWS requires extremely high annotation cost. In this paper, we propose an approach by exploiting domain-invariant knowledge from high resource to low resource domains. Extensive experiments show that our model achieves consistently higher accuracy than the single-task CWS and other transfer learning baselines, especially when there is a large disparity between source and target domains.

1 Introduction

Chinese word segmentation (CWS) is a fundamental task for Chinese natural language processing (NLP). Most state-of-art methods are based on statistical supervised learning and neural networks. They all rely heavily on human-annotated data, which is a time-consuming and expensive work. Specially, for domain CWS, e.g., medical field , the annotation expense is even higher because only domain experts are qualified for the work.

Moreover, CWS tools trained from open source datasets, e.g., SIGHAN2005[1], face a significance performance drop when dealing with domain text. The ambiguity caused by domain terms and writing style makes it extremely difficult to train a universal CWS tool. As shown in Table 1, given a medical term "高铁血红蛋白血症" (methemoglobinemia), Chinese medical experts would annotate it as "高/铁/血红蛋白/血症", which means anemia caused by hemoglobin with "high iron" (in Chinese, means iron with valence of 3), corresponding to the morphology of "Methemoglobinemia". "PKU" stands for a model trained on PKU's People's Daily corpus, we can see that after segmentation, the word "铁血" (jagged) is treated as one word, which is wrong semantically. Also, another popular Chinese CWS tool Jieba [2] mistakenly puts the characters "高" and "铁" together, which stands for the high-speed bullet train in China.

CWS tool	**高铁血红蛋白血症**			
PKU	高 high	铁血 jagged	红蛋白 albumen	血症 anemia
Jieba	高铁 train	血红蛋白 hemoglobin		血症 anemia
Medical	高 high	铁 iron	血红蛋白 hemoglobin	血症 anemia

Table 1: Medical CWS ambiguity with CWS tools. PKU stands for a model trained on PKU dataset.

In summary, domain specific CWS task poses significant challenges because:

1. Tools built on open source annotated corpus works badly on domain specific CWS.

2. Annotated domain data is scarce due to high cost.

3. How to leverage open source annotated data despite their generality is an open question.

Recently, efforts have been made to exploit open source (high resource) data to improve the performance of domain specific (low resource) tasks and decrease the amount of domain annotated data (Yang et al., 2017; Peng and Dredze, 2016; Mou et al., 2016). In this paper, we further this line of work by developing a multi-task learning (Caruana, 1997; Peng and Dredze, 2016) framework, named *Adaptive Multi-Task Transfer Learning*. Inspired by the success of *Domain Adaptation* (Saenko et al., 2010; Tzeng et al., 2014; Long and Wang, 2015b), we propose to minimize distribution distance of hidden representation between the source and target domain, thus make the hidden representations *adapt* to each other and obtain domain-invariant features. Finally, we annotated 3 medical datasets from different medical departments and medical forum, together with 3 open source datasets[??]. The contribution of this paper can be summarized as follows:

- We propose a novel framework for Chinese word segmentation in the medical domain.
- To the best of our knowledge, we are the first to analyze the performance of transfer learning methods against the amount of disparity between target/source domains.
- Our framework outperforms strong baselines especially when there is substantial *disparity*.
- We open source 3 medical CWS datasets from different sources, which can be used for further study.

2 Related Work

2.1 Chinese word segmentation

Statistical Chinese word segmentation has been studied for decades. Xue and others (2003) was the first to treat it as a sequence tagging problem, using a maximum entropy model. Peng et al. (2004) achieved better results by using a conditional random field model (Lafferty et al., 2001). This method has been followed by many other works (Zhao et al., 2006; Sun et al., 2012).

Recently, neural network models have been applied on CWS. These methods use automatically derived features from neural network instead of hand-crafted discrete features. Zheng et al. (2013) first adopted neural network architecture to CWS. Chen et al. (2015b) used Long short-term memory(LSTM) to capture long term dependency. Chen et al. (2015a) proposed a gated recursive neural network (GRNN) to incorporate context information. In this paper, we adopt Bidirectional LSTM-CRF Models (Huang et al., 2015) as our base model.

2.2 Transfer Learning

Transfer learning distills knowledge from source domain and helps target domain to achieve a higher performance (Pan and Yang, 2010). In feature-based models, many transfer approached have been studied, including instance transfer (Jiang and Zhai, 2007; Liao et al., 2005), feature representation transfer (Argyriou et al., 2006; Argyriou et al., 2007), parameter transfer(Lawrence and Platt, 2004; Bonilla et al., 2007) and relation knowledge transfer(Mihalkova et al., 2007; Mihalkova and et al., 2009).

Recently, the transferability of neural networks is also studied. For example, (Mou et al., 2016) studied two methods (INIT, MULT) on NLP applications. Peng and Dredze (2016) proposed to use domain mask and linear projection upon multi-task learning (MTL) (Long and Wang, 2015a). In this paper, we follow MTL and extend the framework with a novel loss function.

3 Single-Task Chinese word segmentation

In this section, we briefly formulate the Chinese word segmentation task and introduce our base model, Bi-LSTM-CRF (Huang et al., 2015).

3.1 Problem Formulation

Chinese word segmentation is often treated as a sequence tagging problem on character level. BIES tagging scheme is broadly accepted by annotators, each character in sentence is labeled as one of $\mathcal{L} = \{B, I, E, S\}$, indicating begin, inside, end of a word, and a word consisting of a single character.

Given a sequence with n characters $X = \{x_1, \ldots, x_n\}$, the aim of the CWS task is to find a mapping from X to $Y^* = \{y_1^*, \ldots, y_n^*\}$:

$$Y^* = \arg\max_{Y \in \mathcal{L}^n} p(Y|X) \tag{1}$$

where $\mathcal{L} = \{B, I, E, S\}$

The general architecture of neural CWS contains: (1) a character embedding layer; (2) an encoder automatically extracts feature and (3) a decoder inferences tag from the feature.

In this paper, we utilize a widely-used model as the base of our framework, which consists of a bi-directional long short-term memory neural network (BiLSTM) as encoder and conditional random fields (CRF) (Lafferty et al., 2001) as decoder.

3.2 Encoder

In neural network models, an encoder is usually adopted to automatically extract feature instead of human-crafted feature engineering.

Bi-LSTM LSTM is a popular variant of RNN in order to alleviate the vanishing gradient problem (Bengio et al., 1994; Hochreiter and Schmidhuber, 1997). In addition to considering *past* information from left, Bidirectional LSTM also captures *future* information from the right of the token.

3.3 Decoder

We deploy a conditional random fields layer as decoder. Specifically, $p(Y|X)$ in Eq. (1) could be formulated as

$$p(Y|X) = \frac{\exp(\Phi(X, Y))}{\sum_{Y' \in \mathcal{L}^n} \exp(\Phi(X, Y'))} \tag{2}$$

Here, $\Phi(\cdot)$ is a potential function, consider the situation that we only take the influence between two consecutive variables into account:

$$\Phi(X, Y) = \sum_{j=1}^{n} \phi(X, i, y_i, y_{i-1}) \tag{3}$$

$$\phi(X, i, y_i, y_{i-1}) = s(X, i)_{y_i} + t_{y_i y_{i-1}} \tag{4}$$

where $s(X, i) \in \mathbb{R}^{|\mathcal{L}|}$ is a function that measure the score of the i_{th} character for each label in $\mathcal{L} = \{B, I, E, S\}$, and $t \in \mathbb{R}^{|\mathcal{L}| \times |\mathcal{L}|}$ denotes the transition score between labels. More formally:

$$s(X, i) = \mathbf{W}^\top h_i + \mathbf{b} \tag{5}$$

where h_i is the hidden state of the i^{th} character after BiLSTM; $\mathbf{W} \in \mathbb{R}^{d_h \times |\mathcal{L}|}$ and $\mathbf{b} \in \mathbb{R}^{|\mathcal{L}|}$ are all parameters in the model.

4 Adaptive Multi-Task Transfer Learning

With the motivation to leverage domain-invariant knowledge from high resource domain, we utilize the framework of multi-task learning (Caruana, 1997), which is one of the methods in *transfer learning*, and further introduce three models under the proposed *Adaptive Multi-Task Transfer Learning* framework (**AMTTL**). We exploit three statistical distance measures as the *Adaptive* part to test the generality of our framework.

4.1 Notations and Definitions

In this paper, multi-task learning is defined as a *dual-task* learning, which contains two *domains* $\mathcal{D}_S$ and $\mathcal{D}_T$. Our purpose is to improve the performance of *target domain* by exploiting knowledge from *source domain*.

Each domain $\mathcal{D}$ contains two components: a feature space $\mathcal{X}$ and a marginal probability distribution $P(X)$, where X is a sample sentence, and $X = \{x_1, \ldots, x_n\} \in \mathcal{X}$.

Given a single domain, $\mathcal{D} = \{\mathcal{X}, P(X)\}$, a *task* contains two components: a label space $\mathcal{Y}$ and a predictive function $f(\cdot)$, which can be learned during the training phase. Formally, $\mathcal{T} = \{\mathcal{Y}, f(\cdot)\}$.

4.2 Formal Definition

We now give the definition of *Adaptive Multi-Task Transfer Learning*.

Definition 4.1. Given two domains $\mathcal{D}_S$ and $\mathcal{D}_T$, and corresponding tasks $\mathcal{T}_S$, $\mathcal{T}_T$, *Adaptive Multi-Task Transfer Learning* aims to improve the learning of target predictive function $f_T(\cdot)$ by using *shared parameter* and *minimizing the distance* between $P(X_S)$ and $P(X_S)$, $P(Y_S|X_S)$ and $P(Y_T|X_T)$, where $\mathcal{D}_S \neq \mathcal{D}_T$, or $\mathcal{T}_S \neq \mathcal{T}_T$.

4.3 Objective Function

The objective function of our proposed *Adaptive Multi-Task Transfer Learning* can be formulated as follows:

$$\mathcal{J}(\theta^{(a)}, \theta^{(b)}) = \mathcal{J}_{seg} + \alpha \mathcal{J}_{Adap.} + \beta \mathcal{J}_{L_2} \tag{6}$$

where $\theta^{(a)}$ and $\theta^{(b)}$ are model parameters for task a and b, α and β are hyper-parameters to be chosen.

$\mathcal{J}_{seg}$ stands for the negative log likelihood for source domain and target domain. At each training step, we minimize the mean negative log likelihood:

$$\begin{aligned} \mathcal{J}_{seg} = &-\frac{1}{n}\sum_{i=1}^{n} \log p(Y_i^{(a)}|X_i^{(a)}) \\ &-\frac{1}{m}\sum_{i=1}^{m} \log p(Y_i^{(b)}|X_i^{(b)}) \end{aligned} \tag{7}$$

$\mathcal{J}_{Adap.}$ is the *Adaptive* loss used to capture domain-invariant knowledge between different domains, which forces the hidden representations between two domains to *adapt* to each other. Given two sets of hidden representation, denoted as $\mathbf{h^{(a)}}$ and $\mathbf{h^{(b)}}$, and a statistic distance function $g(\cdot)$, $\mathcal{J}_{\text{Adap.}}$ can be calculated as:

$$\mathcal{J}_{\text{Adap.}} = g(\mathbf{h^{(a)}}, \mathbf{h^{(b)}}) \tag{8}$$

where $g(\cdot)$ can be, but is not limited to, KL divergence, maximum mean discrepancy (MMD) (Gretton et al., 2012) or central moment discrepancy (CMD) (Zellinger et al., 2017); $\mathbf{h^{(a)}}$ and $\mathbf{h^{(b)}}$ are different for different model setting, which will be defined in Sec 4.4.

$\mathcal{J}_{L_2}$ is the L_2 regularization which is used to control overfitting problem:

$$\mathcal{J}_{L_2} = \left|\left|\theta^{(a)}\right|\right|_2^2 + \left|\left|\theta^{(b)}\right|\right|_2^2 \tag{9}$$

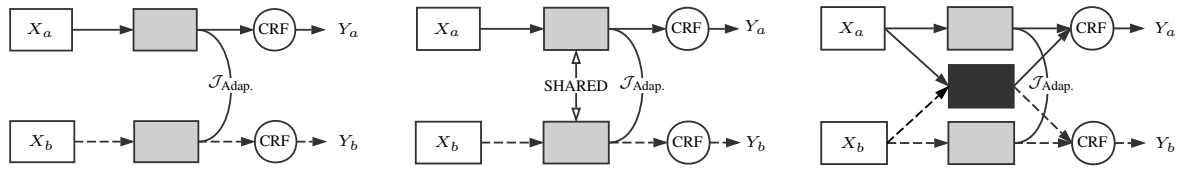
4.4 Models

In this section, we present the design of three variants of our framework in detail. The architectures are presented in Figure 1.

4.4.1 Model-I Specific LSTM

This model can be interpreted as two *parallel tasks* connected with $\mathcal{J}_{\text{Adap.}}$ after specific Bi-LSTM layers of two tasks. We design the model in order to see whether knowledge can actually be transfered through the *Adaptive* loss alone.

The hidden representation and CRF score of *task* t at position i can be computed as:



(a) Model-I (b) Model-II (c) Model-III

Figure 1: Three models with different settings. The white block represents Embedding lookup layer, while the gray and black block represents Bi-LSTM layer. The "SHARED" in Figure 1b stands for shared Bi-LSTM for both tasks. The "$\mathcal{J}_{\text{Adap.}}$" represents *Adaptive* loss for the hidden representation after corresponding layer, which is formally discussed in Sec 4.3. The solid arrow and dotted arrow show the flow of task a and task b respectively.

$$h_i^{(t)} = \text{Bi-LSTM}(X^{(t)}, \theta^{(t)}) \tag{10}$$

$$s(X, i)^{(t)} = \mathbf{W^{(t)}}^\top h_i^{(t)} + \mathbf{b}^{(t)} \tag{11}$$

where $h_i^{(t)} \in \mathbb{R}^{2d_h}$, $\mathbf{W^{(t)}} \in \mathbb{R}^{2d_h \times |\mathcal{L}|}$, $\mathbf{b}^{(t)} \in \mathbb{R}^{|\mathcal{L}|}$, $\theta^{(t)}$ denotes parameters of domain specific Bi-LSTM. The $\mathcal{J}_{\text{Adap.}}$ between two tasks, denoted by a and b, is formulated as:

$$\mathcal{J}_{\text{Adap.}} = g(\mathbf{h}^{(a)}, \mathbf{h}^{(b)}) \tag{12}$$

where $\mathbf{h}^{(t)} = \{h_i^{(t)} | X^{(t)} \in \mathcal{X}^{(t)}\}$, $\mathcal{X}^{(t)}$ is a batch of input sequences.

4.4.2 Model-II Shared LSTM

Model-II is designed to adopt domain specific embedding layers, shared Bi-LSTM layer and domain specific CRF layers. Note that traditional *multi-task learning* uses shared embedding (Ruder, 2017). Shared embedding means that source and target domain share the same set of embedding parameters while domain-specific embedding means that the two domains maintain their own sets.

The hidden representation of *task* t at position i can be computed as:

$$h_i^{(t)} = \text{Bi-LSTM}(X^{(t)}, \theta) \tag{13}$$

where two tasks share Bi-LSTM parameter θ, which is the only difference with Model-I. CRF score and $\mathcal{J}_{\text{Adap.}}$ is the same as (11)(12).

4.4.3 Model-III Shared & Specific LSTM

Model-III is a combination of Model-I and Model-II, with both domain specific and shared Bi-LSTM layers.

The hidden representation and CRF score of *task* t at position i can be computed as:

$$\begin{aligned} h_i^{(t)} &= \text{Bi-LSTM}(X, \theta^{(t)}) \oplus \text{Bi-LSTM}(X, \theta) \\ &= h_{i(specific)}^{(t)} \oplus h_{i(shared)}^{(t)} \end{aligned} \tag{14}$$

$$s(X, i)^{(t)} = \mathbf{W^{(t)}}^\top h_i^{(t)} + \mathbf{b}^{(t)} \tag{15}$$

where $h_i^{(t)} \in \mathbb{R}^{4d_h}$, $\mathbf{W^{(t)}} \in \mathbb{R}^{4d_h \times |\mathcal{L}|}$, and $\mathbf{b}^{(t)} \in \mathbb{R}^{|\mathcal{L}|}$. $\theta^{(t)}$ and θ denote the parameter of domain specific and shared Bi-LSTM. $\mathcal{J}_{\text{Adap.}}$ can be calculated as :

$$\mathcal{J}_{\text{Adap.}} = g(\mathbf{h}^{(a)}, \mathbf{h}^{(b)}) \tag{16}$$

where $\mathbf{h}^{(t)} = \{h_{i(specific)}^{(t)} | X^{(t)} \in \mathcal{X}^{(t)}\}$, $\mathcal{X}^{(t)}$ is a batch of input sequences.

5 Experiment

In this section, we evaluate our proposed models on real-world medical Chinese word segmentation tasks[3], where annotated data is scarce and domain-drift is significant with open source annotated data. We conduct extensive experiments and discuss the result in detail. We also conduct an ablation test.

5.1 Datasets

We use three open source CWS datasets, namely PKU and MSR from SIGHAN2005 Bakeoff[4] and WEIBO from (Qiu et al., 2016). The information of the datasets is shown in Table 2a.

We annotated three medical datasets for our experiment and future research. The first two datasets are electronic medical records (EMR) from different departments. The third dataset is medical forum data from *Good Doctor Online*[5], which is a Chinese forum for medical consult. The information of the datasets is shown in Table 2b.

The electronic medical records are collected from our partner hospital, the data only permits non-commercial/academical use. The annotation was done by several doctors. It was carried out following a Chinese word segmentation criteria [6] created by Institute of Computational Linguistics at Peking University. For quality control, annotators were trained until they achieve about 80% inter-annotator agreement on previously annotated materials. Then we conducted double-blind annotation, with resolution of disagreements by a senior annotator. The entire annotation process follows Cohen et al. (2017).

On medicolegal issues, the EMR data we received had already been anonymized and de-identified. Given the fact that China doesn't offer an act like HIPPA(Health Insurance Portability and Accountability Act), we only released the medical forum dataset.

5.2 Disparity Study

Transfer Learning aim to improve the performance of low-resource domain task by exploiting the annotated data form high-resource domain, thus the *Disparity* between different tasks is a leading factor to influence the *transferability* between different domains with different methods.

In this paper, we used $\mathcal{X}^2$ test (Kilgarriff and Rose, 1998) to quantify the *Disparity* between three medical corpus. If the size of corpus 1 and corpus 2 are N_1, N_2 and word w has observed frequencies $o_{w,1}$, $o_{w,2}$, then expected value $e_{w,1} = \frac{N_1 \times (o_{w,1}+o_{w,2})}{N_1+N_2}$, and likewise for $e_{w,2}$, then

$$\mathcal{X}^2 = \sum \frac{(o-e)^2}{e} \tag{17}$$

$\mathcal{X}^2$ test shows that *Disparity* between forum dataset and two EMR datasets are similar, but both are much larger than the *Disparity* between the two EMR datasets, as shown in Table 3.

Due to the fact that $\mathcal{X}^2$ test doesn't permit comparison between corpus of different sizes (Kilgarriff and Rose, 1998), we propose a simple *agreement* test, using the size of the intersection between the most common n tokens (bi-gram) to quantify the *disparity* between medical corpus and open source corpus. We set n to 500.

[3]Our code and data are released at `https://github.com/adapt-sjtu/AMTTL`

[4]http://sighan.cs.uchicago.edu/bakeoff2005/

[5]http://www.haodf.com

[6]`http://sighan.cs.uchicago.edu/bakeoff2005/data/pku_spec.pdf`

Table 3: Result of $\mathcal{X}^2$ test between medical datasets, the larger the higher disparity.

Dataset	Cardiology	Respiratory	Forum
Cardiology	0	0.069	0.126
Respiratory	0.069	0	0.122
Forum	0.126	0.122	0

Table 4: Result of *agreement* test between medical datasets and open source datasets, the smaller the higher disparity.

Dataset	Cardiology	Respiratory	Forum
PKU	25	27	76
MSR	23	25	80
WEIBO	54	50	135

Table 5: Performance (F1-score) of Single-task model compared with state-of-art CWS.

Models	Cardiology	Respiratory	Forum
Single-task	81.10	81.33	75.62
(Cai and Zhao, 2016)	80.1	81.5	73.0
(Zhang et al., 2016)	82.46	81.74	77.14

Agreement test shows that the *Disparity* between PKU/MSR and two EMR datasets are close, both far larger than the *Disparity* between PKU/MSR and forum dataset. WEIBO dataset is more similar with medical datasets than PKU and MSR.

5.3 Single-task Performance

Before introducing our experiments on proposed framework, we first evaluate the effectiveness of the single-task model (Bi-LSTM-CRF), which is our base model. We compare the model with the two state-of-art on Chinese word segmentation, proposed by Cai and Zhao (2016) and Zhang et al. (2016) respectively. We run experiments on our datasets with their code released on github[7,8]. The results show that the performance of single-task model and state-of-art are close, as shown in Table 5, which indicates the single-task model is a strong baseline for our advanced models.

5.4 Training

The training phrase aims to optimize the model parameters $\theta^{(a)}$ and $\theta^{(b)}$ by minimizing the objective function defined in Eq. (6). We use Adam (Kingma and Ba, 2014) with mini-batch. Each batch contains sentences from both domains. The hyper-parameter setting is discussed later.

5.5 Experiment Settings

The dimension of character embedding and the LSTM hidden state dimension are 50. The batch size is 30. We evaluate our framework for a total of 15 transfer learning tasks. For each task, we take all of source training data and 10% of target training data. Hyper-parameters are determined by tuning against the development set.

5.6 Baselines

Several baseline methods are compared.
Single-task uses target domain data only, as discussed in Section 3.
INIT fine-tunes the model trained on source domain using target domain data.
Multi-Task shares parameter for both source and target domain, the model is trained simultaneously.
Linear Projection shares encoder and projects hidden representations into specific feature space.
Domain Mask shares encoder and select different part of hidden representation for source and target domains.

Our implementation of **INIT** follows Mou et al. (2016), and the implementation of **Multi-Task** follows the models we proposed in Sec. 4 by removing $\mathcal{J}_{\text{Adap.}}$, annotating *Model w/o* $\mathcal{J}_{\text{Adap.}}$ in Table 6 and 7. **Linear Projection** and **Domain Mask** both come from (Peng and Dredze, 2016).

5.7 Hyper-parameter

In our framework, we have two hyper-parameters α and β, which controls the weight of $\mathcal{J}_{\text{Adap.}}$ and $\mathcal{J}_{L_2}$. Our experiments show that $\alpha \in [0.3, 0.7]$ and $\beta \in [0.2, 0.3]$ works best.

5.8 Result and Discussion

Table 6 and Table 7 respectively shows the performance of 6 cross medical CWS experiments and 9 experiments between open source datasets and medical datasets. **Bold** indicates scores that outperforms all baselines. Underline indicates the highest score for each task. In general, we learn that

1. All transfer learning methods outperforms strong baseline of single-task method (discussed in Section 5.3). Especially, our models outperforms from 2% to 6% than single-task baseline.

2. The *Adaptive* part of our model, $\mathcal{J}_{\text{Adap.}}$, is proven to be promising. First, Model-I, which is a parallel training without sharing parameters and leveraging pretrained optimized initialization, outperforms single-task baseline by 4% on average. Second, $\mathcal{J}_{\text{Adap.}}$ improves the performance by 1% on average for both Model-II and Model-III. It shows that the $\mathcal{J}_{\text{Adap.}}$ does capture domain-invariant knowledge apart from the shared parameters.

3. Within the three models we proposed, Model-II performs best, outperforming other two on 40/45 experiment instances. Model-I and Model-III are equal in match. We argue that it is because the missing of shared parameter of Model-I and the possible noise encoded by the specific layer of Model-III.

4. For the three statistic distance measures we test in experiment, the overall performance is close. Compared with MMD and CMD, KL gains a more stable improvement on all experiments. However, CMD performs better to hit more best scores than KL and MMD.

Next, we analyze the result from a special aspect, the *Disparity* between source and target datasets:

1. In Table 6, INIT outperforms all other baselines and our approaches in task R $\rightarrow$ C and C $\rightarrow$ R, but downperforms our approaches in the others. We argue that the effectiveness of INIT on task between domain R and C result from the low *Disparity* between the two domains, as shown in Table 3. We speculate that the INIT approach works so well between domains with low disparity because: (a) well trained model in the source domain provides a good start point for training in the target domain, which is very similar to the source; (b) the final model is fine-tuned against the target domain only. Our method is disadvantaged in this scenario because: (a) our model parameters are randomly initialized and are independent between two domains (except for the shared parameters), thus it cannot inherit so much information from the source domain as INIT does; (b) the final model is fine-tuned against both the source and the target domain at the same time; thus noise from the source domain may be introduced into the target domain. This is a research problem we want to tackle in the future.

2. We first refer to Table 4. We can simply categorize the 9 types of domain transfers into 4 levels. P $\rightarrow$ C, P $\rightarrow$ R, M $\rightarrow$ C and M $\rightarrow$ R indicate high disparity, W $\rightarrow$ C, W $\rightarrow$ R indicate low disparity, P $\rightarrow$ F, M $\rightarrow$ F indicate low similarity, W $\rightarrow$ F indicates high similarity. Then we can find that, in 4 tasks of high disparity, our approach outperforms all baselines. When disparity goes down to the second level, our approach underperforms INIT but only with gap of 0.4%. However, when disparity continuously goes down to the third and forth level, INIT outperforms our approach by 3-4%.

At last, we'd like to discuss the effect of transferring from a general-domain dataset (which has the advantage of larger quantity) against that of transferring from a medical dataset (which is better at quality). After comparing the tasks with the same target domain, we conclude that quality weighs more than quantity. Taking Cardiology as an example, the size of source training set used in cross-medical (high quality) tasks is only 1 percent of that used in general-to-medical (high quantity) tasks, but the cross-medical results still outperform the latter.

5.9 Ablation Test

To investigate the effectiveness of different components in our framework, we do ablation test based on Model-II on task (P $\rightarrow$ R) with $\mathcal{J}_{\text{Adap.}}$ calculated by MMD. Results are reported in Table 8. *Model*-II *w/o shared Bi-LSTM* uses domain-specific Bi-LSTM, while *Model*-II *w/o specific embedding* uses shared embedding for both domains.

Results show that the choice of statistic distance measure weights least, since the performance of different measures are close. The test verifies our choice of *shared Bi-LSTM* and *specific embedding*.

Table 8: Comparisons of different settings of our method.

Settings	F1-score	δ
Model-II + $\mathcal{J}_{\text{Adap.}}$-MMD	85.98	0
Model-II + $\mathcal{J}_{\text{Adap.}}$-KL	85.88	-0.10
Model-II + $\mathcal{J}_{\text{Adap.}}$-CMD	85.83	-0.15
Model-II w/o $\mathcal{J}_{\text{Adap.}}$	84.17	-1.49
Model-II w/o shared Bi-LSTM	85.26	-0.40
Model-II w/o specific embedding	82.09	-3.57

6 Conclusion

In this paper, we propose an adaptive multi-task transfer learning framework and three model instances with different settings. 15 experiments between medical datasets and open source datasets show that: *AMTTL*(1) outperforms multi-task learning all the way; (2) outperforms all baselines when the disparity between target and source dataset is high. For future work, we plan to study the transferability between different tasks for Chinese NLP and cross-lingual NLP tasks.

Abstract

Developing conversational systems that can converse in many languages is an interesting challenge for natural language processing. In this paper, we introduce *multilingual addressee and response selection*. In this task, a conversational system predicts an appropriate addressee and response for an input message in multiple languages. A key to developing such multilingual responding systems is how to utilize high-resource language data to compensate for low-resource language data. We present several knowledge transfer methods for conversational systems. To evaluate our methods, we create a new multilingual conversation dataset. Experiments on the dataset demonstrate the effectiveness of our methods.

1 Introduction

Open-domain conversational systems, such as chatbots, are attracting a vast amount of interest and play their functional and entertainment roles in real-world applications. Recent conversational models are often built in an end-to-end fashion using neural networks, which require a large amount of training data (Vinyals and Le, 2015; Serban et al., 2016). However, it is challenging to collect enough data to build such models for many languages. Consequently, most work has targeted high-resource languages, such as English and Chinese (Shang et al., 2015; Serban et al., 2016).

In this work, we aim to develop *multilingual* conversational systems that can return appropriate responses in many languages. Specifically, we assume the two types of systems: (i) **language-specific** systems and (ii) **language-invariant** systems. A language-specific system consists of multiple conversational models, each of which returns responses in a corresponding language. By contrast, a language-invariant system consists of a single unified model, which returns responses in all target languages. A key to building these multilingual models is how to utilize high-resource language data to compensate for low-resource language data. We present several knowledge-transfer methods. To the best of our knowledge, this is the first work focusing on low-resource language enablement of conversational systems.

One challenge when developing conversational systems is how to evaluate the system performance. For generation-based conversational systems, which generate each word for a response one by one, many studies adopt human judgments. However, it is costly and impractical to adopt this evaluation method for multilingual systems, especially for minor-language systems. Thus, as a first step, we develop retrieval-based conversational systems and evaluate the ability to select appropriate responses from a set of candidates. Fig. 1 shows the overview of our multilingual responding systems.

This paper provides: (i) formal task definitions, (ii) several knowledge-transfer methods and (iii) a multilingual conversation dataset. First, we introduce and formalize the two task settings: *single-language adaptation* for language-specific systems and *multi-language adaptation* for language-invariant systems (Sec. 4). Second, we present several methods leveraging high-resource language data to compensate for low-resource language in the two settings (Sec. 5). Our basic method uses multilingual word embeddings and transfers source-language knowledge to target languages (Sec. 5.1 (a)). We also design

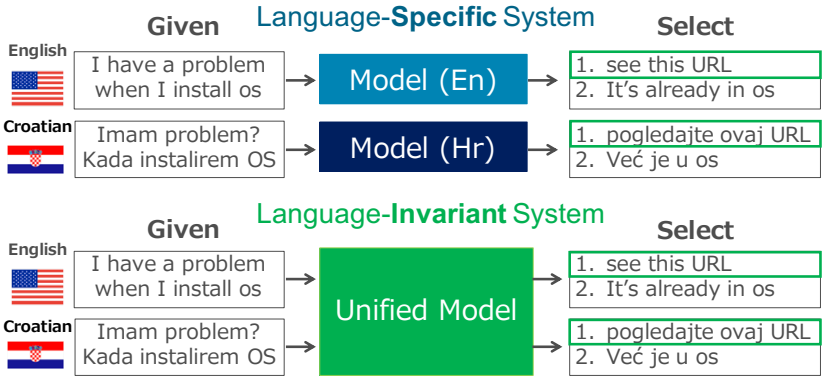

Figure 1: Example of multilingual response selection.

three extended methods. Among them, the fine-tuning method builds a model specific to a single target language (Sec. 5.2 (b)). The joint loss training and the multi-language adversarial training methods build a unified model invariant for multiple target languages (Sec. 5.2 (c) and (d)). Third, we create a multilingual conversation corpus and dataset[1] (Sec. 6). From the Ubuntu IRC Logs[2], we collect the logs in 12 languages.

To show benchmark results, we perform experiments on the created dataset (Sec. 7). The results demonstrate that our methods allow models to effectively adapt to low-resource target languages. In particular, our method using Wasserstein GAN (Arjovsky et al., 2017) achieves high-performance for simultaneously dealing with multiple languages with a single unified model.

2 Related Work

Short Text Conversation

In short text conversation, a system predicts an appropriate response for an input message in *single-turn, two-party conversation* (Ritter et al., 2011). One major approach to it is the generation-based approach, which generates a response using a sequence-to-sequence model (Shang et al., 2015; Vinyals and Le, 2015; Serban et al., 2016; Li et al., 2016; Mei et al., 2017). Another popular approach is the retrieval-based approach, which retrieves candidate responses from a repository and returns the highest scoring one using a ranking model (Wang et al., 2013; Lu and Li, 2013; Ji et al., 2014; Wang et al., 2015). Lowe et al. (2015) proposed next utterance classification (NUC), in which a model has to select an appropriate response from a fixed set of candidates.

Evaluation for Conversational Systems

Evaluation methods for conversational systems are an open question (Lowe et al., 2015; Liu et al., 2016; Lowe et al., 2017). While many of previous studies on conversational systems used human judgements, automatic evaluation methods are attractive because it is much easier and less costly to use. However, according to Liu et al. (2016), for generation-based systems, automatic evaluation metrics, such as BLEU (Papineni et al., 2002), correlate very weakly with human judgements.

For retrieval-based systems, some studies used ranking-based metrics, such as mean average precision and accuracy (Ji et al., 2014; Wang et al., 2015). Lowe et al. (2016) confirmed the feasibility of NUC as a surrogate task for building conversational systems. Although there are controversial issues for these evaluation methods (Lowe et al., 2015), as a practical choice, we adopt the accuracy-based metric for evaluating multilingual conversational systems.

[2]http://irclogs.ubuntu.com/

Addressee and Response Selection

NUC focuses on two-party, *multi-turn conversation*. As an extension of it, Ouchi and Tsuboi (2016) proposed addressee and response selection (ARS) for *multi-party conversation*. ARS integrates the addressee detection problem, which has been regarded as a problematic issue in multi-party conversation (Traum, 2003; Jovanović and Akker, 2004; Bohus and Horvitz, 2011; Uthus and Aha, 2013). Mainly, this problem has been tackled in spoken/multimodal dialog systems (Jovanović et al., 2006; Akker and Traum, 2009; Nakano et al., 2013; Ravuri and Stolcke, 2014). While these systems largely rely on acoustic signal or gaze information, ARS focuses on text-based conversations. Extending these studies, we tackle multilingual, multi-turn, and multi-party text conversation settings.

Cross-Lingual Conversation

The motivation of our task is similar with that of Kim et al. (2016). They tackled cross-lingual dialog state tracking in English and Chinese. While they transfer knowledge from English to Chinese, we transfer knowledge between a high-resource and several low-resource languages.

3 Addressee and Response Selection

Addressee and response selection (ARS)[3], proposed by Ouchi and Tsuboi (2016), assumes the situation where a responding agent returns a response to an addressee following a conversational context.

Formally, given an input conversational situation $\boldsymbol{x} \in X$, a system predicts $\boldsymbol{y} \in Y$, which consists of an addressee a and a response $\boldsymbol{r}$:

$$\textsc{Given} : \boldsymbol{x} = (a_{\mathrm{res}},\ \mathcal{C},\ \mathcal{R}), \quad \textsc{Predict} : \boldsymbol{y} = (a, \boldsymbol{r})$$

where a_{res} is a responding agent, $\mathcal{C}$ is a context (a sequence of previous utterances) and $\mathcal{R}$ is a set of candidate responses. To predict an addressee a, we select an agent from a set of the agents appearing in a context $\mathcal{A}(\mathcal{C})$. To predict a response $\boldsymbol{r}$, we select a response from a set of candidate responses $\mathcal{R} = \{\boldsymbol{r}_1, \cdots, \boldsymbol{r}_{|\mathcal{R}|}\}$.

This task evaluates accuracy on the three aspects: addressee-response pair selection (`ADR-RES`), addressee selection (`ADR`), and response selection (`RES`). In `ADR-RES`, we regard the answer as correct if both the addressee and response are correctly selected. In `ADR`/`RES`, we regard the answer as correct if the addressee/response is correctly selected.

4 Multilingual Addressee and Response Selection

As an extension of monolingual ARS, we propose *multilingual addressee and response selection* (M-ARS). In ARS, a system is given as input a set of candidate responses and a conversational context in a single language. By contrast, in M-ARS, a system receives the inputs in one of multiple languages. In the following, we first explain our motivation for tackling M-ARS and then describe the formal task definitions.

4.1 Motivative Situations

We assume the two multilingual conversational situations:

- You want to build *language-specific* systems, each of which responds in a single language.
- You want to build one *language-invariant* system, which responds in multiple languages.

The first situation is that we build K models, each of which is specialized for one of K target languages. The second one is that we build one unified model that can deal with all K target languages. Taking these situations into account, we present the corresponding two tasks: (i) *single-language adaptation* and (ii) *multi-language adaptation*.

[3]Due to the space limitation, we give a brief overview of ARS. For the complete task definition, please refer to Ouchi and Tsuboi (2016).

4.2 Task Overview

The goal of *single-language adaptation* is to develop and evaluate a language-specific ARS model for a single target language. For example, using English, German and Italian training data, we build a model specialized for German conversation. The goal of *multi-language adaptation* is to develop and evaluate a language-invariant ARS model for multiple target languages. For example, using English, German and Italian training data, we build a model that can respond to not only German but also Italian and English conversation. In the following subsections, we formalize each of these tasks.

4.3 Formal Task Definition

We assume that we have conversation data in each of a set of languages $\mathcal{K}$.

Training
In the training phase, a training dataset is given for each language $k \in \mathcal{K}$:

$$\mathcal{D}^{(k)}_{\text{train}} = \{\, \boldsymbol{x}^{(k)}_i, \boldsymbol{y}^{(k)}_i \,\}^{N^{(k)}}_{i=1}, \;\; k \in \mathcal{K}$$
$$\mathcal{D}_{\text{train}} = \bigcup_k \mathcal{D}^{(k)}_{\text{train}}$$

where $\boldsymbol{x}^{(k)}$ and $\boldsymbol{y}^{(k)}$ are a conversational situation and the target output in language k, respectively. We train a model $\mathcal{F} : \mathcal{X} \rightarrow \mathcal{Y}$ on these training samples.

Evaluation
In single-language adaptation, we evaluate a trained model for a single target language $t \in \mathcal{K}$. The trained model receives an input of the target language, $\boldsymbol{x}^{(t)} \sim \mathcal{D}^{(t)}_{\text{eval}}$, and predicts $\hat{\boldsymbol{y}}^{(t)}$. As evaluation metrics, we use the three accuracies (`ADR-RES`, `ADR` and `RES`) used in ARS (Sec. 3).

In multi-language adaptation, given evaluation datasets for all the languages $\mathcal{K}$, i.e., $\bigcup_k \mathcal{D}^{(k)}_{\text{eval}}$, the trained model receives an input of each language $\boldsymbol{x}^{(k)} \sim \mathcal{D}^{(k)}_{\text{eval}}$ and predicts $\hat{\boldsymbol{y}}^{(k)}$. As evaluation metrics, we use macro average over all the languages: $\texttt{ADR-RES} = \frac{\sum_k \texttt{ADR-RES}^{(k)}}{|\mathcal{K}|}$. `ADR` and `RES` are also computed in the same way.

5 Methods

In this section, we firstly describe a model used for addressee and response selection, and then explain our proposed methods to train parameters of the model.

Our model $\mathcal{F}$ consists of a feature extractor f^E, addressee scoring function f^A and response scoring function f^R. f^A and f^R return relevance scores (probabilities) for an addressee and response:

$$f^A(\boldsymbol{x}, a_i) = \sigma([\mathbf{a}_{\text{res}}, \mathbf{h}_c]^{\mathrm{T}}\, \mathbf{W}_a\, \mathbf{a}_i) \quad (1)$$
$$f^R(\boldsymbol{x}, \boldsymbol{r}_j) = \sigma([\mathbf{a}_{\text{res}}, \mathbf{h}_c]^{\mathrm{T}}\, \mathbf{W}_r\, \mathbf{r}_j) \quad (2)$$

where $\mathbf{a}_{\text{res}}$ is a responding agent vector, $\mathbf{h}_c$ is a conversational context vector, $\mathbf{a}_i$ is an agent vector, and $\mathbf{r}_j$ is a candidate response vector. All these vectors are encoded by the feature extractor f^E. We use the dynamic model (Ouchi and Tsuboi, 2016) as f^E. Fig. 2 shows the overview of the dynamic model. This model represents each agent as a hidden state vector that dynamically changes along with time steps in GRU (Cho et al., 2014). [4]

A model $\mathcal{F}$ is parameterized by $\theta = \{\theta_E \cup \{\mathbf{W}_a, \mathbf{W}_r\}\}$, where θ_E is parameters of f^E. To train these parameters, we present four methods. These methods assume that we have training sets for a set of languages $\mathcal{K}$: some of them are high-resource languages $\mathcal{S} \subseteq \mathcal{K}$ and others are relatively low-resource languages $\mathcal{T} = \bar{\mathcal{S}}$.

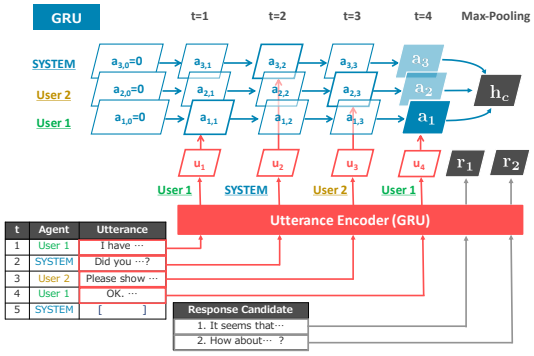

Figure 2: Overview of Dynamic Model.

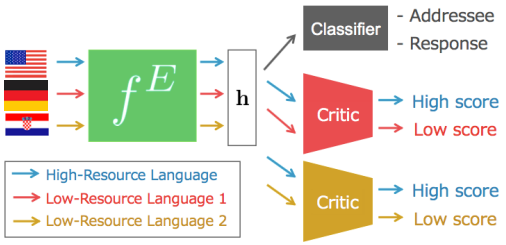

Figure 3: Overview of our W-GAN training method for multiple target languages.

5.1 A Basic Method

(a) Multilingual Embedding Replacement

This method trains a model $\mathcal{F}$ on high-resource language data $\mathcal{D}^{(s)}_{\text{train}}$, where $s \in \mathcal{S}$, and uses the trained model for responding conversations in other languages $\bar{\mathcal{S}}$. To realize this transfer, we use *multilingual embeddings*.

Consider the case where the high-resource language is English (En) and low-resource language is German (De). In the training phase, we use English word embeddings to train model parameters.[5] In the testing phase, instead of the English embeddings, we use German embeddings:

$$\textbf{Train: } \mathbf{w} = \mathbf{W}^{(\texttt{En})}_{\text{emb}}\, w \qquad \textbf{Test: } \mathbf{w} = \mathbf{W}^{(\texttt{De})}_{\text{emb}}\, w$$

where w is a one-hot vector. We just replace the English word embeddings $\mathbf{W}^{(\texttt{En})}_{\text{emb}}$ with the German ones $\mathbf{W}^{(\texttt{De})}_{\text{emb}}$. After looking up each word embedding $\mathbf{w}$, the neural model computes the hidden states. One advantage of this method is to require no target language data. As multilingual embeddings, we use MultiCCA[6] proposed by Ammar et al. (2016). In these embeddings, semantically similar words in the same language or translationally equivalent words in different languages are projected onto nearby.

Besides multilingual embeddings, another option to build a conversational model without no conversation data in a target language is to translate high-resource language data to low-resource one and train a conversational model on the translations. One limitation of this approach is that it is costly to prepare parallel corpora for building the translation model. We discuss this approach in Sec. 7.3.

5.2 Extended Methods

We present the two types of methods which use target language data for building (i) *language-specific models* and (ii) *language-invariant models*.

5.2.1 Methods for Language-Specific Models

(b) Fine-Tuning with Target Language Data

To compensate for the lack of the low-resource language data, this method firstly trains a model $\mathcal{F}_\theta$ on high-resource language data (pre-training phase). Then, using the pre-trained parameters θ as the initial values, this method re-trains them on low-resource language data (fine-tuning phase). We can expect that by gaining the better initial parameters, the tuning effectively adapts the model to the target language.

[4] In this example, a responding agent vector $\mathbf{a}_{\text{res}}$ is $\mathbf{a}_3$. Note that the states of the agents that are not speaking at the time are updated by zero vectors.

[5] The embeddings are fixed, not fine-tuned, during training.

[6] The pre-trained MultiCCA embeddings are provided at http://128.2.220.95/multilingual/data/

5.2.2 Methods for Language-Invariant Models

In order to build language-invariant models, it is critical to consider the two perspectives: (i) *avoiding catastrophic forgetting* and (ii) *learning language-invariant features*. Catastrophic forgetting (Kirkpatrick et al., 2017) is the phenomenon that a model forgets knowledge of previously trained tasks (languages) by incorporating knowledge of the current task (language). Language-invariant features are the features that are common and unchanged in different languages. Taking these two perspectives into account, we present the following two methods.

(c) Joint Loss Training

This method aims to avoid catastrophic forgetting by jointly training model parameters on all the language data at a time. Assuming that we have a set of languages $\mathcal{K}$, this method uses the joint loss function: $\mathcal{J}_{\text{joint}}(\theta) = \sum_k \mathcal{J}(\mathcal{D}^{(k)}, \theta)$ where the loss function $\mathcal{J}$ is the cross-entropy loss used in Ouchi and Tsuboi (2016).

(d) Multi-Language Adversarial Training

To learn language-invariant features, we use a framework of Wasserstein-GAN (W-GAN) (Arjovsky et al., 2017), a recently proposed technique to improve stability for generative adversarial nets (GANs) (Goodfellow et al., 2014). The aim of this method is to match the distributions of feature representations in two languages.

Fig. 3 illustrates an example. English is the high-resource language $s \in \mathcal{S}$, and German and Croatian are low-resource languages $t \in \mathcal{T}$. For each language, the feature extractor f^E receives an input conversation $\boldsymbol{x}$ and computes the hidden features $\mathbf{h} = f^E(\boldsymbol{x})$[7]. Thus, by using f^E, we obtain the hidden feature $\mathbf{h}^{(s)}$ and $\mathbf{h}^{(t)}$ for English and the others, respectively.

A pair of the high- and low-resource language features $\mathbf{h}^{(s)}$ and $\mathbf{h}^{(t)}$ is given to a critic g_π to minimize the Wasserstein distance between the distributions $p(\mathbf{h}^{(s)})$ and $p(\mathbf{h}^{(t)})$:

$$\mathcal{W}(\, p(\mathbf{h}^{(s)}),\, p(\mathbf{h}^{(t)})\,) = \max_{\pi}\, \mathbb{E}_{\mathbf{h}^{(s)}\sim p(\mathbf{h}^{(s)})}[g_\pi(\mathbf{h}^{(s)})] - \mathbb{E}_{\mathbf{h}^{(t)}\sim p(\mathbf{h}^{(t)})}[g_\pi(\mathbf{h}^{(t)})] \tag{3}$$

where the maximum is taken over the set of all 1-Lipschitz functions g_π.[8] By maximizing this equation, the distributions of the feature representations, $p(\mathbf{h}^{(s)})$ and $p(\mathbf{h}^{(t)})$, are made as close as possible. In this paper, as the critic g_π, we use multi-layer perceptron.

Eq. 3 is designed for the two distributions. Thus, we generalize this W-GAN equation to deal with $|\mathcal{S}|$ high-resource languages and $|\mathcal{T}|$ low-resource languages:

$$\mathcal{J}_{\text{wgan}}(\theta) = \sum_{s\in\mathcal{S}} \sum_{t\in\mathcal{T}} \mathcal{W}(\, p(\mathbf{h}^{(k)}),\, p(\mathbf{h}^{(\ell)})\,)$$

This loss function $\mathcal{J}_{\text{wgan}}$ is integrated with the joint loss: $\mathcal{J}_{\text{adv}}(\theta) = \mathcal{J}_{\text{joint}}(\theta) + \lambda\, \mathcal{J}_{\text{wgan}}(\theta)$ where λ is a hyper-parameter that balances these loss functions and we used $\lambda = 0.5$.

6 Corpus and Dataset

One of our goals is to provide a multilingual conversation corpus/dataset that can be used over a wide range of conversation research. We follow the corpus and data creation method of Ouchi and Tsuboi (2016). First, we crawl the Ubuntu IRC Logs[9], and preprocess the logs in many languages. Each language is identified by using a language detection library (Nakatani, 2010). The resulting corpus consists of multilingual conversations in 12 languages, shown in Tab. 1.

Then, we create an M-ARS dataset. For each language, we set the ground-truth/false addressees and responses following Ouchi and Tsuboi (2016). Note that the addressed usernames in utterances have been

[7] Hidden feature representation $\mathbf{h}$ is the concatenation of the responding speaker vector and context vector in Eqs. 1 and 2, i.e. $\mathbf{h} = [\mathbf{a}_{\text{res}}, \mathbf{h}_c]$.

[8] A function g is 1-Lipschitz when $|g(x) - g(y)| \leq |x - y|$ for all x and y. To constrain the critic g to a 1-Lipschitz function, the parameters of g are clipped to a fixed range.

[9] We use a collection of the logs during one year (2015). We plan to expand it by collecting the logs over all the years.

removed for addressee selection. Thus, we have to predict the addressees without seeing the addressed usernames. The number of candidate responses ($|\mathcal{R}|$) is set to 2 or 10. The dataset is then randomly partitioned into a training set (90%), a development set (5%) and a test set (5%). Tab. 2 shows the statistics of the top 5 largest language sections of this resulting dataset.

7 Experiments

7.1 Experimental Setup

7.1.1 Task Settings

We use the following languages: (i) English (En) as the high-resource language, and (ii) Italian (It), Croatian (Hr), German (De), Portuguese (Pt) as the low-resource languages. In the following, we describe the languages used in each task.

(a) Single-Language Adaptation

Train: English + 1 Low-Res. Language, **Dev & Test:** 1 Low-Res. Language

For example, in the case that the target is Italian (It), we use the En and It training sets to train a model, and evaluate the trained model on the It test set. As evaluation metrics, we use the three types

of accuracies, ADR−RES, ARD and RES (described in Sec. 3). We report the macro average accuracies of all source-target language pairs (En-It, En-Hr, En-De, and En-Pt).

(b) Multi-Language Adaptation

Train: English + $|\mathcal{T}|$ Low-Res. Languages, **Dev & Test:** English + $|\mathcal{T}|$ Low-Res. Languages

We use the En, It, Hr, Pt and De training sets to train a unified model, and evaluate it on the test sets for all the languages (En, It, Hr, Pt, De). As evaluation metrics, we use the macro averages of ADR−RES, ARD and RES for all the languages. For example, for two language adaptation ($|\mathcal{T}| = 1$), we report the macro averages over all the language pairs (En-It, En-Hr, En-De, and En-Pt). For five language adaptation ($|\mathcal{T}| = 4$), we report the macro averages over all the five languages. Note that while we evaluate the performance on only the test set of the target low-resource language in single-language adaptation, we evaluate it on the test sets of English and the low-resource languages in multi-language adaptation.

7.1.2 Comparative Methods

We compare several methods. Our proposed methods (Sec. 5) are orthogonal, so that we can combine a method with others. In the following, we list the methods used in the comparison.

- TRGONLY: A dynamic model proposed by Ouchi and Tsuboi (2016) trained on only the low-resource target language data.
- ENONLY: A model built by (a) *multilingual embedding replacement* in Sec. 5.1: training a model on the English data and replacing the English word embeddings with the embeddings of the low-resource language.
- FINETUNE: A model built by (b) *fine-tuning* in Sec. 5.2: training a model on the high-resource language (English), and retraining it on the low-resource language.
- JOINT: A model built by (b) *fine-tuning* and (c) *joint loss training*: building a model by FINETUNE as an initial model, and retraining it with the joint loss functions.
- WGAN: A model built by (b) *fine-tuning* and (d) *multi-language adversarial training*: building a model by FINETUNE as an initial model, and retraining it with W-GAN.

Besides the neural models, we also use the TF-IDF model used in Ouchi and Tsuboi (2016). This model firstly creates TF-IDF vectors for the context and each candidate response. Then, it computes the cosine similarity for each pair of the context vector and a response vector. Finally, it selects the candidate response with the highest similarity.

7.1.3 Optimization

We use stochastic gradient descent (SGD) with a mini-batch method. To update parameters, we use *Adam* (Kingma and Ba, 2014). We describe the details of hyper-parameter settings in Supplementary Material.

7.2 Results

Tab. 3 shows the results of single-language and multi-language adaptation. Note that Tab. 6, Tab. 7, and Tab. 8 shows the detailed results for each language.

Single-Language Adaptation

WGAN achieved the best scores for most of the metrics. This suggests that the W-GAN method successfully transfers knowledge of high-resource language to a low-resource language. Also, FINETUNE outperformed TRGONLY. This means that pre-training parameters on the high-resource language data improves a model for a target low-resource language. Interestingly, ENONLY achieved higher scores than chance-level without any target language data. One possible explanation is that the multilingual embeddings have good alignments to some extent between similar meaning words in different languages.

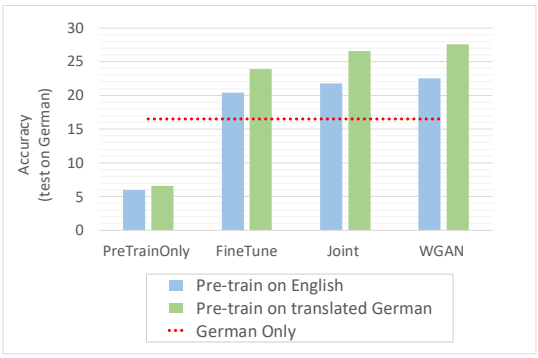

Figure 4: Effects of data augmentation with NMT.

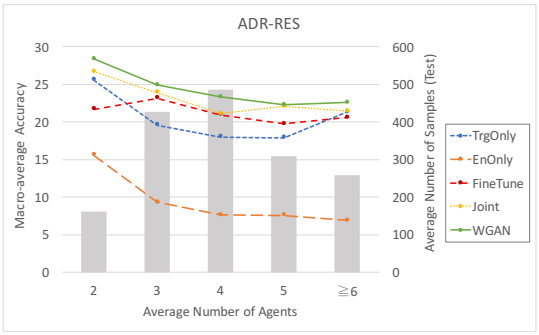

Figure 5: Effects of the number of agents in the context. Left axis: ADR-RES accuracy on test sets (drawn as lines). Right axis: the average number of test samples (drawn as bars).

Multi-Language Adaptation

In both two- and five-language adaptation, WGAN achieved the best scores. Specifically, In five language adaptation, regardless of using a single, unified model, JOINT and WGAN achieved high-performance.[10] Also, WGAN outperformed JOINT in all the metrics. This suggests that WGAN learns language-invariant features more effectively.

In NLP tasks, Chen et al. (2016) applied W-GAN to cross-lingual sentiment classification and successfully transferred the source-side knowledge to the target one. In this paper, we have extended the adaptation of single source-target pair to the adaptation of multiple pairs. Our experimental results show that our method works well for multi-language adaptation in conversation domain.

7.3 Data Augmentation with NMT

As we mentioned in Sec. 5.1 (a), as another approach to compensating for low-resource language, we use data augmentation. To increase the amount of the training set of a low-resource language, we translate high-resource language (English) samples to low-resource ones by using Neural Machine Translation (NMT). Although some translations are noisy, we can obtain much more training samples for a low-resource language. One limitation of this method is that it is costly to prepare parallel corpora, which is often unavailable for low-resource languages. For reproducibility, we use publicly available NMT models already trained on a parallel corpus. Since OpenNMT[11] provides an English-German model, we conduct experiments for the English-German pair.

We investigate the effects of translated German data for pre-training a model. Translating English (En) training utterances to German (De) ones by using the trained NMT model, we can obtain translated German training data (De′). We compare the two settings: (i) pre-training a model on English data and (ii) pre-training a model on translated German data. After pre-training, we apply the methods used in Sec. 7. We evaluate the performance with ADR-RES accuracy on the German test set.

Fig. 4 shows the results ($|\mathcal{R}| = 10$). The red dotted line is the performance of the modes trained on only original German training data (De). In each method, the blue bar at left hand is a model pre-trained on English (En), and the green bar at right hand is a model pre-trained on (De′).

PRETRAINONLY, the left-most method in Fig.4, uses the pre-trained models. The results were almost the same between models pre-trained on English or translated German data, and worse than the model trained on only the original German training data (red dotted line). This suggests that only the translations by NMT are not sufficient for building good multilingual ARS models.

Furthermore, we re-train the pre-trained models by using the three methods, FINETUNE, JOINT and WGAN. In other words, each method uses a pre-trained model as the initial model and re-trains the parameters. In all methods, the models re-trained from the De′ pre-trained model (green bars) were better

[10] Since FINETUNE builds a model for each target language, it cannot analyze multiple languages with a single model. That is why there is no result of FINETUNE in five-language adaptation.

[11] http://opennmt.net/Models/

than the ones from the En pre-trained ones (blue bars). This suggests that by combining the NMT-based data augmentation method with the knowledge-transfer methods, the performance is boosted. Another point is that WGAN consistently outperformed the other methods, which supports the utility of WGAN.

7.4 Analysis of Number of Agents

We investigate how accuracy fluctuates according to the number of agents in the context of length 15, as shown in Fig. 5. Overall, as the number of agents increases, the accuracies of all the methods tend to decline. Among them, WGAN achieved the best results in most of the cases. This suggests that WGAN can stably predicts addressees and responses in conversations with many participants.

8 Conclusion and Future Work

We have introduced *multilingual addressee and response selection* by providing (i) formal task definitions, (ii) several knowledge-transfer methods and (iii) a multilingual conversation corpus and dataset. Experimental results have demonstrated that our methods allow models to adapt multiple target languages. In particular, methods for language-invariant models can simultaneously deal with multiple languages with a single model.

Since our methods and dataset can apply to response generation, tackling the multilingual response generation tasks is an interesting line of our future work. In addition, our language-invariant systems can receive conversation in a language (e.g., English) and reply to it in another language (e.g., German). It can lead to interesting findings that our system is evaluated on code-mixing situations, where two or more languages are used in the same context.

Abstract

Events in text documents are interrelated in complex ways. In this paper, we study two types of relation: **Event Coreference** and **Event Sequencing**. We show that the popular tree-like decoding structure for automated Event Coreference is not suitable for Event Sequencing. To this end, we propose a graph-based decoding algorithm that is applicable to both tasks. The new decoding algorithm supports flexible feature sets for both tasks. Empirically, our event coreference system has achieved state-of-the-art performance on the TAC-KBP 2015 event coreference task and our event sequencing system beats a strong temporal-based, oracle-informed baseline. We discuss the challenges of studying these event relations.

Title and Abstract in Chinese

基于图的事件共指消解以及依序关系解码算法

文本中提及的事件之间常存在着复杂的关系。在这篇文章中，我们主要研究两种关系：事件间的共指关系以及依序关系。我们指出，常被应用在事件指代消歧上的传统的树结构解码方式并不适用于解决事件依序问题。为了解决这个问题，我们提出了一种适用于两种情况的新的图结构解码算法。这个算法让我们可以为这两个任务设计灵活的特征。在实验上，我们的事件共指消解系统在TAC-KBP 2015的共指消解任务上达到了目前最佳的水平。同时，我们的依序关系系统的结果超过了一个基于时间分析并有部分正确答案的基线系统。最后我们分析了结果，并讨论了事件关系判别任务的一些挑战。

1 Introduction

Events are important building blocks of documents. They play a key role in document understanding tasks, such as information extraction (Chambers and Jurafsky, 2011), news summarization (Vossen and Caselli, 2015), story understanding (Mostafazadeh et al., 2016). Conceptually, **events** correspond to state changes and normally include a location, a time interval, and several entities/participants. In a text, events are realized as text spans, normally as verbs and nouns that indicate state changes (Vendler, 1957). The text spans are often referred to as **event mentions** or **event nuggets** (We use the term event mention in this paper.). The textual mentions of events have rich relations among them, and collectively convey the meaning of one or more related documents. In this paper, we study two different types of relation: **Event Hopper Coreference (EH)** and **Event Sequencing (ES)**.

Event Coreference: There is a rich literature on the Event Coreference problem (Liu et al., 2014; Cybulska and Vossen, 2014; Lu et al., 2016; Peng et al., 2016; Lu and Ng, 2017; Araki, 2018). By analogy to entity coreference, the "same" conceptual event may be realized by multiple text spans (event mentions). The coreference problem aims at identifying these relations to recover events from the text spans. The **Event Hopper** Coreference task in the TAC-KBP evaluation campaign defines coreference links as follows (Mitamura et al., 2018): Two event mentions are considered coreferent if they refer to the conceptually same underlying event, even if their arguments are not strictly identical. For example,

Proceedings of the 27th International Conference on Computational Linguistics, pages 3645–3657
Santa Fe, New Mexico, USA, August 20-26, 2018.

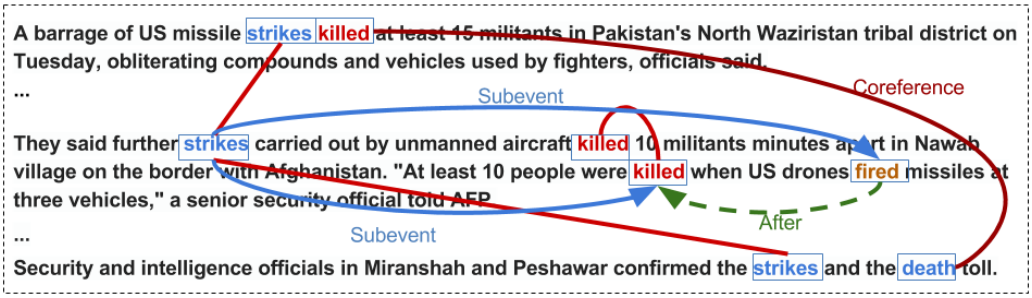

Figure 1: Example of Event Coreference and Sequence relations. Red lines are coreference links; solid blue arrows represent Subevent relations; dotted green arrows represent After relations.

mentions that share similar temporal and location scope, though not necessarily the same expression, are considered to be coreferent (*Attack in Baghdad on Thursday* vs. *Bombing in the Green Zone last week*). This means that the event arguments of coreferential events mentions can be non-coreferential (18 killed vs. dozens killed), as long as they refer to the same event, judging from the available evidence.

Event Sequencing: The coreference relations build up events from scattered mentions. On the basis of events, various other types of relations can then be established between them. The Event Sequencing task studies one such relation. The task is motivated by Schank's *scripts* (Schank and Abelson, 1977), which suggests that human organize information through procedural data structures, reassembling sequences of events. For example, the list of verbs *order, eat, pay, leave* may trigger the restaurant script. A human can conduct reasoning with a typical ordering of these events based on common sense (e.g., *order* should be the first event, *leave* should be the last event).

The ES task studies how to group and order events from text documents belonging to the same script. Figure 1 shows some annotation examples. Conceptually, event sequencing relations hold between the events, while coreference relations hold between textual event mentions. Given a document, the ES task requires systems to identify events within the same script and classify their inter-relations. These relations can be represented as labeled Directed Acyclic Graphs (DAGs). There are two types of relations[1]: **After** relations connect events following script orders (e.g. *order* followed by *eating*); **Subevent** relations connect events to a larger event that contains them. In this paper, we focus only on the **After** relations.

Since script-based understanding is built in the ES task, it has some unique properties comparing to pure temporal ordering: 1) event sequences from different scripts provide separate logical divisions of text, while temporal ordering considers all events to lie on a single timeline; 2) temporal relations for events occurring at similar time points may be complicated. Script-based relations may alleviate the problem. For example, if a `bombing` `kills` some people, the temporal relation of the `bombing` and `kill` may be "inclusion" or "after". This is considered an **After** relation in ES because `bombing` causes the `kill`ing.

For structure prediction, decoding — recovering the complex structure from local decisions — is one of the core problems. The most successful decoding algorithm for coreference nowadays is mention ranking based (Björkelund and Kuhn, 2014; Durrett and Klein, 2014; Lee et al., 2017). These models rank the antecedents (mentions that appear earlier in discourse) and recover the full coreference clusters from local decisions. However, unlike coreference relations, sequencing relations are directed. Coreference decoding algorithms cannot be directly applied to such relations (§3.1). To solve this problem, we propose a unified graph-based framework that tackles both event coreference and event sequencing. Our method achieves state-of-the-art results on the event coreference task (§4.4) and beats an informed baseline on the event sequencing task (§4.5). Finally, we analyze the results and discuss the difficult challenges for both tasks (§5). Detailed definitions of these tasks can be found in the corresponding task documents[2].

2 Related Work

Many researchers have worked on event coreference tasks since Humphreys et al. (1997). Recent advances in event coreference have been promoted by the availability of annotated corpora. However, due to

[1]Detailed definition of relations can be found in http://cairo.lti.cs.cmu.edu/kbp/2016/after/

[2]`http://cairo.lti.cs.cmu.edu/kbp/2017/event/documents`

the complex nature of events, approaches to event coreference adopt quite different assumptions and definitions. Most of event coreference researches are conducted on the popular ACE corpus (Chen and Ji, 2009; Chen et al., 2009; Sangeetha and Arock, 2012; Chen and Ng, 2013; Chen and Ng, 2015). Unlike the TAC KBP setting, the definition of event coreference in the ACE corpus requires strict argument matching. Work on the Intelligence Community (IC) Corpus (Hovy et al., 2013; Cybulska and Vossen, 2012; Liu et al., 2014; Araki et al., 2014) considers event relations on a restricted domain (i.e., terrorist events). Works on the ECB corpus (Lee et al., 2012; Cybulska and Vossen, 2014) focuses on both within-document and cross-document coreference.

Our work follows the line of work promoted by the TAC-KBP event nugget tasks (Mitamura et al., 2015). There is a small but growing amount of work on conducting event coreference on the TAC-KBP datasets (Lu et al., 2016; Peng et al., 2016; Lu and Ng, 2017). The TAC dataset uses a relaxed coreference definition comparing to other corpora, requiring two event mentions to intuitively refer to the same real-world event despite differences of their participants.

For event sequencing, there are few supervised methods on script-like relation classification due to the lack of data. To the best of our knowledge, the only work in this direction is by Araki et al. (2014). This work focuses on the other type of relations in the event sequencing task: **Subevent** relations. There is also a rich literature on unsupervised script induction (Chambers and Jurafsky, 2008; Cheung et al., 2013; Rudinger et al., 2015; Pichotta and Mooney, 2016; Ferraro and Durme, 2016) that extracts scripts as a type of common-sense knowledge from raw documents. The focus of this work is to make use of massive collections of text documents to mine event co-occurrence patterns. In contrast, our work focuses on parsing the detailed relations between event mentions in each document.

Another line of work closely related to event sequencing is to detect other temporal relations between events. Recent computational approaches for temporal detection are mainly conducted on the TimeBank corpus (Pustejovsky et al., 2002). There have been several studies on building automatic temporal reasoning systems (Uzzaman and Allen, 2010; Do et al., 2012; Chambers et al., 2014). In comparison, the Event Sequencing task is motivated by the Script theory, which places more emphasis on common-sense knowledge about event chronology.

3 Model

3.1 Graph-Based Decoding Model

In the Latent Antecedent Tree (LAT) model popularly used for entity coreference decoding (Fernandes et al., 2012; Björkelund and Kuhn, 2014), each node represents an event mention and each arc a coreference relation, and new mentions are connected to some past mention considered most similar. Thus the LAT model represents the decoding structure as a tree. This can represent any coreference cluster, because coreference relations are by definition equivalence relations[3].

In contrast, tree structures cannot always fully cover an Event Sequence relation graph, because 1) the After links are directed, not symmetric, and 2) multiple event nodes can link to one node, resulting in multiple parents.

To solve this problem, we extend the LAT model and propose its graph version, namely the Latent Antecedent Graph (LAG) model. Figure 2 contrast LAT and LAG with decoding examples. The left box shows two example decoded trees in LAT, where each node has one single parent. The right box shows two example decoded trees in LAG, where each node can be linked to multiple parents.

Formally, we define the series of (pre-extracted) event mentions of the document as $M = \{m_0, m_1, ..., m_n\}$, following their discourse order. m_0 is an artificial root node preceding all mentions. For each mention m_j, let A_j be the set of its potential antecedents: $A_j = \{m_0, m_1, ..., m_{j-1}\}$. Let $\mathcal{A}$ denotes the set of antecedents for all the mentions in the sequence $\{A_0, A_1, ..., A_n\}$. The two tasks in question can be considered as finding the appropriate antecedent(s) from $\mathcal{A}$. Similarly, we define the gold antecedent set $\tilde{\mathcal{A}} = \{\tilde{A}_0, \tilde{A}_1, ..., \tilde{A}_n\}$, where $\tilde{A}_i$ represent the set of antecedents of m_i allowed by the gold standard. In the coreference task, $\tilde{A}_i$ contains all antecedents that are coreferent with m_i. In the sequencing task, $\tilde{A}_i$ contains all antecedents that have an $After$ relation to m_i.

[3] An equivalence relation is reflexive, symmetric and transitive.

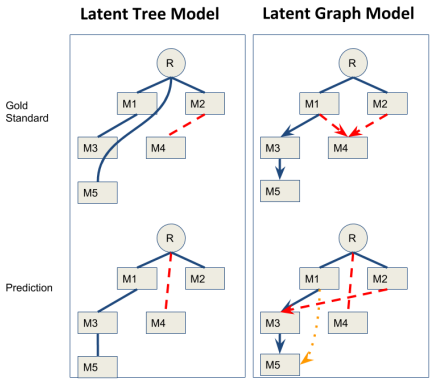

Figure 2: Latent Tree Model (left): tree structure formed by undirected links. Latent Graph Model (right): a DAG form by directed links. Dashed red links highlight the discrepancy between prediction and gold standard. The dotted yellow link (bottom right) can be inferred from other links.

We can now describe the decoding process. We represent each arc as $\langle m_i, m_j, r \rangle (i < j)$, where r is the relation name. The relation direction can be specified in the relation name r (e.g. r can be *after.forward* or *after.backward*). Further, an arc from the root node m_0 to node m_j represents that m_j does not have any antecedent. The score of the arc is the dot product between the weight parameter $\vec{w}$ and a feature vector $\Phi(\langle m_i, m_j, r \rangle)$, where Φ is an arc-wise feature function. The decoded graph z can be determined by a set of binary variables $\vec{z}$, where $\vec{z}_{ijr} = 1$ if there is an arc $\langle m_i, m_j, r \rangle$ or 0 otherwise. The final score of z is the sum of scores of all arcs:

$$score(z) = \sum_{i,j,r} \vec{z}_{ijr} \vec{w} \cdot \Phi(\langle m_i, m_j, r \rangle) \quad (1)$$

The decoding step is to find the output $\hat{z}$ that maximizes the scoring function:

$$\hat{z} = \arg \max_{z \in \mathcal{Z}(\mathcal{A})} score(z) \quad (2)$$

where $\mathcal{Z}(\mathcal{A})$ denotes all possible decoding structures given the antecedent sets $\mathcal{A}$. It is useful to note that the decoding step can be applied in the same way to the gold antecedent set $\tilde{\mathcal{A}}$.

Algorithm 1 shows the Passive-Aggressive training algorithm (Crammer et al., 2006) used in our decoding framework. Line 8 decodes the maximum scored structure from all possible gold standard structures using the current parameters $\vec{w}$. Intuitively, this step tries to find **the "easiest" correct graph** — the correct graph with the highest score — for the current model. Several important components remain unspecified in algorithm 1: (1) the decoding step (line 6, 8); (2) the match criteria: whether to consider the system decoding structure as correct (line 7); (3) feature delta: computation of feature difference (line 9); (4) loss computation (line 10). We detail the actual implementation of these steps in §3.1.2.

3.1.1 Minimum Decoding Structure

Similar to the LAT model, there may be many decoding structures representing the same configuration. In LAT, since there is exactly one link per node, the number of links in different decoding structures is the same, hence comparable. In LAG, however, one node is allowed to link to multiple antecedents, creating a potential problem for decoding. For example, consider the sequence $m_1 \xrightarrow{\text{after}} m_2 \xrightarrow{\text{after}} m_3$, both of the following structures are correct:

1. $\langle m_1, m_2, after \rangle$, $\langle m_2, m_3, after \rangle$
2. $\langle m_1, m_2, after \rangle$, $\langle m_2, m_3, after \rangle$, $\langle m_1, m_3, after \rangle$

However, the last relation in the second decoding structure can actually be inferred via transitivity. We do not intend to spend the modeling power on such cases. We empirically avoid such redundant cases by using the **transitive reduction graph** for each structure. For a directed acyclic graph, a transitive

Algorithm 1: PA algorithm for training

1 **Input:** Training data D, number of iterations T
2 **Output:** Weight vector $\vec{w}$
3 $\vec{w} = \vec{0}$;
4 $\langle \mathcal{A}, \tilde{\mathcal{A}} \rangle \in D$;
5 **for** $t \leftarrow 1..T$ **do**
6 $\quad \hat{z} = \arg\max_{\mathcal{Z}(\mathcal{A})} score(z)$;
7 $\quad$ **if** $\neg Match(\hat{z}, \tilde{\mathcal{A}})$ **then**
8 $\quad\quad \tilde{z} = \arg\max_{\mathcal{Z}(\tilde{\mathcal{A}})} score(z)$;
9 $\quad\quad \Delta = FeatureDelta(\tilde{z}, \hat{z})$;
10 $\quad\quad \tau = \frac{loss(\tilde{z}, \hat{z})}{||\Delta||^2}$;
11 $\quad\quad w = w + \tau\Delta$;
12 **return** w;

reduction graph contains the fewest possible edges that have the same reachability relation as the original graph. In the example above, structure 1 is a transitive reduction graph for structure 2. We call the decoding structures that corresponding to the reduction graphs as *minimum decoding structures*. For LAG, we further restrict $\mathcal{Z}(\mathcal{A})$ to contain only minimum decoding structures.

3.1.2 Training Details in Latent Antecedent Graph

In this section, we describe the decoding details for LAG. Note that if we enforce a single antecedent for each node (as in our coreference model), it falls back to the LAT model (Björkelund and Kuhn, 2014).

Decoding: We use a greedy **best-first decoder** (Ng and Cardie, 2002), which makes a left-to-right pass over the mentions. The decoding step is the same for line 6 and 8. The only difference is that we will use gold antecedent set ($\tilde{\mathcal{A}}$) at line 8. For each node m_j, we keep all links that score higher than the root link $\langle 0, m_j, r \rangle$.

Cycle and Structure Check: Incremental decoding a DAG may introduce cycles to the graph, or violate the minimum decoding structure criterion. To solve this, we maintain a set $R(m_i)$ that is reachable from m_i during the decoding process. We reject a new link ($\langle m_j, m_i \rangle$ if $m_j \in R(m_i)$) to avoid cycles. We also reject a redundant link ($\langle m_i, m_j \rangle$ if $m_j \in R(m_i)$) to keep a minimum decoding structure. Our current implementation is greedy, we leave investigations of search or global inference based algorithms to future work.

Selecting the Latent Event Mention Graph: Note that sequence relations are on the event level. Given a unique event graph, it may still correspond to multiple mention graphs. In our implementation, we use a minimum set of event mentions to represent the full event graph by taking one single mention from each event. Following the "easiest" intuition, we select the single mention that will result in the highest score given the current feature weight w.

Match Criteria: We consider two graphs to match when their inferred graphs are the same. The inferred graph is defined by taking the transitive closure of the graph and propagate the links through the coreference relations. For example, in Figure 1, the mention `fired` will be linked to two `killed` mentions after propagation.

Feature Delta: In structural perceptron training (Collins, 2002), the weights are updated directly by the feature delta. For all the features $\tilde{f}$ of the gold standard graph $\tilde{z}$ and features $\hat{f}$ of a decoded graph $\hat{z}$, the feature delta is simply: $\Delta = \tilde{f} - \hat{f}$. However, a decoded graph may contain links that are not directly presented but inferable from the gold standard graph. For example, in Figure 2, the prediction graph has a link from $M5$ to $M1$ (the orange arc), which is absent but inferable from the gold standard tree. If we keep these links when computing Δ, the model does not converge well. We thus remove the features on the inferable links from $\hat{f}$ when computing Δ.

Loss: We define the loss to be the number of different edges in two graphs. Following Björkelund and Kuhn (2014), we further penalize erroneous root attachment: an incorrect link to the root m_0 adds the loss

Head	Headword token and lemma pair, and whether they are the same.
Type	The pair of event types, and whether they are the same.
Realis	The pair of realis types and whether they are the same.
POS	POS pair of the two mentions and whether they are the same.
Exact Match	Whether the 5-word windows of the two mentions matches exactly.
Distance	Sentence distance between the two mentions.
Frame	Frame name pair of the two mentions and whether they are the same.
Syntactic	Whether a mention is the syntactic ancestor of another.

Table 1: Coreference Features. Parsing is done using Stanford CoreNLP (Manning et al., 2014); frame names are produced by Semafor (Das and Smith, 2011).

by 2. For example, in Figure 2 the prediction graph (bottom right) incorrectly links m_4 to Root and misses a link to m_3, which cause a total loss of 3. In addition, to be consistent with the feature delta computation, we do not compute loss for predicted links that are inferable from the gold standard.

3.2 Features

3.2.1 Event Coreference Features

For event coreference, we design a simple feature set to capture syntactic and semantic similarity of arcs. The main features are summarized in Table 1. In the TAC KBP 2015 coreference task setting, the event mentions are annotated with two attributes. There are 38 event types and subtype pairs (e.g., *Busness.Merge-Org, Conflict.Attack*). There also 3 realis type: events that actually occurred are marked as *Actual*; events that are not specific are marked as *Generic*; other events such as future events are marked as *Other*. For these two attributes, we use the gold annotations in our feature sets.

3.2.2 Event Sequencing Features

An event sequencing system needs to determine whether the events are in the same script and order them. We design separate feature sets to capture these aspects: the Script Compatibility set considers whether mentions should belong to the same script; the Event Ordering set determines the relative ordering of the mentions. Our final features are the cross products of features from the following 3 sets.

1. **Surface-Based Script Compatibility**: these features capture whether two mentions are script compatible based on the surface information, including:
   - Mention headword pair.
   - Event type pair.
   - Whether two event mentions appear in the same cluster in Chambers's event schema database (Chambers and Jurafsky, 2010).
   - Whether the two event mentions share arguments, and the semantic frame name of the shared argument (produced by the Semafor parser (Das and Smith, 2011)).
2. **Discourse-Based Script Compatibility**: these features capture whether two event mentions are related given the discourse context.
   - Dependency path between the two mentions.
   - Function words (words other than Noun, Verb, Adjective and Adverb) in between the two mentions.
   - The types of other event mentions between the two mentions.
   - The sentence distance of two event mentions.
   - Whether there are temporal expressions (AGM-TMP slot from a semantic parser (Tratz and Hovy, 2011)) in the sentences of the two mentions.
3. **Event Ordering**: this feature set tries to capture the ordering of events. We use the discourse ordering of two mentions (forward: the antecedent is the parent; backward: the antecedent is the child), and temporal ordering produced by Caevo (Chambers et al., 2014).

Taking the *after* arc from `fired` to `killed` in Figure 1 as an example, a feature after the cross product is: Event type pair is *Conflict.Attack* and *Life.Die*, discourse ordering is *backward*, and sentence distance is 0.

4 Experiments

4.1 Dataset

We conduct experiments on the dataset released in Text Analysis Coreference (TAC-KBP) 2017 Event Sequencing task (released by LDC under the catalog name LDC2016E130). This dataset contains rich event relation annotations, with event mentions and coreference annotated in TAC-KBP 2015, and additional annotations on Event Sequencing[4]. There are 158 documents in the training set and 202 in the test set, selected from general news articles and forum discussion threads. The event mentions are annotated with 38 type-subtype and 3 realis status (Actual, Generic, Other). Event Hopper, After, and Subevent links are annotated between event mentions. For all experiments, we develop our system and conduct ablation studies using 5-fold cross-validation on the training set, and report performance on the test set.

4.2 Baselines and Benchmarks

Coreference: we compare our event coreference system against the top performing systems from TAC-KBP 2015 (LCC, UI-CCG, and LTI). In addition, we also compare the results against two official baselines (Mitamura et al., 2015): the Singleton baseline that put each event mention in its own cluster and the Match baseline that creates clusters based on mention type and realis status match.
Sequencing: This work is an initial attempt to this problem, so there is currently no comparable prior work on the same task. We instead compare with a baseline using event temporal ordering systems. We use a state-of-the-art temporal system named Caevo (Chambers et al., 2014). To make a fair comparison, we feed the gold standard event mentions to the system along with mentions predicted by Caevo[5]. However, since the script-style After links are only connected between mentions in the same script, directly using the output of Caevo produces very low precision. Instead, we run a stronger baseline: we take the gold standard script clusters and then only ask Caevo to predict links within these clusters (Oracle Cluster + Temporal).

4.3 Evaluation Metrics

Evaluating Event Coreference: We evaluate our results using the official scorer provided by TAC-KBP, which uses 4 coreference metrics: *BLANC* (Recasens and Hovy, 2011), *MUC* (Chinchor, 1992), B^3 (Bagga and Baldwin, 1998) and *CEAF-E* (Luo, 2005). Following the TAC KBP task, systems are ranked using the average of these 4 metrics.
Evaluating Event Sequencing: The TAC KBP scorer evaluates event sequencing using the metric of the TempEval task (UzZaman, 2012; UzZaman et al., 2013). The TempEval metric calculates special precision and recall values based on the closure and reduction graphs:

$$Precision = \frac{|Response^- \cap Reference^+|}{|Response^-|} \quad Recall = \frac{|Reference^- \cap Response^+|}{|Reference^-|}$$

where $Response$ represents the After link graph from the system response and $Reference$ represents the After link graph from the gold standard. G^+ represents the graph closure for graph G and G^- represents the graph reduction for graph G. As preprocessing, relations are automatically propagated through coreference clusters (currently using gold standard clusters). The final score is the standard F-score: geometric mean of the precision and recall values.

[4]http://cairo.lti.cs.cmu.edu/kbp/2016/after/
[5]We keep the mentions predicted by Caevo because its inference may be affected by these mentions.

	B^3	CEAF-E	MUC	BLANC	AVG.
`Singleton`	78.10	68.98	0.00	48.88	52.01
`Matching`	78.40	65.82	**69.83**	76.29	71.94
LCC	82.85	74.66	68.50	**77.61**	75.69
UI-CCG	83.75	75.81	63.78	73.99	74.28
LTI	82.27	75.15	60.93	71.57	72.60
This work	**85.59**	**79.65**	67.81	77.37	**77.61**

Table 2: Test Results for Event Coreference with the `Singleton` and `Matching` baselines.

	B^3	CEAF-E	MUC	BLANC	AVG.

-Distance	81.92	74.48	76.02	77.55	77.50
-Frame	82.14	75.01	76.28	77.74	77.79
-Syntactic	81.87	74.89	75.79	76.22	77.19

Table 3: Ablation study for Event Coreference.

4.4 Evaluation Results for Event Coreference

The test performance on Event Coreference is summarized in Table 2. Comparing to the top 3 coreference systems in TAC-KBP 2015, we outperform the best system by about 2 points absolute F-score on average. Our system is also competitive on individual metrics. Our model performs the best based on B^3 and CEAF-E, and is comparable to the top performing systems on MUC and BLANC.

Note that while the `Matching` baseline only links event mentions based on event type and realis status, it is very competitive and performs close to the top systems. This is not surprising since these two attributes are based on the gold standard. To take a closer look, we conduct an ablation study by removing the simple match features one by one. The results are summarized in Table 3. We observe that some features produce mixed results on different metrics: they provide improvements on some metrics but not all. This is partially caused by the different characteristics of different metrics. On the other hand, these features (parsing and frames) are automatically predicted, which make them less stable. Furthermore, the Frame features contain duplicate information to event types, which makes it less useful in this setting.

Besides the presented features, we have also designed features using event argument. However, we do not report the results since the argument features decrease the performance on all metrics.

4.5 Evaluation Results for Event Sequencing

The evaluation results on Event Sequencing is summarized in Table 4. Because the baseline system has access to the oracle script clusters, it produces high precision. However, the low recall value shows that it fails to produce enough After links. Our analysis shows that a lot of After relations are not indicated by clear temporal clues, but can only be solved with script knowledge. In Example 3, the baseline system is able to identify "fled" is after "ousted" from explicit marker "after". However, it fails to identify that "extradited" is after "arrested", which requires knowledge about prototypical event sequences.

(3) Eight months after the [transport fled] Ivory Coast when Gbagbo, the former president, was [End.Position ousted] by the French military. Blé Goudé was subsequently [Jail arrested] in Ghana and [transport extradited] Megrahi,[Jail jailed] for [Attack killing] 270 people in 1988. [6]

In our error analysis, we noticed that our system produces a large number of relations due to coreference propagation. One single wrong prediction can cause the error to propagate.

Besides memorizing the mention pairs, our model also tries to capture script compatibility through discourse signals. To further understand how much these signals help, we conduct an ablation study of the features in the discoursed based compatibility features (see §3.2.2). Similarly, we remove each feature group from the full feature set one by one and observe the performance change.

[6]The small red text indicates the event type for each mention.

	Prec.	Recall	F-Score
Oracle Cluster+Temporal	**46.21**	8.72	14.68
Our Model	18.28	**16.91**	**17.57**

Table 4: Test Results for event sequencing. The Oracle Cluster+Temporal system is using Caevo's result on the Oracle Clusters.

	Prec.	Recall	F-Score	Δ
Full	37.92	36.79	36.36	
- Mention Type	32.78	29.81	30.07	6.29
- Sentence	33.90	30.75	31.00	5.36
- Temporal	37.21	36.53	35.81	0.55
- Dependency	38.18	36.44	36.23	0.13
- Function words	38.08	36.51	36.18	0.18

Table 5: Ablation Study for Event Sequencing.

The results are reported in Table 5. While most of the features only affect the performance by less than 1 absolute F1 score, the feature sets after removing *mention* or *sentences* show a significant drop in both precision and recall. This shows that discourse proximity is the most significant ones among these features. In addition, the *mention* feature set captures the following *explain away* intuition: the event mentions A and B are less likely to be related if there are similar mentions in between. One such example can be seen in Figure 1, the event mention `fired` is more likely to relate to the closest `killed`, instead of the other `killed` in the first paragraph.

In addition, our performance on the development set is higher than the test set. Further analysis reveals two causes: 1) the coreference propagation step causes the scores to be very unstable, 2) our model only learns limited common sense ordering based on lexical pairs, which overfit to the small training corpus. Since the annotation is difficult to scale, it is important to use methods to harvest script common sense knowledge automatically, as in the script induction work (Chambers and Jurafsky, 2008).

5 Discussion

5.1 Event Coreference Challenges

Although we have achieved good performance on event coreference, upon closer investigation we found that most of the coreference decisions are still made based on simple word/lemma matching (note that the type and realis baseline is as high as 0.72 F1 score). The system exploits little semantic information to resolve difficult event coreference problems. A major challenge is that our system is not capable of utilizing event arguments: in fact, Hasler and Orasan (2009) found that only around 20% of the arguments in the same event slot are actually coreferent for coreferential event pairs in the ACE 2005 corpus. Furthermore, the TAC-KBP corpus uses a relaxed participant identity requirement for event coreference, which makes argument-based matching more difficult.

5.2 Event Sequencing Challenges

Our event sequencing performance is still low despite the introduction of many features. This task is inherently difficult because it requires a system to solve both the script clustering and event ordering tasks. The former task requires both common-sense knowledge and discourse reasoning. Reasoning is more important for long-term links since there are no explicit clues like prepositions and dependencies to be exploited. The ablation study shows that discourse features like sentence distance are more effective, which indicates that our model mainly relies on surface clues and has limited reasoning power.

Furthermore, we observe a strong locality property of After links by skimming the training data: most After link relations are found in a small local region. Since reasoning and coreference based propagation will accumulate local decisions, a system must be accurate on them.

5.2.1 The Ambiguous Boundary of a Script

Besides the above-mentioned challenges, a more fundamental problem is to define the boundary of scripts. Since the definition of scripts is only prototypical event sequences, the boundaries between them are not clear. In Example 3, the event `jailed` is considered to belong to a "Judicial Process" script and `killing` is considered to belong to an"Attack" script[7]. No link is annotated between these two mentions since they are considered to belong to different clusters, even though the "jailed" event is to punish the "killing". Therefore essentially, the current Event Sequencing task simply requires the system to fit these human defined boundaries. In principle, the "Judicial Process" script and the "Attack" script can form a larger script structure, on a higher hierarchical level.

While it is possible to manually define scripts and what kind of events they may contain specifically in a controlled domain, it is difficult to generalize the relations. Most previous work on script induction (Chambers and Jurafsky, 2008; Cheung et al., 2013; Rudinger et al., 2015; Pichotta and Mooney, 2016; Ferraro and Durme, 2016) treats scripts as statistical models where probabilities can be assigned, thereby avoiding the boundary problem. While the script boundaries may be application dependent, a possible solution may rely on the "Goals" in Schank's script theory. The Goal of a script is the final state expected (by the script protagonist) from the sequence of events. Goal oriented scripts may be able to help us explain whether `killing` and `jailed` should be separate: if we take the"killer" as the protagonist, the goal of "kill" is achieved at the point of the victim dying. We leave the investigation on proper theoretical justification to future work.

6 Conclusion

In this paper, we presented a unified graph framework to conduct event coreference and sequencing. We have achieved state-of-the-art results on event coreference and report the first attempt at event sequencing. While we only studied two types of relations, we believe the method can be adopted in broader contexts. In the future, we plan to build a joint model to allow the tasks to mutually improve each other.

In general, analyzing event structure can bring new aspects of knowledge from text. For instance, Event Coreference systems can help group scattered information together. Understanding Event Sequencing can help clarify the discourse structure, which can be useful in other NLP applications, such as solving entity coreference problems (Peng et al., 2015). However, in our investigation, we find that the linguistic theory and definitions for events are not adequate for the computational setting. For example, proper theoretical justification is needed to define event coreference, which should explain the problems, such as argument mismatches. In addition, we also need a theoretical basis for script boundaries. In the future, we will devote our effort to understanding the theoretical and computational aspects of events relations, and utilizing them for other NLP tasks.

Abstract

We present a corpus of spoken Dutch image descriptions, paired with two sets of eye-tracking data: *free viewing*, where participants look at images without any particular purpose, and *description viewing*, where we track eye movements while participants produce spoken descriptions of the images they are viewing. This paper describes the data collection procedure and the corpus itself, and provides an initial analysis of self-corrections in image descriptions. We also present two studies showing the potential of this data. Though these studies mainly serve as an example, we do find two interesting results: (1) the eye-tracking data for the description viewing task is more coherent than for the free-viewing task; (2) variation in image descriptions (also called *image specificity*; Jas and Parikh, 2015) is only moderately correlated across different languages. Our corpus can be used to gain a deeper understanding of the image description task, particularly how visual attention is correlated with the image description process.

Title and Abstract in Dutch

DIDEC: Een corpus van afbeeldingen met Nederlandstalige beschrijvingen en eye-tracking data

Wij presenteren DIDEC, een corpus van foto's met gesproken Nederlandse beschrijvingen en twee verschillende soorten *eye-tracking* data: ofwel verzameld tijdens het beschrijven van de afbeeldingen, ofwel verzameld terwijl de proefpersonen alleen maar keken naar de afbeeldingen (zonder ze te hoeven beschrijven). Dit artikel beschrijft de dataverzameling, alsook een eerste analyse van de zelf-correcties in de beschrijvingen. Daarnaast beschrijven we twee voorbeeldstudies om aan te geven wat er mogelijk is met DIDEC. Deze studies geven twee interessante resultaten: (1) de eye-tracking data verzameld tijdens het beschrijven van de afbeeldingen is eenduidiger dan de data verzameld tijdens het bekijken van de afbeeldingen; (2) de variatie in de beschrijvingen voor iedere afbeelding (ook wel *afbeeldingsspecificiteit* genoemd; Jas and Parikh, 2015) is slechts matig gecorreleerd tussen verschillende talen (Duits, Nederlands, Engels). Ons corpus kan gebruikt worden om beter te begrijpen hoe mensen afbeeldingen beschrijven, en in het bijzonder wat de rol is van visuele aandacht op het beschrijvingsproces.

1 Introduction

Automatic image description is a task at the intersection of Computer Vision (CV) and Natural Language Processing (NLP). The goal is for machines to automatically produce natural language descriptions for any image (Bernardi et al., 2016). The field of automatic image description saw an explosive growth in 2014 with the release of the Flickr30K and MS COCO datasets: two corpora of images collected from Flickr, with 5 crowd-sourced descriptions per image (Young et al., 2014; Lin et al., 2014). These resources enabled researchers to train end-to-end systems that automatically learn a mapping between images and text (Vinyals et al., 2015), but also to better understand how humans describe images (e.g.,

Figure 1: Example item from DIDEC, with the annotated raw transcription, and the intended description. Left: image from MS COCO (originally by Jacinta Lluch Valero, CC BY-SA 2.0), Right: image overlaid with an eye-tracking heatmap. Glosses were only added for presentation in this paper.

Van Miltenburg et al., 2016). However, existing datasets can only provide limited insight into the way humans produce image descriptions, because they only contain the *result* of that process, and do not tell us anything about *how the descriptions came about*. This kind of process information can be very insightful for developing image description systems, which is why we decided to collect a new dataset.

One important part of the human image description process is *visual attention*, i.e. which parts of the image people look at when they are asked to describe an image. Coco and Keller (2012) show that there are similarities between sequences of fixated objects in scan patterns and the sequences of words in the sentences that were produced about the images. This idea has been carried over to automatic image description systems in the form of *attention-based models*. Xu et al. (2015) show that one can improve the performance of an image description model by adding an attention module that learns to attend to salient parts of an image as it produces a description. Their model produces attention maps at every time step when it produces the next word. Lu et al. (2017) improve this approach by having the model learn when visual information is or is not relevant to produce a particular word or phrase.

To better understand the role of visual attention in image description, we need a real-time dataset that shows us where the participants are looking as they are producing the descriptions. We present such a dataset: the Dutch Image Description and Eye-tracking Corpus (DIDEC). DIDEC contains 307 images from MS COCO that are both in SALICON (Jiang et al., 2015) and the Visual Genome dataset (Krishna et al., 2017). SALICON is a growing collection of mouse-tracking data, which is used to generate *attention maps*: heatmaps that show which parts of an image are salient and attract attention. The Visual Genome is a knowledge base that combines metadata from different sources about the images it contains. Thus, future researchers can use information from all these different sources in their analysis of our data.

Each image in DIDEC is provided with spoken descriptions and real-time eye-tracking data. There are between 14 and 16 spoken descriptions per image. Each of these descriptions was manually transcribed and annotated. We provide the audio with two kinds of transcriptions (an example is given in Figure 1):

1. Raw descriptions, annotated with markers for repetitions, corrections, and (filled) pauses.
2. Normalized descriptions, without repetitions, and with the corrections suggested by the speaker.

Having these two kinds of descriptions enables us to get a better understanding of the language production process, for example showing exactly where participants experience increased cognitive effort. The normalized descriptions facilitate comparison with written descriptions and improve searchability of the corpus. We also provide two kinds of eye-tracking data:

1. Free viewing: eye-tracking data collected without any concurrent task.
2. Description viewing: eye-tracking data collected simultaneously with the spoken descriptions.

These two sets of eye-tracking data allow us to study the influence of the description task on visual attention. Earlier studies have shown that different tasks may cause different patterns of visual attention (Buswell, 1935; Yarbus, 1967; Coco and Keller, 2014). Our eye-tracking data is complementary to the mouse-tracking data in SALICON, which can only be used to study *bottom-up* attention (driven by the image), and not *top-down* attention (driven by a specific task, such as image description). This difference is further discussed in Section 4. Furthermore, because we collected *spoken* image descriptions, the descriptions are aligned with the eye-tracking data in the description viewing task. This is useful when studying phenomena like self-correction (Section 3.2).

Contributions. This paper introduces DIDEC, a corpus of spoken image descriptions with eye-tracking data. We explain how the corpus was created (§ 2), and provide general statistics about the resource, along with a short discussion of the annotated corrections, providing insight in the description process (§ 3). Then, we present two initial studies to show different possible uses of our dataset. The first study focuses on the effect of task on visual attention, where we show that the eye-tracking data for the image description task is more coherent than the free-viewing data (§ 4). The second study looks at *image specificity* (Jas and Parikh, 2015) across different languages, and whether it is possible to predict image specificity from eye-tracking data. We provide a more efficient, multilingual re-implementation of Jas and Parikh's measure, and show that image specificity is only moderately correlated across different languages, and cannot be predicted directly from attention map similarity (§ 5). Our corpus is freely available, along with an exploration interface, and all the materials that were used to create the dataset.[1]

2 Procedure

We carried out an eye tracking experiment consisting of two separate sub-experiments, which represented two tasks: (1) a free viewing task, during which participants looked at images while we tracked their eye movements, and (2) a task in which participants were asked to produce spoken descriptions of the images, while again their eye movements were recorded. There were different participants for the two sub-experiments, so no image was viewed twice by the same participant.

Data and Materials. Our image stimuli came from MS COCO (Lin et al., 2014), which contains over 200K images with 5 English descriptions each. We selected 307 images matching the following criteria: they should be in landscape orientation, and be part of both the SALICON and the Visual Genome dataset (Krishna et al., 2017). The latter was done for maximum compatibility with other projects.

In order to avoid lengthy experiments, we made three subsets of images, which we refer to as lists in the corpus: one list of 103 images, and two lists of 102 images. In both tasks, participants saw only one list of images. Participants were randomly assigned to one of the lists, with each between 14 and 16 participants. To avoid order effects, we made two versions of each list, which reflect the two fixed random orders in which the images were shown. We registered eye movements with an SMI RED 250 device, operated by the IviewX and the ExperimentCenter software packages.[2] We recorded the image descriptions using a headset microphone.

Free viewing versus Production viewing. In the free viewing task, subjects viewed images for three seconds while their eye movements were recorded. In the image description task, participants also viewed images, but this time they were also asked to produce a description of the current image (while their eye movements were again tracked). The instructions for this task were translated from the original MS COCO instructions. Participants could take as much time as needed for every trial to provide a proper description. In both tasks, every trial started with a cross in the middle of the screen, which had to be fixated for one second in order to launch the appearance of the image. All images in our study both occurred in the free viewing task and in the image description task, but always with different participants. This way, each image viewed by the participants was new to them, preventing any possible

[1] Our resource is available at: `http://didec.uvt.nl`

[2] The eye tracker had a sampling rate of 250 Hz. The stimulus materials were displayed on a 22 inch P2210 Dell monitor, with the resolution set to 1680 x 1050 pixels. The images were resized to 1267 x 950 pixels (without changing the aspect ratio), surrounded by grey borders. These borders were required because eye-tracking measurements outside the calibration area (i.e., in the most peripheral areas of the screen) are not reliable. The viewing distance was 70 cm.

familiarity effects. Avoiding any confounding from familiarity effects also means we are forced to carry out a between-subjects analysis to study the effect of the task on the viewing patterns for the same image.

Transcription and annotation. After exporting the recordings for each trial, we automatically transcribed the descriptions using the built-in Dictation function from macOS Sierra 10.12.6.[3] The transcriptions were manually corrected by a native speaker of Dutch. To get an idea of the actual quality of the automatic transcriptions, we computed the word error rate (WER) for the automatic transcriptions, as compared to the corrected transcriptions.[4] This resulted in a WER-score of 37%.

We refer to the transcribed descriptions in the corpus as *literal descriptions*. In addition, the annotator marked repetitions, corrections, and (filled) pauses (*um, uh*, or silence longer than 2 seconds) by the speaker. We will later use these meta-linguistic annotations to gain more insight into the image description process. Finally, our annotator provided the *normalized descriptions*, without filled pauses or repetitions and with the repairs taken into account.

Participants. Our participants were 112 Dutch students who earned course credits for their participation: 54 students performed the free viewing task, while 58 students completed the image description task. We could not use the data of 19 participants (6 in the free viewing task; 13 in the image description task), since eye movements for these people were not recorded succesfully, or only partially. This was mainly due to the length of the experiments, and to the fact that speaking could distort the eyetracking signal. We tried to prevent this issue by calibrating participants' eyes to the eyetracker twice: once before the start, and once halfway. The final data set consists of data for 48 participants (34 women) in the free-viewing condition, with a mean age of 22 years and 3 months; and data for 45 participants (35 women) in the image description condition, with a mean age of 22 years and 6 months.[5]

Our experiment followed standard ethical procedures. After entering the lab, participants were seated in a soundproof booth, and read and signed the consent form. This form contained a general description of the experimental task, an indication of the duration of the experiment, contact information, and information about data storage. Participants needed to give explicit permission to make available their audio recordings and eye movement data for research purposes; otherwise, they would not participate. Also, participants were allowed to quit the experiment at any stage and still earn credits.

3 General results: the DIDEC corpus

In the description condition, 45 participants produced 4604 descriptions (59,248 tokens), leading to an average of 15 descriptions per image (min 14, max 16). The average description length for the normalized descriptions is 12.87 tokens (Median: 12, SD: 6.45). By comparison, the written English descriptions in MS COCO are shorter (average: 10.78 tokens) and have a lower variance in description length (SD: 2.65).[6] We checked to see if the difference in length is due to any differences between Dutch and English, using the Flickr30K validation set (data from Van Miltenburg et al., 2017). We found that the English descriptions are in fact *longer* than the Dutch ones (with a mean of 12.77 tokens for English (SD: 5.67) versus 10.47 tokens for Dutch (SD: 4.45)). These findings are in line with earlier findings from Drieman (1962) and others that spoken descriptions are typically longer than written ones. We discuss the differences between spoken and written language in more detail in (van Miltenburg et al., 2018).

We found a high degree of variation in description length across different participants. The difference between the lowest and highest median description length is 16.5 tokens (Lowest: 8, Highest: 24.5, Mean: 12.30, SD: 4.15). We also checked whether sentence length decreases with length of experiment, by correlating sentence length with the order in which the images were presented. We found a Spearman correlation of 0.06, suggesting that order had no effect on description length. Following this, we looked

[3] This required us to emulate a microphone using SoundFlower 2.0b2, to use Audacity 2.1.0 to play the recordings and direct the output through the emulated microphone to the Dictation tool.

[4] We used the evaluation script from: `https://github.com/belambert/asr-evaluation`

[5] For 3 participants in the description task, and 4 participants in the free viewing task only a small subset of the eye-tracking data is missing (14 trials in total for the description task, and 7 trials in the free viewing task). We decided to keep these participants and treat the trials as missing data.

[6] We only counted the description lengths for the 307 images that are also in DIDEC. Since DIDEC lacks periods at the end of the descriptions, we also stripped them from the MS COCO descriptions. We used the SpaCy tokenizer to obtain the tokens.

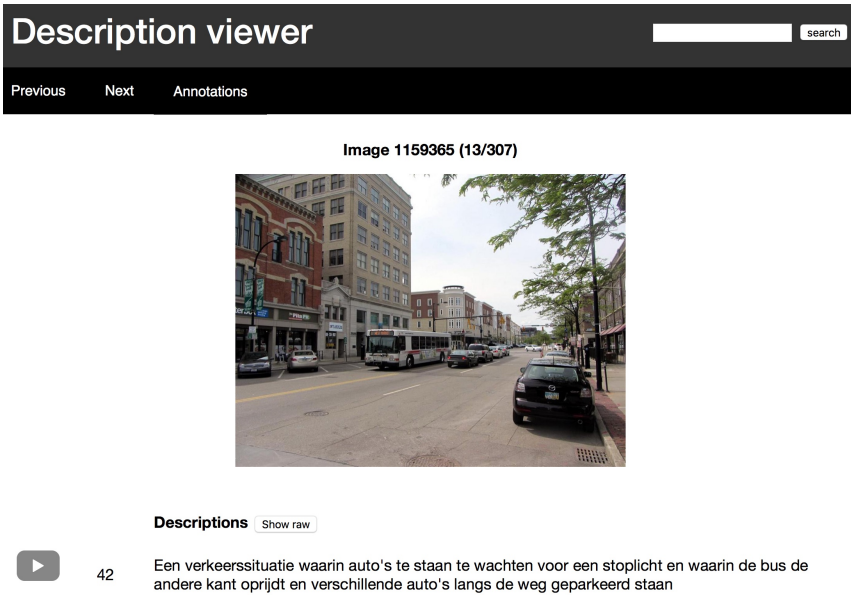

Figure 2: The description viewer provides a browser-based interface to the corpus. Users can browse through the images, search for specific words or annotations, and listen to the spoken descriptions. (Displayed image by David Wilson, CC BY 2.0)

at the variation in description length between images. We found that the difference between the lowest and highest median description length is 15 tokens (Lowest: 6, Highest: 21, Mean: 11.75, SD: 2.46). We conclude that there is a greater variability between participants than between images.

3.1 Viewer tool

We made a description viewer application that allows users to browse through the images, read the annotated descriptions, and listen to the spoken descriptions. Users can also search the descriptions for particular annotations, or for the occurrence of particular words. The description viewer will then return a selection of the images where at least one of the descriptions contains that particular word or annotation. See Figure 2 for an impression of the interface. The viewer tool can be downloaded along with our data from the corpus website.

3.2 Exploring the annotations in the dataset: descriptions with corrections

Recall that we also annotated basic meta-linguistic information to the raw descriptions, such as pauses, repetitions, and corrections. Table 1 shows the number of times each label was annotated. We chose to add these labels because they may inform us about the image description process. For example, one might expect participants to use more filled pauses and repetitions if the image is more complex or unclear (cf. Gatt et al., 2017). Repetitions, in this case, would signal initial uncertainty about the interpretation of the image, followed up by a confirmation that their initial interpretation was correct.

Tag	Meaning	Count
<uh>	Filled pause	1277
<corr>	Correction	693
<rep>	Repetition	139
<pause>	Pause	123
<?>	Inaudible	23

Table 1: Annotation counts.

We will now look at some examples of corrections in the image description data. This will give us some idea of why people tend to make corrections in their descriptions, and what this process looks like. One of the first studies on this topic is provided by Levelt (1983), who discusses a corpus of 959 repairs that were spontaneously made by Dutch speakers after they were asked to describe visual patterns. The difference between DIDEC and Levelt's corpus is that the latter consists of abstract stimuli while DIDEC uses pictures of real-life situations. Levelt used his data to study monitoring (roughly: critically observing one's own speech production), the use of editing terms (e.g. *uh, sorry, no, I mean* ...), and how people actually carry out repairs. Studies like these informed Levelt's seminal model of speech

Figure 3: Eye-tracking data for example (3). Numbers indicate the following: 1. Start of experiment, 2. Speech onset, 3. Speaker realizes her mistake: the group hasn't ordered yet, 4. Start of corrected description, 5. End of description. (Original image by Malcolm Manners, CC BY 2.0)

production (Levelt, 1989). For reasons of space, we will only look at four examples from our dataset, but we hope to show that these kinds of examples warrant further consideration. Looking through the data, many corrections are due to mispronunciations, as in (1).

(1) Een hele grote prie <corr> pizza met drie jongens
A very large pri <corr> pizza with three boys

This particular mispronunciation is a so-called *anticipation error*, one of the most frequent kinds of speech errors (Fromkin, 1971). As the speaker is saying *pizza*, she is already preparing to say *three*, and accidentally inserts the *r* in the onset of *pizza*. Besides mispronunciations, there are also more complex cases. Figure 1 already provided an interesting example, repeated for convenience in (2):

(2) Een hele kudde schapen <uh> met een man <corr> met een herder erachter en een pakezel.
A whole herd of sheep <uh> with a man <corr> with a shepherd behind them and a mule.

What is interesting about this example is that the original expression *with a man* was already correct. The correction *man* → *shepherd* was made to be more specific, so as to produce a more informative description. A possible reason why the speaker did not immediately say 'shepherd' instead of 'man' is that the former is a *(social) role* (Masolo et al., 2004). We cannot determine that the man is a shepherd based on his visual appearance alone, but rather we label him as a shepherd on the basis of the context of him interacting with a herd of sheep. After making this inference, the original label is replaced.

The example in (3) shows a correction after making an incorrect prediction about the situation in Figure 3. Initially the speaker thinks the group is already eating, but actually they haven't ordered yet.

(3) Gezelschap die aan het eten is of <corr> die in een restaurant zit en iets willen gaan bestellen.
Group of people that is eating or <corr> that is sitting in a restaurant and is about to order.

What is interesting here is that we can actually see the correction reflected in the eye-tracking data. Figure 3 shows the attention map along with the scanning pattern corresponding to the eye movements. (Underline colors in the example correspond to the colors in the figure.) The participant starts by scanning the situation and looking at the people at the table. During this time, she starts speaking, but then she realizes her mistake upon seeing the menu on the table. She then updates her beliefs about the situation and corrects her utterance. This is a good example of *predictive coding* (see e.g. Clark, 2013).

Finally, (4) provides an example of a participant who rephrases her description when she realizes that her description is ambiguous; Dutch *knuffel* could both mean 'hug/cuddle' and 'cuddly toy' while *knuffeldier* only means 'cuddly animal.' (We ignore the first correction here.)

(4) Een vrouw die een meisje <corr> klein meisje een knuffel geeft <**corr**> knuffeldier.
A woman giving a girl <corr> little girl a cuddle <**corr**> cuddly animal.

The remainder of this paper discusses two case studies – one comparing eye movements during free viewing versus image description, and one looking into the effects of image specificity on the description

	Compared to attention maps from the other task, attention maps from the same task are…		
Task	More similar	Equally similar	Less similar
Description viewing	300	0	7
Free viewing	116	0	191

produced– both highlighting the potential usage of the DIDEC corpus.

4 Task-dependence in eye tracking: free viewing versus producing descriptions

A potential issue in studying visual attention is that eye-tracking data may differ across tasks. In one of the first ever eye-tracking studies, Buswell (1935) shows that we can observe differences in eye-tracking behavior between people who are freely looking at an image, versus when they are asked to look for particular objects in the same image. Yarbus (1967) presents a study in which participants are asked to carry out seven different visual tasks, and shows that we can observe differences in eye-movement patterns between each of the different tasks. He argues that "eye movements reflect the human thought process." Finally, Coco and Keller (2014) show that it is possible to train a classifier to distinguish eye-tracking data for three different tasks: object naming, scene description, and visual search. This suggests that in order to model different tasks, one should also collect different sets of eye-tracking data.

Bottom-up versus top-down attention. The literature on visual attention modeling identifies two kinds of salience. On the one hand, there is bottom-up, task-independent visual salience, which is typically image-driven. On the other hand, there is top-down, task-dependent salience, where attention is driven by the task that people may have in viewing the image (Borji and Itti, 2013; Itti and Koch, 2000). Visual attention models are usually designed to predict general, task-free salience (Bylinskii et al., 2016). This prediction task is exactly what the SALICON dataset was developed for.

Free viewing versus description viewing. DIDEC was developed with this top-down versus bottom-up distinction in mind, so that we could compare different modes of viewing the images. The free-viewing task corresponds to bottom-up attention; because there are no explicit instructions of where to look at or what to do, participants only have the image to guide their attention. As such, they are drawn towards the most salient parts of the image. The description viewing task corresponds to top-down attention; because our participants are asked to describe the images, their attention is also guided by what they think might be the most conceptually important parts of the images.

Analysis. To what extent do people differ in their visual attention, between our two tasks? We decided to test this by comparing the attention maps computed on the basis of the eye-tracking data for both tasks. For each image, for each participant, we used their fixations to generate an attention map. Then, for each image, we computed the within-task and between-task average pairwise similarities between the attention maps.[7] By looking at the difference between the within-task similarity and the between-task similarity, we can see if there is consistently more agreement within each task than between the tasks.

Results. Table 2 shows the results. We find that, on average, attention maps from the image description task tend to be more similar to each other than to the attention maps from the free viewing task. But when we look at the attention maps from the free viewing task, we see that they are only more similar to each other 38% of the time (116 out of 307). In 62% of the cases, the between-task similarity is higher than the within-task similarity for the free viewing data. Figure 4 shows the distribution of the scores. We conclude that the image description task reduces noise in the collection of eye-tracking data, and produces a more

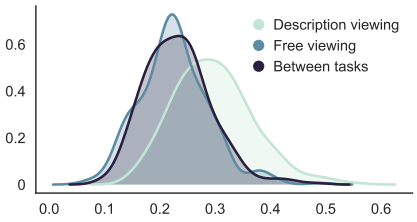

Figure 4: Distribution of the similarity scores within and between tasks.

[7] We use existing code to analyze this data: `https://github.com/NUS-VIP/salicon-evaluation/` The pairwise similarity between attention maps (`CC_score`) is computed using the Pearson correlation.

coherent set of attention maps.

5 Image specificity

Whenever you ask multiple people to describe the same image, you rarely get the same description. Jas and Parikh (2015) show that this variation is not consistent: some images elicit more variation than others. In their terminology: some images are *specific*, resulting in little variation in the descriptions, while others are more *ambiguous*. Following up on this observation, Jas and Parikh (2015) propose an automated measure for image specificity in English, and show that it correlates well with human specificity ratings collected for the images from the image memorability dataset (Isola et al., 2011). With a Spearman's ρ of 0.69, their measure is close to human performance (0.72). To show that specificity is really a property of the image, Jas and Parikh (2015) carry out two experiments:

1. Replicating an image description task: if we ask another group of people to provide descriptions for the same set of images, do we then see the same amount of variation for each image? In their experiment, Jas and Parikh obtained a fairly strong correlation of 0.54 between groups, meaning that the variation did not just arise by chance.

2. A regression analysis: can we predict variation between the image descriptions on the basis of an image? Jas and Parikh reveal that image specificity can indeed be predicted from different properties of an image, such as the presence of people and large objects, the absence of generic buildings or blue skies, and the importance of objects that are visible. (Importance is calculated based on the number of mentions for certain objects in a set of image descriptions.)

But if image specificity is indeed a property of the image, we should also be able to correlate image specificity scores across different languages. We will first test this hypothesis for Dutch, English, and German using existing datasets, and then replicate the correlation between Dutch and English specificity scores using DIDEC. In a second step, we will see if we can directly correlate differences in eye-tracking behavior with the Dutch specificity scores. This experiment builds on the results from Coco and Keller (2012), who showed that scan patterns can be used to predict what someone will say about an image.

5.1 The image specificity metric

Jas and Parikh compute image specificity by taking the average similarity between all descriptions of the same image. The similarity between pairs of sentences is determined using WordNet (Fellbaum, 1998):

1. For each word in the first sentence, compute the maximum path similarity between all possible synsets of that word, and all possible synsets of all words in the second sentence. This is an alignment strategy to find the best matches between both sentences.
2. Repeat the process in the opposite direction: for each word in the second sentence, compute the maximum path similarity with the words in the first sentence.
3. Compute the average path similarity, weighted by the importance of each word (determined using TF-IDF on the entire description corpus under consideration).

Using this method, Jas and Parikh (2015) get a correlation of 0.69 with human specificity ratings, close to the inter-annotator correlation of 0.72. Their conclusion is that this is a reliable measure to estimate image specificity. One problem with this measure is that it requires a lexical resource (WordNet) that is not available for every language. Since we want to run the evaluation corpus on the Dutch descriptions, and because the original implementation is relatively slow and difficult to modify, we re-implemented Jas and Parikh (2015)'s image specificity measure. Our reimplementation also achieves a correlation of 0.69 with the human ratings, and 0.99 with the original implementation.[8] Having validated our reimplementation, we replaced WordNet similarity with cosine similarity, using the GoogleNews word vectors (Mikolov et al., 2013). With this modification, we achieve a correlation with human ratings of 0.71, and a correlation of 0.87 with the original implementation. We also ran the same measure using the FastText

[8] We also found that the WordNet lookup is the main bottleneck, and we can significantly speed up the algorithm by caching the word-to-word similarities. We used the built-in `@lru_cache` decorator in Python 3, storing a million input-output pairs.

Language	Type	Source
Dutch	word2vec	Mandera et al. (2017)
English	word2vec	Mikolov et al. (2013)
German	word2vec	Müller (2015)
All	FastText	Bojanowski et al. (2017)

Table 3: Word embeddings used to compute the image specificity metric.

Comparison	Split	word2vec	FastText
NLD, DEU	validation	0.23	**0.47**
NLD, ENG	validation	0.36	**0.40**
DEU, ENG	validation	0.18	**0.41**
DEU, ENG	train	0.16	**0.39**

Table 4: Spearman correlation between automated image specificity scores in different languages, using two sets of word embeddings.

embeddings (Bojanowski et al., 2017), achieving a correlation of 0.69 with the human ratings and 0.86 with the original implementation. This means that the metric performs on par with Jas and Parikh's original measure, but captures slightly different information about the image descriptions.

5.2 Correlating image specificity between different languages

We used the embedding-based specificity metric to compare image descriptions in 3 different languages, using off-the-shelf embeddings (listed in Table 3).[9] We compare English (ENG) descriptions from the Flickr30K dataset (Young et al., 2014) with German (DEU) and Dutch (NLD) descriptions for the same dataset (Elliott et al., 2016; van Miltenburg et al., 2017). Note that the Dutch data comes from a different dataset than ours, which allows for comparison with both English *and* German.

Table 4 presents the correlations between the scores. Our results show a striking difference between scores computed using word2vec embeddings and those computed using FastText embeddings. This difference seems to be due to poor performance of the German model, as the correlations between the Dutch and English scores are reasonably similar between word2vec and FastText (0.36 versus 0.40). The reason for this may be that the word2vec model has limited coverage, while the FastText model uses subword information to compute vectors for tokens that are out-of-vocabulary. This is especially important for languages like German, which uses more compounding and has a richer morphology than English. We observe that the scores based on the FastText embeddings have correlations between 0.39 and 0.47. This means that, to some extent, image specificity is indeed language-independent. In other words, the data suggests that some images just elicit more varied responses than others, and it does not matter whether you speak Dutch, English, or German.

5.3 Replicating the results using DIDEC

Having found a fairly consistent Spearman correlation of about 0.4 between the different languages, we asked ourselves whether this result could be replicated. We pre-registered our hypothesis (yes it can) with the Open Science Foundation before collecting the image description data.[10] After the data collection procedure was finished, we computed the correlation between the Dutch and English image specificity scores for the 307 images in our dataset. We found a Spearman correlation of 0.23, which is lower than expected. One possible explanation for this is that the descriptions in MS COCO are shorter and have a lower variance in description length (as mentioned in §3), which reduces noise in the comparison. To see if this is indeed the case, we repeated the experiment with only 5 descriptions per image, always selecting the median 5 descriptions when sorted by length. With this approach, we find an even lower correlation of 0.20. We conclude that image content only has a limited influence on description diversity.

5.4 Predicting image specificity from eye-tracking data: a negative result

We now turn to look at whether the image specificity scores are correlated with our eye-tracking data. As noted above, this experiment builds on Coco and Keller's (2012) work, which shows that scan patterns can be used to predict what people will say about an image. Rather than taking Coco and Keller's more

[9] Even though wordnets exist for Dutch (Postma et al., 2016) and German (Hamp and Feldweg, 1997; Henrich and Hinrichs, 2010), we did not use them because they have lower coverage, and we do not need to worry about lemmatization.

[10] Our preregistration can be found at: `https://osf.io/6pc2t/register/565fb3678c5e4a66b5582f67` We deviated from our preregistration in two areas: (1) the experiment took more time than expected, so we split the experiment in two parts; (2) we had to discard more data than expected, so we collected data from more participants to compensate.

advanced approach (involving image segmentation), we use a more naive strategy: (1) We first compute the average pairwise similarity scores between the attention maps. If our participants agreed on where to look, this score will be higher than if our participants attended to different parts of the image. (2) We then correlate those scores with the image specificity scores we computed earlier.

We found no correlation between the eye-tracking data and the image specificity scores. Because Coco and Keller (2012) did find correlations between eye-tracking similarity and description similarity, we conclude that our naive approach is probably too weak to detect any effect. This shows us the limitations of using raw eye-tracking data, which may be too noisy to be compared directly for these kinds of fine-grained predictions. In cases like this, following Coco and Keller, it is better to combine our eye-tracking data with the object-level annotations in MS COCO.

6 Conclusion

We collected a corpus of Dutch image descriptions and eye-tracking data for 307 images, and provided an initial analysis of the self-corrections made by the participants. We have also presented two studies that show some possible uses of our data, but we believe many more analyses are possible. For reasons of space, we have not discussed the effect of modifying the modality of the image description task from written to spoken language, even though we know that modifying the prompt may have an effect on the response (e.g. Baltaretu and Castro Ferreira 2016). In a companion paper, we compare spoken and written image descriptions in both Dutch and English (van Miltenburg et al., 2018). We still plan to semi-automatically annotate Speech Onset Times (SOT) using Praat (Boersma and Weenink, 2017), and to manually correct the output. We define SOT as the start of the utterance, including filled pauses (but excluding coughs and sighs). This is a measure of response time for each image, which is a proxy for the difficulty of producing a description, that could be correlated with e.g. image complexity (cf. Gatt et al., 2017).

Finally, the development of multilingual image description datasets (like Multi30K), has opened up new avenues of research, such as multimodal machine translation (Elliott et al., 2016; Elliott et al., 2017). To the best of our knowledge, a dataset like DIDEC does not exist yet for any other language. We hope that our corpus may serve as an example, inspiring the development of parallel eye-tracking and image description datasets in other languages. This multilingual aspect is important because speakers of different languages may also display differences in familiarity with the contents of an image or, if their language uses a different writing directionality, different eye-tracking behavior (van Miltenburg et al., 2017; Baltaretu et al., 2016). We made all code and data used to build the corpus available on the corpus website, so as to encourage everyone to further study image description as a dynamic process.

Narrative Schema Stability in News Text

Dan Simonson
Georgetown University

des62@georgetown.edu

Anthony Davis
Ashland, Oregon
tonydavis0@gmail.com

Abstract

We investigate the stability of *narrative schemas* (Chambers & Jurafsky, 2009) automatically induced from a news corpus, representing recurring narratives in a corpus. If such techniques produce meaningful results, we should expect that small changes to the corpus will result in only small changes to the induced schemas. We describe experiments involving successive ablation of a corpus and cross-validation at each stage of ablation, on schemas generated by three different techniques over a general news corpus and topically-specific subcorpora. We also develop a method for evaluating the similarity between sets of narrative schemas, and thus the stability of the schema induction algorithms. This stability analysis affirms the heterogeneous/homogeneous document category hypothesis first presented in Simonson & Davis (2016), whose technique is problematically limited. Additionally, increased ablation leads to increasing stability, so the smaller the remaining corpus, the more stable schema generation appears to be. We surmise that as a corpus grows larger, novel and more varied narratives continue to appear and stability declines, though at some point this decline levels off as new additions to the corpus consist essentially of "more of the same."

1 Introduction

Narrative schemas complement other approaches to the automated analysis of topical and narrative information in documents. Unlike template-filling techniques, they do not require a defined set of human-crafted templates; instead, template-like structures are induced. Unlike topic models, they generate representations in which event types and participant types are organized into relational structures, specifying shared participants between events. Unlike automatic summarization, they generalize over similar but distinct narratives, with the goal of revealing their underlying common elements.

Scripts (or schemas or frames) have long been touted as a way to provide artificial intelligence systems with world knowledge and understanding (Schank & Abelson, 1977). Building these scripts by hand is labor intensive, so automatically learning script knowledge has attracted attention for decades (Balasubramanian et al., 2013; Chambers & Jurafsky, 2009; Mooney & DeJong, 1985; Pichotta & Mooney, 2014, 2015). However, we are also interested in what such techniques reveal about broad, quantitative properties of discourse in general.

Like many unsupervised tasks, the evaluation of schemas is still a matter of debate and depends on their intended use; there is no one broadly accepted method, and nothing that closely models human intuitions about narrative. Chambers & Jurafsky (2008, 2009) proposed and used the *cloze task* to evaluate their procedure, widely adopted in subsequent work (Cheng & Erk, 2018; Jans et al., 2012; Pichotta & Mooney, 2014, 2015). In the cloze task, an event from a sequence in holdout data—either a coreference or sentence-to-sentence sequence—is removed and must be guessed by a model of the events in text.

However, it is questionable whether the cloze task actually requires script knowledge to perform well (Mostafazadeh et al., 2016; Rudinger et al., 2015; Simonson, 2018), and thus whether it is an *effective* measure of schema quality. Cloze does not evaluate schemas directly—only indirectly through the score

Proceedings of the 27th International Conference on Computational Linguistics, pages 3670–3680
Santa Fe, New Mexico, USA, August 20-26, 2018.

used to generate schemas—and is fundamentally unsolvable, even by humans, so it is an open question whether the information needed to perform well on a cloze task corresponds closely to the information within narrative schemas. Others have evaluated schemas directly. Balasubramanian et al. (2013) evaluated schemas manually using mechanical turkers, but this is labor intensive and pre-supposed specific properties about schemas—for example, that "a child exploded a blast" cannot be part of a valid schema, despite that we live in a world where such incidents occur on a regular basis. Simonson & Davis (2016) introduced the NASTEA task for schema evaluation where schemas are used to identify salient entities in a document, but this is dependent on a set of "salient entity annotations" from the New York Times corpus (Sandhaus, 2008). We noted that some document categories are *homogeneous*—that is, requiring only one schema to obtain optimal performance on their task—and others are *heterogeneous*—requiring multiple schemas for optimal performance. It is not clear whether their findings are robust or a mere artifact of the idiosyncrasies of NYT annotations.

In this paper, we turn instead to the stability of narrative schemas, as a method of gauging schema quality complementary to cloze and the NASTEA task. We assume that high-quality schemas are robust; that is, the addition, deletion, or modification of a few narratives in the corpus should not drastically affect the schemas generated. We conducted experiments using both corpus ablation and cross-validation at each stage of ablation. This kind of evaluation is relatively easy to carry out in many sorts of corpora; it does not require any annotation effort and is conceptually straightforward. Two challenges, however, are the computationally intensive nature of these experiments, and the similarity measure employed in comparing sets of narrative schemas.

In Section (2), we describe the data set used in this paper. In Section (3), we describe the schema germinators used in this study, including one novel technique intended to complement the others from prior work. In Section (4), we explain the ablation and cross-validation procedure used to perform a schema stability analysis. in Section (5), we propose the "Fuzzy Jaccard" coefficient used for comparing sets of schemas. In Section (6), we present the results of this study. In Section (7), we discuss the results. In Section (8), we conclude this paper.

2 Data

We performed our stability analysis of narrative schemas on a subset of the *New York Times* Annotated Corpus (Sandhaus, 2008), the same subset as Simonson & Davis (2016). containing over 1.8 million articles from 1987 to 2007.

We selected the same document set from Simonson & Davis (2016) for direct comparison with our previous work, to affirm or disprove our homogeneity-heterogeneity hypothesis. Note that in these earlier results, included an "Education and Schools" category is mentioned (Simonson & Davis (2016), Figure 3), but is unfortunately omitted in Table (1) in that paper. This has been included in our Table (1) here.

Table 1: Counts of document categories selected from the `online_producer` tag for use in this study after pre-processing. Simonson & Davis (2016) chose categories to contain roughly the same number of articles and to represent different sorts of topics.

`online producer` category	counts	`online producer` category	counts
Law and Legislation	52110	United States Armament and Defense	50642
Weddings and Engagements	51195	Computers and the Internet	49413
Crime and Criminals	50981	Labor	46321
Education and Schools	50818	Top/News/Obituaries	36360

For NLP preprocessing, the Stanford CoreNLP suite of tools (Manning et al., 2014),[1] was chosen for comparability to Simonson & Davis (2016)'s original work, itself chosen because it has both parsing and coreference capabilities (de Marneffe et al., 2006; Lee et al., 2013), which are essential for generating schemas. Using the same version of tools as Simonson & Davis (2016), we were able to replicate their

[1] Stanford CoreNLP, Version 3.4.1 (2014-08-27), (via Simonson (2018))

category counts after excluding a number of articles that produced no coreference chains or failed to survive pre-processing.

3 Germinators for Schema Generation

The heart of Chambers & Jurafsky (2009)'s schema induction technique, and our variants derived from it, is a similarity measure between *narrative chains* in the context of a schema and a candidate event verb. A narrative chain is a set of verb-dependency pairs—i.e. slots—that share a common participant filling all the slots. These are constructed from verbs that are statistically associated using a PMI-based measure plus a preference for verb-argument slot pairs in which the argument slot is filled by participants of a consistent type. This similarity measure determines the best candidate verb-argument slot pair to add to an existing chain; a score termed $chainsim'$ is computed for each candidate pair, summing this similarity measure for each candidate and the existing elements of the chain. Lastly, narrative schemas, consisting of merged sets of chains sharing events, are produced.

Here, we focus primarily in generating schemas. The cloze task does not directly evaluate schemas. Rather, it evaluates a component of the model used to generate schemas. For example, in the case of Chambers & Jurafsky (2008, 2009), $chainsim$ and $chainsim'$ are used to rank event verbs in the cloze task. The schemas therein generated are not directly evaluated. Thus, we draw a line after $chainsim'$ and other techniques used on the cloze task, referring to them as the *candidate score*.

However, a candidate score alone is not enough to generate schemas. We must decide on a technique for traversing candidates and interpreting their scores as prospective additions to a schemas under construction. We will refer to these techniques collectively as *germinators*.

We employ two previously devised germinators for schema generation (Section 3.1): counter-training (Simonson & Davis, 2015) and Chambers' original technique or schema germination (Chambers & Jurafsky, 2009), though here referred to as "linear induction." Both of these techniques are relatively deterministic, so for comparison, we present a novel stochastic technique for schema generation called the "random walker" germinator (Section 3.2). We expect this stochastic technique to be less stable than its deterministic counter-parts.

All of the implementations for narrative schema germinators can be found in `durruti`.[2]

3.1 Prior Techniques

Linear induction is what we call Chambers & Jurafsky (2009)'s technique for inducing schemas. In this technique, the event verbs are considered in order for adding to narrative schemas. Each event verb is compared against an ever-growing set of schemas. New schemas are created when the event verb does not pass a threshold parameter β. In Chambers & Jurafsky (2009)'s original implementation, if a candidate event verb's $chainsim'$ score is greater than β, it is added to the schema that best fit the event verb. We differ in this regard, adding the candidate event verb to every schema for which its $chainsim'$ score crossed the threshold.

Alternatively, *counter-training* (Simonson & Davis, 2015)—inspired by Yangarber (2003)—considers a fixed set of schemas simultaneously, which start as a set of seeds. Candidate events are scored against all schemas, then those scores are penalized based on how many different schemas each candidate fit into. After penalties have been applied, the best candidate event for each schema is added to each schema.

With respect to both techniques, once the decision has been made to add an event to a schema, we insert new events into each schema the same way in both germinators, following Chambers & Jurafsky (2009)'s technique for doing so. Additionally, for both prior germinators and the random walker—described in Section 3.2—$chainsim'$ is used as the underlying score.

3.2 Random Walker

Both prior techniques are deterministic. Adding a "random walker" stochastic germinator potentially provides a nice contrast to these deterministic techniques. For a particular schema, all possible insertions are treated as weighted random choices based on the scores between chains already in a schema and

[2] `https://github.com/thedansimonson/durruti`

candidate events. However, because the scores are pmi-based, the values, if turned into a probability distribution, are nearly uniformly distributed. This causes events selected for schemas to be effectively unrelated to one another. Instead, we use a weighting function to weight the score more appropriately for random selection, in this case $weight(C, vd) = 2^{chainsim'(C,vd)}$, which effectively undoes the $\log$ contained in the score function.

This algorithm departs from a simple random walk, because the weights on the graph change at each step; the current score value for each schema depends not only on the last event added, but on all of the events previously added. The "graph" is thus recomputed based on the current state of the schema being grown.

4 Stability Ablation and Cross-Validation

The stability evaluation procedure alternates two stages: an ablation step and a cross-validation step. At each ablation step, 10% of the total set of documents are removed (not 10% of the previous ablation). Then, using the corpus at each ablation stage, ten-fold cross-validation partitions the set of documents and 9/10ths of the available documents are used in each fold to generate schemas. These splits are not preserved across ablations. While these procedures involve removing portions of the original corpus, the most intuitive way to interpret the intent is in reverse—that is, to think of some sort of search and retrieval procedure yielding slightly different results (cross-validation step) at each step in a larger data collection effort (ablation step).

We generate schemas using each of the three schema germinators described above. Separate sets of schemas are generated from the documents in each category in Table (1), using separate PMI models produced from documents in each category, at each stage of ablation, and for each fold of cross-validation. These sets of schemas are what we compare to one another to gauge their stability in different experimental configurations.

Since the total number of schemas generated is about 4 million, we did not attempt to optimize various parameter values pertinent to each germinator, instead using a single set of approximately optimized values from an earlier study of schemas in a salient named entity detection task.

5 Fuzzy Jaccard Coefficient and the Jaccard Reciprocal Fraction

The result from each run (using a given schema germinator, on documents from a given category at a specified stage of ablation and fold of cross-validation) is a set of narrative schemas. How can we then measure the similarity between different sets of schemas? A schema in one set may be highly similar but not identical to a schema in the other set; see, for example, any two schemas in Figure (3). We wish to take their similarity into account in our overall measure of the similarity between the two sets. It is simple to measure the similiarity J_e between two individual schemas σ and τ, using the Jaccard coefficient, where σ_e and τ_e are the sets of events contained in each schema:

$$J_e(\sigma, \tau) = \frac{|\sigma_e \cap \tau_e|}{|\sigma_e \cup \tau_e|} \tag{1}$$

But evaluating the similarity between two sets of schemas is not so straightforward, particularly when we need to compare thousands of pairs of sets of schemas. Essentially, we would like to determine, for each schema in one set, how similar its best match is in the other. We therefore define a fuzzy Jaccard measure over two sets (of schemas, in this case), by redefining the intersection cardinality in a "fuzzy" way, as:

$$J_{J_e}(S, T) = \frac{|S \cap_{J_e} T|}{|S \cup_{J_e} T|} \tag{2}$$

where S and T are sets and J_e is a symmetric and well-defined comparison between elements of S and T, with values between 0 and 1. We invoke the identity ($|S \cup T| = |S| + |T| - |S \cap T|$) to derive a fuzzy counpart for the cardinality of the union. The fuzzy similarity measure then becomes:

$$J_{J_e}(S, T) = \frac{|S \cap_{J_e} T|}{|S| + |T| - |S \cap_{J_e} T|} \tag{3}$$

This allows us to have to only define $|S \cap_{J_e} T|$, which we define as:

$$|S \cap_{J_e} T| = \sum_{\tau \in T} \max_{\sigma \in S} J_e(\sigma, \tau) \tag{4}$$

The values rendered by this approximation are somewhat misleading, however. It tends to skew low, especially when considering schemas. Two schemas with six events each, sharing five events, have a Jaccard score of only 71%, since the schemas are "punished" for having two events that do not match. The Fuzzy Jaccard measure J_{J_e} further exaggerates this discrepancy. Assume that all of the schemas in two sets of schemas have a J_e value as described above, at 71%. In other words, these are fundamentally two very similar sets of schemas—each schema in one set has a counterpart in the other set sharing five out of six events. Assume also that both sets of schemas are the same size. This gives us:

$$J_{J_e}(S, T) = \frac{|T| \times 0.71}{2|T| - |T| \times 0.71} = 55\% \tag{5}$$

This value misleadingly implies that the sets of schemas are only 55% similar despite each schema in one set having a close match in the other.

If we make a few assumptions about J_{J_e}, we can find a better interpretation for the values it computes. Essentially, what we want to know is the typical value of $|\sigma_e \cap \tau_e|$ implied by a given J_{J_e} value. We define $|\sigma_e \cap \tau_e| = x$ since that is what we want to solve for. If there is such a value, we will assume it is fixed under the maximization in the defined cardinality of the intersection. This also allows us to reduce the summation over T to the cardinality of T. We also assume that $|\sigma_e| = |\tau_e| = \sigma'$ since our schema germinator ceases at a maximum of six events for all germinators:

$$|S \cap_{J_e} T| = \sum_{\tau \in T} \max_{\sigma \in S} \frac{|\sigma_e \cap \tau_e|}{|\sigma_e| + |\tau_e| - |\sigma_e \cap \tau_e|} = |T| \frac{x}{2\sigma' - x} \tag{6}$$

Let us allow for one more approximation, that $|S| = |T|$. This is absolutely true for the counter-training, random walker, and linear induction truncated germinators, since they generate a fixed number of schemas. It is approximately true for the linear induction germinator. Substituting Formula (6) into Formula (3) and making the given approximation yields:

$$J_{J_e}(S, T) = \frac{|S \cap_{J_e} T|}{|S| + |T| - |S \cap_{J_e} T|} = \frac{|T| \frac{x}{2\sigma' - x}}{2|T| - |T| \frac{x}{2\sigma' - x}} = \frac{\frac{x}{2\sigma' - x}}{2 - \frac{x}{2\sigma' - x}} = \frac{x}{2(2\sigma' - x) - x} = \frac{x}{4\sigma' - 3x} \tag{7}$$

Solving for x, we get the Jaccard Reciprocal Fraction, or JRF:

$$x = \frac{4}{J_{J_e}^{-1}(S, T) + 3} = JRF \tag{8}$$

This gives us the typical fraction of shared events between schemas in two sets of schemas, regardless of the size of schemas in each set. As the Fuzzy Jaccard value approaches 1, so does the JRF; as the Fuzzy Jaccard value approaches 0, the denominator approaches infinity, and thus the JRF approaches 0. For the example shown above, $JRF = 4/(1/0.55 + 3) = 0.83 = 5/6$. This is more intuitive while simultaneously preserving the underlying set theoretic machinery and justification for the comparisons performed.[3]

It has been suggested that we include a more sophisticated lexical similarity metric—for example, those presented by Corley & Mihalcea (2005) or Kusner et al. (2015). However, fundamentally, these would obscure the answers to the questions we are asking here, which is, through the lens of coreference chains, dependencies, event verbs, and their pointwise mutual information, how stable are the schemas produced to perturbations in the data used? Were the models used to generate the schemas more dependent on a lexical similarity measure, such would be essential in answering that question—and while a

[3]Preliminary results indicate that the JRF values are quite similar to the raw numeric values computed.

great potential next step in improving schema induction, the problem of lexical similarity has largely been neglected in narrative schemas and the narrative cloze task. We suspect adherence to editorial guidelines within a single publication will likely normalize the most interchangeable terms—for example, selectively choosing "pursue" over "chase." In a multi-newspaper corpus, we suspect lexical distance would be much more important.

6 Results

For each individual pair of sets of schemas within an ablation, we compute Fuzzy Jaccard scores, their means and their standard deviations, transformed into JRF form. Presenting these values here is too cumbersome, however. As an overview, average JRF values across germinators and document categories are shown in Figures (1) and (2).

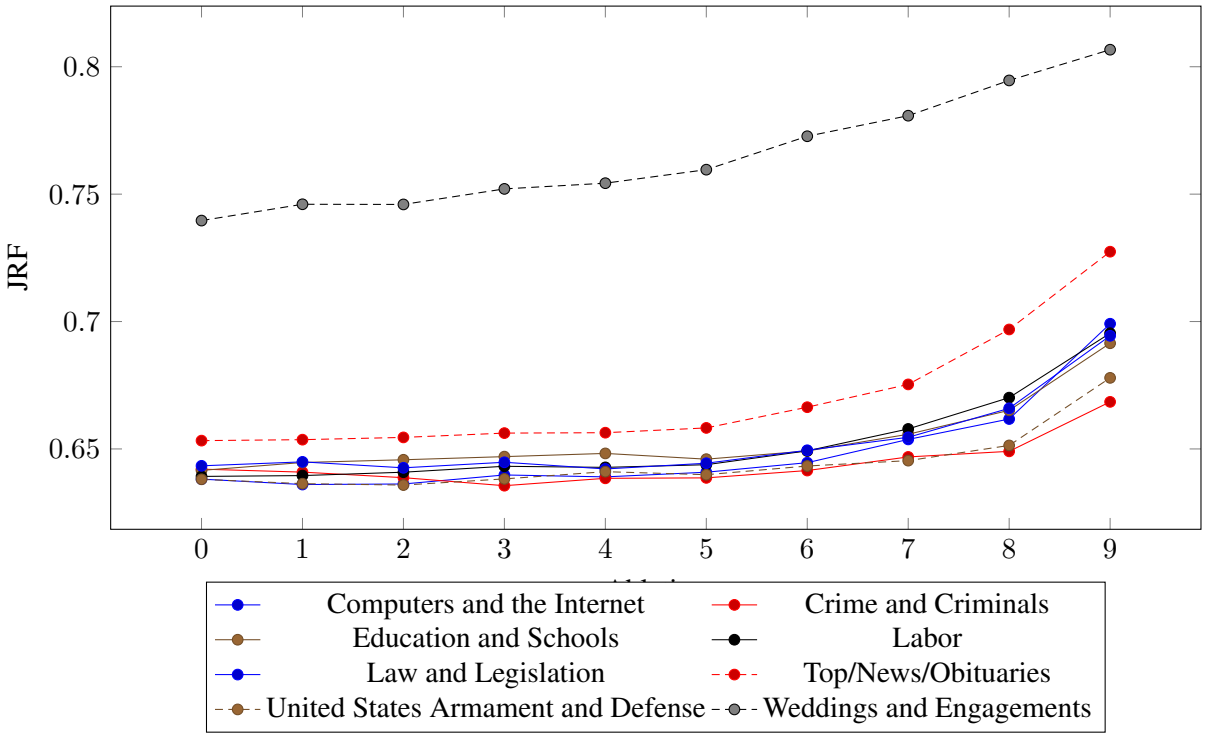

Figure 1: Stability averaged across document categories. Ablation is on the x-axis; Jaccard Reciprocal Fraction (e.g. events typically shared) is on the y-axis.

Note that increasing ablation number refers to a decreasing number of documents; in other words, ablation 8 refers to $8/10^{ths}$ of the documents having been *removed*.

In total, the series of experiments generated a total of 3,978,865 schemas. These are not "unique," as the whole point was to generate schemas that are hopefully as similar to one another as possible. Linear induction produced 2,698,865 schemas, in part a product of its open-ended generation process. Both counter-training and random walker generated 640,000 schemas, as the number of schemas generated within each category was fixed at 800 for practical computational reasons. [4]

Figures (1) and (2) contain the stability values as averaged across different dimensions. Figure (1) averages all stability values for a given ablation across all algorithms, leaving separate values for each category. Conversely, Figure (2) averages the stability values across document categories, leaving each algorithm individually expressed.

In both figures, stability generally increased as the number of total documents decreased. The one exception to this was the linear induction schemas, as shown in Figure (2). The causes and consequences

[4]Since the linear induction truncated algorithm is simply linear induction but with a few schemas clipped off the end, it is not counted as a separate instance of generation.

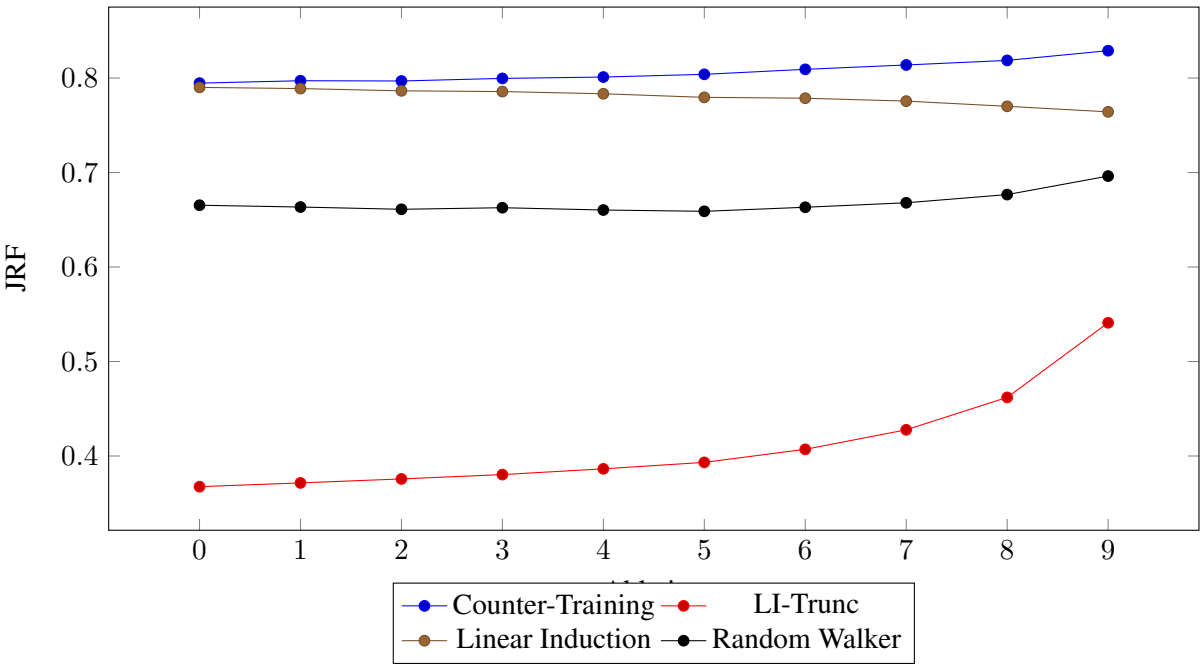

Figure 2: Performance averaged across algorithms. Ablation is on the x-axis; Jaccard Reciprocal Fraction (e.g. events typically shared) is on the y-axis.

of this will be discussed in the next section.

In Figure (1), the document categories Simonson & Davis (2016) found to be homogeneous are notably more stable than the categories we found to be heterogeneous. The difference between similarity scores in each cross-validation was significant ($p < 0.001$) in 140/140 comparisons (t-tests) between the similarity scores of "Weddings and Engagements" and the other document categories for both counter-training and the random walker germinators; the difference was significant ($p < 0.001$) in 137/140 comparisons between "Top/News/Obituaries" and the other document categories for both as well. Two of the insignificant differences occurred during the 9^{th} ablation against "Computers and the Internet" and "Labor," one occurred during the 2^{nd} ablation against "Education and Schools." This does not itself have to do with the content of the schemas, but the differences in similarities internal to the document category itself.

Some examples of schemas generated in this process—six from the counter-training germinator in two different cross-validations of the 0^{th} ablation—are contained in Figure (3). Schemas containing these sorts of events are typical of the Obituaries section. Note that "bear" is simply the lemmatized form of "be born". In each schema, participants of the same chain of argument slots of the verbs are indicated by the same color and shape, but this does not extend across schemas. Each column of shapes is, from left to right, in each schema, `SUBJ`, `OBJ`, and `PREP`, respectively. Dotted boxes indicate slots attested in the data but not linked to a chain; completely blank slots were never attested in the data. Each chain shares a number of types, too many to explicitly enumerate here. The object slot of "survive," for example from the idiom "person was survived by," was typically a generic person type or type that would qualify as a subset of person: "woman," "man," "boy," "microbiologist," "lawyer," etc.

7 Discussion

The first striking aspect of these results is the affirmation that the Weddings and the Obituaries categories, the two determined to be *homogeneous* by Simonson & Davis (2016), were consistently more stable at all ablations than the rest of the document categories. The differences were significantly different the vast majority of the time (277/280), and in cases where this was not the case, only a handful of the stability scores of the heterogeneous categories had increased. This affirms our earlier findings from another angle

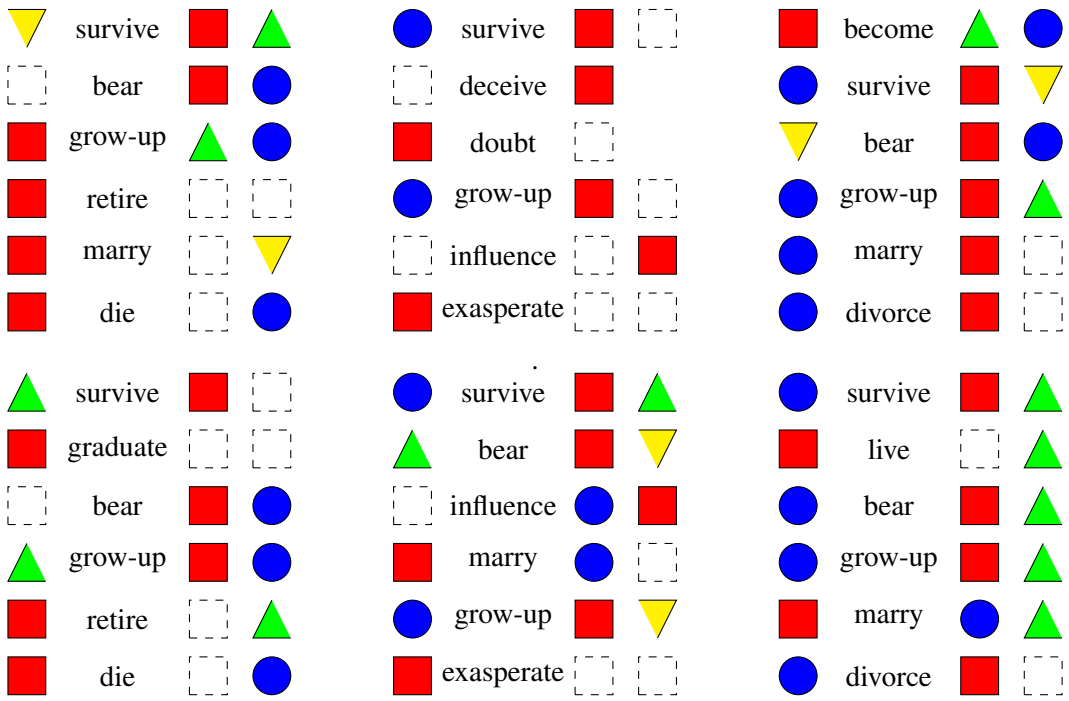

Figure 3: Six schemas generated by the counter-training germinator in two cross-validations, showing varying degrees of similarity between schemas. The two rows show schemas generated from two different cross-validation of the data in the same ablation.

unrelated to the NYT corpus' salient entity annotations, as we managed to show a similar distinction between homogeneous and heterogeneous document categories without salient entity annotations. The document categories are written from templates, so in some respects, it's not surprising that a template extractor should exhibit different properties on the categories written from templates. Simonson & Davis (2016) showed that this can be ascertained from labelled evaluation data; the stability procedure used here shows the same distinction, significantly without labelled data.

Unexpectedly, however, stability increased as the number of documents decreased.

Our initial expectations were that stability would increase with the number of documents. The rationale, as with many statistical learning algorithms, is that the more documents in the training data, the better the algorithm performs, as it has more examples to leverage and overall improves performance. This presupposes that better stability mirrors performance improvements, and that with more data, a germinator can better converge on the ground truth reflecting underlying knowledge about narratives in the news.

In most circumstances, contrary to expectations, as the number of documents decreases, stability increases, with linear induction constituting the sole exception. There are two possible explanations for this: (1) the number of documents withheld in cross-validation decreases with the number of documents, and stability depends more on the number of documents that differ between cross-validations than on the fraction of documents that differ, or (2) a fixed number of schemas can better capture the information contained in a smaller set of documents because new documents add more novel and unique narratives, thereby making the content of the narratives more difficult to capture in a finite set. In other words, provided with more and more documents, the germinators do not converge to some finite set of schemas, but instead are presented with an increasingly difficult problem to solve. These two explanations are not completely orthogonal; however, the first is a far more mechanical explanation. It is simply that more word types are contained in a larger set of documents, and therefore will be subject to a larger Zipfian tail, which is more difficult for a finite set of recorded event verbs to cover. The second presupposes that the system has some semblance of understanding the language data and narrative, and the challenge comes from the increased diversity of narratives contained therein. The second explanation could cause the first,

but the second claim requires a much greater burden of evidence because of its deeper implications.

Unlike the other germinators, linear induction has no limit to the number of schemas it can produce, albeit with a great number of schemas containing single events. This means there are two possible explanations for its behavior. The first is the explanation originally hoped for—that as the algorithm is given more documents, it begins to converge on a stable core of knowledge derived from the source data that in one form or another represents a consistent understanding of the data. The second explanation is more mundane—that what's actually stable is the schemas containing single events, schemas which then bias the apparent stability upward as more events that do not cross the β threshold are observed in a greater number of documents.

The second explanation is more likely here. The linear induction schemas here generated 1,544,879 single event containing schemas, roughly 57.2% of the total schemas generated by linear induction. Additionally, the LI-Truncated stability provides some insight here. If there is a stable content core that linear induction is approaching, then the first 800 schemas generated should reflect that. What we see instead is the lowest stability scores across the board. However, note that as ablation 9 is approached, the stability of the LI-Truncated schemas increases, likely because the number of schemas actually produced by linear induction is approaching 800, so the effect of the truncation is vanishing.

While the arbitrary clipping of the linear induction schemas greatly decreases stability, this may point to the unexpected decrease in stability in the other germinators as the number of documents increases. Given their hard limit on the number of schemas used, they are in some sense performing a similar "clipping" of the content contained in the documents. However, their increased stability, while still conducting a form of clipping, could be attributed to performing a more informed clipping than the LI-Truncated schemas.

8 Conclusions

We have explored the stability of narrative schemas. We used both an ablation and cross-validation of the data to produce different sets of schemas and compared them using the Fuzzy Jaccard coefficient and the Jaccard Reciprocal Fraction, which produces a transformation of the Fuzzy Jaccard coefficient that is easier to interpret.

Our results affirmed the homogeneous-heterogeneous distinction found in Simonson & Davis (2016). The homogeneous categories produced more stable batches of schemas than the heterogeneous ones. The counter-training and linear induction germinators produced more stable results, but the linear induction truncated results indicate that much of the apparent stability of the linear induction germinator is contained in its long tail of schemas.

Additionally, contradicting expectations, the schemas produced were more stable when given fewer documents. It is difficult to say whether this is because fewer documents were removed at every step of the cross-validation or because there is simply fewer narratives to capture in the same number of schemas. These explanations do not necessarily contradict one another, and the effect witnessed may be a mixture of both.

Understanding the stability of schemas provides us with a window into the quantitative properties of news narratives at large. Additionally, stability provides another technique for evaluating what makes a "good set of schemas:" as objects that are consistent regardless of what subset of a corpus they are derived from. Not for all purposes is this property necessarily "good," but the stability procedure provides a quantitative metric for this property if it is desired.

For sake of comparison, further analysis, and potential use in other projects, we have also made our schemas publicly available for potential use in the future.[5]

Abstract

We present *bot#1337*: a dialog system developed for the 1st NIPS Conversational Intelligence Challenge 2017 (ConvAI). The aim of the competition was to implement a bot capable of conversing with humans based on a given passage of text. To enable conversation, we implemented a set of skills for our bot, including chit-chat, topic detection, text summarization, question answering and question generation. The system has been trained in a supervised setting using a dialogue manager to select an appropriate skill for generating a response. The latter allows a developer to focus on the skill implementation rather than the finite state machine based dialog manager. The proposed system bot#1337 won the competition with an average dialogue quality score of 2.78 out of 5 given by human evaluators. Source code and trained models for the bot#1337 are available on GitHub.

1 Introduction

A conversational or a dialogue agent is a system that interacts with a human via voice or text messages. Dialog systems can be task-oriented, i.e. supposed to solve specific tasks such as reserving flight tickets, or general purpose. Another way to differentiate dialog systems is to compare them by domain: closed or open one. When open-domain dialog systems cover a wide range of supported topics, closed-domain are usually specialized on a few topics.

The early dialog systems used a rule-based approach to control dialog flow (Weizenbaum, 1966; Wallace, 2009). Rule-based systems are hard to maintain and new rules should be created for each new domain. This approach is still widely used in cases where the full control of dialog is crucial (e.g., production systems). The availability of dialog datasets (DSTC (Williams et al., 2016), Twitter Corpus (Ritter et al., 2010), Ubuntu Dialogue Corpus (Lowe et al., 2015)) makes it possible to train end-to-end dialog systems (Sordoni et al., 2015; Vinyals and Le, 2015). End-to-end systems are usually based on recurrent neural networks (Graves, 2013) and sequence-to-sequence models (Sutskever et al., 2014), and use raw dialogues as a training data.

One of the main challenges in the field of open-domain dialogue systems is their evaluation. The reason for that is the absence of good evaluation metrics. While goal-oriented systems can be evaluated with the percentage of dialogues when user's task was accomplished, there is no formal measure of the dialogue quality for open-domain systems. The goal of such systems is to generate responses which suits the context. The quality of the response can be measured by its perplexity measure (Serban et al., 2015) which, however, can not assess the adequacy of an answer. In order to measure it researchers often use metrics that compare a generated string to some oracle answer, e.g. BLEU (Papineni et al., 2002) and METEOR (Lavie and Agarwal, 2007) originally used for evaluating Machine Translation model. This is not an optimal way of evaluating chatbots either, because a relevant answer can be different from an oracle (Liu et al., 2016). In recent works on the evaluation of dialogue systems the authors suggest training evaluation metrics on a set of human-labelled dialogues (Lowe et al., 2016; Lowe et al., 2017).

Proceedings of the 27th International Conference on Computational Linguistics, pages 3681–3692
Santa Fe, New Mexico, USA, August 20-26, 2018.

However, obtaining such corpora takes much time and effort, so those metrics are rarely used up to our knowledge.

A competition of open-domain dialogue systems is one way to organize a large-scale evaluation by humans. There are some competitions in the field such as Loebner Prize annual competition (Mauldin, 1994) and Alexa Prize Competition (Ram et al., 2018). The First Conversational Intelligence Challenge was organized as a part of NIPS conference in 2017. The task was to build a conversational agent, which discusses a given text with a human.

A typical competition bot is equipped with a set of skills, such as greeting, asking a question on a certain topic, etc., and decides when to use a specific one. The main challenge here is to understand when to use a specific skill[1], in other words, to develop a dialog manager (DM). The finite state machine (FSM) can be seen as an instrument of the first choice in rule-based dialog managers. The main advantage of the FSM is a deterministic and transparent control of the conversation, but its complexity quickly grows for large systems. Updating of large FSM with new rules is usually hard due to the high volume of required conflict resolutions between parts of the system. This results in the lack of scalability for the FSM approach.

2017 Loebner Prize winner bot Mitsuku[2] uses a rule-based approach based on Artificial Intelligence Markup Language (AIML) (Wallace, 2009). 2017 Alexa Prize participant MILABOT conversational agent (Serban et al., 2017) uses a combination of deep learning, reinforcement learning and rules. MILABOT agent team used a lot of human-annotated data collected from Amazon Mechanical Turk to train the dialog manager. Mitsuku requires a lot of rules, so it is hardly scalable, while MILABOT requires a lot of human-annotated data. In addition those bots do not initiate a dialog with the user, but only give replies to a user.

Instead, we implemented a supervised DM for our bot. It takes the dialog context[3] as an input and outputs the label of the skill to be used. This simplifies developing the proposed DM in comparison with the FSM and allows to focus on the skill development.

Next sections describe our conversational agent *bot#1337* that won the NIPS Conversational Intelligence Challenge. Section 2 describes the implemented skills and Section 3 describes Dialogue Manager (DM). Section 4 gives a high-level view on how skills, DM and user interact together. Section 5 provides detailed information about the participation in the NIPS Conversational Intelligence Challenge, including comparison with other winning system, analysis of skills usage frequency, dialog manager performance and dialogs reading insights. Information about the bot#1337 license, source code and demonstration given in Section 7. To show how the bot works in practice, we have included a sample dialog between the bot and user in the Appendix A.

2 Skills

Discussion of the text require different skills. First of all, a bot should be able to greet the user, to answer and to ask questions about the text. Secondly, text summarization skill may be required, because the user may not read a long paragraph. Often one just wants to chit-chat with a bot without a thorough discussion.

Chit-chat skills Chit-chat skills are required to discuss some common topics, which are often not connected with a given text. We have built three following skills for the chit-chat.

OpenSubtitles and Facebook news seq2seq chit-chat skills use a neural machine translation attention-based sequence-to-sequence models. They are trained using OpenNMT framework. OpenNMT is a generic deep learning framework mainly specialized in sequence-to-sequence models covering a variety of tasks such as machine translation, summarization, image to text, and speech recognition. The framework has also been extended for other non sequence-to-sequence tasks like language modelling and sequence tagging (Klein et al., 2017).

[1] We defined *skill* as a model that takes text and dialog context as an input and outputs a response.

[2] `http://www.mitsuku.com`

[3] We defined *dialog context* as the concatenation of dialog history and the current user utterance.

Training performed with word-level representations and ADAM optimizer. Word embeddings dimension was set to 150 and their weights are updated during the training.

OpenSubtitles seq2seq skill uses the dialog context as an input and generates an utterance as an output. The model is a 2-layer encoder-decoder LSTM with 2048 hidden units. It is trained on the OpenSubtitles dataset (Tiedemann, 2009).

The Facebook news seq2seq skill, in addition to the dialog context, may use a paragraph as an input. Paragraph and dialog context divided with special "EOP" (end of paragraph) token. It also generates an utterance as an output. The model is a one-layer encoder-decoder LSTM with 1024 hidden units. It is trained on the Facebook news dataset[4], which consists of posts and comments from Facebook.

The Alice (Wallace, 2009) *chit-chat skill* uses the dialog context as an input and generates an utterance as an output. It is built upon AIML rules. We used the open source version of Alice from GitHub[5].

Sequence-to-sequence chit-chat skills generate several response candidates. Often generative models may generate short responses or responses with many identical or undesirable words. These candidate responses are processed by a filtering algorithm (Alg. 1) and if there is no candidate responses left after filtering, then the Alice skill is executed or one of the escape plan template responses is selected. Escape plan responses are a set of pre-defined utterances, such as "Do you like this text?", "What do you think about the competition?".

Algorithm 1: Filtering candidate responses

Data: candidate responses
Result: filtered responses
remove duplicate responses;
remove short responses;
remove responses with majority of identical words;
remove responses with majority of stopwords;
remove responses with undesirable words;
return filtered responses;

Q&A skills Discussion of text often consists of asking and answering questions. We developed three skills to generate questions and to answer the questions about the text.

For the question-asking skill we reproduced the feature-rich sequence-to-sequence with attention model (Zhou et al., 2017). The model is a 2-layer encoder-decoder GRU with 512 hidden units. It is trained on the SQuAD dataset (Rajpurkar et al., 2016) using word-level representations and the OpenNMT framework with ADAM optimizer. Word embeddings dimension was set to 300. Lexical and answer features embedded to 32-dimensional vectors. This skill takes a paragraph, named entities and lexical features extracted using Stanford CoreNLP (Manning et al., 2014) as an input and outputs a question. In the training phase, all the SQuAD answers were used to generate questions. During the inference the model used named entities extracted from the text by the Stanford CoreNLP. We use these named entities as an answers and to generate questions.

The answer-checking skill is connected with the question-asking skill. Right answer on each question is prepared by question-asking skill described above. This skill checks the user's answer using fuzzy matching algorithms (e.g. based on Levenshtein distance). Afterwards, it uses a template to generate a response to the user, such as "You can do better! Hint: first 3 letters is *goo*".

The question-answering skill uses the bidirectional attention flow (BiDAF) model (Seo et al., 2016). It takes a user's question and the relevant text as an input and outputs an answer. Finally, these answer were added to template phrases, such as "I think the answer is ...". We used the open source version of BiDAF model from GitHub[6].

[4]https://github.com/jbencina/facebook-news
[5]https://github.com/sld/convai-bot-1337/tree/master/ALICEChatAPI
[6]https://github.com/allenai/bi-att-flow

Summarization skill Usually, a text passage to discuss is a long (5-10 sentences) read. Text summarization skill helps to save time and to engage the user.

We used a sequence-to-sequence model with attention pretrained on a Gigaword dataset with OpenNMT[7]. The model is a 2-layer encoder-decoder LSTM with 500 hidden units. Word embeddings dimension was set to 500. We applied the model to chunks of a provided text to generate possible summaries. Finally, these summaries were added to template phrases, such as "Maybe this article's main idea is ...". To select the best response, we used Alg. 1.

Topic detection skill Mentioning the main topic of the text may engage the user in a conversation. We analyzed data from the first round of the NIPS Conversational Intelligence Challenge and it proved our hypothesis.

The topic detection skill is built upon the BigARTM topic modeling framework. BigARTM is a tool to infer topic models, based on a technique called Additive Regularization of Topic Models. This technique effectively builds multi-objective models by adding the weighted sums of regularizers to the optimization criterion (Vorontsov et al., 2015).

The model takes text as an input and outputs its possible topics. Then, detected topic names are added to template phrases, such as "Am I right that topic of the text is ... ?". We used the Wikipedia corpora from the BigARTM website datasets sections[8]. The model was trained[9] to predict 15 topics. Topic names such as "Politics", "Culture", etc., were set up manually by analyzing top-tokens.

Additional skills We implemented two skills that are independent from the input. They both have handwritten sets of phrases, which are randomly selected to be sent to the user.

The greeting skill is used in the beginning of the conversation if the user does not say anything after some time. It includes such phrases as "Well hello there!", "Hiya!", etc.

The common phrases skill is used when the user does not say anything for some time or when the used skill output is empty. It includes such phrases as "What do you think about ConvAI competition?", "Do you like this text?", etc.

3 Dialog manager

The DM (Fig. 1) runs two classifiers on user utterance (and, possibly, dialog context) to detect what skill should produce an answer.

The first classifier works on a small supervised set (few key phrases for each skill) and is based on the mean word embeddings (we used GloVe embeddings[10]) and the k-nearest neighbors classifier (k-NN).

The second classifier is based on a large training corpora and we used the fastText library for this case. FastText is a library for efficient text classification and representation learning (Joulin et al., 2016). The fastText supervised model was trained[11] to predict 5 classes (Fig. 1).

All implemented skills can be one of two types: with or without a training dialog dataset. For chit-chat and question-answering skills we have datasets with utterances, questions, and answers. It allows us to train the classifier to select which dataset (and it infers which skill) is more suitable for the incoming user utterance. Summarization, topic detection, and the ask-question skills do not have good common known dialog datasets, which provide utterances that should activate these skills. For these skills we wrote few key phrases (3-10 for each skill) by our own and used them with k-NN classifier based on mean word embeddings.

For example, we have 2 skills - Open Subtitles and Topic Detection. First skill classifier is trained with fastText, because it has many dialog utterances (e.g. "They still behind us?", "Senora, give me a break!" and many others). Second one does not have any dialog utterances, so we should add a few of

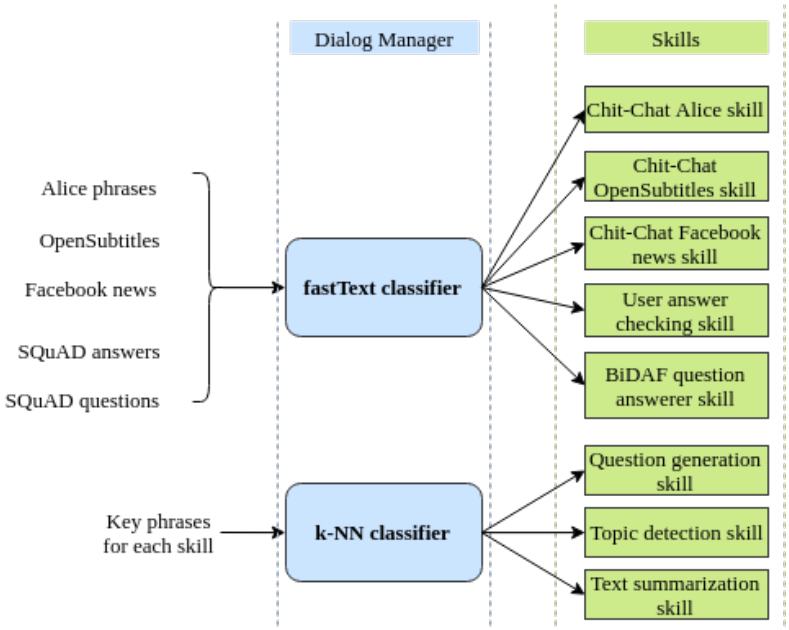

Figure 1: Dialog manager: classifiers, datasets and skills corresponding to them.

them ourselves to train a k-NN classifier (e.g. "What is the theme of text?", "Say me theme", "This text main topics").

Skills without dialog datasets have a higher priority; if the k-NN classifier prediction confidence level exceeds the threshold value (90%), then the skill selected by this classifier is used to generate the response. Otherwise, the skill is selected by the fastText classifier.

4 Dialog system and user interaction flow

Dialog system and user interaction flow (Fig. 2) shows how user interacts with a dialog system.

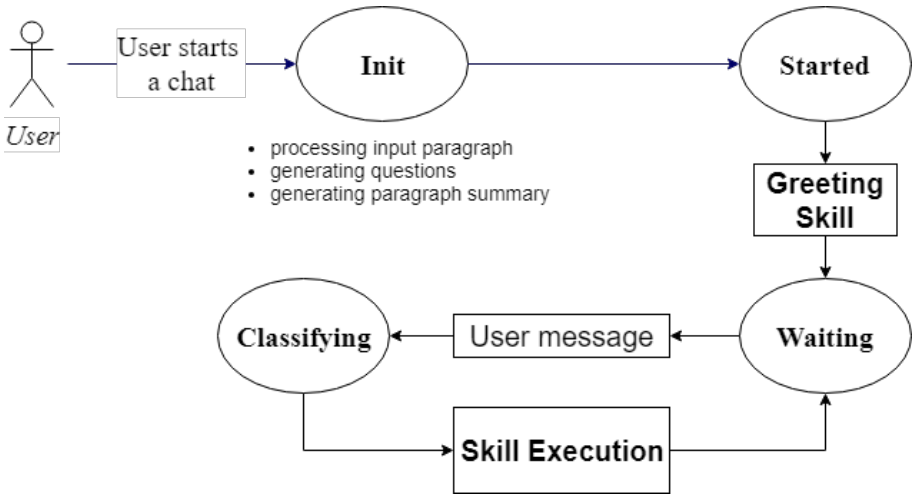

Figure 2: Dialog system and user interaction flow.

The dialog agent initialization begins when a user starts a chat. At the **init state**, the DM and skills are initialized. Some skills, such as question generation and text summarization, process input paragraphs and generate responses for further usage. Thus, the DM can choose from these responses to send a message to the user.

After that, the dialog agent switches to the **started** state. A user or a bot can start the conversation.

Thus, at this state, the bot waits for the first user message or executes the greeting skill if there is no message from the user after some time.

Answering to user message is the most important task to handle. When receiving a message from the user, the **classifying** state activates. At this state, the DM decides which skill to use. The DM runs two classifiers on user utterance (and, possibly, dialog context) to decide which skill should produce an answer. After that, the bot executes the skill and sends a generated message to the user.

After the skill execution, the bot goes to the **waiting** state. This state is about engaging the user in conversation when he or she is not talking to the bot. If after some time there is no message from the user, the bot tries to motivate the user to talk. It executes a random skill, such as question asking, and sends a message to the user. If there is no reaction from the user for a long time, then the bot ends the conversation.

5 Participation in the Conversational Intelligence Challenge

The main task of the NIPS Conversational Intelligence Challenge 2017 (ConvAI[12]) was to build a conversational agent, which discusses a given text with a human. Each dialog was evaluated by a human at the end of the conversation on a scale from 1 (bad) to 5 (excellent) in three dimensions: quality, breadth, and engagement. Each bot utterance could be also marked as appropriate or not. The first round dataset (2778 dialogues) was released at the end of the first human evaluation round[13].

The early version of our bot had a chit-chat, Q&A skills and a dialog manager based on rules and fastText classifier. This approach took the second place in the first round of the Conversational Intelligence Challenge with an average quality score 2.31 out of 5. A winner bot took 2.38 out of 5, while human 3.8 out of 5. The dataset released after this round provided insights on how to improve our conversational agent and helped to detect undesirable behavior. Particularly we decided to add a chit-chat Alice, paragraph's topic mention to the greeting and text summarization skills. Newly added skills required new logic to support. We enhanced the dialog manager by adding k-NN classifier for skills without dialog data described in Section 3. It helped us to avoid using rules and simplified conversational agent's development. As a result of introducing the above-mentioned changes, our bot won the Conversational Intelligence Challenge Finals (Table 1).

Bot name	Quality (average human evaluation score)	# dialogues
bot#1337	2.779	68
poetwannabe	2.623	53
RLLChatBot	2.462	13
kAIb	2.2	35
PolyU	1.75	28
DeepTalkHawk	1.262	42

Table 1: Results of the Conversational Intelligence Challenge Finals.

5.1 Comparison with *poetwannabe*

Poetwannabe is the other winning system from University of Wroclaw which also used a multi-skill architecture, but focused on extracting knowledge from external resources (Wikipedia, DBPedia, Wikiqoute). Instead of supervised dialog manager to control dialog flow they used confidence scores from each skill, based on linguistic features, dialog history and internal state (Chorowski et al., 2018).

5.2 ConvAI finals dataset analysis

To understand better bot's issues and to develop further its improvement strategy, we analyzed the frequencies of skills usage, dialog manager performance and user dialogues of the Conversational Intelligence Challenge finals dataset. The dataset was provided by the competition organizers. We have

[12] http://convai.io/2017/

[13] http://convai.io/2017/data/

manually labeled 68 dialogs with our bot. Each bot's utterance in the dialog was tagged with predicted skill and true skill labels. Predicted skill label is the one selected by the supervised dialog manager. True skill label is the one that we found to be the most appropriate for the dialog context.

5.2.1 Frequency of skills usage

Frequency of skills usage was calculated by predicted skill label grouped by a dialog score for each dialog (Table 2). After analyzing the frequency of skills usage we saw that chit-chat skills should be carefully implemented. Chit-chat skills were most frequently selected by the dialogue manager. Skills like topic detection or summarization are used rarely because usually they are executed only one time during the dialog. It does not imply that summarization or topic detection skills are unnecessary. They provide good user experience in a conversation. A fragment of best-scored dialog shows a positive user reaction to a summarization skill:

User: What do you think about this text?

Bot: I suppose that this text main idea is: New rules on investment?

User: Maybe you are right

Other fragment with worst-scored dialog shows negative reaction for chit-chat skills:

Bot: What country borders the south of guinea-bissau?

User: I don't know. Can you tell me?

Bot: I don't know.

User: Senegal is to the north, isn't it?

Bot: I will not.

Dialog score	Chit-chat skills, %	Q&A skills, %	Summarization, %	Topic Detection, %	Greeting, %	Common Phrases, %
5	71.4	16.3	0.7	3.2	3.9	4.6
4	56.2	23.3	2.7	6.8	8.2	2.7
3	57	21	1.1	5.9	7.5	7.5
2	55.3	24.9	2.3	6.8	7.6	3
1	64.3	15.6	1.7	4.5	6.7	7.2

Table 2: Bot#1337's percentage of skills usage in the ConvAI Finals dialogs. They are grouped by a dialog score (human evaluation score). We count how many times each type of skill was invoked in each dialog. Chit-chat skill is the one of OpenSubtitles, Facebook news and Alice skills. Q&A is the one of question-asking, answer-checking and question-answering skills.

5.2.2 Dialog manager performance

By using true skill and predicted skill labels, F1 measure was calculated. Topic detection, greeting, common phrases skills were not included to the calculations because they were executed in a waiting state almost every time (described in Section 4) and dialog manager was not used here.

Skill Name	Precision	Recall	F1	Total utterances count
OpenSubtitles chit-chat	0.79	0.84	0.81	249
Answer-checking	0.82	0.70	0.75	57
Alice chit-chat	0.81	0.68	0.74	152
Facebook chit-chat	0.63	0.85	0.73	53
Question-asking	1.00	0.56	0.71	9
Summarization	0.67	0.57	0.62	14
Question-answering	0.56	0.60	0.58	25
Average	*0.77*	*0.76*	*0.76*	*559*

Table 3: Dialog manager performance

Bot#1337's supervised dialog manager (described in Section 3) average F1 equals to 0.76. Question-asking and summarization skills that were selected by the k-NN classifier show lower F1 score than skills selected by the fastText classifier (chit-chat and answer-checking skills). F1 for these skills can be improved by adding more examples to the k-NN classifier. However this approach does not apply to a question-answering skill. It is selected by the fastText classifier and has the lowest F1 in the Table 3. The error analysis showed that the user often asks complex questions that are not covered by the training set from SQuAD. For example:

> **User:** Let's talk about Guinea-Bissau then. What do you know about it?" [classified as Open Subtitles]

But even with the perfect F1 score, analysis of how each skill works in a dialog is necessary. Dialog reading helps to analyze skills errors, to find new skills that should be developed and to find the direction of bot's improvement.

5.2.3 Dialogs reading insights

After reading 68 dialogs with our bot from the finals, we can conclude that having diverse and high quality chit-chat skills and engaging a user into talking when he or she is not responding for some time (waiting state described in the Section 4) helped the bot to make a conversation better.

Other insights that will be able to help to improve our bot in the future described below.

The bot starts to talk fast and a user complains to it.

> **Bot:** Yo! [Greeting skill]
>
> **Bot:** I think this text is connected with nationalities. I can ask you a question about it. [Topic detection skill]
>
> **User:** Wait, I am still reading it
>
> **Bot:** Why is this news? [OpenSubtitles chit-chat skill]

It would be better to have a separate skill to detect if a user still reading the text and reply to the user with "Okay, I am waiting" message.

A user asks the bot about the competition, but it does not have the skill to response.

> **User:** What are my instructions for today?
>
> **Bot:** I'm not sure. [OpenSubtitles chit-chat skill]
>
> **User:** Do you something about CONVAI?
>
> **Bot:** No, i'm not. [OpenSubtitles chit-chat skill]

Lack of semantic model of the text does not allow the bot to talk about the facts in the text.

> **User:** What kind of sport is this text about?
>
> **Bot:** I suppose that this article can be described as: Win club world cup..? [Text Summarization skill]
>
> **User:** But what sport? Football, hockey, basketball?
>
> **Bot:** I'd like to say that correct answer is: barcelona accomplished two new records in spanish [Question-answering skill]
>
> **User:** I want to know more about Barcelona
>
> **Bot:** Tell me about your likes and dislikes? [Alice Chit-chat skill]
>
> **User:** Ok, is this article about football?
>
> **Bot:** I think this article main idea is: Season begins. [Text Summarization skill]

We have the Q&A skills, but they do not cover cases like in the dialog above. A high quality conversation about the facts in text requires using knowledge bases like DBpedia. Besides it is worth to use some Web APIs (e.g. BabelNet knowledge base at `https://babelnet.org`), but rules of the ConvAI competition do not allow to do it. According to the rules everything should work without any connection to external services.

Sometimes the bot is not polite.

User: It was basically my answer
Bot: February was basically his answer? very interesting. [Alice Chit-chat skill]
User: What did you base my gender on?
Bot: Nothing. [OpenSubtitles chit-chat skill]
User: Then why "his answer"? And why talk to me in the third person?
Bot: Oh darn, I broke you. [OpenSubtitles chit-chat skill]

Answer-checking skill and question-answering skill should be more intelligent. Answer-checking skill sees the difference between a number and a word representing that number. But it should not and dialog below describes the case:

Bot: How many mathematical treatises have managed to survive? [Question-Asking skill]
User: 3?
Bot: It is incorrect:) Hint: first 3 letters is thr. Try again [Answer-checking skill]
User: 3
Bot: No [Answer-checking skill]
Bot: I think that answer is: three [Answer-checking skill]
User: Infact I did mentioned the same
Bot: How old are you? [OpenSubtitles chit-chat skill]

Sometimes users ask the bot to answer the question asked by the bot in the first place. However, the bot can't answer if the user uses anaphora constructions.

User: Ask me question
Bot: How many years did nbc universal sell in 2006? [Question-Asking skill]
User: I dont know
Bot: Why wouldn't they have taken the meeting? [OpenSubtitles chit-chat skill]
User: Do you know?
Bot: I dont know what you're doing. [OpenSubtitles chit-chat skill]

User tries to teach the bot, but the bot does not understand it.

User: What was article about?
Bot: Maybe this text can be described as: Father and grandfather born in hungary..? [Text Summarization skill]
User: No! It was about von Neumann
User: Which city lies on seven hills?
Bot: What a joke. [OpenSubtitles chit-chat skill]
User: Answer me
Bot: Try asking me again using simpler words. [Alice chit-chat skill]
User: Which city lies on seven hills. Answer: Rome.
Bot: Why is this news? [Facebook news chit-chat skill]

Bot's conversation style is the same. It may be worth to make different conversation styles to engage the users who have already talked to a bot.

6 Conclusion

In this paper, we have described the conversational agent *bot#1337*. This bot took the first place in the NIPS Conversational Intelligence Challenge 2017 with an average dialogue quality score of 2.78 out of 5. The supervised dialog manager allowed us to focus on the skills implementation, to avoid rules and to simplify the development of a bot. Skills like topic detection, Q&A, text summarization are engaging a user into a conversation about the given text. According to the conversational data received during the competition, a user often chit-chats with a bot. AIML-based Alice chit-chat skill covers a wide range of topics, while sequence-to-sequence based chit-chat skill trained on Open Subtitles dataset makes a conversation more enjoyable. Open source machine learning software like OpenNMT, BigARTM,

fastText gives us a big boost on the conversational agent's implementation. By making the framework for *bot#1337* publicly available, we gave an opportunity for the community to get acquainted with its various modules and to develop further the conversational intelligence.

7 Availability

Conversational agent demonstration is accessible as a Telegram[14] bot: `https://t.me/ConvAI1337Bot`. Also we have public JSON API that documented at `https://github.com/sld/convai-bot-1337/wiki/Api-Documentation`. The source code is released under GNU GPLv3 license and available on GitHub: `https://github.com/sld/convai-bot-1337`.

Acknowledgements

We thank Mikhail Burtsev, Luiza Sayfullina and Mikhail Pavlov for comments that greatly improved the manuscript. We would also like to thank the Reason8.ai company for providing computational resources and grant for NIPS 2017 ticket. We thank Neural Systems and Deep Learning Lab of MIPT for ideas and support.

In 2015-2016, Notre Dame ranked 18th overall among "national universities" in the United States in U.S. News & World Report's Best Colleges 2016. In 2014, USA Today ranked Notre Dame 10th overall for American universities based on data from College Factual. Forbes.com's America's Best Colleges ranks Notre Dame 13th among colleges in the United States in 2015 ... According to payscale.com, undergraduate alumni of University of Notre Dame have a mid-career median salary $110,000, making it the 24th highest among colleges and universities in the United States. The median starting salary of $55,300 ranked 58th in the same peer group.

Abstract

There are few corpora that endeavor to represent the semantic content of entire documents. We present a corpus that accomplishes one way of capturing document level semantics, by annotating coreference, implicit roles and bridging relations on top of gold Abstract Meaning Representations of sentence-level semantics. We present the methodology of developing this corpus, alongside analysis of its quality and a plausible baseline for comparison. It is hoped that this Multi-Sentence AMR corpus (MS-AMR) illustrates a feasible approach to developing rich representations of document meaning, useful for tasks such as information extraction and question answering.

1 Introduction

Although Abstract Meaning Representation (AMR) (Banarescu et al., 2013) shows promise for a range of tasks such as summarization (Liu et al., 2015; Viet et al., 2017) and information extraction (Garg et al., 2016), it is restricted to capturing the semantics of individual sentences. For many purposes, when examining the semantics of a document, one also needs access to cross-sentence information such as coreference.

We suggest that the AMR approach to semantic representation has useful characteristics for an extension to discourse-level representations. AMR represents sentence meaning in a simple, readable semantic graph, such that annotators may directly mark coreference relations upon the AMR graph itself. AMR also annotates implicit roles in some within-sentence contexts, and the PropBank predicate annotations provide a resource for extending those implicit roles annotations to a document level.

The Multi-Sentence Abstract Meaning Representation (MS-AMR) corpus is a corpus annotated on top of existing gold AMRs, extending them with this additional information. By linking those AMRs together, it presents an integrated representation of the meaning of an entire document or discourse, as the addition of the coreference, implicit role reference and bridging relations across each AMR helps to build a larger representation of the entire propositional content of the document. Because these MS-AMR representations are annotated directly onto the variables within an AMR semantic representation, it is also a different task from traditional coreference, event coreference or implicit role coreference tasks, and results in a fundamentally different kind of data. We present a baseline system and inter-annotator agreement scores, which we hope will illuminate the nature and quality of the dataset, and outline methods for how to score MS-AMR system outputs.

2 Annotation Methodology

2.1 Background: Within-sentence Abstract Meaning Representation

AMRs are directed acyclic graph representations of sentence meaning (Banarescu et al., 2013), designed to capture the important meaning elements of a sentence while abstracting away from syntactic details

Proceedings of the 27th International Conference on Computational Linguistics, pages 3693–3702
Santa Fe, New Mexico, USA, August 20-26, 2018.

Bill left for Paris
(l / leave-11
:ARG0 (p / person :wiki - :name (n / name :op1 “Bill”))
:ARG2 (c / city :wiki “Paris” :name (n / name :op1 “Paris”)
He arrived at noon
(a / arrive-01
:ARG1 (h / he)
:ARG3 (*i / implicit role: start point*)
:ARG4 (i2 / implicit role: end point; destination)
:TIME (d / date-entity :dayperiod (n3 / noon)))

Figure 1: Example of MS-AMR annotation; annotators link coreferent variables (such as marking a relation between between *p* and *h* (in red)) and implicit roles, here linking the destination (arg4) in the second sentence to the previous variable *c* (in blue)

of how that meaning was expressed. AMRs capture basic representations of semantic roles (using the numbered arguments of PropBank (Palmer et al., 2005)), as well as within-sentence coreference, named entity and entity linking information. Thus, a simple sentence such as “Bill left for Paris” can be represented as in the first AMR in Figure 1, with “leave-11” denoting the physical departure sense of “leave”, numbered arguments such as “arg2” denoting semantic roles that are unique to that sense (e.g. for leave-11, arg2 is the destination), and “Bill” and “Paris” both having named entity labels (person and city) as well as links to Wikipedia when possible. One can therefore think of an AMR as a graph of the meaning of a sentence, with “variables” such as *l*, *p* and *c* being nodes in that graph, and “/” denoting an “instance-of” relation, showing that *p* is a thing of type *person* and that *c* is a thing of type *city*.

2.2 Annotating Multi-sentence Coreference Over AMRs

Annotating multi-sentence AMR has fundamentally different characteristics from coreference annotation over surface forms. Annotators start with gold AMR annotations (using the upcoming AMR public release), and add coreference relations (and related annotations such as bridging and implicit roles) as a layer on top of those gold AMRs. Therefore, rather than annotating spans, annotators label clusters of variables that refer to the same entity or event over the AMRs constituting a document. Figure 1 illustrates a basic example of coreference in MS-AMR, showing both coreference and an example of implicit role coreference.

This annotation is structured so that alongside the annotation of explicit coreference information, annotators can also capture implicit role information. Because within-sentence AMR has all predicates annotated with PropBank senses, we have access to the lexicon with a list of all numbered arguments we might expect for that predicate. We can therefore produce a list of the numbered arguments that are not explicitly filled in the text and show these unfilled roles to annotators. These unfilled roles are temporarily added during annotation – as is illustrated with the arg3 and arg4 of the predicate “arrive-01” in Figure 1 – and can be added to coreference clusters just like any other variable. This is similar to prior works in implicit role annotation (Gerber and Chai, 2010) in that we are using semantic role inventories to prompt annotators with possible implicit roles, while adding the innovation of fitting this within a coreference task. However, while previous annotations prompted annotators with an implicit role and asked them to look through prior text for its referents, this annotation fits implicit roles into the task of coreference labeling. An example of the actual act of annotation with the Anafora toolkit(Chen and Styler, 2013) for these additional implicit role options can be seen in Figure 2.

This annotation also labels some examples of “bridging” coreference relations (Clark, 1977; Poesio et al., 1997). We annotate two more common bridging relations, part/whole relations (as in example 1) and set/member relations (as in example 2), with a focus upon those between named entities and common nouns.

1. *I think this shows that pretty much every President can do any design thing they want with both* **the**

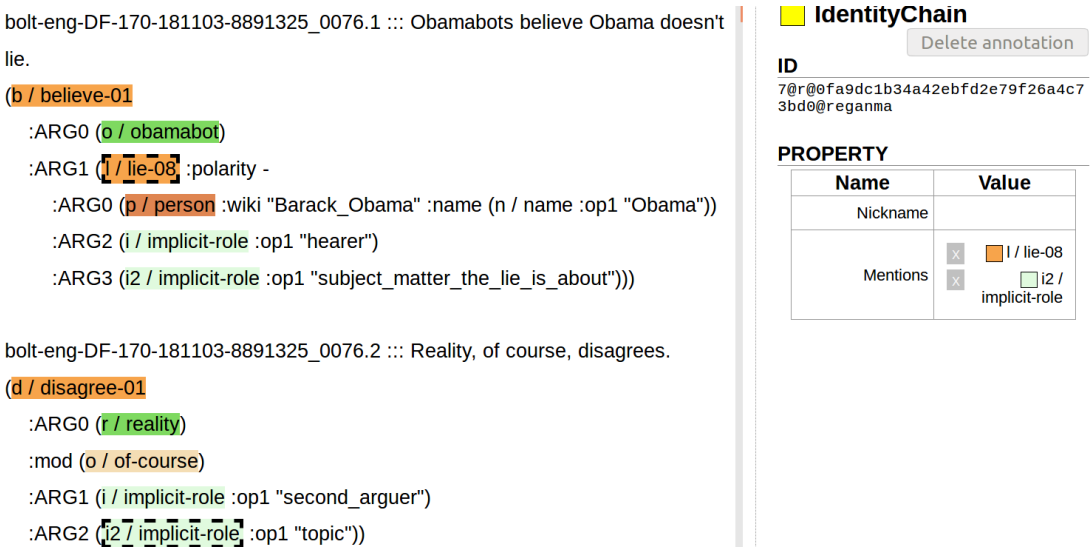

Figure 2: Annotation interface, illustrating implicit role links. Annotators click on boxes within the AMR (left) to add them to coreference chains (full chains shown on the right), as with the link between the implicit topic ("i2") and the earlier "l / lie" mention.

Residence *and* **the Office Wings** (both given part/whole relation to "the White House")

2. *I also liked* **"Deception point"**. *So I have read* **all four of his books** *and enjoyed them.* (set/member relation)

Those examples illustrate the emphasis upon capturing part/whole and set/member relations that require contextual understanding; annotators were instructed not to link part/whole relations that are only knowable through world knowledge, specifically those between named, wikified entities (such as knowing that Damascus is part of Syria).

This annotation also captures more event coreference phenomena than what is captured in OntoNotes-style coreference annotations (Pradhan et al., 2011). While those prior annotations focused upon nominal coreference, capturing verbal mentions only occasionally (when they were coreferent with a nominal mention), multi-sentence AMR annotators were instructed to link together coreferent variables regardless of their part of speech. Furthermore, because of the AMR normalization of surface-form variation, complex details regarding how to represent an event (such as the span to use for light verbs) is already normalized into single PropBank rolesets during AMR annotation. Annotation guidelines are publicly available at `https://github.com/timjogorman/Multisentence-AMR-guidelines/`.

2.3 Annotation Toolkit and Pipeline

MS-AMRs are annotated using the Anafora toolkit (Chen and Styler, 2013), a web-based system designed for coreference and temporal annotation. An example of the actual annotation interface is shown in Figure 2. As MS-AMR representations provide an annotation layer on top of gold AMRs – rather than as a change to the format of the AMRs themselves – the output of this annotation does not modify the AMRs. THis results in a set of stand-off annotations linking to each variable within a given AMR. We assert this is a useful characteristic of any modifications of the AMR corpus, as it allows the AMRs to remain compatible with existing parsing or generation systems.

Some coreference information was already provided during within-sentence AMR annotation, as AMR annotations are annotated with links between named entities and the relevant Wikipedia ID. This gold "wikification" information was provided as pre-annotations, and allowed annotators to focus upon more difficult coreference links involving pronouns, common nouns, verbs and implicit roles.

Quality control tested for consistency and coverage of the data. First and second person pronouns were checked against speaker metadata to confirm that annotators were properly keeping track of discourse

	Train	Test	Double Annotation

Implicit Roles	2386	67	371
Bridging Relations	1792	54	160

Table 1: Basic statistics about size of the MS-AMR corpus

participants, and certain highly anaphoric elements (such as "he" and "she") flagged whenever not annotated as anaphoric. As the AMR corpus was also being corrected and revised during this annotation to improve predicate coverage and treatment of comparatives (Bonial et al., 2018), annotations were stored with their concept labels and double-checked for changes in the underlying AMR.

Final data (included in an upcoming AMR public release) includes a description of each AMR document (as defined by LDC segmentations of multi-thread discourse into tractable discussions), defined as an ordered list of AMRs identified by their IDs. Each coreference cluster identifies explicit mentions by the ID within the normal AMR release and the variable within that AMR; implicit roles are identified by the identity of the predicate they are an argument of, with a label for the numbered argument that is implicit.

2.4 Corpus Profile

Multi-Sentence AMR was annotated over previously annotated gold AMRs of colloquial written English (from multi-post discussion forums and web blogs), filtered for discussions with fewer than 100 sentences. The corpus is composed of 293 annotated documents in total, with an average of 27.4 AMRs (429 words) per document, covering roughly 10% of the total AMR corpus. Counts for different types of mentions are listed in Table 1.

A small test split is also defined, annotated over documents from the test split of the AMR corpus. This is a small test set for systems to report preliminary results; it is hoped that this can result in shared tasks that might test against larger sets of unseen data. Annotation of this corpus is complete, and will be released in the next public release of AMR data through the Linguistic Data Consortium.

2.5 Related Work

Densely annotated datasets in which semantic data and coreference have been represented in the multiple layers of the OntoNotes corpus (Pradhan et al., 2011) and the Prague Czech-English Dependency Treebank (PCEDT) (Čmejrek et al., 2004). This MS-AMR data differs primarily in that the data is more directly joined into a single set of connected graphs, rather than many different layers of annotation. Annotations such as ACE and ERE also capture roles and entity annotations alongside coreference, but only cover a small portion of the total semantics of a document, filtering only the elements relevant to a task-specific ontology (Song et al., 2015; Bies et al., 2016).

Li Song and Xue (2018) annotates dropped pronouns over Chinese AMR annotators, but only deals with implicit roles in specific constructions. Annotations independent of AMR have provided implicit role annotations with PropBank or NomBank(Palmer et al., 2005; Meyers et al., 2004) semantic roles, but both resources were limited to a small inventory of 5-10 predicate types, rather than all implicit arguments in a text(Gerber and Chai, 2012; Moor et al., 2013).

Bridging information has also been annotated in a range of recent corpora (Nedoluzhko et al., 2009; Poesio et al., 2008; O'Gorman et al., 2016; Roesiger, 2018) and resulted in systems (Poesio et al., 2004) capable of predicting such relations. Some bridging relations were also captured by within-sentence AMR annotations, encoded by the "include-91" relation.

While MS-AMR focuses upon capturing the *propositional* content of a document, it does not capture other dimensions of discourse annotation, such as rhetorical structure. Corpora such as RST (Carlson

et al., 2003), SDRT (Baldridge et al., 2007), GraphBank (Wolf et al., 2004) or PDTB (Miltsakaki et al.,) therefore capture dimensions of meaning that differ from the propositional content captured in this corpus.

3 Measuring MS-AMR Corpus Quality

For a subset of the training data, we took each document (i.e. the sequence of AMRs that reflect a document) and double-annotated it, to measure inter-annotator agreement and check for persistent errors. These additional annotations are listed in Table 1 under the "Double Annotation" column, and provided in the release.

3.1 Coreference Chain Quality

When dealing with two MS-AMR annotations done over the same set of gold AMRs – as with inter-annotator agreement data here – we can treat a given variable in each AMR as a possible "mention", just as one might treat a span of text in a document. With that assumption, we may therefore measure MS-AMR IAA coreference scores using standard means of measuring coreference quality. One current approach – used because it is the standard for scoring coreference systems – is to use an average of the BCUB (Bagga and Baldwin, 1998), MUC (Vilain et al., 1995) and CEAF-E (Luo, 2005) metrics, referred to as the "CoNLL-2012 F1 score" (calculated using the reference implementation of Pradhan et al (2014a)).

Under those assumptions, the annotations get a CoNLL-2012 F1 of 69.86, using the reference implementation for these scores. For comparison, more traditional span-based coreference annotations (O'Gorman et al., 2016) found inter-annotator agreement of 65.5 for event F1, and 70.4 for entity F1 (CoNLL F1 score). This is therefore in the rough range of where one might expect human performance to be. However, this does not have actual comparability to other annotation schemes, as this data uses both event and entity coreference, and does not encompass within-sentence coreference (which is already provided in gold AMR annotations).

3.2 Agreement when underlying AMRs are not identical

Because MS-AMR was annotated on top of gold AMRs, most inter-annotator agreement pairs were annotated over an identical set of within-sentence AMRs for the document. This has the advantage of separating multi-sentence AMR disagreements from other AMR disagreements, but it left open the question of whether that agreement would change drastically if the underlying AMRs were different. Starting with documents where two separate annotators provided different AMRs for each sentence, we separately annotated two multi-sentence AMR annotations for that same document, each annotated on top of a different set of AMRs.

The challenges in evaluating this kind of agreement presage the challenges of measuring the quality of system-predicted MS-AMR. In traditional annotations of coreference over surface forms, one can assume that two mentions are identical when they refer to the same span of text. However, with two separate AMRs, one cannot directly infer whether two mentions reference the same span, but must determine a mapping between the variables of each AMR. The SMATCH (Cai and Knight, 2013) algorithm, used for evaluating AMRs, calculates such a mapping. Using SMATCH to align those AMRs and coreference scores from the reference implementation of the scoring metrics (Pradhan et al., 2014b), we find the CoNLL-2012 F1 to be 66.72. Such a score is limited in that it was measured over a very small exploration set (40 AMRs), but it provides some preliminary suggestion that the identical underlying AMRs used in the IAA numbers above are not dramatically inflating the inter-annotator agreement.

3.3 Implicit Role Agreement

Implicit roles have been annotated in prior corpora, but those annotations have been limited in size or coverage (Ruppenhofer et al., 2010; Gerber and Chai, 2010). The most comparable prior annotation is that of Gerber and Chai (2010), which looked at 10 nominal predicates in WSJ data, presenting annotators with numbered arguments without explicit mentions and instructions to link these arguments to

Relation Type	Resource	Metric	Score
Coreference	This work	CoNLL-F1	69.9
	RED-Entities (O'Gorman et al. 2016)	CoNLL-F1	70.4
	RED-Events (O'Gorman et al. 2016)	CoNLL-F1	65.5
Implicit Role	This work	Cohen's κ	0.59
	Gerber and Chai (2010)	Cohen's κ	0.64

Table 2: Agreement, alongside agreement in similar corpora (not perfectly comparable)

previously mentioned terms. That annotation resulted in a Cohen's kappa (Cohen, 1960) of κ=0.64. The current annotations result in a lower kappa of κ=0.59, which is a testament to the difficulty of the task.

As found in Gerber and Chai (2010), the bulk of this type of error is in the task of discerning whether a given referent is implicit at all. When both annotators agreed that a given implicit role was present, κ=0.85.

The implicit roles that annotators disagreed on were often those whose referents could be construed either as a specific referent in context or as a generic reference, most commonly with the non-focused element in a communication or mental state verb – such as the person being interested in "that's interesting", or the cause of "I laughed out loud". A similar issue involved the recipient or listener role for verbs like "say-01" or "ask-01", which can sometimes be inferable from context but are low in prominence.

4 Measuring MS-AMR similarity — scoring system performance

4.1 A baseline implementation

We present a simple baseline that hints at a lower bound for the task. We use the publicly available version of the Brandeis transition-based AMR parser (Wang et al., 2016) combined with an off-the-shelf coreference system (Clark and Manning, 2016) using an AMR-to-surface-form aligner (Flanigan et al., 2014) to convert the surface coreference to links between AMR nodes.

4.2 Simple evaluation of system prediction

As mentioned in section 3.2, one hurdle in evaluating system predictions comes from the absence of clearly alignable "mentions" for use in coreference metrics. We can use the SMATCH metric on each individual sentence within an AMR document to resolve this, as calculating a SMATCH score involves determining the highest scoring alignment between variables within a system prediction and a gold AMR. We can then score against that mapping.

The simple baseline outlined above was evaluated according to this metric, and we found a 27.79 CoNLL-F1 average (evaluating against the inter-annotator agreement data, which we use as a development set). While some amount of this may reflect simple differences such as the shift in domain to discussion forum data, it also underlines the inherent challenge of the task.

4.3 Evaluation with Document-level SMATCH

One hope with MS-AMR data is to encourage people to produce systems that go from strings to a representation of the meaning of a document. We therefore may want to have metrics that do not simply score coreference, but which score the entire quality of a resultant knowledge graph. One method to accomplish this goal is to use these multi-sentence AMR annotations to combine all the AMRs of a document into a single large "document graph", and to score entire document graphs using the SMATCH metric.

We follow prior work in abstractive summarization (Liu et al., 2015), which originally outlined simple methodologies for combining AMRs into a larger AMR for a document. This fundamentally involves a combination of two things – concatenating all sentences together under a new root node, and merging variables that are coreferent into a single variable.

Earlier work on this (Liu et al., 2015) merged only identical named entities and date-entity subgraphs, and therefore did not run into the complexities in terms of merging documents with similar

Bill left for Paris
(l / leave-11
:ARG0 (p / person :wiki - :name (n / name :op1 “Bill”))
:ARG2 (c / city :wiki “Paris” :name (n / name :op1 “Paris”)
He arrived at noon
(a / arrive-01
:ARG1 (h / he)
:ARG4 (i2 / implicit role: end point; destination)
:TIME (d / date-entity :dayperiod (n3 / noon)))

Merged form:
(m / multi-sentence)
:snt1 (l / leave-11
:ARG0 (p / person :wiki - :name (n / name :op1 “Bill”))
:instance-of “he”
:ARG2 (c / city :wiki “Paris” :name (n / name :op1 “Paris”)
:snt2 (a / arrive-01
ARG1 p
ARG4 c
:TIME (d / date-entity :dayperiod (n3 / noon)))

Figure 3: Example of merging multiple documents into a single AMR.

but non-identical information. When two triples are identical – such as twice labeling “Hillary Clinton as “:instance-of person”, or adding multiple “:wiki” links to “Hillary_Clinton” – we merge those redundant bits of information. However, if a variable has different concepts or relations (e.g. “person” in one AMR and “woman” in another), the additional concepts are added as additional “instance-of” relations to the resultant merged entity. Figure 3 illustrates how the merging of AMRs is actually enacted into an output AMR.

We then score these two document graphs using the SMATCH metric, originally proposed to score single-sentence AMRs. SMATCH scores each relation within an AMR graph, as measured as a triple containing the variable, the relation, and the variable or constant that is being linked to. These triples can reflect an actual relation, such as saying that there is a TIME relation between variable *a* and variable *d*, or can express the “instance-of” relations captured by the “/” in AMR, such as *a* being an instance-of “arrive-01”. The SMATCH metric calculates an F1 measuring how many of the triples within the gold AMR correspond to a triple in the system AMR. The issue is that AMR variable names are somewhat arbitrary — “a” and “d” in one AMR do not necessarily correspond to “a” and “d” in another AMR — and therefore one needs to calculate how to map the variables within another AMR onto the variables within the gold AMR; Cai and Knight (2013) introduced a hill-climbing method allowing one to calculate the alignment that gives the highest F1 over these triples. Importantly for multi-sentence AMR, we can utilize the same metric over a much larger AMR graph, although this becomes computationally expensive with larger document sizes.

We therefore score these document AMRs by treating them as single AMRs to be scored using SMATCH. As such, this is an evaluation of both the quality of within-sentence AMRs and coreference information. Table 3 illustrates the performance of the baseline system, compared with inter-annotator agreement scores. Following the suggestion to approach coreference evaluation based on how it works on edge cases (such as leaving all mentions as singletons) (Recasens and Hovy, 2011), we also report scores for the document-level graphs when no cross-sentence coreference information is used. The “AMR=identical” condition illustrates most instances of double annotation in our data, where both versions were annotated over the same AMRs; these receive very high SMATCH scores, due to the identical underlying AMRs. The “AMR=human” condition illustrates a small set where two different annotations of each AMR were used; this therefore represents human performance at this task. One can see that there

System type	AMR	Coreference	Double-annotation data	Test
baseline	system	none	53.0	43.2
baseline	system	system	53.6	44.0
IAA	human	none	58.0	
IAA	human	human	68.9	
IAA	identical	none	78.5	80.6
IAA	identical	system	80.1	82.9
IAA	identical	human	87.3	

Table 3: Agreement and baseline performance using SMATCH over document graphs. The AMR=human condition is evaluated on a much smaller set of AMRs where we have two annotated AMRs for each sentence.

is still a quite meaningful gap between this performance and the baseline system performance.

Notably, the simple baseline systems do not have dramatic increases over simply scoring the document SMATCH of a sequence of AMRs with no coreference. Basic analysis of this shows that some of this error is a consequence of the discussion genre: a baseline coreference model that did not track speakers in the AMRs makes important errors in coreference chains regarding "I" and "you". However, one can also see from Table 3 that the MS-AMR score is still very dependent upon the quality of the within-sentence AMRs, as one might expect from a measure of the general quality of a document representation.

5 Conclusions

We present here a new corpus of coreference, partial coreference and implicit roles on top of the Abstract Meaning Representation corpus. While this is fundamentally an extension of AMR, we frame this in relation to prior coreference work and propose a methodology for evaluating multi-sentence AMR system predictions against these gold annotations. Such an annotation does not fully capture all of the information one might hope to represent about the meaning of a document, as these representations leave unmarked a great deal of information about temporal and aspectual structure, discourse structure or information structure. However, this corpus illustrates a methodology of annotating new layers of meaning on top of AMR representations, which might be extended to such other representations.

Abstract

In this paper, we investigate the issue of persuasiveness evaluation for argumentative comments. Most of the existing research explores different text features of reply comments on word level and ignores interactions between participants. In general, viewpoints are usually expressed by multiple arguments and exchanged on argument level. To better model the process of dialogical argumentation, we propose a novel co-attention mechanism based neural network to capture the interactions between participants on argument level. Experimental results on a publicly available dataset show that the proposed model significantly outperforms some state-of-the-art methods for persuasiveness evaluation. Further analysis reveals that attention weights computed in our model are able to extract interactive argument pairs from the original post and the reply.

1 Introduction

Computational argumentation is a growing field in natural language processing. Existing research covers argument unit detection (Al-Khatib et al., 2016), argument structure prediction (Peldszus and Stede, 2015; Stab and Gurevych, 2014), argumentation scheme classification (Feng et al., 2014), etc. Recently, the automatic assessment of argumentation quality has started gaining attention. It can be analyzed at two levels, namely monological argumentation and dialogical argumentation.

Monological argumentation refers to a composition of arguments on a certain issue (Wachsmuth et al., 2017). A typical example of quality evaluation for monological argumentation is automated essay scoring, which aims to process argumentative essays without human interference (Taghipour and Ng, 2016). It takes an essay as the input and outputs a numeric score, considering features of content, grammar, discourse structure and lexical richness (Burstein et al., 2013). Most of the efforts are made on the exploration for better document representation.

Dialogical argumentation refers to a series of interactive arguments related to a given topic, involving argument retraction, view exchange, and so on (Besnard et al., 2014). With the popularity of online debating forums like *convinceme* [1], *debatepedia* [2] and *change my view (CMV)* [3], researchers pay increasing attention to evaluating the quality of debating or persuasive content (Tan et al., 2016; Wei and Liu, 2016; Wei et al., 2016; Habernal and Gurevych, 2016a). Although some similarity features of content between the reply and the original post are used to evaluate the quality of the given reply, they are computed on word level without considering the exchange of opinions on the basis of arguments.

An example of dialogical argumentation is shown in Figure 1. There are three posts, one is original and the other two are replies. The repliers post to change the view of the original poster. And the *positive reply* is deemed to be more persuasive than the *negative reply*. We have three observations. First, viewpoints of the original poster and repliers are expressed via multiple arguments. Second, content of replies is organized in-line with arguments in the original post. Third, interactions between a reply and the

Proceedings of the 27th International Conference on Computational Linguistics, pages 3703–3714
Santa Fe, New Mexico, USA, August 20-26, 2018.

Original Post: Philosophy doesn't seem to have any practical applications. [What value does philosophy have in the modern age, right now, aside from contemplating things?] I have read the argument that it is impossible to argue that philosophy is useless without using philosophy. [What do you gain from studying philosophy that could not be gained from thoughtful introspection?]	
Positive Reply	**Negative Reply**
What do you gain from studying philosophy that could not be gained from thoughtful introspection? [Two answers. #1 rigor and #2 it saves us from reinventing the wheel.] [Why do you think we should start from scratch in all value decisions rather than seeking to understand the work that has been done in the past?]	What do you gain from studying philosophy that could not be gained from thoughtful introspection? [Ask yourself the same question about math.] Your argument seems to be that studying philosophy is a waste of time because it has no practical use.

Figure 1: An example of dialogical argumentation consists of one original post and two persuasion replies from *change my view*, a sub-forum of *Reddit.com*. Different types of underlines are used to highlight the interactive relationship. The labels of the positive and negative replies are assigned by the original poster.

original post provide some indications for the persuasive comment identification. Inspired by the three findings, we aim to analyze dialogical argumentation on argument level and explore how argument-based interactions can help persuasiveness evaluation. Our datasets are collected from an on-line forum [4]. The content of posts is usually informal and not strictly grammatical. It is extremely difficult to parse the argument in a finer-grain with premise, conclusion and other components. Therefore, we treat each sentence as an argument for simplicity.

In this paper, we propose to incorporate argument-level interactions within dialogical argumentation for better persuasion comments quality evaluation. We propose a novel framework that includes three components, namely, argument representation, co-attention network and aggregation network. We first learn two different representations for each argument via a hierarchal neural network. Co-attention network captures the interactions between the reply and the original post on argument level via three kinds of attentions. Aggregation network combines the results of the co-attention network. Finally, a persuasiveness score is assigned to the target comment using a linear transformation. Experimental results on a benchmark dataset show that with the assistance of argument-level interactions, our proposed model can achieve much better performance than some state-of-the-art methods. In order to further understand how attention mechanism works for capturing the argument-level interactions, we formalize a task of interactive argument pair extraction. Experimental results on a self-constructed dataset show that our attention-based strategy significantly outperforms a word-overlap based strategy for the identification of interactive arguments.

2 Proposed Model

Given an original post and two corresponding replies, our task is to automatically identify which reply is more persuasive. In practice, we evaluate the quality of the two replies separately given the original post and treat the one with higher persuasiveness score as the winner. The overall architecture of our model is shown in Figure 2. It takes an original post and a reply as inputs, and outputs a real value as its persuasiveness score. It mainly consists of three components, namely, *Argument Representation*, *Co-attention Network* and *Aggregation Network*. We learn two representations for each single argument. One is based on its internal words and the other considers information of context arguments. What's more, three types of attentions are proposed to model the detailed interactions between the original post and the reply on argument level. The *Aggregation Network* integrates the results of *Co-attention Network*.

[4]Datasets are available at : https://github.com/lji0126/Persuasion-Comments-Evaluation

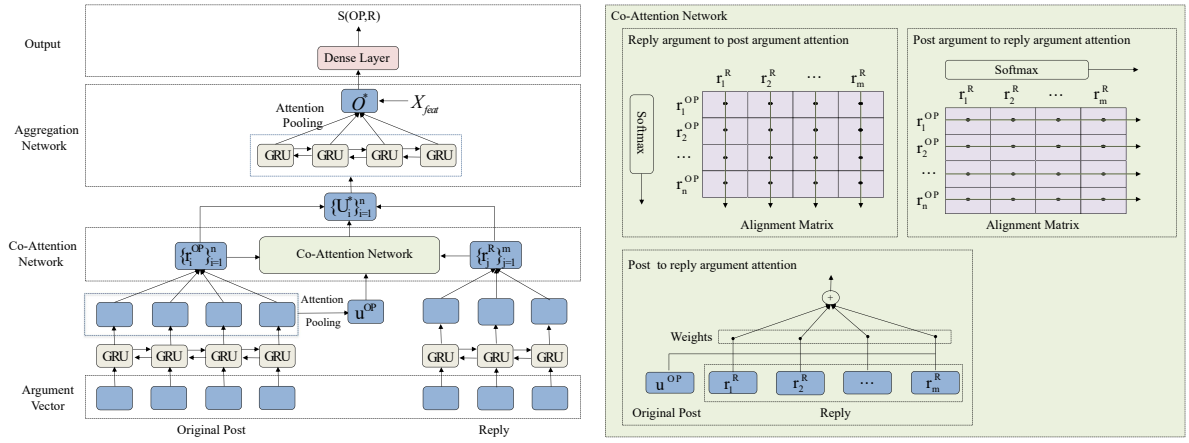

Figure 2: Overall architecture of the proposed model. The left part is the main framework of this work. The right part is the detailed structure of the co-attention network.

2.1 Argument Representation

Inspired by Dong et al. (2017), we employ a hierarchical architecture to obtain two different representations for each single argument. For simplicity, we consider each sentence as an argument.

Representation based on internal words given an argument with words $w_1, w_2, ..., w_T$, we first map each word to a dense vector obtaining $x_1, x_2, ..., x_T$ correspondingly. We then employ a convolution layer to incorporate the context information on word level.

$$z_i = f(W_z \cdot [x_i : x_{i+h_w-1}] + b_z) \tag{1}$$

where W_z and b_z are weight matrix and bias vector. h_w is the window size in the convolution layer and z_i is the feature representation. Not all words contribute equally to the representation of the argument. Therefore, we conduct an attention pooling operation over all the words to get the contribution of each word.

$$m_i = \tanh(W_m \cdot z_i + b_m) \tag{2}$$

$$u_i = \frac{e^{W_{u \cdot m_i}}}{\sum_j e^{W_{u \cdot m_j}}} \tag{3}$$

$$a = \sum_i u_i \cdot z_i \tag{4}$$

where W_m and W_u are weight matrix and vector, b_m is the bias vector, m_i and u_i are attention vector and attention weight of the i-th word. a is the argument representation.

Representation incorporating context arguments in order to incorporate information of context arguments, we employ a bi-directional GRU (Cho et al., 2014) to get the representation of an argument under its context. A BiGRU consists of both forward and backward GRU that handle the sequence from the left and the right end, respectively. In practice, we concatenate the hidden states of two GRUs for each argument to get final argument representation. $r_i^{OP} = BiGRU(r_{i-1}^{OP}, a_i^{OP}) \in R^{n \times d}, i \in [1 \cdots n]$, $r_j^R = BiGRU(r_{j-1}^R, a_j^R) \in R^{m \times d}, j \in [1 \cdots m]$, where a_i^{OP}, a_j^R are representations of arguments in the original post and the reply, respectively. r_i^{OP}, r_j^R are the hidden state of the i-th argument in the original post and the j-th argument in the reply. d is the dimension of hidden units. n and m stand for the number of arguments for the original post and the reply, respectively.

2.2 Co-attention Network

Attention mechanism is a common way to link and fuse information from two content-related texts (Weston et al., 2014; Hill et al., 2016; Sordoni et al., 2016; Shen et al., 2017). In order to capture the

interactions between the original post and the reply, we propose a novel co-attention network that includes three kinds of attentions. In particular, *Post argument to reply argument attention* computes the relevance of each post argument with every reply argument and helps learn a series of new reply representations. *Reply argument to post argument attention* computes the relevance of each reply argument with every post argument and finally obtains a series of new post representations. *Post to reply argument attention* computes the relevance of each reply argument with the entire post argument which contributes to learn a new reply representation.

Post argument to reply argument attention We first compute the alignment matrix $A \in R^{n \times m}$ that contains similarity scores corresponding to all possible pairs of arguments between the original post and the reply via Equation 5.

$$A_{ij} = W_a^T [r_i^{OP}; r_j^R; r_i^{OP} \circ r_j^R] \tag{5}$$

where W_a is the weight parameter, $\circ$ is the Hadamard product. A_{ij} indicates the similarity between i-th argument in the original post and j-th argument in the reply.

For i-th argument in the original post, we could signify which arguments in the reply are relevant to it by this attention. Similar to in Seo et al. (2016), we normalize the alignment matrix A row-wise to produce the attention weights across the reply for each argument in the original post. The calculation is described in Equation 6.

$$V_i = softmax(A_{i:}), i \in [1 \cdots n] \tag{6}$$

Based on the attention probability V_i of i-th argument in the original post, the new representation of the reply can be calculated by Equation 7.

$$U_i^1 = \sum_t V_{it} \cdot r_t^R \tag{7}$$

Based on all the arguments in the original post, we could obtain a series of new reply representations, which constitute U^1.

Reply argument to post argument attention We normalize the alignment matrix A column-wise to produce the attention weights across the original post for each argument in the reply. The attention weights can be calculated by Equation 8.

$$Q_j = softmax(A_{:j}), j \in [1 \cdots m] \tag{8}$$

Subsequently, each attended argument representation of original post is shown in Equation 9.

$$U_j^2 = \sum_t Q_{jt} \cdot r_t^{OP} \tag{9}$$

Based on all the arguments in the reply, we could get a series of new post representations, which constitute U^2.

Post to reply argument attention In order to evaluate the importance of arguments in the reply, we propose this attention. Firstly, we learn a representation u^{OP} for the original post via applying the attention pooling operation over all its hidden states $r_i^{OP}, i \in [1 \cdots n]$. We then compute attention weights with the original post based on u^{OP} for each argument in the reply. In practice, we conduct dot product between u^{OP} and each hidden state representation r_j^R in the reply and a softmax layer is used to obtain an attention distribution. The calculation process is shown in Equation 10.

$$v_j = softmax(u^{OP} \cdot r_j^R) \tag{10}$$

Based on the attention probability v_j of the j-th argument in the reply, the new representation of the reply can then be constructed as Equation 11.

$$u^3 = \sum_j v_j \cdot r_j^R \tag{11}$$

Finally, we put all of the attention representations in a linear function to get the integrated information. The detail is illustrated in Equation 12.

$$U = f(U^1, U^2, U^3, \{r_i^{OP}\}_{i=1}^n, \{r_j^R\}_{j=1}^m) \tag{12}$$

where f is a simple linear function, U^3 is a matrix that is tiled n times by u^3.

2.3 Aggregation Network

After acquiring the local alignment representation by the co-attention network, we employ a filtration gate to hold the interactive information. Then, we fuse the interactive information via a bi-directional GRU and compute the persuasiveness score.

Filtration Gate We utilize the filtration gate (Wang et al., 2017b) to hold the information that helps to understand the argument-level interactions between the original post and the reply. The formulas are in Equation 13 and 14.

$$gt = sigmoid(W_g U + b) \tag{13}$$

$$U^* = gt \odot U \tag{14}$$

We fuse the interactive information reserved by the filtration gate via a bi-directional GRU. The calculation is described in Equation 15.

$$O_t = BiGRU(O_{t-1}, U_t^*) \tag{15}$$

Then, we use an attention pooling operation over the whole hidden states of this BiGRU to summarize the interactive features into a dense vector O^*.

Scoring Tay et al. (2017) prove that adding some manual features such as word-overlap to models is helpful for improving performance. We incorporate some word-overlap features X_{feat} to the proposed model, i.e. similarities between original post and the reply in terms of word-overlap. Then, we use two fully connected layers to obtain a higher-level representation r. Finally, the persuasiveness score S is obtained by a linear transformation via Equation 16 and 17 .

$$r = f(W_r[O^*; X_{feat}] + b_r) \tag{16}$$

$$S = W_s r + b_s \tag{17}$$

where W_r and W_s stand for the weight matrices, while b_r and b_s are weight vectors.

2.4 Loss Function and Training

Given an original post and two corresponding replies, we want to automatically identify which reply is more persuasive. We formalize this issue as a ranking task and utilize a pairwise hinge loss for training. Given a triple (OP, R^+, R^-), where R^+ and R^- respectively denote the positive and the negative reply for OP. The loss function is defined in Equation 18.

$$L = max(0, 1 - S(OP, R^+) + S(OP, R^-)) \tag{18}$$

where $S(OP, R^+)$ and $S(OP, R^-)$ are the corresponding persuasiveness scores.

The model is trained by stochastic gradient descent on 105 epochs, and evaluated on the development set at every epoch to select the best model. Dropout (Srivastava et al., 2014) has proved to be an effective method and is used in our work. We use Glove (Pennington et al., 2014) word embeddings, which are 50-dimension word vectors trained with a crawled large corpus with 840 billion tokens. Embeddings for words not present are randomly initialized with sampled numbers from a uniform distribution [-0.25,0.25]. We set initial learning rate to 0.1, batch size to 20, filter sizes to 5, filter numbers to 100 and the hidden unit of BiGRU to 200. Early stopping was used with a patience of 15 epochs. We implemented our model using TensorFlow. The model converged in 23 hours on an NVIDIA Titan X machine.

	Training Set				Test Set			
	Ave_w	Var_w	Ave_p	Var_p	Ave_w	Var_w	Ave_p	Var_p
Original post	10	49.5	14	163.7	11	53.2	15	133.7
Positive reply	10	46.3	14	125.0	10	44.1	13	123.8
Negative reply	10	39.2	11	82.0	10	44.7	10	69.5

Table 1: Statistics of the evaluation dataset. Ave_w represents the average number of words per argument. Ave_p represents the average number of arguments per post. Var_w indicates the variance of the number of words per argument. Var_p indicates the variance of the number of arguments per post.

3 Experiments

3.1 Dataset and Metric

We use the same dataset as Tan et al. (2016) for evaluation, which focuses on arguments from root reply. The dataset is collected from the */r/ChangeMyView* subreddit (CMV). In CMV, users submit posts to elaborate their perspectives on a specific topic and other users are invited to argue for the other side to change the posters' opinions. Users can give *delta* to a reply if it changes their original mind about the topic. In this dataset, for the same original post, the reply with *delta* is treated as *positive reply*, otherwise it is chosen as the *negative reply*.

The whole dataset consists of 3,456 training instances and 807 testing instances, where each instance includes an original post with one positive and one negative reply respectively. We randomly select 10% of the training instances to form the development set. In preprocessing, we use NLTK [5] for tokenization and lowercase conversion. We also filter out stop words and low frequency words. The constructed word vocabulary contains 15,767 distinct words. The detailed statistics are shown in Table 1.

Since we treat this task as a pairwise ranking problem, pairwise accuracy is conducted as the evaluation metric, which also mentioned in Tan et al. (2016).

3.2 Models for Comparing

We compare our model with the previous state-of-the-art model and the variant models of our model.
– **Tan et al. (2016)**: Tan et al. (2016) regard this task as a binary classification problem and use logistic regression model to classify replies based on some manually designed features, including interplay features, argument-related features and text style features. Because there is no source code published, we directly present the result reported in their paper for comparison.
– **Word-level BiGRU (WB)**: This model employs BiGRU to encode the original post and the corresponding reply on word level. Both representations of the original post and the reply are then concatenated to compute its persuasiveness score using a fully connected layer.
– **CNN + BiGRU (CB)**: This model encodes the original post and the corresponding reply via a hierarchical neural network. All the hidden states from the BiGRU are input into the aggregation network to compute the persuasiveness score. This is a part of our model without the co-attention network and the word-overlap features.
– **Word Overlap Features (WOF)**: This model directly uses the word-overlap features to evaluate the quality of arguments. More concretely, word-overlap features contain Jaccard similarity and some scores based on common words between the original post and the reply.
– **CNN+BiGRU+Co-Att (CBCA)**: This model is a part of our model without the word-overlap features. We input argument representations of the original post and the corresponding reply into the co-attention network and then obtain the persuasiveness score via the results of aggregation network.
– **CNN + BiGRU + Word Overlap Features (CBWOF)**: This model is a part of our model without the co-attention network. After obtaining argument representations of the original post and the corresponding reply, we input the hidden states of BiGRU into the aggregation network. We then concatenate the result of aggregation network with the word-overlap features to get the persuasiveness score.

[5] http://www.nltk.org/

Model	Pairwise accuracy
Tan et al. (2016)	<u>65.70</u>
Word-level BiGRU (WB)	61.22
CNN+BiGRU (CB)	63.34
Word Overlap Features (WOF)	63.59
CNN+BiGRU+Co-Att (CBCA)	66.96‡
CNN+BiGRU+Word Overlap Features (CBWOF)	68.08‡
CNN+BiGRU+Att_III+Word Overlap Features (CBAWOF_III)	69.95‡
CNN+BiGRU+Att_I+Word Overlap Features (CBAWOF_I)	70.07‡
CNN+BiGRU+Att_II+Word Overlap Features (CBAWOF_II)	70.20‡
CNN+BiGRU+Co-Att+Word Overlap Features (CBCAWOF)	**70.45**‡*

Table 2: The performance of different approaches on our datasets. The model underlined is the state-of-the-art method. The models that outperform the state-of-the-art method are highlighted with ‡. Our model that significantly outperforms the state-of-the-art method is marked with * (p<0.01, Student's paired t-test and Wilcoxon signed rank test). Best result is in **bold**.

– **CNN+BiGRU+Att_I+Word Overlap Features (CBAWOF_I)**: This model is a part of our model with the post argument to reply argument attention in the co-attention network.
– **CNN+BiGRU+Att_II+Word Overlap Features (CBAWOF_II)**: This model is a part of our model with the reply argument to post argument attention in the co-attention network.
– **CNN+BiGRU+Att_III+Word Overlap Features (CBAWOF_III)**: This model is a part of our model with the post to reply argument attention in the co-attention network.
– **CNN + BiGRU + Co-Att+Word Overlap Features (CBCAWOF)**: This is our proposed model.

3.3 Results and Discussion

The overall result of the comparison is shown in Table 2. We have following findings.
– The model proposed by Tan et al. (2016) achieves an accuracy of 65.70 % on the dataset. The performance actually shows the effectiveness of human generated features on this task. However, some writing style features used are very difficult to obtain, limiting its ability to generalize. The authors also explore to use interactive features between the original post and the reply, however, only word-level text similarity is considered.
– The performance of *CB* is much better than that of *WB*. This proves the effectiveness of representing posts on argument level instead of word level.
– The performance of *WOF* is comparable to that of *CB*. This indicates that correlation between the original post and the reply is an important feature for persuasiveness evaluation.
– The performance of *CBCA* is much better than that of *CB*. This indicates the effectiveness of the co-attention network.
– By combining both argument representations and word-overlap features, the performance of *CBWOF* is significantly better than that of *CB* and *WOF*.
– The performance of *CBAWOF_I*, *CBAWOF_II*, *CBAWOF_III* is better than that of all models except *CBCAWOF*. This proves the effectiveness of the three kinds of attentions separately.
– Our proposed model *CBCAWOF* generates the best performance among all the models. This confirms the effectiveness of our proposed co-attention model.

In order to further prove the effectiveness of our model, we conduct the *Student's paired t-test* [6] and

[6]https://en.wikipedia.org/wiki/Student's_t-test.

Original Post: [I'm talking about making the human race smarter, forever.] [We could use the IQ scale (for want of a better intelligence measure) to determine the number of offspring a person should be able to genetically contribute to.] [A man and a woman with average IQ can have two children and average IQs of 125-174 can contribute towards 3 children.] This would make human more likely to survive.

Positive Reply
[When the proposal comes up I am reminded of why it's a bad idea: not because we couldn't do it, but because we don't know how to do it right.][Why would a more intelligent society automatically be a better one?] We don't know enough about the biology. [Simply, we are not ready for eugenics.]

Negative Reply:
[As you put it, the entire goal of eugenics is to make the human race to advance and survive, but the irony of eugenics is that one of the best ways we can guarantee our survival is to maximize the size of our gene pool.] However, it's dangerous to call certain genes good and other genes bad.

Figure 3: A sample consists of one original post with two persuasion replies. Interactive argument pairs are highlighted with the same kind of underline. Pairs are extracted via co-attention network.

the *Wilcoxon signed rank test* [7]. Because Tan et al. (2016) don't publish their source code, we are unable to obtain detail results of their model. In Table 2, we find that the performance of CBWOF is better than that of Tan et al. (2016), so we carry out the significance tests between the results of our model and CBWOF. The p-value of the two significance tests is less than 0.01 respectively, which proves that our model significantly outperforms the state-of-the-art method.

4 Further Analysis on Co-attention Network

In order to further understand the capability of our co-attention network for capturing interactions between the original post and the reply on argument level, we perform an additional experiment to evaluate the effectiveness of the attention weights for the identification of interactive argument pairs. Therefore, we propose a novel task of extracting the interactive argument pairs between the original post and the corresponding reply. We first build an evaluation dataset and then compare the extraction performance of attention-based extraction strategy with a word-overlap based strategy on this dataset.

4.1 Dataset for Interactive Argument Pair Extraction

We sample 50 triples in the form of (original post, positive reply, negative reply) from the training set and split these into 100 original post-reply pairs in the form of (original post, positive reply) and (original post, negative reply). Given two collections of arguments from the original post and the reply, namely, $OP = \{op_1, op_2, op_3, ..., op_n\}$ and $R = \{r_1, r_2, r_3, ..., r_m\}$, for each argument r_j in the reply, we aim to identify arguments in the original post that interact with it.

Two annotators are hired to annotate the dataset independently and a third annotator is asked to solve the conflict between the two annotators. Two annotators identify 371 and 355 pairs of interactive arguments respectively. The inter-annotator agreement measured by Co-hens Kappa (Carletta et al., 1996) is 91.83%. With the final decision from the third annotator, we obtain 365 pairs in total. In detail, 234 interactive argument pairs come from positive replies, and the other 131 pairs are generated by negative replies. This re-confirms that the degree of interaction is a good indicator for persuasive reply identification.

4.2 Automatic Argument Extraction

We use two methods to extract argument pairs automatically. One is based on the attention weights computed in our proposed model and the other extracts pairs based on word-overlap similarity.

[7] https://en.wikipedia.org/wiki/Wilcoxon_signed-rank_test.

	P@1	P@2	P@3	P@4	P@5	MRR
WS	17.53	30.41	39.72	48.49	53.97	31.33
CN	22.19	36.71	43.84	49.86	54.24	39.41

Table 3: Experimental results of *WS* and *CN* for interactive argument pair extraction on the self-constructed dataset.

Co-attention Network (CN): We extract interactive argument pairs based on the results of our co-attention network. Because not every argument in the reply has interactive relationship, we choose 10 arguments in each reply based on the top-10 weights of the *post to reply argument attention* (this attention vector computes the importance of arguments in the reply in the perspective of the original post). Secondly, we choose the top-5 arguments in the original post for the 10 arguments in reply respectively in terms of the *reply argument to post argument attention* weights.

Word-overlap Similarity (WS): The extraction of arguments in the reply is the same as *CN*. We use the number of common words to identify interactive arguments in the original post for each argument in the reply. Top-5 arguments obtaining most common words with the argument in the reply are kept.

4.3 Results and Analysis

For each argument from the reply in the gold pair, we will see whether its corresponding argument is ranked in top k by automatic models. We report Mean Reciprocal Rank (MRR), precision at position 1, 2, 3, 4 and 5 as evaluation metrics. Table 3 shows the experiment results of *WS* and *CN*. We can see great differences between the two methods. In detail, the performance of CN in terms of P@1∼P@5 and MRR is higher than those of WS by 4.66%, 6.30%, 4.12%, 1.37%, 0.27% and 8.08% respectively. This confirms the effectiveness of our co-attention network for capturing interactions between the original post and the reply. However, the overall performance of both *CN* and *WS* are relatively low. This indicates that the task is difficult in nature. A sample of interacting argument pairs extracted by the attention-based approach can be seen in Figure 3.

5 Related Work

Two major areas related to our work are argumentation quality evaluation and attention mechanism.

5.1 Argumentation quality evaluation

Computational argumentation is a growing sub-field of natural language processing in which arguments are analyzed in various respects. Previous works in computational argumentation mainly focus on the methods for argument mining, which arms to determine the argumentative structure in texts. Recently, argumentation quality evaluation has become an active topic in this field.

There have been several attempts to address tasks related to argumentation quality evaluation. Habernal and Gurevych (2016b) propose a new task of predicting which argument from an argument pair is more convincing and use SVM and bidirectional LSTM to experiment on their annotated datasets. Tan et al. (2016) construct datasets from the ChangeMyView subreddit. They study factors affecting whether a challenger can successfully change the view of a commenter expressed in the original post and employ logistic regression to predict which reply in the pair is more persuasive.

In addition, Wei and Liu (2016) acquire discussion threads from the ChangeMyView subreddit to study the mechanisms behind persuasion. They propose and evaluate a set of features to predict the persuasiveness of debate posts, including textual features and social interaction related features. Wei et al. (2016) propose a task for quality evaluation of disputing argument. They manually annotate a real dataset collected from an online debating forum and analyze the correlation between disputing quality and different disputation behaviors. Wang et al. (2017a) use linguistic features of arguments, latent persuasive strengths of different topics and the interactions of debate comments to predict the debate outcome. Persing and Ng (2017) study the persuasiveness by designing five respects of error that have

negative impacts on persuasiveness. They not only focus on determining how persuasive an argument is, but also tell us why an argument is unpersuasive.

From the brief descriptions given above, we can find that most of the existing research focuses on the interactions among debate comments only from the perspective of text similarity. The interactions among argument pairs are ignored. In this work, we evaluate the quality of debate comments through the interactions among them on argument level.

5.2 Attention mechanism

Attention mechanism allows models to focus on specific parts of inputs at each step of a task. Moreover, attention mechanism has been proved to be significantly effective in natural language processing tasks.

Co-attention mechanism has recently attracted lots of research interest in the fields of machine translation (Bahdanau et al., 2014), question answering (Wu et al., 2017), text generation (Li et al., 2015), etc. It is computed as an alignment matrix based on two inputs, which can model complex interactions between the two inputs. Xiong et al. (2016) present a co-attention encoder to focus on relevant parts of the representations of the question and document and use a dynamic pointing decoder to locate the answer. Cui et al. (2016) propose a two-way attention mechanism to encode the passage and question mutually and induce attended attention for final answer predictions.

Self-attention mechanism is an attention mechanism aiming at aligning the sequence with itself, which has been successfully used in a variety of tasks. In Cheng et al. (2016), both encoder and decoder are modeled as LSTMs with self-attention for extractive summarization of documents. In Lin et al. (2017), the authors conduct a self-attention over the hidden states of a BiLSTM to extract the sentence embedding. Instead of sentence vector, they use a 2-D matrix to represent the embedding, with each row of the matrix attending on a different part of the sentence.

In this work, we employ a co-attention mechanism to capture the interactions between the original post and the reply on argument level. What's more, we use a self-attention mechanism to obtain the argument representation, which is called attention pooling in the previous sections.

6 Conclusions and Future Work

In this paper, we propose to incorporate argument-level interactions for dialogical argumentation. A novel co-attention network is proposed to capture the detailed interactions between the original post and the reply on argument level for better persuasiveness evaluation. Experimental results on a benchmark dataset show that the proposed model can achieve much better performance than the previous state-of-the-art method. Further analysis of extracting interactive argument pairs from the original post and the reply also proves the effectiveness of our co-attention network.

The future work will be carried out in three directions. First, we will fully investigate the usage of our model for applying to other dialogical argumentation related tasks, such as debate summarization. Second, we will enlarge the annotated dataset for interactive argument pair identification and explore more effective methods to generate argument pairs automatically. Third, we will explore to utilize topic information for the quality evaluation of persuasion comments.

Abstract

We study the problem of grounding distributional representations of texts on the visual domain, namely visual-semantic embeddings (VSE for short). Begin with an insightful adversarial attack on VSE embeddings, we show the limitation of current frameworks and image-text datasets (*e.g.*, MS-COCO) both quantitatively and qualitatively. The large gap between the number of possible constitutions of real-world semantics and the size of parallel data, to a large extent, restricts the model to establish a strong link between textual semantics and visual concepts. We alleviate this problem by augmenting the MS-COCO image captioning datasets with textual contrastive adversarial samples. These samples are synthesized using language priors of human and the WordNet knowledge base, and enforce the model to ground learned embeddings to concrete concepts within the image. This simple but powerful technique brings a noticeable improvement over the baselines on a diverse set of downstream tasks, in addition to defending known-type adversarial attacks. Codes are available at https://github.com/ExplorerFreda/VSE-C.

1 Introduction

The visual grounding of language plays an indispensable role in our daily lives. We use language to name, refer, and describe objects, their properties and generally, visual concepts. Distributional semantics (*e.g.*, global word embedding (Pennington et al., 2014)) based on large-scale corpora have shown great success in modeling the functionality and correlation of words in the natural language domain. This further contributes to the success in numerous natural language processing (NLP) tasks such as language modeling (Cheng et al., 2016; Inan et al., 2017), sentiment analysis (Cheng et al., 2016; Kumar et al., 2016), and reading comprehension (Cheng et al., 2016; Chen et al., 2016; Shen et al., 2017). However, effective and efficient grounding of distributional embeddings remains challenging. Being ignorant of the corresponding visual concepts, pure textual embeddings demonstrate inferior performances when incorporating with visual inputs. Typical tasks include image/video captioning, multi-modal retrieval/understanding, and visual reasoning, some of which are further extensively studied in the paper.

Visual concept and its link with textual semantics, as a cognitive alignment, provide rich supervision to learning systems. Visual-Semantic Embedding (VSE) aims at building the bridge between natural language and the underlying visual world. Introduced by Kiros et al. (2014), the embedding spaces of both images and descriptive texts (captions) are jointly optimized and aligned. Nevertheless, even for large-scale datasets such as MS-COCO (Lin et al., 2014), the number of image-caption pairs are far less than the number of possible constitutions of real-world semantics, making the dataset inevitably sparse and biased.

To reveal this, we begin with constructing textual adversarial samples to attack the state-of-the-art system VSE++ (Faghri et al., 2017). Specifically, we study the composition of sentences in two aspects: (1) content words including nouns and numerals and (2) prepositions indicating spatial relations (*e.g.*, in,

[*] Work was done when HS, JM and TX were intern researchers at Megvii Inc. HS, JM and TX contribute equally to this paper.

Proceedings of the 27th International Conference on Computational Linguistics, pages 3715–3727
Santa Fe, New Mexico, USA, August 20-26, 2018.

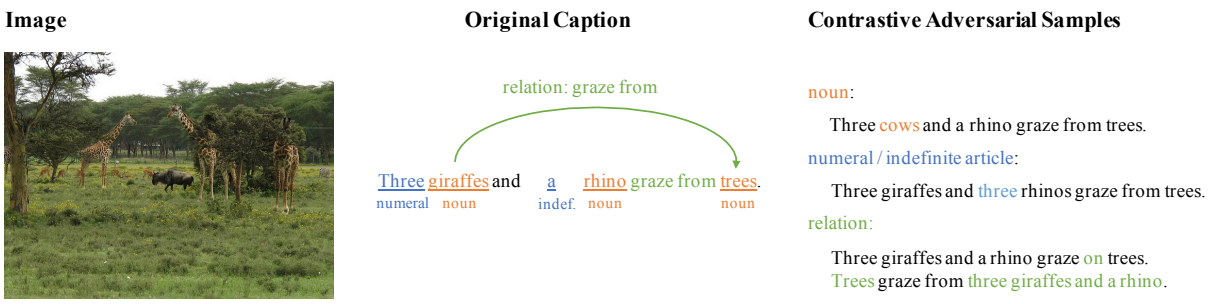

Figure 1: An overview of our textual contrastive adversarial samples. For each caption, we have three paradigms to generate contrastive adversarial samples, *i.e.*, noun, numeral and relation. For an given image, we expect the model to distinguish the real captions against the generated adversarial ones.

on, above, below). As shown in Figure 1, we manipulate the original caption to construct hard negative captions with similar structure but completely contradictory semantics. We found that the models easily get confused, suffering a noticeable drop in confidence or even wrong predictions in the caption retrieval task.

We propose VSE-C, which enforces the learning of correlation and correspondence between textual semantics and visual concepts by providing contrastive adversarial samples during the training procedure, incorporating with an intra-pair hard negative sample mining. Instead of defending adversarial attacks, we focus on the study of limitations of current visual-semantic datasets and the transferability of learned embeddings. To fulfill the large gap between the number of parallel image-caption pairs and the expressiveness of natural languages, we augment the data by employing a set of heuristic rules to generate large sets of contrastive negative captions, as demonstrated in Figure 1. The candidates are selectively used for training by an intra-pair hard-example mining technique. VSE-C alleviate the bias of dataset and provide rich and effective samples on par with original image captions. This strengthen the link between text and visual concepts by requiring models to detect a mismatch on the level of some precise concepts.

VSE-C learns discriminative and visually-grounded word embeddings on the MS-COCO dataset (Lin et al., 2014). It is extensively compared with existing works with rich experiments and analyses. Most importantly, we explore the transferability of the learned embeddings on several real-world applications both qualitatively and quantitatively, including image-to-text retrieval and bidirectional word-to-concept retrieval. Furthermore, VSE-C demonstrates a general framework for augmenting textual inputs considering semantical consistency. The introduction human priors and knowledge bases alleviates the sparsity and non-contiguity of languages. We hope the framework and the released data are beneficial for building more robust and data-efficient models.

2 Related works

Joint embeddings Joint embedding is a common technique for a wide range of tasks incorporating multiple domains, including audio-video embeddings for unsupervised representation learning (Ngiam et al., 2011), shape-image embeddings (Li et al., 2015) for shape inference, bilingual word embeddings for machine translation (Zou et al., 2013), human pose-image embeddings for pose inference (Li, 2011), image-text embeddings for visual description (Reed et al., 2016), and global representation learning from multiple domains (Castrejon et al., 2016). These embeddings map multiple domains into a joint vector space which describes the semantical relations between inputs (*e.g.*, distance, correlation).

We focus on the visual-semantic embedding (Mao et al., 2016; Kiros et al., 2014; Faghri et al., 2017), learning word embeddings with visually-grounded semantics. Examples of related applications include image caption retrieval and generation (Kiros et al., 2014; Karpathy and Fei-Fei, 2015), and visual question-answering (Malinowski et al., 2015).

Image-to-text translation Canonical Correlation Analysis (CCA) (Hotelling, 1936) is a statistical method that projects two views linearly into a common space to maximize their correlation. (Andrew et al., 2013) proposes a deep learning framework to extend CCA so that it is able to learn nonlinear projections

and has better scalability on relatively large datasets.

In the state-of-the-art frameworks, the pairwise ranking is often adopted to learn a distance metric (Socher et al., 2014; Niu et al., 2017; Nam et al., 2017). (Frome et al., 2013) proposes a cross-modal feature embedding framework that uses CNN and Skip-Gram (Mikolov et al., 2013) to extract representations for images and texts respectively, then an objective is applied to ensure that the distance between the matched image-text pair is smaller than that between the mismatched pair. A similar framework proposed by (Kiros et al., 2014) uses a Gated Recurrent Unit (GRU) as the sentence encoder. (Wang et al., 2016) uses a bidirectional loss function with structure-preserving constraints. An attention mechanism on both image and caption is used by (Nam et al., 2017) where the model estimates the similarity between images and texts by sequentially focusing on a subset of image regions and words that have shared semantics. (Huang et al., 2017) utilizes a multi-modal context-modulated attention mechanism to compute the similarity between an image and a caption. (Faghri et al., 2017) proposes a novel loss to penalize the hard negatives, *i.e.*, the closest mismatched pairs, instead of averaging the individual violations across all negatives in (Kiros et al., 2014).

Adversarial attack in text domain Adversarial attacks have recently drawn significant attention in the deep learning community. The adversarial attacks spread over multiple domains including image classification (Nguyen et al., 2015), image segmentation and object detection (Xie et al., 2017), and textual reading comprehension (Jia and Liang, 2017), and deep reinforcement learning (Kos and Song, 2017).

In this paper, we present textual adversarial attacks in image-to-text translation systems such as image caption frameworks. While focusing on the problem of learning visually-grounded semantics, the adversarial attack brings new solutions to fulfill the gap between limited training data and numerous constitutions of natural languages. With extensive experiments on the effects of the adversarial samples, we reach the conclusion that current visual-semantic embeddings are "insensitive" to the underlying semantics. The proposed VSE-C shows advance across multiple visual-semantic tasks.

3 Method

3.1 Preliminaries

Word embeddings We manually split the embeddings of each word into two parts: distributional embeddings, and visually-grounded embeddings. We use GloVe (Pennington et al., 2014) as the distributional embeddings, pre-trained unsupervisedly on large-scale corpora. We focus on the visually-grounded embeddings of words. The embeddings are optimized using the visual-semantic embedding (VSE) technique.

Visual-semantic embeddings VSE optimizes and aligns the latent space of both visual and textual domains. Parallel data are typically obtained from image captioning datasets such as Flickr30K (Young et al., 2014) or MS-COCO (Lin et al., 2014). The training set $S = \{(i_n, c_n)\}_N$ contains N image-caption pairs. Typically all $(i_n, c_m), n \neq m$ and $(i_m, c_n), n \neq m$ form the negative samples for a specific pair (i_n, c_n).

Following the notations used by (Kiros et al., 2014), domain-specific encoders are first employed to extract latent features of both images and captions, denoted as $\phi(i)$ and $\psi(c)$, respectively. We use ResNet-152 (He et al., 2016) as visual domain encoder and GRU as text domain sentence encoder, which are both effective for VSE. They are projected into a joint latent space with a linear transformation. A hinge loss with margin α is employed to optimize the alignment:

$$\ell^{VSE}(i, c) = \sum_{c'} [\alpha + s(i, c') - s(i, c)]_+ + \sum_{i'} [\alpha + s(i', c) - s(i, c)]_+ , \tag{1}$$

where $[\cdot]_+ = \max(0, \cdot)$, and $s(i, c) = W_i^T f(i; \theta_i) \cdot W_c^T g(c; \theta_c)$ measuring the distance between projected image embedding $W_i^T f(i; \theta_i)$ and caption embedding $W_c^T g(c; \theta_c)$. The summations are taken over all image-caption pairs within a sampled batch.

Class	Original Caption	Contrastive Adversarial Example
Noun	A person feeding a **cat** with a banana.	A person feeding a **dog** with a banana.
Numeral	A person feeding **a cat** with a banana.	A person feeding **five cats** with a banana.
Relation-1	**A person** feeding **a cat** with a banana.	**A cat** feeding **a person** with a banana.
Relation-2	A person feeding a cat **with** a banana.	A person feeding a cat **in** a banana.

Table 1: Examples of contrastive adversarial samples generated with our heuristic rules and knowledge from WordNet. The samples can be classified into four types: noun replacement, numeral replacement, relation shuffling, and relation replacement.

3.2 Generating contrastive adversarial samples

Our contrastive adversarial samples can be split into three classes: *noun*, *numeral* and *relation*. Each class of samples is generated separately.

Noun. We extract a list of heads (Zwicky, 1985) of noun phrases in MS-COCO dataset and label those with frequency larger than 200 be frequent heads. In addition, since images usually reflect concrete concepts better than abstract ones, we compute the concreteness of words following Turney et al. (2011), and only consider those heads with concreteness larger than $\theta = 0.6$. Only frequent concrete heads can be replaced by other frequent concrete heads with different meaning to form contrastive adversarial samples.

While replacing, we utilize the hypernymy/hyponymy relations in WordNet (Miller, 1995) to confirm the original noun and the corresponding contrastive adversarial sample are semantically different. Only words without hypernymy or hyponymy relations can be used as the replacement for adversarial sample generation. For example, "animal" is a hypernym of "cat". Therefore, "A person feeding an animal with a banana" cannot be a valid generated contrastive adversarial caption for the image with the caption of "A person feeding a cat with a banana."

Numeral. For each caption, we detect numerals and replace them with other numerals indicating different quantities to form contrastive adversarial samples. Note that "a" and "an" are treated as "one" here, though they are (indefinite) articles instead of numerals. Meanwhile, we singularize or pluralize the corresponding nouns when necessary.

Relation. The relation class includes two different paradigms.

The first one can be viewed as *shuffle of noninterchangeable noun phrases*. After extracting noun phrases of a caption, we shuffle them and put them back to the original positions. Although the bag of words features of the two sentences (caption) remain the same, the semantic meaning alters through this process.

The second one is *replacement of prepositions.* We extract the prepositions with frequency higher than 200 in MS-COCO dataset. Then we manually annotate a semantic overlap table, which can be found in Appendix A. In this table, words in the same set may have semantic overlap with each other, *e.g.*, by and with, in and among.

The noun phrase detection, preposition detection and numeral detection mentioned above are performed with SpaCy (Honnibal and Johnson, 2015). Examples of different classes of contrastive adversarial sample generation are shown in Table 1.

3.3 Intra-pair hard negative mining

We extend the online hard example mining (OHEM) technique used by VSE++(Faghri et al., 2017). The original hinge loss is computed by choosing the hardest sample within an batch (inter-pair). Mathematically,

$$\ell^{\text{VSE++}}(i, c) = \max_{c' \neq c}[\alpha + s(i, c') - s(i, c)] + \max_{i' \neq i}[\alpha + s(i', c) - s(i, c)]. \quad (2)$$

There are two major concerns regarding the in-batch hard negative mining. On one hand, mining negatives from a single batch is inefficient when batch size is not comparable with the size of the dataset.

On the other hand, for real-world datasets, taking the max in loss function tends to be very sensitive to label noise, resulting in fake negative samples.

In contrast, given an image-caption pair (i, c), we employ human heuristics and WordNet knowledge base to generate contrastive negative samples $\mathcal{C}'(c)$. To utilize these candidate caption sets, we employ an intra-pair hard negative mining strategy. Specifically, during the optimization, we add an extra loss term:

$$\ell^{\text{VSE-C}}(i, c) = \ell^{\text{VSE++}}(i, c) + \max_{c'' \in \mathcal{C}'(c)} [\alpha + s(i, c'') - s(i, c)]_+. \tag{3}$$

In our implementation, the candidate set $\mathcal{C}'$ has approximately $1,000$ samples. In each iteration, we randomly sample $N = 8$ negatives from it. This simple sample technique are effective and computation-friendly based on our empirical studies.

4 Experiments

We begin our experiments with an extensive study on the effect of adversarial samples on the baseline models. Even trained with hard negative mining techniques, VSE++ fails to discriminate words with completely contradictory visually-grounded semantics. Furthermore, we study the improvement brought by the introduction of contrastive adversarial samples on a diverse set of tasks. We release our code at `https://github.com/ExplorerFreda/VSE-C`.

4.1 Adversarial attacks

We select 1,000 images for test in MS-COCO 5k test split following (Karpathy and Fei-Fei, 2015). Each image is associated with five captions. Each caption in the selected test set can be manipulated to generate at least 20 contrastive adversarial samples by all manners (noun, numeral, and relation adversary). The image-to-caption retrieval task is defined as ranking the candidate captions based on the distance between their semantics and the given image.

We follow the metric used in Faghri et al. (2017) computing R@1, R@10, median rank and mean rank w.r.t. the top-ranked correct caption for each image. For each image, the database of retrieval contains the full set of 1000×5 captions, in which only 5 captions are labeled as positive. The R@k metric essentially measures the percentage of images where the set of top-k ranked captions contains at least one positive caption.

We attack the existing models by adversarial samples. We extend each caption with 60 adversarial samples (20 noun-typed, 20 numeral-typed and 20 relation-typed). Therefore, each image has 60×5 contrastive adversarial samples in total. The candidate retrieval set for each image now becomes $5000 + 300$. We discuss the experimental results as follows:

VSE-C are more robust to known-typed adversarial attacks than VSE and VSE++. We compare the performance of VSE-C with VSE (Kiros et al., 2014) and VSE++ (Faghri et al., 2017) in Table 2. Both VSE and VSE++ have a significant drop in performance after adding adversarial samples, while VSE-C training with contrastive adversarial samples is less vulnerable to the attacks. This phenomenon reflects that the text encoders of VSE and VSE++ do not actually make a good use of the image encodings, as the image encodings are fixed in all experiments.

Detailed attacking results are shown in Table 3. The three hyper-columns show the ability of the models to defend the adversarial attack of noun, numeral, and relation-typed respectively. Among three types of attacks, VSE and VSE++ suffer least from the noun attack. As the constitution of the dataset ensures the frequency in the entire dataset of the words used for replacement, the visual grounding of these frequent nouns is easy to obtain. However, the semantics of relations (including prepositions and entity relations) or numbers are not diverse enough in the dataset, leading to the poor performance of VSE against these attacks.

Numeral-typed VSE-C improves the counting ability of models. As shown in Table 3, numeral-typed contrastive adversarial samples improve the counting ability of models. However, it is still not clear about where the gain comes from, as the creation of numeral-typed samples may change the form (*i.e.*,

Model	MS-COCO Test				MS-COCO Test (w/. adversarial)			
	R@1	R@10	Med r.	Mean r.	R@1	R@10	Med r.	Mean r.
VSE	47.7	87.8	2.0	5.8	28.0	71.6	4.0	11.7
VSE++	**55.7**	**92.4**	1.0	**4.3**	35.6	72.5	3.0	11.8
VSE-C (+n.)	50.7	90.7	1.0	5.2	40.3	80.2	2.0	9.2
VSE-C (+num.)	53.3	90.2	1.0	5.8	46.9	86.3	2.0	6.9
VSE-C (+rel.)	52.4	89.0	1.0	5.7	42.3	82.5	2.0	7.2
VSE-C (+all)	50.2	89.8	1.0	5.2	**47.4**	**88.8**	2.0	**5.5**

Table 2: Evaluation on image-to-caption retrieval. Although VSE++ (Faghri et al., 2017) obtains the best performance on original MS-COCO test set, it is more vulnerable to the caption-specific adversarial attack compared with the proposed VSE-C, and so does VSE (Kiros et al., 2014).

Model	MS-COCO Test (+n.)			MS-COCO Test (+num.)			MS-COCO Test (+rel.)		
	R@1	R@10	Mean r.	R@1	R@10	Mean r.	R@1	R@10	Mean r.
VSE	37.6	85.8	6.9	38.5	82.3	7.7	30.7	76.7	8.8
VSE++	45.7	89.1	5.5	45.9	82.3	7.2	42.3	80.0	7.6
VSE-C (+n.)	49.2	88.4	5.7	42.1	80.3	9.1	40.4	83.3	7.1
VSE-C (+num.)	**51.0**	**89.5**	6.1	**53.3**	**90.2**	5.8	49.0	87.0	6.6
VSE-C (+rel.)	48.0	88.8	**5.3**	45.4	83.9	6.7	**50.1**	**90.2**	**4.9**
VSE-C (+all.)	49.4	89.3	**5.3**	49.9	89.6	**5.2**	47.9	89.4	5.3

Table 3: Detailed results on each type of adversarial attack. Training VSE-C on one class gains the best performance on robustness against the adversarial attack of the class itself. In addition, training with numeral-typed adversarial samples helps improve the robustness against noun-typed and relation-typed attack. We hypothesis that this is attributed to the singularization or pluralization of the corresponding nouns in the process of numeral-typed adversarial sample generation.

Model	MS-COCO Test (plural split, +plurals)		
	R@1	R@10	Mean r.
VSE++	43.7	78.3	9.1
VSE-C (+num.)	**50.6**	**84.4**	**7.8**

Table 4: Results on plural-typed adversarial attack to the plural split of MS-COCO test set. This split consists of 205 images, together with the 1,025 original captions. VSE-C outperforms VSE++ by a large margin on all the three considered metrics.

singular or plural) of nouns to make a sentence plausible. Does the gain comes from the improved ability to distinguish singulars and plurals?

We conduct the following evaluation to study the counting ability. We extract all the images associated with captions including plurals from our test split of MS-COCO, forming a plural-split of the dataset, and generate only plural (numeral)-typed contrastive adversarial samples (changing the numerals) w.r.t. the plurals in the captions. We report the performance of VSE++ and numeral-typed VSE-C on this plural split in Table 4. It clearly shows that what VSE-C does not only distinguish singulars against plurals, but also, at least, distinguish plurals against other plurals (*e.g.*, 3 vs. 5).

It is worth noting that such counting ability is still not evaluated completely due to the limitation of the current MS-COCO test split. We find that 99.8% of the plurals in MS-COCO test set comes from one of "two", "three", "four" and "five". This may reduce the counting problem to a much simpler classification one.

Figure 2: Saliency analysis on adversarial samples. The left column shows the saliency of VSE-C on the image (what is the difference between the image and the image you imagine from caption c'), while the right column shows the saliency of both VSE++ and VSE-C on the caption (what is the difference between the caption and the caption you summarize from image i). The magnitude of values indicates the level of saliency. For better visualization, the image saliency is L_{inf}-normalized and the caption saliency is L_1-normalized. For all the three classes of textual adversarial samples, the image encoding model (ResNet-152) almost only focuses on the main part of the image, *i.e.*, elephant. For numeral-typed and relation-typed adversarial samples, VSE-C pays much more attention to the manipulated segments of the sentence than VSE++.

4.2 Saliency visualization

Given an image-caption pair and its corresponding textual adversarial samples, we are interested in the following question: what is the semantic distance between the image an adversarial caption? In other words, *which part in the image or caption, in particular, makes them semantically different?*

We visualize the saliency on input images and captions w.r.t. changes in sentence semantics. Specifically, given an image-caption pair (i, c), we manually modify the semantics of the caption c with the techniques introduced in Section 3.2, and obtains $c' \neq c$. We compute the saliency of i or c' w.r.t. this change by visualizing the Jacobian:

$$\mathbf{J} = \nabla_i s(i, c') = \nabla_i W_i^T f(i; \theta_i) \cdot W_c^T g(c'; \theta_c), \tag{4}$$

where $s(i, c')$ is the similarity metric for image-caption pairs.

Shown in Figure 2, as for captions, VSE-C captures the change in sentence semantics and thus possesses large saliency on the manipulated words. In contrast, although trained with hard-negative mining, it is difficult for VSE++ to capture differences other than nouns.

Interestingly, the saliency of images shows less correlated response to semantics changes while the replaced word is not the major component in the image. We attribute this to the image embedding extractor, ResNet, because it is pre-trained on the ImageNet classification task. As the ResNet learns to produce shift-invariant features focusing on the major components (or concepts) of images, it inevitably learns less about secondary (and other) concepts.

4.3 Correlate words and objects

As only textual adversarial samples are provided during the training, the model may overfit the training samples by memorizing incorrect co-occurrence of words or concepts. To quantitatively evaluate the

Image	Captions
	A table with a huge glass vase and fake flowers come out of it. A plant in a vase sits at the end of a table. A vase with flowers in it with long stems sitting on a table with candles. A large centerpiece that is sitting on the edge of a dining table. Flowers in a clear vase sitting on a table.
Positive Objects: table, plant, vase. **Negative Objects**: screen, pickle, sandwich, toy, hill, coat, cat, etc.	

Table 5: An example of the image-to-word retrieval dataset. We extract objects by detecting heads of noun phrases in captions. We only collect the "object" words with frequency higher than 200 in MS-COCO full dataset as available positive/negative objects for each image.

learned word embeddings, we conduct experiments on word-level image-to-word retrieval. Specifically, we first examine how each noun is linked with a visual object. This task shows the concrete link between words and image concepts, which supports the effectiveness of adversarial samples in enforcing the learning of visually-grounded semantics beyond co-occurrence memorizing.

Dataset Based on captions, we extract *positive objects* for each image in MS-COCO dataset by detecting heads of noun phrases using SpaCy. As mentioned in Section 3.2, we only let those objects without direct hypernymy/hyponymy relation to positive objects of the image be *negative objects* to avoid ambiguity. Table 5 shows an example of the preparation of image-object dataset.

Training Inspired by Gong et al. (2018), we train an image-word alignment network through the interaction space, since this structure reflects the property of "alignment" better than just concatenating the feature vectors of word and image. In the training stage, the network is fed by batches of samples in the form of (image, word, label), where the label is 0 or 1, indicating whether the word is a negative or positive object of the image. Let $\mathbf{v}_W(w)$ denote the embedding of word w and $\mathbf{v}_I(img)$ denote the feature vector of image img extracted by ResNet-152 (He et al., 2016). As shown in Figure 3, we use the full interaction matrix $\mathbf{v}_W(w)\mathbf{v}_I(img)^T$ as the feature for object retrieval. While fixing both the image and word features, we only tune the parameters of multi-layer perceptron (MLP).

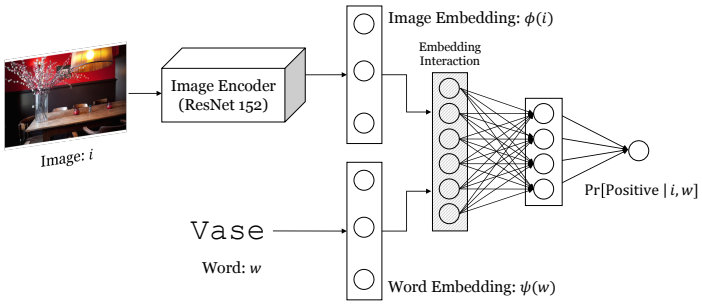

Figure 3: Model structure for image-to-word retrieval. The network is trained though the interaction space. Note that only parameters in MLP are tuned during training.

Model	MAP
GloVe	58.69
VSE	61.65
VSE++	61.08
VSE-C (+all)	62.16
VSE-C (+n.)	**62.80**
VSE-C (+rel.)	62.29
VSE-C (+num.)	61.96

Table 6: Evaluation result (MAP in percentage) on image-to-word retrieval.

Testing We use mean average precision (MAP), which is a widely-applied metric in information retrieval, to evaluate the performance of the word embeddings. For each image, we treat it as a query. The average precision (AP) is defined by

$$AP = \frac{\sum_{k=1}^{n} P(k) \times positive(k)}{\text{number of positive objects}} \tag{5}$$

where n is the quantity of objects in data base, *i.e.*, both positive and negative objects, $P(k)$ is the precision at cut-off k in the list, $positive(k)$ is an indicator function equaling 1 if the object at rank k is a positive one, 0 otherwise (Turpin and Scholer, 2006).

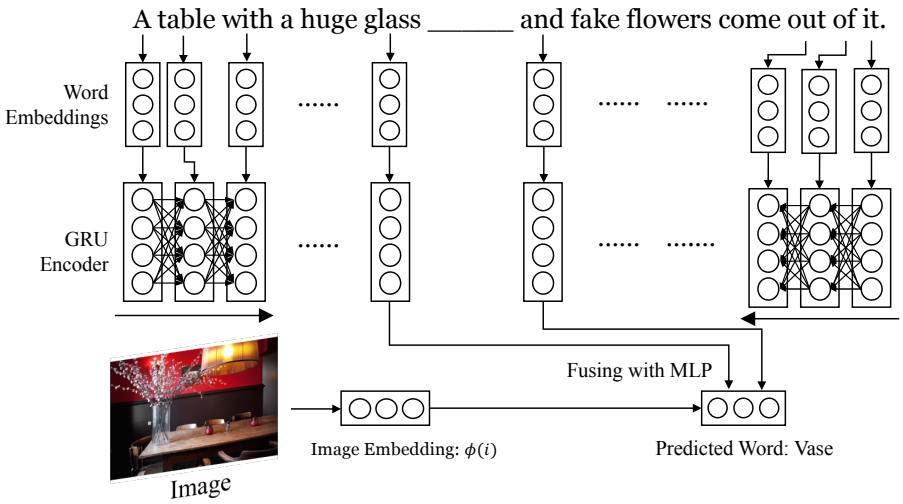

Figure 4: Model structure for fill-in-the-blank.

Based on the definition of AP, MAP can be computed by $MAP = \frac{\sum_{i=1}^{|Q|} AP(i)}{|Q|}$, where Q is the query set, *i.e.*, image set. It is worth noting that the database for retrieval of each query may be different from others, which is similar to Section 4.1.

Results We show the evaluation results in Table 6. It is as expected that VSE-C (+n.) achieves the best performance in the image-object retrieval task. All of the VSE-C models outperform the baselines produced by VSE (Kiros et al., 2014), VSE++ (Faghri et al., 2017) and GloVe (Pennington et al., 2014), showing the concrete link between learned word semantics and visual concepts. With surprise, VSE-C with only relation adversarial samples shows comparable performance as VSE-C with noun adversarial samples. This further supports the effectiveness of sentence-level manipulation (relation-shuffle in Figure 1) on strengthening the link.

4.4 Concept to word

We quantitatively evaluate the performance of concept-to-word retrieval performance by introducing a sentence completion task. Given an image-caption pair (i, c), we manually replace concept words (nouns and relational words) with blanks. A separate model is trained to fill in the blanks.

Dataset and implementation details Based on captions, we extract nouns and relational words from captions for each image in MS-COCO dataset using SpaCy. These selected words are marked as "concept" representatives. During training, we randomly sample a word from the representative set, and the word is masked as a blank to be filled. Given the image and the rest of the words, the model is trained to predict the embedding of the word.

Model The sentences with blank are encoded by two mono-directional GRU layer. The words before the blank and after the blank are separately encoded using GRU_f and GRU_b respectively. The image feature extracted from a pre-trained ResNet152 is then concatenated with the last output of both GRUs. The prediction of embedding is made by a two-layer MLP taking in the concatenated feature. We use cosine similarity as the loss function. Figure 4 shows the demonstration of our fill-in-the-blank model.

Results We present in Table 7 the performance of the proposed VSE-C on filling in both nouns and prepositions. VSE-based models outperform GloVe without visual grounding and concretely correlate word semantics with image embeddings. We found that only small gaps exist between VSE++ and VSE-C on preposition filling, which again shows the limited diversity on visual relations within the dataset.

Model	Noun Filling		Prep. Filling		All (n. + prep.)	
	R@1	R@10	R@1	R@10	R@1	R@10
GloVe	23.22	58.75	23.34	79.92	23.27	66.55
VSE++	24.98	61.74	34.88	84.88	28.44	68.12
VSE-C (ours)	**27.30**	**62.87**	**35.17**	**85.24**	**30.02**	**70.98**

Table 7: Evaluation result on the fill-in-the-blank task (in percentage). The word embeddings learned by VSE-C with all classes of contrastive adversarial samples help reach a better performance than those learned by VSE++ (Faghri et al., 2017).

5 Discussion and conclusion

In this paper, we focus on the problem of learning visually-grounded semantics using parallel image-text data. With extensive experiments on adversarial attacks against existing frameworks (Kiros et al., 2014; Faghri et al., 2017), we obtain new insights on the limitation of datasets as well as frameworks. (1) Even for large-scale datasets such as MS-COCO captioning, the large gap between the number of possible constitutions of real-world visual semantics and the size of dataset still exists. (2) Existing models are not powerful enough to fully capture or extract the information contained in visual embeddings.

We propose VSE-C, introducing contrastive adversarial samples in the text domain and an intra-pair hard-example mining technique. To delve deeper into the embedding space and its transferability, we study a set of multi-modal tasks both qualitatively and quantitatively. Beyond being robust to adversarial attacks on image-to-caption retrieval tasks, experimental results on image-to-word retrieval and fill-in-the-blank reveal the correlation between the learned word embeddings and visual concepts.

VSE-C also demonstrates a general framework for augmenting textual inputs considering semantical consistency. The introduction human priors and knowledge bases alleviates the sparsity and non-contiguity of languages. We hope the framework and the released data are beneficial for building more robust and data-efficient models.

Table 8 shows our manually annotated semantic overlap sets. Prepositions in each row has overlap in semantics, *i.e.*, can be replaced by each other in some level. A preposition can appear in several sets.

B Training Details of VSE-C

In all experiments, we use Adam (Kingma and Ba, 2015) as the optimizer of which the learning rate is set to 1e-3, with the batch size of 128. The learning rate is updated by multiplying 0.1 after every 15 epochs. We do not apply any regularization or dropout term. Word embeddings are initialized with the 300-dimensional GloVe (Pennington et al., 2014)[1]. The text encoder is a bidirectional 512-dimensional (in total 1024D) 1-layer GRU. The dimensionality of joint (multimodal) embedding is also 1,024. Empirically, with training data and hyper-parameters fixed, there is no significant variance in performance caused by different random seeds for the sampling.

Abstract

Online debates can help provide valuable information about various perspectives on a wide range of issues. However, understanding the stances expressed in these debates is a highly challenging task, which requires modeling both textual content and users' conversational interactions. Current approaches take a collective classification approach, which ignores the relationships between different debate topics.

In this work, we suggest to view this task as a representation learning problem, and embed the text and authors jointly based on their interactions. We evaluate our model over the Internet Argumentation Corpus, and compare different approaches for structural information embedding. Experimental results show that our model can achieve significantly better results compared to previous competitive models.

1 Introduction

In recent years, social media platforms play an increasingly important role in shaping political discourse. Online debate forums allow users to voice their opinions and engage with other users holding different views. Understanding the interactions between the users on these platforms can help provide insight into current political discourse, argumentation strategies and can help gauge public sentiment on policy issues on a large scale. The importance of understanding debate dialog has motivated significant research efforts (Somasundaran and Wiebe, 2010; Anand et al., 2011; Ghosh et al., 2014; Walker et al., 2012b; Hasan and Ng, 2013; Sridhar et al., 2015; Mohammad et al., 2016; Dong et al., 2017).

In this paper, we focus on stance prediction, automatically identifying the stance expressed in debate posts on various issues. For example, Figure 1 describes a short debate dialog about marijuana legalization between three users (denoted a_1, a_2, a_3). The content associated with each user is classified as supportive of legalization (PRO), or not (CON).

Author	Discussion Text	Stance
a_1	*"There are no deaths related to the actual use for marijuana this past year"*	Pro
a_2	*"Whether it kills people or not, it still is harmful to your body."*	Con
a_3	*"There are many things that are harmful. Alcohol is more harmful than marijuana.*	Pro
a_2	*"But that doesn't mean marijuana should be made legal because the other two are."*	Con
a_3	*"If we were to make everything illegal because it was harmful we would be living with nothing."*	Pro

Figure 1: Example of excerpts from a debate between three users about marijuana legalization.

Proceedings of the 27th International Conference on Computational Linguistics, pages 3728–3739
Santa Fe, New Mexico, USA, August 20-26, 2018.

Early work took a text classification approach (Somasundaran and Wiebe, 2010; Anand et al., 2011), classifying individual posts using a rich feature set. Since debate posts are not written in isolation, but rather express the conversational interactions between users, modeling these interactions can help alleviate some of the difficulty of this task. More recent work take a collective classification approach (Hasan and Ng, 2013; Sridhar et al., 2015), which models the dependencies between authors and their content and captures the debate structure. For example, the interactions between users can express *agreements* (or *disagreements*), which would entail a similar (or different) stance prediction associated with their content. The stance decision can also be considered as a user level decision, as users tend to maintain the same stance throughout the debate, forcing stance agreement between all of their posts. Unfortunately, despite these efforts, stance classification remains a challenging problem.

In this paper we suggest a new approach for representing the structural dependencies of debate dialogs, by taking a *structured representation learning* approach. Intuitively, our system is designed to exploit the advantages of collective relational classification methods (often discussed in the context of graphical models) and distributed representation learning (often discussed in the context of deep learning and embedding). We suggest a method for combining the two approaches in a single framework that can exploit their complimentary strengths.

Our key intuition is that the embedding function can be trained to respect the relevant structural dependencies. We jointly embed all the debate objects (i.e., authors, stances and textual posts), by considering the relationships between these objects. For example, we model stance classification as a relationship between a post and a given stance label, by measuring the similarity between their embedded representations. We can also model the relationships between input objects; the similarity between the representations of two posts would entail agreement between the labels associated with them, thus allowing us to perform collective classification over all the input instances. Specifically, we define the factor graph corresponding to the dependencies between stance predictions in a debate thread, and use the similarity between the embedded representation of objects as a scoring function for the factors. We explain this process in more detail in Section 3.

The main strength of distributed representations is in their ability to share information between the represented objects. We exploit this property, and show that by adding additional information to the embedding space, the overall performance of the model improves, *even if this information is not directly relevant to the classification task*. We demonstrate this fact by comparing stance prediction performance, when trained over the multiple topic separately or jointly (thus allowing the model to share information between the representations of multiple debate topics).

We evaluate our approach over the Internet Argument Corpus (Walker et al., 2012a; Abbott et al., 2016), collected from two debate websites,CREATEDEBATE and 4FORUMS. We conduct several experiments, both using in-domain data and out-of-domain data (when we train and test on different debate topics). Our experiments show that formulating the problem as structured representation learning indeed allows debate entities to share information and generalize better, resulting in even larger improvements when multiple stances (corresponding to different output labels) are trained jointly. Furthermore, we show that by using inference over the relationships between the learned representations we can outperform traditional collective classification methods.[1]

Our contributions include (1) joint relational embedding for debate entities, allowing the model to share information between related topics and underlying ideologies (2) suggest a collective classification approach, defined over the embedding space, and using it to cast representation learning as a structured prediction problem, and (3) an extensive experimental study in which we evaluate several different modeling choices and information sharing scenarios.

2 Related Work

Stance prediction in online debates is an important subjectivity classification task. Early work viewed the problem as a binary classification task and focused on feature representations (Somasundaran and Wiebe, 2010; Anand et al., 2011), while later work took a collective approach (Walker et al., 2012b;

[1]Please refer to `https://github.com/BillMcGrady/StancePrediction` for data and source code.

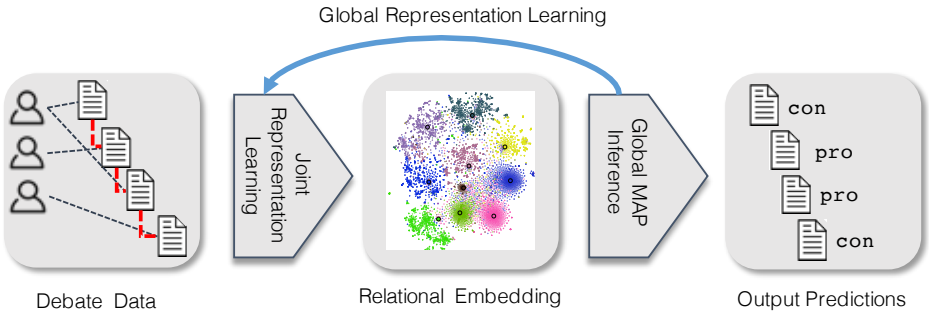

Figure 2: Overall Learning and Inference Processes

Hasan and Ng, 2013; Sridhar et al., 2015). Stance prediction is not limited to online debates, as was also studied in the context of congressional speeches (Bansal et al., 2008; Burfoot et al., 2011) and social media outlets, such as Twitter (Johnson and Goldwasser, 2016; Augenstein et al., 2016; Ebrahimi et al., 2016), including a recent SemEval-16 task (Mohammad et al., 2016). While most work view the task as supervised classification tasks, several work suggest exploiting the interactions between users as a form of distant supervision (Johnson and Goldwasser, 2016; Dong et al., 2017). This task is broadly related to argumentation mining (Ghosh et al., 2014) and stance reason classification (Hasan and Ng, 2014).

Our technical work relies on exploiting distributed representations (i.e., embedding), building on highly influential work on embedding words (Mikolov et al., 2013b; Pennington et al., 2014), sentences (Kiros et al., 2015) and even full documents (Le and Mikolov, 2014). Our work explores the connections between text, users and attributes, attempting to create a common representation for the them. The closest to our work is (Li et al., 2015), that jointly integrates different kinds of cues (text, attribute, graph) into a single latent representation to get user embeddings.

Our work is also broadly related to deep learning methods that capture the structural dependencies between decisions. This can be done either by modeling the dependencies between the hidden representations of connected decisions using RNN/LSTM (Vaswani et al., 2016; Katiyar and Cardie, 2016), or by explicitly modeling the structural dependencies between output predictions (Durrett and Klein, 2015; Lample et al., 2016; Andor et al., 2016). Unlike these work, we formulate our problem as a structured representation learning problem, which to our knowledge is the first work to identify the ties between the two problems.

3 Model Overview

In this paper we suggest casting stance classification as a structured representation learning task. Our approach revolves around two key ideas.

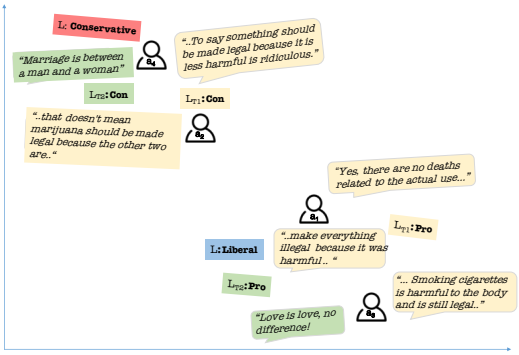
First, stance classification can be done by embedding both the input objects (i.e., posts) and the output labels in the same space. The actual classification is performed by comparing the similarity between the embedded representations of an input object and the competing output labels.

Second, we can augment this representation with additional structural constraints, capturing relevant domain information, such as the connection between posts by the same author, the disagreements between debate participants.

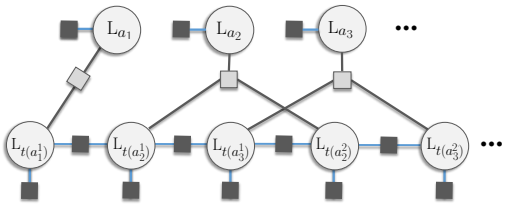
To help clarify these ideas intuitively, consider the debate dialog in Figure 1. Our learning approach uses the structural and textual information in the dialog in three ways, as shown in the process depicted in Figure 2.

1. Joint Representation Learning The embedding learning objective is designed to represent relevant relational information, allowing the representation of different input objects to share information. For example, stances on different topics may share a similar ideology. Figure 3a demonstrates the joint embedding space. The relationship between authors and their posts is preserved by the proximity of their embedded representations. Similar relationships between posts and their corresponding stances and

underlying ideologies are also represented. To accomplish this goal we define a joint objective function over different relations.



(a) Relational embedding representing authors, stances and posts on various topics in the same embedding space



(b) Collective decision over debate thread structure and authors

Figure 3: Model Overview Demonstration

The model is trained to maximize the similarity between corresponding entities (positive examples) compared to irrelevant ones (negative examples). We define the positive examples based on relational information, and negative examples to capture disagreements between authors and posts. We explain this process in detail in Section 5.

2. Global MAP Inference (Collective Classification) Representing the input objects and their labels in the same embedding space allows us to reason about the relationships between them. We view the prediction task as a collective classification, in which all the posts in one or more given debate threads are decided together. We model inference required for the MAP assignment using a factor graph. For example, the graph described in Figure 3b, contains nodes corresponding to author level stance decisions (denoted L_{a_i}), their posts levels stance decision (denoted $L_{t(a_i^j)}$). We score these decisions using the learned embedding. For example, scoring the output assignment PRO to the post corresponding to $L_{t(a_i^j)}$ will be done by observing the similarity (dot product) between their vectorized representations v_{PRO} and $v_{t(a_i^j)}$.

Factor nodes can either have a degree of 1 (scoring the similarity between an author or post and an output label), or 2 (scoring the relationship between consecutive posts in a debate discussion thread). We also allow hard constraints (light gray factors in Figure 3b), which force the model to produce consistent assignments.We explain this process in detail in Section 4.

3. Global Representation Learning A natural extension is to combine the previous two steps, and adopt a global training approach that uses joint prediction during training. In this case the loss function used when learning the embedding is defined with respect to the structural dependencies imposed by the factor graph. This approach is similar in spirit to deep structured learning approaches (Andor et al., 2016), however, in this case the structured learning process is defined directly over the embedding space. This process is explained in Section 5.5.

4 Collective Classification

Our joint embedding model maps authors, attributes, and text into the same space. Thus it allows us to compute the similarity between any pair of authors, texts, attributes, or their combination. This is a very useful property, as information from all aspects can now be used for predicting the target of interest. For example, more information are available for identifying the stance of a post by using its author and neighboring posts comparing to the post's embedding alone. We exploit this property by defining the classification as a global inference process, enforcing the constraints and preferences on all of the predictions.

ILP Formulation We exploit the dependencies described above, using joint prediction over the different aspects. We formulate the decision as an Integer Linear Programming (ILP) which allows us to enforce the consistency or preferences between decisions. The ILP objective function is defined over the similarity scores between objects' vector representation in the joint embedding space. Since integer linear constraints over 0-1 variables can represent logical constraints, we define the ILP constraints using both representations to help improve readability.

In the stance prediction task, all the posts from multiple debate threads that potentially share authors form a single ILP instance. The ILP global optimization objective is defined over authors a_i, the textual content (posts) $\{t_i^0, ..., t_i^k\}$ associated with a_i, and other textual posts $\{t_m^p, ..., t_l^q\}$, responding to or responded by a_i's posts.

We create different types of boolean decision variables corresponding to the decision tasks above. We assign a boolean variable $\texttt{AuthorLabel}(a_i, r_j)$ to represent author a_i has attribute r_j (i.e., its stance), and associate a score $sim(e_{a_i}, e_{r_j})$ with that variable. Similarly, we assign a boolean variable $\texttt{TextLabel}(t_i^k, r_j)$ to represent that the text t_i^k is labeled with an attribute r_j, and associate a score $sim(e_{t_i^k}, e_{r_j})$ with that variable.

To ensure the consistency of the predicted variables, we define two types of constraints.

1. *Single output value on a debate topic*:

$\forall i \ \sum_j \texttt{AuthorLabel}(a_i, r_j) = 1$

$\forall i, k \ \sum_j \texttt{TextLabel}(t_i^k, r_j) = 1$

2. *Output consistency*:

$\forall i, j, k \ \ \texttt{AuthorLabel}(a_i, \ r_j) = \texttt{TextLabel}(t_i^k, \ r_j)$

Note that in the debate domain, this constraint forces agreement between all the posts by the same author.

We also add variables capturing the dependencies between connected posts. For debate threads, a boolean variable $\texttt{Disagree}(t_i^p, t_l^q)$ is created for any two posts t_i^p, t_l^q when t_l^q is a response to t_i^p, and associate a score $disagree\_parameter$ with that variable. This score is a hyper-parameter for local models, capturing the preference towards disagreement between consecutive posts in a debate. It is set according to the training set. When using global learning, it is also included in training, such that similarity scores of consecutive posts will be adjusted appropriately (similar intuition as a margin constraint).

$$\forall t_i^p, t_l^q \ \texttt{Disagree}(t_i^p, t_l^q) \wedge \texttt{TextLabel}(t_i^p, r_j) \rightarrow \neg \texttt{TextLabel}(t_l^q, r_j)$$

The set of all possible decisions for the three set of variables are denoted as A for $\texttt{AuthorLabel}$, B for $\texttt{TextLabel}$, Γ for $\texttt{Disagree}$.

Given these variables, our prediction function can be define as follows -

$$\arg\max_{\alpha,\beta,\gamma} \sum_{\alpha \in A} \alpha \cdot score(\alpha) + \sum_{\beta \in B} \beta \cdot score(\beta) + \sum_{\gamma \in \Gamma} \gamma \cdot score(\gamma)$$

Subject To **C**

Where **C** is a set of constraints defined above.

5 Representation Learning

5.1 Embedding Perspectives

Let A and T denote the set of all authors and text respectively, let R denote the set of all attributes for those authors and text. Stance on various topics are the major attributes considered in this paper. For each topic, we have an embedding vector for the Pro stance and another vector for the Con stance, such as $Pro_{abortion}$ and $Con_{abortion}$. We train our embedding over multiple views of the data, each view connecting users and their content.

Author vs. Text: This objective is to predict text t_j linked with author a_i given the author representation. Each post is a text unit in our experiments.

$$L_{AT} = \sum_{i=1}^{n} \sum_{j=1}^{text_{a_i}} logP(t_j|a_i) \tag{1}$$

Author vs. Attribute: This objective is to predict attribute r_j linked with author a_i given the author representation. Stance on different topics and user profile information form the attributes set in debate datasets. Each user attribute value (e.g. male or female in gender attribute) is represented by a vector.

$$L_{AR} = \sum_{i=1}^{n} \sum_{j=1}^{attri_{a_i}} logP(r_j|a_i) \tag{2}$$

Text vs. Attribute: This objective is to predict attribute r_j of the text given text t_i. In our experiments, we only used the stance label as attributes of text. However, it may also be possible to inherit attributes from the author of the text.

$$L_{TR} = \sum_{i=1}^{m} \sum_{j=1}^{attri_{t_i}} logP(r_j|t_i) \tag{3}$$

Text vs. Text: This objective is to predict text t_j given the text t_i that share the same attribute. It is used to promote similarity between posts sharing the same stance on a certain topic.

$$L_{TT} = \sum_{i=1}^{m} \sum_{j=1}^{text_{t_i}} logP(t_j|t_i) \tag{4}$$

All the conditional probabilities can be computed using a softmax function. Taking $P(t_j|a_i)$ as an example:

$$P(t_j|a_i) = \frac{exp(e_{a_i}^T e_{t_j})}{\sum_{k \in T} exp(e_{a_i}^T e_{t_k})}$$

5.2 Embedding Initialization

In our model, the embedding for each author and attribute can be randomly initialized. The text is a special case since there are complex structures involved. One way to capture this is to use an pre-trained text embedding model to get an initial representation, and then learn an neural network to map it to one in the shared space. Note that this also allows our model to generate embedding for unseen text in the new space.

Specifically, for a text input x, we can compute its embedding e using M hidden layers $l_i, i = [0, M-1]$. The first hidden layer l_0 is computed from the input x:

$$l_0 = f(W_0 x + b_0)$$

Subsequent layers are computed recursively:

$$l_i = f(W_i l_{i-1} + b_i), i = 1, ..., M-1$$

Then the output from the final layer produces the embedding:

$$e = l_{M-1}$$

f is the non-linear activation function. We used hyperbolic tangent (tanh) in our experiments.

Note that our model offers the flexibility to use more complex neural network structures, including CNN and RNN, to learn a mapping from the initial word embedding sequences of the text to an embedding in the joint space.

5.3 Joint Embedding Learning

Our objective is to learn a semantic embedding for authors, text and attributes associated with them so that they are close in the embedding space if they are semantically close to each other.

Joint Embedding Loss Function: We can combine these embedding losses from Equations 1-4 into a joint training objective:

$$L_{Joint}(A, T, R) = \sum_{i \in (AT, AR, TR, TT)} \lambda_i L_i \tag{5}$$

where λ_i is the coefficient for each view, indicating the relative importance in the loss function. We set all λ_i to the default value 1 in all our experiments.

This is the general framework. Additional views may be added or removed for a certain dataset. For example, we can add a term representing the author vs. author view in the loss function if links between them are available.

5.4 Model Optimization

We train our model using mini-batch Adam optimizer to minimize the loss in Eq.5. However, computing gradient for Eq.1, and Eq.4 is expensive due to the size of the authors or text. To address this problem, we refer to the popular negative sampling approach (Mikolov et al., 2013a), which reduce the time complexity to be proportional to the number of positive example pairs.

5.5 Global Embedding Learning

Although different views of the data are captured in our joint loss function, it does not ensure that the information they provide at inference time will be "cooperative", i.e., it will result in consistent global prediction over all the debate outputs. One potential problem is that examples associated with one view will dominate the training and skew the prediction, when constraints are applied. To handle this issue, we included the inference procedure during training. Instead of making sure the loss for each local view is minimized, the global objective promotes the rank of all the gold predictions *jointly*. For instance, at training, posts, together with their author and neighboring posts (if available) are used to infer their stance based on the inference procedure described in section 4. Then structured hinge loss can be used to define the prediction loss as in Eq.6.

$$L_{pred} = \sum_{i \in instances} max(0, max_{y \in Y}(\Delta(y, t_i) + score(x_i, y)) - score(x_i, t_i)) \tag{6}$$

where x_i and t_i are the problem instances and corresponding gold predictions, Y denotes all possible predictions, and score$(\cdot)$ is the inference score function. $\Delta(\cdot, \cdot)$ is the hamming loss. It measures the difference between two predictions and is used to create a margin between gold and other predictions.

The loss function used for updating the parameters in the global model is defined as follows.

$$L_{Global} = \lambda_{pred} L_{pred} + \lambda_{AT} L_{AT} + \lambda_{TT} L_{TT} \tag{7}$$

The coefficients for different terms in the global loss function can adjust the contribution of prediction objective (L_{pred}) versus information sharing objective (L_{AT} and L_{TT}). Again, we set all λ to the default value 1 in experiments of this paper. We leave the exploration of different coefficient settings to future work. Since the inference is used during global training, the scores for text stance and author stance are part of the inference scores. So they will get updated according to L_{pred}. Therefore we do not include L_{AR} and L_{TR} explicitly in the global loss function.

In our experiments, a mini-batch of debate threads is regarded as an instance during training. To reduce the computational cost, we used the parameters learned with the joint embedding loss function as the starting point for the global training.

Dataset	Topic	Posts	Users
CREATEDEBATE	Abortion	1741	340
	Gay Rights	1376	370
	Marijuana	626	258
	Obama	985	278
4FORUMS	Abortion	7937	342
	Evolution	6069	311
	Gay Marriage	6897	296
	Gun Control	3755	281

Table 1: Data Statistics for 4FORUMS and CREATEDEBATE

6 Experiments

To evaluate the different properties of our model and demonstrate their advantages, we evaluate the quality of our structured embedding model on two datasets 4FORUMS and CREATEDEBATE for stance classification tasks at post level, consisting of eight topics in total. The datasets are taken from the Internet Argumentation Corpus (Abbott et al., 2016). Table 1 shows statistics about these datasets.

Experimental Design Our experiments are designed to evaluate the different properties of our model. To accomplish that, we compare different variations of the model, corresponding to (1) only the joint embedding (denoted *Joint*), (2) using inference at test time, over the joint embedding (denoted *Inference*), and (3) using global training (denoted *Global*), which also uses inference during training. We report the results of these experiments in the two datasets in Tables 2 and 3.

Our second set of experiments are designed to evaluate the joint embedding model's ability to share information between the representations of different objects. In this case we compare the performance of the *Joint* and *Inference* models when additional information is available. We compare three settings (1) In-Domain, when the available training and testing data are from the same domain (2) In+Out Domain, where we augment the In-Domain training data with additional debate threads from other topics. In this case the model can represent the relationships between stances on different topics and potentially generalize better. Finally, (3) User-Attribute, where we augment the author attributes with profile information extracted from the debate website. We conduct all of these experiments over the CREATEDEBATE dataset, and report the results in Table 4.

6.1 Experimental Settings:

We used PyTorch (Paszke et al., 2017) to implement the embedding model and Gurobi (Gurobi Optimization, 2016) as our ILP solver. Each debate post is initially represented using the Skip-Thought Vectors (Kiros et al., 2015), and then mapped to an embedding in the shared space through one hidden layer. We do not add more layers as both datasets are relatively small. Hyperbolic tangent (tanh) is used as non-linear activation function. All other embeddings are randomly initialized following a normal distribution with variance $1/\sqrt{dim}$. The embedding size dim for all experiments is 300. For the training of the neural network, we used mini-batch Adam optimizer to update parameters. Dropout with probability 0.7 is used as regularization. The termination criteria is convergence on training loss. Five epoch of non-improvement on loss is considered as convergence for joint models, and one epoch for global models. Other parameters in our model includes negative sample size k=5, mini-batch size b=10.

6.2 Results

Our results on stance classification are described in Table 2 and Table 3. The results are computed using 5-fold cross-validation. For the CREATEDEBATE dataset, We used the same five data folds as in (Hasan and Ng, 2013) to ensure our results are directly comparable with theirs. For the 4FORUM dataset, we randomly divided debate threads into five folds since the data split is not available in (Sridhar et al., 2015). We regarded the same user in the training and test folds as different ones to avoid leaking label

Model	Abortion	Gay Rights	Marijuana	Obama	Average
Majority	56.2	64.5	72.0	56.1	62.2

Table 3: Average Accuracy on 4FORUMS dataset

information from training to test. *NB* and *CRF* stands for the best local and collective models in (Hasan and Ng, 2013). Note that their system also uses the author constraints, as well as a highly engineered feature set and additional weakly-supervised data that we did not use. Despite that fact, our global model significantly outperforms their model with the exception of Obama domain. In the 4FORUM experiments we compare our models to result with *PSL* based model (Sridhar et al., 2015) which performs similar collective classification defined over a feature-rich representation. In this case as well, our Global model achieves the best overall performance.

We evaluate the contribution of two constraints sets, Author constraints (*AC*) enforce author and their posts share the same stance. *Consecutive* will encourage disagreement in stance between neighboring posts as introduced in section 3. The addition of these two constraints leads to significant increase in performance when used together. This is because AC and Consecutive add agreement and disagreement constraints between test posts, grouping them into clusters and making it easier to be predicted correctly. For instance, given multiple posts from the same author, the model can make correct decisions on all of them even if the prediction based on each individual post may be wrong. Finally, we observe that structured representation learning (i.e., Global) leads to a performance improvement compared to inference over the joint embedding objective (Inference). This shows the effectiveness of the global learning.

Table 4 shows the result on CREATEDEBATE when additional information is available. We extracted user profile information (User-Attribute) from the website[2], consisting of five attributes (Gender, Marital Status, Political Party, Religion, and Education). Clearly richer user information results in a better representation, both for users and as a result, also for the text they author, leading to improved performance. A similar trend occurs when out-of-domain data is available (In+Out Domain). Stances over different debate topics impact the text and author representations. Interestingly, when this data is available, our model is able to outperform the collective approach of (Hasan and Ng, 2013) in all debate topics, showing that our model can indeed exploit the information shared by the underlying ideologies.

7 Conclusions and Future Work

We study the problem of stance prediction, a challenging text classification problem, which requires connecting textual content analysis, conversational interactions and author information. Traditionally, this is done using a graphical model, which learns a scoring function for each aspect, over a fixed feature representation. We follow the observation that all of these problems are connected, and allow the model to capture these dependencies by allowing it to *learn* a representation for all these aspects jointly, rather than using a fixed representation. We show that by formulating the decision problem over the representation directly, and requiring the representation to respect the global dependencies between these aspects, our model can generalize better and exploit additional information even when it is not directly relevant.

To the best of our knowledge, this work is the first to cast representation learning as a structured prediction problem, we believe that this approach is applicable to many other domains where the input has complex inter-connected structure. Such domains can include other conversation analysis tasks, shared representations of text and images and information networks such as citations graphs and social network analysis. In the future we intend to study additional domains and evaluate whether including additional aspects, can help provide better generalization. Providing sufficient supervision is one of the main bottlenecks of NLP, we intend to apply our approach in weakly and distantly supervised settings, to help alleviate this difficulty.

Abstract

Multi-turn conversation understanding is a major challenge for building intelligent dialogue systems. This work focuses on retrieval-based response matching for multi-turn conversation whose related work simply concatenates the conversation utterances, ignoring the interactions among previous utterances for context modeling. In this paper, we formulate previous utterances into context using a proposed deep utterance aggregation model to form a fine-grained context representation. In detail, a self-matching attention is first introduced to route the vital information in each utterance. Then the model matches a response with each refined utterance and the final matching score is obtained after attentive turns aggregation. Experimental results show our model outperforms the state-of-the-art methods on three multi-turn conversation benchmarks, including a newly introduced e-commerce dialogue corpus.

1 Introduction

Human-computer interactive systems are booming due to their promising potentials and alluring commercial values (Qiu et al., 2017; Cui et al., 2017; Yan et al., 2017; Huang et al., 2018; Jia and Zhao, 2014). With the development of neural models (Zhang et al., 2018c; He et al., 2018; Li et al., 2018; Cai et al., 2018; Zhang and Zhao, 2018), building an intelligent dialogue system as our personal assistant or chat companion, is no longer a fantasy, among which multi-turn natural language understanding still keeps extremely challenging, requiring the system to comprehend the conversation context and reply in an informative and coincident manner.

Multi-turn conversation modeling plays a key role in dialogue systems, either for generation-based (Serban et al., 2017b; Serban et al., 2017a; Zhou et al., 2017; Wu et al., 2018) or retrieval-based ones (Wu et al., 2017; Zhou et al., 2016) in which the latter is the focus of this paper. A natural approach for multi-turn modeling is simply concatenating the context utterances (Lowe et al., 2015; Yan et al., 2016). However, this will introduce much noise since previous utterances as the context is lengthy and redundant. The gist is to identify pertinent information in previous utterances and properly model the utterance relationships to ensure conversation consistency. To avoid unnecessary information loss, (Wu et al., 2017) matches a response with each utterance in the context, paying little attention on distrinct importance of each utterance and also failing to touch internal semantics inside utterances.

In fact, the relevance of each utterance to the supposed response usually varies. As shown in Figure 1, the last utterance in a conversation empirically conveys the user intention while the other utterances depict the conversation in different aspects [1]. Thus, instead of considering all the conversation turns

Santa Fe, New Mexico, USA, August 20-26, 2018.

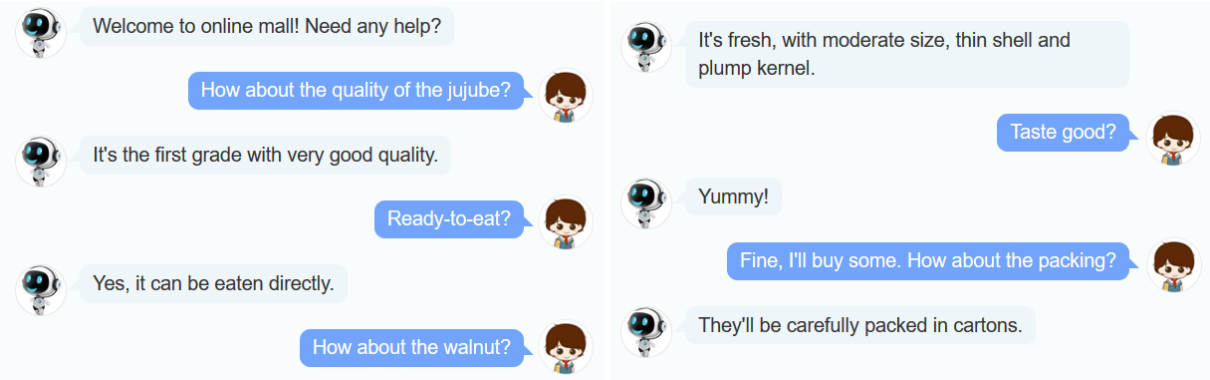

Figure 1: An example of E-commerce Dialogue Corpus.

equally, we have to weigh previous conversations in a more sophisticated way. With a turns-aware aggregation design, our model alleviates the drawback of previous work.

In addition, words in an utterance also hold different importance to the whole utterance representation. Our solution is to employ attention-based recurrent networks on each utterance against utterance itself, aggregating the vital pieces of the contextual utterances.

Finally, in conjunction with this paper, we release an E-commerce Dialogue Corpus (ECD) to facilitate the related studies. To our best knowledge, this is the first public e-commerce dataset for dialogue system development that is extracted from real human conversations. Different from previous datasets that only focus on a single type of dialogue like chitchat, this dataset is more comprehensive due to diverse types of conversations (e.g. *commodity consultation, logistics express, recommendation, negotiation* and *chitchat*) concerning various commodities. Our improved retrieval-based multi-turn dialogue response matching model is evaluated on three benchmark datasets, including our newly released one, giving state-of-the-art performance.

The rest of this paper is organized as follows. The next section reviews related work. Our proposed model is introduced in Section 3, then the experiments and analysis are reported in Section 4, followed by the conclusion in Section 5.

2 Related Work

With the impressive success of various referential natural language processing studies (Zhang et al., 2016; Cai and Zhao, 2017; Zhang et al., 2018d; Qin et al., 2017; Zhang et al., 2018b; Bai and Zhao, 2018), developing an intelligent dialogue system becomes realizable, which means training machines to converse with human in natural languages (Williams et al., 2017; He et al., 2017; Dhingra et al., 2017; Zhang et al., 2018a). Towards this end, a number of data-driven dialogue systems are designed (Lowe et al., 2015; Wu et al., 2017; Wen et al., 2017; Mei et al., 2017; Young et al., 2018; Lipton et al., 2018), in which modeling multi-turn conversation has drawn more and more attention. To acquire a contextual response, previous utterances are taken as input. Lowe et al. (2015) concatenated all previous utterances and last utterance as the context representation and then computed the matching degree score based on the context representation to encode candidate response. Yan et al. (2016) selected the previous utterances in different strategies and combined them with last utterance to form a reformulated context. Zhou et al. (2016) performed context-response matching with a multi-view model on both word level and utterance level. Wu et al. (2017) improved the leveraging of utterances relationship and contextual information by matching a response with each utterance in the context based on a convolutional neural network.

Different from previous studies, our model for the first time discriminates the importance of previous conversations and also accumulates substantial parts from each utterance according to each word in the utterance itself in a multi-turn scenario.

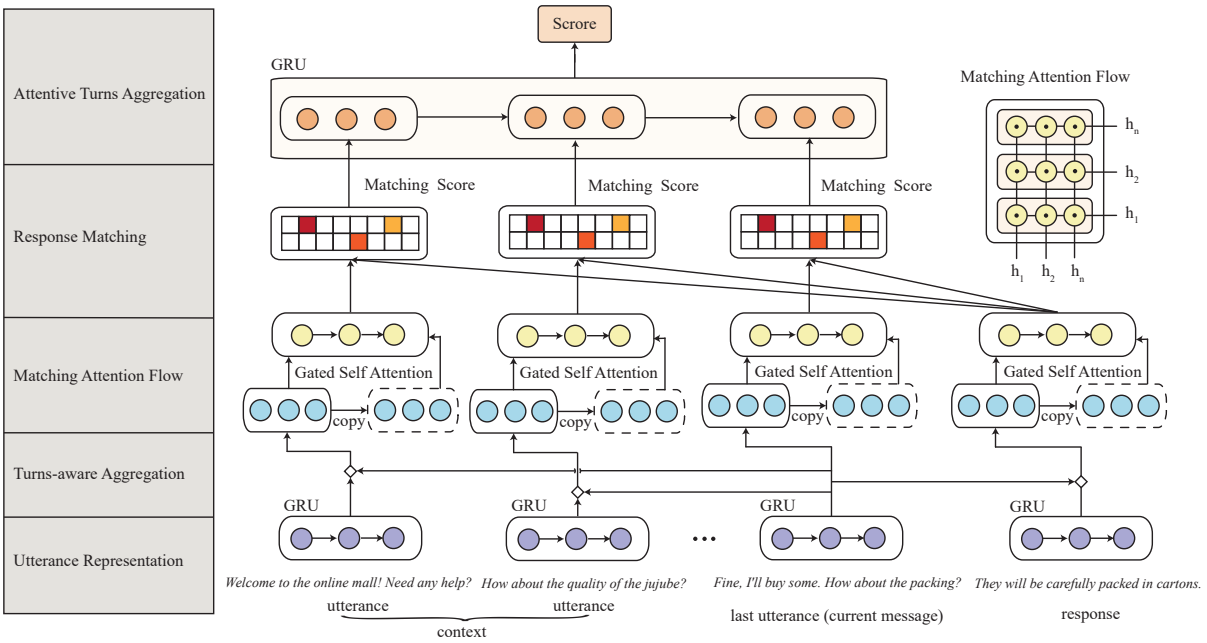

Figure 2: Structure overview of the proposed dialogue system.

3 Deep Utterance Aggregating Strategy

Each conversation in the concerned multi-turn response retrieval task can be described as a triple $< C, R, Y >$. $C = \{U_1, ..., U_t\}$ is the conversation context where $\{U_k\}$ denotes the k-th utterance. R is a response of the conversation and Y belongs to $\{0, 1\}$, where $Y_i = 1$ means the response is proper, otherwise $Y_i = 0$. The aim is to build a discriminator $\mathcal{F}(\cdot, \cdot)$ on $< C, R, Y >$. For each context-response pair $\{C, R\}$, $\mathcal{F}(C, R)$ measures the matching score of the pair.

In this section, we will introduce our Deep Utterance Aggregation (DUA) model for the multi-turn conversation task. Figure 2 shows the architecture. DUA formulizes utterances into the context and mines the key information from utterances and response. Then DUA conducts semantic matching between each utterance and the response candidate to obtain a matching score. Specifically, there are five modules within DUA. Each utterance or response is fed to the first module to form an utterance or response embedding. The second module combines the last utterance with the preceding utterances. Then, the third module filters the redundant information and mines the salient feature within the utterances and response. The fourth module matches the response and each utterance at both word and utterance levels to feed a Convolutional Neural Network (CNN) for encoding into matching vectors. In the last module, the matching vectors are delivered to a gated recurrent unit (GRU) (Cho et al., 2014) in chronological order of the utterances in the context and the final matching score of $\{U, R\}$ is obtained.

DUA is superior to existing models in the following ways. First, the last utterance which is the most important in dialogue is especially fused within preceding utterances, thus the key guideline information from the last utterance can be handled in a more semantically pertinent way. Second, in each utterance, the salient information can be highlighted and those redundant pieces will be neglected to some extent, both of which can effectively guide the later response matching. Third, after attentive turns aggregation, the connections in the conversation are accumulated again to calculate the matching scores.

3.1 Utterance Representation

To use deep neural networks, symbolic data needs to be transformed into distributed representations, namely, word embedding (Bengio et al., 2003; Mikolov et al., 2013). Given a context-response pair, $\{C, R\}$ whose context are split into utterances, $C = \{U_1, ..., U_t\}$, a lookup table is used to map each word into a low-dimensional vector. Let n_u and n_r denote the length of the k-th utterance and response, U_k and R can be represented as $U_k = [u_1, ..., u_{n_u}]$ and $R = [r_1, ..., r_{n_r}]$, where u_i, r_i are the i-th word

in the utterance and response respectively.

To encode each utterance and response, we employ a GRU to propagate information along the word sequence of U_k and R. Suppose $H_k = [h_1, ..., h_n]$ is the hidden states of the input sequence, the structure of GRU is described as follows.

$$\begin{aligned} z_i &= \sigma(W_z u_i + V_z h_{i-1}) \\ r_i &= \sigma(W_r u_i + V_r h_{i-1}) \\ \tilde{h_i} &= tanh(W_h u_i + V_h(r_i \odot h_{i-1})) \\ h_i &= z_i \odot \tilde{h_i} + (1 - z_i) \odot h_{i-1} \end{aligned} \tag{1}$$

where $\sigma(\cdot)$ is the sigmoid function, z_i and r_i are the update and reset gates respectively, $\odot$ denotes the element-wise multiplication, and $W_z, W_r, W_h, V_z, V_r, V_h$ are parameters. We fed each utterance and response sequence to the GRUs and obtain the utterance representation S_k and response representation S_r, respectively.

3.2 Turns-aware Aggregation

Encoding the utterance sequence and response in the above way, there comes a drawback that all the utterances in the conversation are fairly dealt with, which fails to mine the connections between the last utterance and the rest preceding utterances. Thus, a first-stage turns-aware aggregation mechanism is proposed to address this problem.

Let $S = [S_1, ..., S_t, S_r]$ denote the representation of the utterances and response. Suppose $F = [F_1, ..., F_t, F_r]$ is the fusion of each $S_j \in S$ with the last utterance S_t, for each $\forall j \in \{1, ..., r\}$, $F_j \in F$, we define the fusion of the utterance as

$$F_j = S_j \diamond S_t \tag{2}$$

where $\diamond$ denotes the aggregation operation. In this work, we adopt a simple concatenation strategy[2]. So far, the turns-aware representation F is obtained via aggregation.

3.3 Matching Attention Flow

After turns-aware aggregation, the representations of the preceding utterances and response have been refined by the last utterance. However, the sequences are quite lengthy and redundant, which makes it hard to distill the pivotal information. In order to address this problem, we adopt a self-matching attention mechanism to directly match the fused representation against itself, which is similar as that adopted in (Wang et al., 2017). It dynamically collects information from the input sequence and filters the redundant information. Suppose $\hat{F} = [f_1, ..., f_n] \in F$ is the input and $P = [p_1, ..., p_n]$ is the output of the self-matching attention on response, then $\forall t$, $p_t \in P$ is defined as

$$p_t = GRU(p_{t-1}, [f_t, c_t]) \tag{3}$$

where $GRU(\cdot, \cdot)$ denotes the same calculation as (2), $[\cdot, \cdot]$ is the concatenation of two vectors and $c_t = att(\hat{F}, f_t)$ is the result of the self-matching attention. $\forall t$, $f_t \in \hat{F}$, c_t is defined as

$$\begin{aligned} s_j^t &= v^T tanh(W_v f_j + W_{\tilde{v}} f_t + b_r) \\ a_i^t &= exp(s_i^t) / \sum_{j=1}^{n} exp(s_j^t) \\ c_t &= \sum_{i=1}^{n} a_i^t f_i \end{aligned} \tag{4}$$

[2]We empirically investigated *concatenation*, *element-wise summation*, *element-wise multiplication* in this work and $concatenation$ strategy shows the best performance.

where W_r, $W_{\tilde{v}}$, b_r are the parameters and v^T is a context matrix which is randomly initialized and jointly trained.

Self-matching attention pinpoints important parts from the utterance according to the current word and the whole utterance representation through fusing each previous utterance and the last utterance.

3.4 Response Matching

Following (Wu et al., 2017), we use word-level and utterance-level representations to build two matching matrices and employ CNN to obtain salient matching information from the matrices. Suppose we have matching matrices M_1 and M_2 in word-level and utterance-level for each utterance-response pair. Then, $\forall k$, $U_k \in U$ and $\forall(i,j)$, the (i,j)-th element of M_1 and M_2 is defined respectively

$$e_{1,i,j} = u_i^T r_j \tag{5}$$

$$e_{2,i,j} = P_{u_i}^T A P_{r_j} \tag{6}$$

where P_{u_i} and P_{r_j} denote the outputs of the utterance and response after *Matching Attention Flow* respectively. $A \in \mathbb{R}^{c \times c}$ is a linear transforming matrix.

A convolutional operation followed by a max-pooling operation will be applied to M_1 and M_2 for each utterance. The convolutional layer is used to extract and combine local features from adjacent words and the following max-pooling layer forms the representations for the current word. For the convolutional operation, a group of filter matrices K with variable sizes $l*l$ and bias b are utilized. The filter transforms the word matrices M_1 and M_2 to another two matrices M_{1c} and M_{2c}. $\forall i\ k \in (1,2)$, the transformed matrices M_{kc} is define as:

$$M_{kc,[i][j]} = ReLU(\sum_{i}^{i+l-1}\sum_{j}^{j+l-1} K \cdot M_{k,[i:i+l-1][j:j+l-1]} + b) \tag{7}$$

where i and j index the row i-th and column j-th element, respectively. Next, a max-pooling operation is adopted and the representation m_p for p-th utterance in a conversation is obtained through flattening and concatenating the two matrices after pooling as follows:

$$\hat{m}_{k,[i][j]} = \max(M_{kc,[i:i+l-1][j:j+l-1]}) \tag{8}$$

$$m_p = [flatten(\hat{m}_1) \oplus flatten(\hat{m}_2)] \tag{9}$$

where $flatten()$ is the flatten operation and $\oplus$ is the concatenation operation.

3.5 Attentive Turns Aggregation

To aggregate the matching information of the attentive turns in the last stage, The outputs of CNN, $M = [m_1, ..., m_n]$ are fed to GRU to obtain $H_m = [h_{m_1}, ..., h_{m_n}]$. $\forall i$, $h_{m,i} \in H_m$ is defined as

$$h_{m,i} = GRU(h_{m_{i-1}}, m_i) \tag{10}$$

where $GRU(\cdot,\cdot)$ denotes the same calculation and parameterization as Eq.(2). Suppose $v_f = L(H_m)$ is the attention operation which is defined as:

$$\begin{aligned} t_i &= v^T \tanh(W_t P_{u_i} + V_t h_{m_i} + b) \\ \alpha_i &= \exp(t_i) / \sum_{j=1}^{n} \exp(t_j) \\ L(H_m) &= \sum_{i=1}^{n} \alpha_i h_{m_i} \end{aligned} \tag{11}$$

where W_t, V_t and b are parameters. With v_f, we define $\mathcal{F}(U,R)$ as:

$$\mathcal{F}(U,R) = softmax(W_s v_f) \tag{12}$$

	Ubuntu			Douban			ECD		
	Train	Valid	Test	Train	Valid	Test	Train	Valid	Test

Avg # turns per context	10.13	10.11	10.11	6.69	6.75	6.45	5.51	5.48	5.64
Avg # words per utterance	11.35	11.34	11.37	18.56	18.50	20.74	7.02	6.99	7.11

Table 1: Data statistics template for latter use.

where W_s is the parameter. During the training phase, model parameters are updated according to a cross-entropy loss.

Note that *Turns-aware Aggregation* and *Attentive Turns Aggregation* can be seen as two stages of interaction across the utterances (we call all these two process as "*Context Fusion*" henceforth). Specifically, the former is simply a combination after the *Utterance Representation* for richer turns-aware information while the latter is to aggregate matching states of previous turns after attention learning against each utterance itself and the response.

4 Experiment

4.1 Dataset

We evaluate our model on three multi-turn conversation datasets, the Ubuntu Dialogue Corpus (Ubuntu) (Lowe et al., 2015), the Douban Conversation Corpus (Douban) (Wu et al., 2017) and our released E-commerce Dialogue Corpus (ECD) [3]. Data statistics are in Table 1.

Ubuntu Dialogue Corpus *Ubuntu Dialogue Corpus* consists of multi-turn human-computer conversations constructed from Ubuntu IRC chat logs. The training set contains 1 million label-context-response triples where the original context and corresponding response are labeled as positive and negative response are selected randomly on the dataset. On both validation and test sets, each context contains one positive response and 9 negative responses.

Douban Conversation Corpus *Douban conversation corpus* is an open domain dataset constructed from Douban group which is a popular social networking service in China. Response candidates on the test set are collected by a standard search engine *Apache Lucene*[4], other than negative sampling without human judgment on Ubuntu Dialogue Corpus. That is, the last turn of each Douban dialogue with additional keywords extracted from the context on the test set is used as query to retrieve 10 response candidates from the Lucene index set.

E-commerce Dialogue Corpus In this part, we will introduce our E-commerce Dialogue Corpus. Though previously described public datasets have served in solid studies, there is no comprehensive e-commerce dataset available for research. We collect real-world conversations between customers and customer service staff from our E-commerce partners in Taobao [5], which is the largest e-commerce platform in China [6]. It contains over 5 types of conversations (e.g. commodity consultation, logistics express, recommendation, negotiation and chitchat) based on over 20 commodities. As word segmentation treatment is the primary step in Chinese language processing tasks (Zhao et al., 2017; Cai et al., 2017; Cai and Zhao, 2016), we adopt *BaseSeg* (Zhao et al., 2006) to tokenize the texts. For a discriminative learning, we add negative responses by ranking the response corpus based on the last utterance along with the top-5 key words in the context using *Apache Lucene*. The ratio of the positive and the negative is 1:1 in training and validation, and 1:9 in testing.

[3] Our released dataset along with source code can be accessed via `https://github.com/cooelf/DeepUtteranceAggregation`.

[4] `http://lucene.apache.org/`

[5] `https://www.taobao.com`

[6] All the data have been carefully desensitized and anonymized with the consent of our partners and avoid privacy issues.

Table 2: Comparison of different models on Ubuntu Dialogue Corpus and Douban Conversation Corpus. All the results except ours are from (Wu et al., 2017).

4.2 Settings

Our evaluation is based on the following information retrieval metrics: Mean Average Precision (MAP), Mean Reciprocal Rank (MRR), Precision at 1 (P@1) and Recall at position k in n candidates ($Rn@k$) , which are widely used for relevance evaluation (Wu et al., 2017; Lowe et al., 2015). For the sake of computational efficiency, the maximum number of utterances is specialized as 10 and each utterance contains at most 50 words. We apply truncating and zero-padding when necessary. Word embedding is trained by Word2Vector (Mikolov et al., 2013) on the training data and the dimension is 200. Our model is implemented using the Theano [7]. We use stochastic gradient descent with ADAM (Kingma and Ba, 2014) updates for optimization. The batch size is 200 and the initial learning rate is 0.001. The window size of convolution and pooling is (3, 3) and the number of hidden units for the character GRU is set to 200. All of our models are run on a single GPU (GeForce GTX 1080 Ti). We run all the models up to 5 epochs and select the model that achieves the best result in validation.

Our baselines include:

• **Single-turn matching models**: Basic models in (Kadlec et al., 2015; Lowe et al., 2015), including TF-IDF, CNN, RNN, LSTM and biLSTM ; We also explore other advanced single-turn matching models, MV-LSTM (Wan et al., 2016), Match-LSTM (Wang and Jiang, 2015), Attentive-LSTM (Tan et al., 2015), Multi-Channels (Wu et al., 2017); These models concatenate the context utterances together to match a response.

• **Advanced multi-turn matching models**: Multi-view model of (Zhou et al., 2016) that models utterance relationships from word sequence view and utterance sequence view; Deep Learning-to-Respond (DL2R) model of (Yan et al., 2016) which reformulates the last utterance (query) with other utterances in the context via neural model; Sequential Matching Network (SMN) (Wu et al., 2017) that matches a response with each utterance in the context.

The results of baseline models on Ubuntu and Douban are from (Wu et al., 2017). For evaluation on our ECD dataset, we reproduce the models following their same settings.

4.3 Experimental Results

Table 2-3 show the results on the three corpora. Our model outperforms all other models greatly in terms of most of the metrics. Single matching models which concatenate the previous utterances, perform much worse than our model, showing the importance of utterance relationships and simply concatenating

Table 3: Comparison of different models on E-commerce Dialogue Corpus.

utterances together is not an appropriate solution for multi-turn conversation modeling. Our model also achieves a great improvement (4.8% $R_{10}@1$ on ECD corpus) over the state-of-the-art multi-turn response matching model, SMN, which matches each utterance and response without turns-aware aggregation and matching attention flow. This comparison indicates the effectiveness of our context composing approach. The advantage on ECD dataset further indicates our model can well imitate the conversations of real customer service instead of merely being good at chitchat.

4.4 Discussion

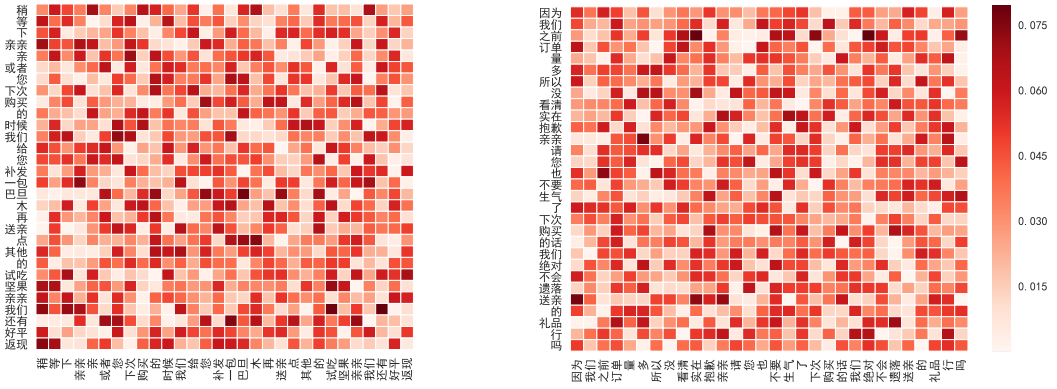
Conversation Type Analysis To evaluate the model performance on different types of conversations, we manually separate our ECD test set into 5 categories.

- **Consultation**: consultations about commodity's property, usage, packaging, etc.
- **Logistics**: questions about logistics partners, delivery progress.
- **Recommendation**: commodity comparisons and recommendations.
- **Negotiation**: customer complaints and negotiations.
- **Chitchat**: greetings, non task-oriented conversations and chitchats.

Table 4 shows the statistics and the model results. As we see, the types of chitchat and logistics tend to be easily handled. Recommendations, consultation and negotiations are relatively harder to respond since they often involve with various topics (e.g. the concerned commodities) and intentions, which makes our corpus more challenging than previous chitchat or question answering based corpora.

Visualization To analyze the effectiveness of the attention mechanism of our model, we draw the self-matching distributions after *matching attention flow*. From the validation set of our ECD data, Figure 3 shows the word weights of a momentous utterance (with high weights in the response matching component) and the response respectively. We see the model could accurately distill the linchpin from the utterance, {*Next consumption, reissue, a bag of almond, send you, some nuts, cashback*} and from the response {*too many orders before, really sorry, don't be angry, your gift*}. When a user complained about the missing gift and slow delivery, our model could distinguish the user's intention after self-matching and seek out the suitable response substantially according to the crux of the presented utterance. This shows our model is effective at selecting the vital points after *Matching Attention Flow*, guiding the *Response Matching* layer to collect more relevant pieces.

Ablation Study To have an insight of the effectiveness of each component in DUA, we remove one each time. The steepest reduction (6.9% $R_{10}@1$) is observed when we remove *Matching Attention Flow* which shows it quite vital to draw the linchpins of each utterance. The performance also drops substan-



(a) Highlighted utterance (b) Response

Last utterance (user): How can you miss my gift! And the delivery is so slow. You are spoiled !!!
Highlighted utterance (bot): please wait a moment dear. For compensation, we'll reissue you a bag of almonds at your next consumption. Besides, we will also send you some nuts to taste. If you give us five-star rating and comments, you'll also receive some cashback.
Response: Because we had too many orders before, we unfortunately misread your order. We are really sorry for the mistake. Please don't be angry, we will never forget your gift again.

Figure 3: Pair-wise attention visualization on utterance and response after matching attention flow.

	$R_{10}@1$	$R_{10}@2$	$R_{10}@5$
Consultation (36.1%)	0.474	0.696	0.900
Logistics (7.3%)	0.510	0.707	0.916
Recommendation (4.4%)	0.487	0.590	0.897
Negotiation (5.9%)	0.385	0.462	0.846
Chitchat (26.3%)	0.573	0.762	0.931
Overall(100%)	0.501	0.700	0.921

Table 4: Results on different types of conversations.

tially (4.8% $R_{10}@1$) when removing *Context Fusion* including the first turns-aware aggregation (first-stage aggregation) and replacing the last GRU (last-stage aggregation) for matching accumulation with a multi-layer perceptron. This indicates that utterance relationships are indeed important. Without *Context Fusion* and *Matching Attention Flow* mechanisms, the model performs the worst which verifies our proposed mechanism indeed improves the context representation essentially.

4.5 Error Analysis

After carefully analyzing the predicted responses, we find the error cases could be classified into the following categories for later further improvement.

Multiple intentions In E-commerce conversations users extremely likely express various intentions in a single message, which is another big difference from previous multi-turn conversation corpus besides diverse types of conversations among various commodities. For example, {*User: How about the packaging of skin care products. By the way, which delivery company will be responsible for shipping and how long can I receive the goods?*}. This would seriously confuse the model where the given response might be preferential to one or another aspect.

Topic errors Our model retrieves response according to semantic similarity with the context, with no special attention on the conversation topic, such as the currently discussed commodities. In most cases, the concerned commodity would be picked out from the context with high attention weights and guide the model to select responses. However, when the conversation involves several goods, for example, {*User: How about nuts? Bot: Nuts is good. User: Ok then, how about zongzi?*}, the model might give the response about *nuts* instead of *zongzi*. This indicates there exists much potential for improvements

	$R_{10}@1$	$R_{10}@2$	$R_{10}@5$
DUA	0.501	0.700	0.921

Table 5: Ablation study on ECD dataset. CF and MAF denote the *Context Fusion* and *Matching Attention Flow*. The bracket means the context fusion approach adopted by the model.

by considering extra topic recognition.

Multiple suitable responses In our ECD dataset, we assume there is only one correct response for each conversation which is the same setting as Ubuntu Dialogue Corpus. However, the model sometimes gives responses having similar meaning with the ground-truth one, but they would be regarded as wrong during evaluation, especially for fairly long conversations. This could make the task rather challenging with the strict restriction of exact match. This might be alleviated by involving expert labeling like (Wu et al., 2017). However, this is quite labour-intensive and subjective. In the future, we would explore more automatic solutions.

5 Conclusion

In this paper, we propose a deep utterance aggregation approach to form a fine-grained context representation. We also release the first e-commerce dialogue corpus to research communities. Experiments on three datasets show the model can yield new state-of-the-art results. Various analyses are conducted to evaluate the model and the released dataset. In the future, we may study how to improve modeling of contextual semantics and design a better neural network for multi-turn conversations in terms of various intentions and topics.

Argumentation Synthesis following Rhetorical Strategies

Abstract

Persuasion is rarely achieved through a loose set of arguments alone. Rather, an effective delivery of arguments follows a rhetorical strategy, combining logical reasoning with appeals to ethics and emotion. We argue that such a strategy means to *select*, *arrange*, and *phrase* a set of argumentative discourse units. In this paper, we model rhetorical strategies for the computational synthesis of effective argumentation. In a study, we let 26 experts synthesize argumentative texts with different strategies for 10 topics. We find that the experts agree in the selection significantly more when following the same strategy. While the texts notably vary for different strategies, especially their arrangement remains stable. The results suggest that our model enables a strategical synthesis.

1 Introduction

The primary use of arguments in natural language is to persuade others of a stance towards a controversial topic (Mercier and Sperber, 2011). According to Johnson and Blair (2006), an argument is logically cogent if its premises are relevant as support for its conclusion, individually acceptable, and together sufficient to draw the conclusion. In real life, however, argumentation is by far not only about logic (Allwood, 2016). Without a *rhetorical strategy*, arguments will hardly ever unfold their persuasive effectiveness.

Following Aristotle (2007), we see a rhetorical strategy as the purposeful encoding of three means of persuasion in a well-arranged and well-phrased speech or text: *logos* (providing logically reasoned arguments), *ethos* (demonstrating good character and credibility), and *pathos* (evoking the right emotions). Listeners or readers then decode the encoding, forming their view of the author's logos, ethos, and pathos. In the realm of the area of computational argumentation, rhetorical strategies are particularly relevant for technologies that synthesize argumentative text and that aim to deliver arguments effectively.

Existing argument mining research largely focuses on the logical structure of arguments, identifying their units (premises vs. conclusions) and relations (support vs. attack). Recently, a few studies have tackled strategy-related aspects, such as explicit expressions of ethos (Duthie et al., 2016) and the effects of logical and emotional arguments across audiences (Lukin et al., 2017). So far, however, strategies have not been considered in argumentation synthesis, which altogether has not received much attention (see Section 2).

In this paper, we study the role of rhetorical strategies when synthesizing argumentation. In particular, we consider monological argumentative texts where an author seeks to persuade target readers of his or her stance towards a given topic, such as news editorials and persuasive essays. Conceptually, we argue that an author synthesizes a text of such genres in three subsequent steps:

1. *Selecting content* in terms of argumentative discourse units (along with facts, anecdotes, and similar) that frame the given topic in a way that is effective for the intended stance,
2. *arranging the structure* of the units considering ordering preferences, and
3. *phrasing the style* of the resulting text to match the genre and the encoded means of persuasion.

We expect that the encoding of the means of persuasion becomes manifest in measurable text properties related to selection, arrangement, and phrasing. Figure 1 sketches the analysis of such properties in a

Proceedings of the 27th International Conference on Computational Linguistics, pages 3753–3765
Santa Fe, New Mexico, USA, August 20-26, 2018.

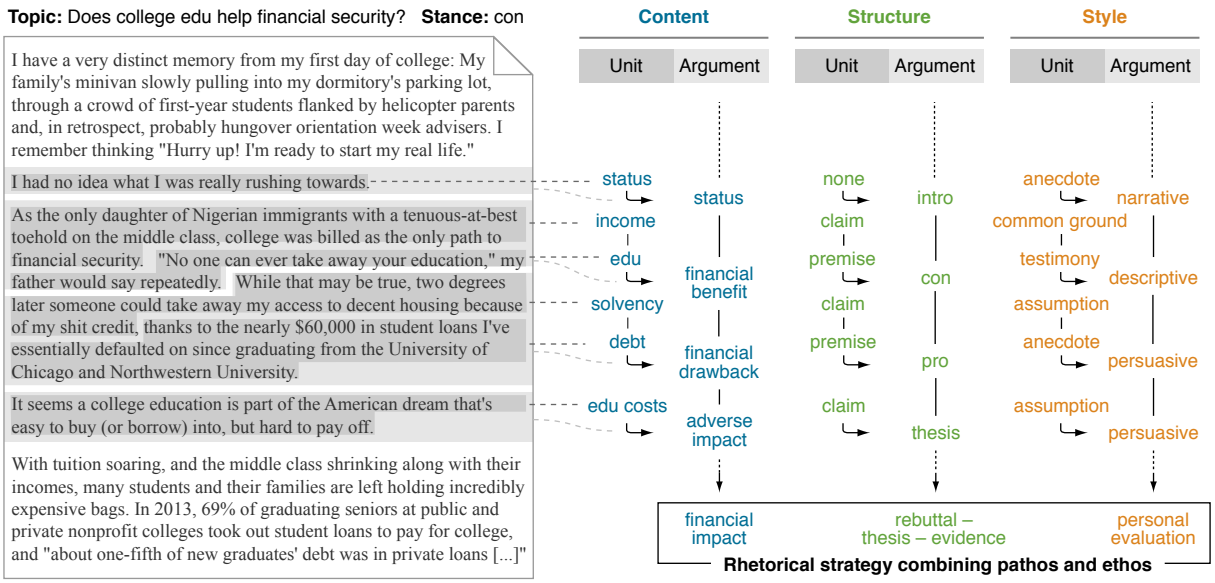

Figure 1: A monological argumentative text (a news editorial from Al-Khatib et al. (2016)), along with exemplary content, structure, and style properties captured by the envisioned model of rhetorical strategies.

pathos and ethos-oriented news editorial. Thereby, it also hints at our envisioned computational model of rhetorical strategies. We discuss this model and its application when synthesizing an argumentative text following a particular rhetorical strategy in Section 3. In Section 4, we design a dataset for studying argumentation synthesis with 200 argumentative discourse units for 10 pairs of topic and stance from the Arg-Microtexts corpus (Peldszus and Stede, 2016). To evaluate the adequacy of the general synthesis process reflected by our model, we then carry out an experiment where 26 human experts select, arrange, and re-phrase short argumentative texts following principled rhetorical strategies, thereby also creating benchmark data for computational approaches (Section 5).

We find that humans agree significantly more when selecting argumentative discourse units to encode specific means of persuasion, and we observe clear differences between strategies. At the same time, the arrangement of the texts remains stable across strategies. Their phrasing requires further investigation in future work. The results suggest that our model captures both general and strategy-specific aspects of synthesizing argumentation. As such, it defines a first substantial step towards computational argumentation synthesis following rhetorical strategies. In total, our main contributions are:

1. *A computational model* of rhetorical strategies for synthesizing monological argumentative texts.
2. *A benchmark dataset* with manually synthesized arguments that follow rhetorical strategies.
3. *Empirical evidence* that humans agree in strategy-specific argumentation synthesis.

2 Related Work

Aristotle (2007) revealed that persuasion is achieved through a well-arranged speech with a clear and appropriate style that delivers an adequate mix of the three means of persuasion: (1) *logos*, the use of logically reasoned arguments, (2) *ethos*, the demonstration of the speaker's credibility and good character, and (3) *pathos*, the evoking of the right emotions in the target audience. As Aristotle, we target argumentation that aims for persuasion — as opposed to critical discussions where *strategic maneuvering* is needed to achieve reasonableness (van Eemeren et al., 2014). Jovičić (2006) proposed a procedure to evaluate the effectiveness of persuasive argumentation, though not in a computational way.

In natural language processing, most computational argumentation research focuses on the mining of argumentative units and relations from text (Stab and Gurevych, 2014; Peldszus and Stede, 2015; Ajjour et al., 2017). Argument mining infers the logical structure of arguments, but it does not analyze the strategy used to compose arguments. Feng and Hirst (2011) classify the five most common argumentation *schemes* of Walton et al. (2008). Such a scheme defines a pattern capturing the logical inference from an

argument's premises to its claim, i.e., it primarily aims at logos only. Song et al. (2014) combine the idea of schemes with strategy-related considerations, and Habernal and Gurevych (2015) annotate pathos in forum comments and blog posts. Likewise, Duthie et al. (2016) develop a corpus and an approach to mine explicit expressions of ethos from political debates, whereas Hidey et al. (2017) even annotate all three means of persuasion for the premises of arguments. The provided data and methods may be helpful for studying persuasive effectiveness, but they have not been employed so far for that purpose.

In (Wachsmuth et al., 2016), we use the output of argument mining to assess four quality dimensions of persuasive essays. Some assessed dimensions relate to rhetoric, such as argument strength, which is defined based on how many readers are persuaded. Habernal and Gurevych (2016) examine the reasons that make arguments convincing, and Lukin et al. (2017) study how effective logos-oriented and pathos-oriented arguments are depending on the target audience. However, none of these works considers the application of rhetorical strategies.

Tan et al. (2016) find that the chance to persuade someone in good-faith discussions on *Reddit Change My View* is increased through multiple interactions and an appropriate linguistic style. Cano-Basave and He (2016) analyze the impact of the semantic framing of arguments (e.g., "taking sides" and "manipulation") in political debates. Similarly, Wang et al. (2017) reveal the importance of selecting the right framing of a discussion topic for winning classical debates. In such dialogical situations, the arguments of opposing parties are usually fragmented into several alternating parts. Our work, in contrast, analyzes the rhetorical strategies of complete monological texts where an author presents his or her entire argumentation.

Studying persuasive blog posts, Anand et al. (2011) develop a scheme with 16 persuasion tactics of four types: those that postulate outcomes of an uptake, those that generalize in some way, those that appeal to external authorities, and those that rely on interpersonal factors. These tactics are found in small text spans and could be seen as the local counterpart of the global strategies we consider. To our knowledge, only we have explicitly worked towards a computational analysis of such strategies so far. In particular, we presented a corpus with 300 news editorials whose units are labeled with their roles in the argumentation, such as "testimony" and "common ground" (Al-Khatib et al., 2016). In (Al-Khatib et al., 2017), we then trained a classifier on this corpus to find sequential role patterns in 30k New York Times editorials. While we observed insightful variances in the use of evidence across editorial topics, it still remains unclear to what extent such patterns really reflect rhetorical strategies.

Clearly diverging from previous research, we consider rhetorical strategies in argumentation *synthesis*, for which related work is generally still scarce. Bilu and Slonim (2016) generate new claims by recycling topics and predicates from existing claims, whereas Reisert et al. (2015) synthesize complete arguments based on the model of Toulmin (1958) where a claim is supported by data that is reasoned by a warrant. Like us, those authors rely on a pool of argument units from which arguments are built. However, they restrict their view to logical argument structure. The same holds for Green (2017) who generates arguments with particular schemes (e.g., "cause to effect") that are used to teach learners how to argue.

Yanase et al. (2015) present a method that arranges the sentences of an argumentative text in a natural way. Sato et al. (2015) build upon this method. Their system pursues similar goals as we do, phrasing an ordered text with multiple arguments. We extend their idea by rhetorical considerations, and we propose a general argumentation synthesis model. It is in line with classical concepts of building natural language generation systems (Reiter and Dale, 1997), but it targets argumentative texts in particular. With that, we seek to contribute a missing aspect to technologies that synthesize arguments such as *The Debater* (Rinott et al., 2015), namely, how to deliver arguments *effectively*. So far, strategical systems exist only for formal argumentation (Rosenfeld and Kraus, 2016).

Our synthesis-oriented model covers content, structure, and style properties. For computational purposes, such properties need to be mined before. To capture content, some works identify the different frames under which a topic can be viewed (Naderi and Hirst, 2017), model key aspects of a topic (Menini et al., 2017), or analyze potentially strategy-related topic patterns in campaign speeches (Gautrais et al., 2017). In terms of structure, Persing et al. (2010) learn sequences of discourse functions in essays (e.g., "rebuttal" or "conclusion") that correlate with a good organization, and we have modeled flows of arbitrary types of information to classify text properties, such as stance or quality (Wachsmuth and Stein, 2017).

In (Wachsmuth et al., 2017), we extend this idea to model sequential and hierarchical argumentation structure simultaneously. Regarding style, Lawrence et al. (2017) analyze rhetorical figures in arguments, Song et al. (2017) classify discourse modes in essays, and Zhang et al. (2017) study rhetorical questions in political discourse. All such methods may be relevant when we operationalize our model.

Finally, the use of strategies in synthesis scenarios follows up on early work on discourse planning (Young et al., 1994; Zukerman et al., 2000). The computational approaches relied on rule-based techniques to create effective arguments (Carenini and Moore, 2006) for a few selected tactics. More recent research on general text generation uses probabilistic models to employ text structure (Barzilay, 2010), or synthesizes texts such that they have a certain style in terms of sentiment or similar (Hu et al., 2017; Shen et al., 2017). Our model is meant to provide an abstract framework to be exploited in such approaches.

3 Model

We now delineate our model of rhetorical strategies for synthesizing a monological argumentative text following a specified rhetorical strategy. As clarified below, its three main building blocks follow Aristotle (2007). While we do not operationalize the model computationally in this paper, we will study its general adequacy with human experts in Section 5. An instance of the model has been given in Figure 1.

3.1 Argumentation Synthesis following Rhetorical Strategies

Given a controversial topic or question (such as "Does college edu help financial security?" in Figure 1) and a stance towards it (such as "con"), the goal of a rhetorical strategy can be seen as delivering arguments along with facts, anecdotes, etc. to persuade some target audience of the intended stance in an effective way. In line with Aristotle (2007), we hypothesize that such a strategy can be manifested in a monological argumentative text through a purposeful encoding of the three means of persuasion (see Section 2). i.e., logos, ethos, and pathos. An instance of a strategy (which is tailored to a specific target audience) thus specifies to what degree each means should be present, such as *logos 70%, ethos 10%, pathos 20%*.[1]

For giving a persuasive speech, Aristotle (2007) postulates five consecutive *canons of rhetoric*: (1) *inventio*, the selection of arguments, (2) *dispositio*, the arrangement of the arguments to achieve maximum impact, (3) *elocutio*, the phrasing of the arguments in a clear and appropriate style, (4) *memoria*, the memorization of the speech, and (5) *actio*, the delivery of the speech with gestures, prosody, and further means. Since we focus on written argumentation, the latter two are obsolete in the given context. Accordingly, we model a rhetorical strategy for synthesizing monological argumentative texts as a process of the three steps mentioned in Section 1: selecting content, arranging structure, and phrasing style.

Technically, we regard a strategy as a script of operators from a set $\Omega = \Omega_s \cup \Omega_a \cup \Omega_p$, where Ω_s are select operators, Ω_a are arrange operators, and Ω_p are phrase operators. These operators can be combined to form complex, nested n-ary operations on a set of input units. We expect that an applied strategy becomes manifest in measurable text properties at different granularity levels, ranging from single words and phrases over argumentative units and complete arguments, up to the full argumentation in a text. The identification of the best properties is beyond the scope of this paper, but the box in the lower right corner of Figure 1 summarizes an exemplary overall manifestation of a pathos and ethos-oriented strategy: The author focuses on the financial impact of college education to support her stance against it. She rebuts existing views, before she states her thesis and provides evidence, all in a personal evaluation.[2]

For a concrete operationalization of the model, the input to the operators may be pre-fabricated text units (roughly: clauses corresponding to single propositions), semantic representations in a suitable formalism (as in the case of classical "deep" text generation), or some intermediate form like partially-analyzed text units, where information about syntax, named entities, etc. is available. In line with the experiment reported in Section 5, we here assume that a set of candidate text units, which we call the *pool*, is available to make informed selections. Ideally, the units have been analyzed for (1) means of persuasion present, (2) stance on the topic, (3) framing of the topic, and (4) effectiveness when functioning in an argument.

[1] Also, a rhetorical strategy will have to consider conventions of the intended text genre (news editorial, persuasive essay, etc.), but we leave that aside for present purposes.

[2] The distinction of content, structure, and style may not be perfectly orthogonal in all cases, which is rooted in the complexity and polythetic nature of natural language. Notice in this regard that all labels depicted in Figure 1 are exemplary only.

3.2 Selecting the Content (Inventio)

The first step of synthesizing argumentation is to decide on those frames under which to view a topic that support the intended stance best, while matching the desired means of persuasion (as specified by the strategy). In accordance with these decisions, a set of units is to be selected from the pool. For instance, the editorial in Figure 1 frames college education in terms of its financial benefits and drawbacks, among other frames. A different strategy could put the focus on the freedom of career choice. When making the selection, facts, anecdotes, and similar statements may be added to the arguments, particularly to demonstrate credibility or to evoke emotions (if the strategy favors ethos or pathos, respectively). In Figure 1, we find a personal anecdote in the beginning, whereas the last paragraph gives statistical and testimonial evidence. Technically, the set Ω_s will contain operators of two types:

$$frames: \ select(topic, stance, strategy) \qquad units: \ select(frames, strategy)$$

To establish the knowledge base behind Ω_s, a preceding corpus analysis will be needed, which associates frames and units for topic-stance combinations with information about their persuasive effectiveness and the encoded means of persuasion. As summarized in Section 2, several computational techniques to implement various steps of this analysis have been proposed, such as unit segmentation (Ajjour et al., 2017), frame classification (Naderi and Hirst, 2017), and key aspect clustering (Menini et al., 2017).

3.3 Arranging the Structure (Dispositio)

Given the units, the next step is to compose the selected units in structured arguments and to sequentially order them, in a way that maximizes their impact. The financial drawback argument in Figure 1, for instance, gives the debts from student loans as the premise for the author's claimed solvency problems. The resulting argument (pro the intended stance) rebuts the preceding con argument and — probably for rhetorical reasons — is immediately followed by the main thesis within the sequential flow of the editorial (indicated by the vertical lines). To illustrate the means of persuasion, an emphasis on pathos could, for example, lead to a preference for gradually increasing the strength of emotional appeal throughout the text. In contrast, for a logos-oriented strategy, it may be important that the sequence of units *coheres* locally and globally (which for a pathos-oriented argument may be less relevant, or even detrimental). Technically, we distinguish two types of arrange operators in Ω_a:

$$arguments: \ arrange(units, strategy) \qquad flow: \ arrange(arguments, strategy)$$

For executing this step, knowledge about the roles of units in arguments (Stab and Gurevych, 2014) and about effective flows of text units (Wachsmuth and Stein, 2017) is needed. This script-like knowledge fuses the information on the means of persuasion and of unit strength on the one hand with principles of text coherence and rhetorical organization on the other.

3.4 Phrasing the Style (Elocutio)

Finally, the sequence of units is to be presented in an argumentative text, making stylistic decisions, which in turn are governed by the strategy. The technical approach depends much on the type of "unit" that is being implemented (see end of Section 3.1). For minimally-analyzed text units, one can add connectives indicating the relation between units. If deeper analyses are available, it may be possible to use markers encoding evidence types or discourse modes, among other rhetorical devices. If syntax can be controlled, then a pathos-oriented argument may prefer relatively flat structures, while a logos-oriented one may lean towards more complex embedding, inviting the reader to follow the path of reasoning. In the mentioned pro argument from the editorial, a concession is expressed through the word "while", indicating that the con argument is outweighed by the pro argument. A personal anecdote is then given as a sarcastic ("thanks to") causal evidence, which is used as a pathos-oriented persuasion attempt. Technically, we thus consider the set Ω_p to be composed of at least two basic types:

$$sentences: \ phrase(units, arguments, strategy) \qquad text: \ phrase(sentences, flow, strategy)$$

Existing techniques to identify the right phrasing operators include evidence type classification (Rinott et al., 2015; Al-Khatib et al., 2017), discourse mode identification (Song et al., 2017), and others.

Question (with Marked Controversial Topic)	# Texts
Should the fine for leaving **dog excrements** on sideways be increased?	9
Should **shopping malls** generally be allowed to open on holidays and Sundays?	8
Should public health insurance cover treatments in complementary and **alternative medicine**?	8
Should Germany introduce the **death penalty**?	8
Should only those viewers pay a **TV licence fee** who actually want to watch programs offered by public broadcasters?	7
Should there be a cap on **rent increases** for a change of tenant?	6
Should all universities in Germany charge **tuition fees**?	6
Should the statutory **retirement age** remain at 63 years in the future?	6
Should the the **morning-after pill** be sold over the counter at the pharmacy?	6
Should **intelligence services** be regulated more tightly by parliament?	4

Table 1: The 10 questions from the Arg-Microtexts corpus from which we use ADUs for our dataset.

4 Data

This section describes the dataset in terms of a pool of argumentative discourse units that we built in order to study the adequacy of the proposed model for strategical argumentation synthesis.

4.1 Source Texts of the Argumentative Discourse Units

We decided to work with the English version of the Arg-Microtexts corpus (Peldszus and Stede, 2016), which was designed to provide crisp argumentation in a "pro and con" manner. The corpus contains 112 short argumentative texts that have been written in response to 18 questions on different controversial topics. The stance of each text towards the topic is labeled (*pro* or *con*). Every text consists of 3 to 10 manually segmented *argumentative discourse units (ADUs)* with a mean of about 5. ADUs can range from a single clause to (in principle) multiple sentences, which together contribute a single function to the argumentative structure. The structure is inspired by the model of Freeman (2011) and allows for linked, convergent, and serial support, as well as two kinds of attack (rebuttals and undercutters).

From the annotated structure, we can directly derive the *thesis* of each text (aka the main claim) and, for each other ADU, the stance that it takes towards this thesis (*pro* or *con*). In total, the Arg-Microtexts corpus contains 576 ADUs (112 theses, 339 pros, and 125 cons).

4.2 Decontextualization of the Argumentative Discourse Units

For our purposes, we need ADUs to be as independent as possible of the context in which they originally occurred. At this point, the fact that the corpus texts are relatively short and hence free of complex inter-relationships, becomes helpful. We semi-automatically preprocessed each unit in four steps:

1. *Removal of sentence information.* We removed all capitalizations of words that were due to sentence beginnings as well as all sentence delimiters.
2. *Removal of unit prefixes.* We removed all discourse markers and connectives at unit beginnings. The top 10 terms were "but" (43 times), "and" (39), "as" (18), "however" (15), "besides" (11), "for" (11), "also" (1), "that's why" (10), and "yet" (10). Together, they made up 61% of all removed prefixes.
3. *Removal of unit infixes.* We removed the following markers within units: "also" (16 times), "however" (14), "therefore" (10), "hence" and "thus" (3 each), as well as "though" (2).
4. *Pronoun resolution.* Finally, we resolved all pronouns in the units whose reference was unclear or ambiguous when given only the question of the respective text. For example, we replaced "they" by "murderers and rapists" in "the have taken or destroyed another life" from a text on the death penalty.

4.3 A Pool of 200 Argumentative Discourse Units for 10 Controversial Topics

The goal of our study is to imitate the computational synthesis of monological argumentative texts, given a topic, a stance towards the topic, and a strategy specification. To ensure a reasonably large pool of ADUs for synthesis for each topic, we restrict our view to the 10 most frequent questions in the Arg-Microtexts corpus. The number of texts for each of them is listed in Table 1 (controversial topics are marked bold).

Type	#	Argumentative Discourse Unit
Thesis	t1	Germany should by no means introduce capital punishment
	t2	Germany should not introduce capital punishment
	t3	the death penalty is a legal means that as such is not practicable in Germany
	t4	the state ought to prevent murder - not avenge it
Con	c1	criminals should not be put in luxury prisons
	c2	many people think that a murderer has already decided on the life or death of another person
	c3	murderers and rapists have taken or destroyed another life
	c4	proponents of the death penalty count on its deterring effect as well as and the ultimate elimination of any potential threat
Pro	p1	a death would not be of any more use to those affected and their relatives than if the felon receives a long sentence
	p2	a door must remain open for making amends
	p3	capital punishment is not a solution
	p4	courts are subject to human error
	p5	despite the death penalty there are significantly more homicides in the US than in Germany
	p6	every human, even those who have committed a despicable crime, can bring themselves to regret and change their opinion
	p7	everyone must be given the chance to hone their conscience and possibly make amends for their deed
	p8	it is a much graver punishment to be imprisoned forever and be tortured by one's own thoughts than to be killed quickly and easily by an injection
	p9	it turns out time and again that innocent people are convicted and executed
	p10	no one can claim the right to rule over the life or death of another human being
	p11	no one may have the right to adjudicate upon the death of another human being
	p12	we don't live in medieval times anymore
Topic		Should Germany introduce the death penalty? **Stance** Con

Table 2: The candidate thesis, con, and pro units for one topic-stance pair from the dataset we provide.

To reduce the bias of the expert's personal opinions in the study, we use only theses for one stance towards the respective topic. In particular, we kept only those with the majority stance on the topic, resulting in at least four theses for each of the 10 topics.[3] We kept all other ADUs, but we inverted the stance of an ADU in case it referred to one of the discarded theses, because, for instance an ADU that is against a discarded con thesis can be assumed to be in favor of a pro thesis on the same topic.

As a result, we had at least four con and 12 pro units for the four theses on each topic. Additional units were discarded randomly to end up with an equal number of units for all 10 topics.The resulting distribution of the unit types matches the desired distribution in the source corpus. We ordered the theses, con units, and pro units alphabetically (to avoid ordering bias). Table 2 exemplary shows the list of 20 units for one topic. Each such list represents the pool of candidate units for one task in our experiment.[4]

5 Experiments

We now report on the experiment that we carried out with human experts in order to study whether the general process of selecting, arranging, and phrasing defined by our model from Section 3 is suitable for a strategical synthesis of argumentative texts.

5.1 Experimental Set-up for Manual Argumentation Synthesis following Rhetorical Strategies

We hypothesized that humans (1) agree when synthesizing arguments for the same strategy more than for different ones, and (2) synthesize differently depending on their strategy, especially in terms of selection.

Participants A diverse set of 26 qualified experts participated in the study (10 female, 16 male) with diverse demographic backgrounds (9 from North America, 11 from Europe, 6 from Asia). 16 came from groups related to computational linguistics, while the others were writing experts, acquired on *upwork.com*. 16 had a PhD or master, 7 a bachelor, and 3 a high school degree. No author of this paper participated.

Strategies To emphasize the effects of a strategical synthesis, we consider only two somehow principled rhetorical strategies, for which we gave the following short intuitions:

[3] In case of the question "Should shopping malls generally be allowed to open on holidays and Sundays?", pro and con theses were balanced (4 each). We chose con, so we ended up with five pro-topic and five con-topic cases in total.

[4] We provide the output of all main steps of the described dataset construction at: `http://arguana.com/data`

Unit	Strategy	Selection		Arrangement	
		Majority	κ	Majority	κ
Thesis	Logos-oriented	59%	* 0.25	51%	0.16
	Pathos-oriented	51%	* 0.10	57%	0.23
	Logos to pathos	**43%**	**−0.02**	**53%**	**0.18**
Con	Logos-oriented	52%	0.13	45%	0.11
	Pathos-oriented	49%	0.10	54%	0.17
	Logos to pathos	**46%**	**0.08**	**48%**	**0.15**
3 pros	Logos-oriented	20%	* 0.14	31%	0.04
	Pathos-oriented	21%	* 0.11	31%	0.04
	Logos to pathos	**18%**	**0.04**	**30%**	**0.07**
Overall	Logos-oriented	59%	* 0.16	48%	0.10
	Pathos-oriented	52%	* 0.11	54%	0.15
	Logos to pathos	**46%**	**0.04**	**49%**	**0.13**

Table 3: Majority and mean Cohen's κ agreement in selecting and arranging units of each type within the arguments of each principled strategy and across (*logos to pathos*).

Connection	Phrasing		
	Majority	κ	Top Category
Before initial thesis	94%	0.35	None
Before initial con	40%	−0.22	Comparison
Before initial pro	92%	−0.21	None
Thesis → pro	46%	−0.29	Comparison
Thesis → con	41%	−0.32	None
Con → thesis	57%	−0.24	None
Con → pro	48%	−0.37	Comparison
Pro → thesis	69%	−0.26	Contingency
Pro → con	39%	−0.25	Comparison
Pro → pro	37%	−0.18	Expansion

Table 4: Majority and mean Cohen's κ agreement, as well as the top category of discourse markers and connectives in phrasing for each connection between unit types.

- *Logos-oriented.* Argue based on logical reasoning, which means to make rational and logical conclusions towards the intended stance on the given topic.
- *Pathos-oriented.* Argue based on emotional reasoning, which means to appeal to the emotions of the reader regarding the topic within your arguments.[5]

Tasks All participants had to create one short argumentative text for each topic-stance pair, five logos-oriented and five pathos-oriented texts. Pair-strategy combinations varied across participants, but were balanced in overall terms. For each pair, the participants first had to *select* one thesis unit, one con unit, and three pro units from our pool that they thought could best form a persuasive argument following the given strategy.[6] Then, they had to *arrange* these five units in the most suitable way they saw. Finally, they should *phrase* a coherent text by adding discourse markers and connectives (example terms were given) as well as punctuation marks before and after each unit. We provided a spreadsheet that made this process as easy as possible. The participants were not trained in order to avoid biasing them towards our hypotheses.

5.2 Agreement and Differences in Selection, Arrangement, and Phrasing

The results of our experiment is a benchmark dataset with 13 manually synthesized texts for each combination of topic-stance pair and principled strategy. We provide it at `http://arguana.com/data`.

Agreement To make strategy differences explicit, Table 3 shows the participants' agreement in selecting units and in arranging the three unit types for arguments *within* each of the two strategies and *across* them ("logos to pathos"). Majority agreement is given when over 50% of all participants decided equally about choosing a unit, and the mean pairwise Cohen's κ agreement captures the average agreement of two participants. It is expected that the κ values are low, since various meaningful arguments can be synthesized for each topic from our pool. Accordingly, other measures such as Fleiss' κ are not suitable.[7]

For the *selection*, the decisive observation is that the κ is much higher within each strategy (e.g., 0.25 for logos and 0.10 for pathos in case of *thesis*) than across (−0.02). κ differences between each strategy and across marked with * are significant with at least $p < 0.05$ (t-test in case of normal distribution, Wilcoxon test otherwise). This speaks for the truth of Hypothesis 1, i.e., unit selection depends on the strategy. The majority agreement indicates that, especially for logos-oriented arguments, *thesis* (59%) and *con* (52%) are often selected uniformly. In contrast, the agreement for *arrangement* is similar within and across strategies, rather deviating between logos and pathos. We further explore this finding below.

[5]We told the participants that the two strategies may overlap. Ethos-oriented argumentation was not considered, because the demonstration of credibility seems hard, given that we required the participants to build arguments from our given pool of units.

[6]We use units as proxies for frames in the selection, as we do not have information on the exact frames covered by the units.

[7]High κ values would even be doubtful, because they would imply that the participants often selected *exactly the same* units, which would render the potential of our pool of argumentative discourse units questionable.

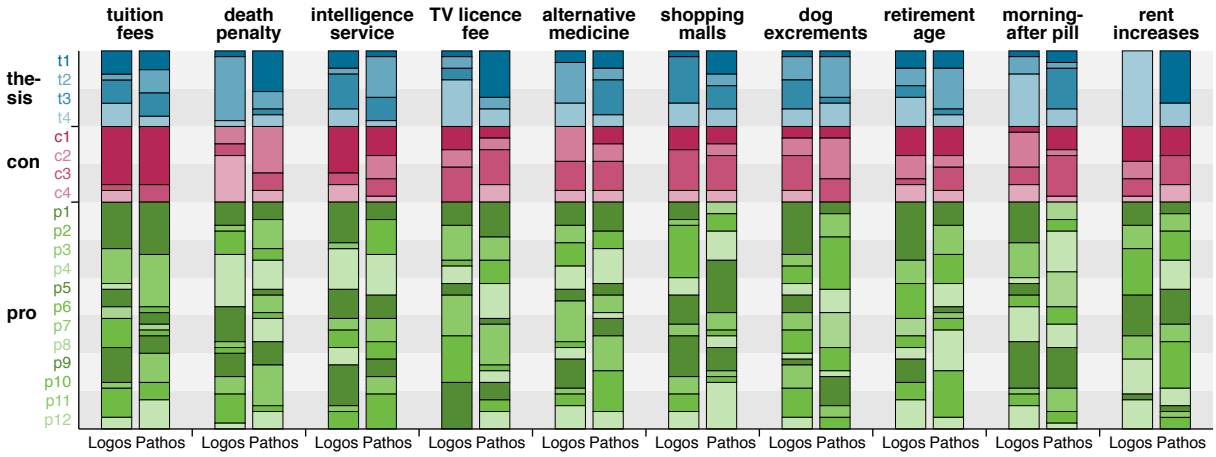

Figure 2: Distribution of the thesis units t1–t4 (blue), con units c1–c4 (red), and pro units p1–p12 (green) selected by all 13 annotators for each combination of topic and rhetorical strategy (logos/pathos-oriented).

Unit	Strategy	1	2	3	4	5	Mean
Thesis	Logos	50%	21%	10%	2%	17%	2.1
	Pathos	56%	18%	5%	4%	17%	2.1
	Overall	**53%**	**19%**	**8%**	**3%**	**17%**	**2.1**
Con	Logos	23%	42%	24%	8%	2%	2.3
	Pathos	25%	51%	17%	5%	2%	2.1
	Overall	**24%**	**47%**	**20%**	**7%**	**2%**	**2.2**
Pro	Logos	9%	12%	22%	30%	27%	3.5
	Pathos	6%	11%	26%	30%	27%	3.6
	Overall	**8%**	**11%**	**24%**	**30%**	**27%**	**3.6**

Table 5: Difference between strategies in the distribution of unit types over the five positions of the synthesized arguments, and mean rank of each type.

Unit Type Flow	Means	Frequency	Rank
(thesis, con, pro, pro, pro)	Logos	34.6%	1
	Pathos	43.1%	1
	Overall	**38.8%**	**1**
(con, thesis, pro, pro, pro)	Logos	13.1%	2
	Pathos	13.8%	2
	Overall	**13.5%**	**2**
(thesis, pro, con, pro, pro)	Logos	12.3%	3
	Pathos	12.3%	3
	Overall	**12.3%**	**3**

Table 6: Differences between strategies in the relative frequency and the rank of the three most common unit type flows in the synthesized arguments.

For *phrasing*, we just show in Table 4 to what extent the experts agreed in connecting consecutive unit types. We assume agreement if the same category of discourse marker or connective was used, distinguishing comparison, contingency, concession, expansion, other, and none. The majority agreement is high in many cases, while we see systematic κ disagreement. This implies that there were two opposing camps, although statistical reliability is limited. Quite intuitively, comparison terms (e.g., "although" or "but") come often before or after con, whereas consecutive pros usually expand each other (e.g., with "and").

Differences For brevity, we compare the relative frequencies of *selecting* each unit in logos-oriented and pathos-oriented arguments visually in Figure 2. For the theses, we observe clear strategy differences. For instance, nearly all logos texts on *death penalty* use t2, whereas the majority selected t1 for pathos there. In general, the thesis selection seems more uniform for logos. The distribution of con units is rather similar across strategies for many topics, suggesting that natural candidates to be rebutted exist among these. Conversely, the stacked bars of the pro units diverge often, as in the case of *dog excrements*. As far as our limited unit pool permits, these results support Hypothesis 2, i.e., different strategies lead to different selections of units and topic frames.

We analyze the *arrangement* in terms of the distribution of each unit type over the five positions in the synthesized texts as well as in terms of the resulting sequential unit type flows. As Table 5 reveals, the distributions are very stable across strategies. About half of all texts begin with the thesis, whereas pro units rather come at the end. Only for the con units, we see some differences, such as 42% (logos-oriented) versus 51% (pathos-oriented) at position 2. Accordingly, both strategies yield the same three most common flows, listed in Table 6, with *(thesis, con, pro, pro, pro)* at rank 1. We omit significance tests, since these results rather entail the conclusion that arrangement is not specific to the given strategies.

	Comparison		Contingency		Concession		Expansion		Other		None
Strategy	**Top**	**Frequency**	**Top**	**Frequency**	**Top**	**Frequency**	**Top**	**Frequency**	**Top**	**Frequency**	**Frequency**
Logos	but	20%	because	16%	indeed, of course	6%	and	15%	for one thing	2%	42%
Pathos	but	21%	because	18%	indeed, admittedly	8%	and	13%	for one thing	2%	39%
Overall	**but**	**20%**	**because**	**17%**	**indeed, admittedly**	**7%**	**and**	**14%**	**for one thing**	**2%**	**41%**

Table 7: The top terms and relative frequency of each discourse marker/connective category in phrasing.

Strategy	**#**	**Text Manually Synthesized From Five Argumentative Discourse Units**
Logos-oriented	t2	Germany should not introduce capital punishment.
	c4	Proponents of the death penalty count on its deterring effect as well as and the ultimate elimination of any potential threat.
	p5	*However,* despite the death penalty there are significantly more homicides in the US than in Germany.
	p4	*Furthermore,* courts are subject to human error.
	p9	It turns out time and again that innocent people are convicted and executed.
Pathos-oriented	t1	Germany should by no means introduce capital punishment.
	c2	Many people think that a murderer has already decided on the life or death of another person.
	p2	*Still,* a door must remain open for making amends.
	p6	Every human, even those who have committed a despicable crime, can bring themselves to regret and change their opinion.
	p11	*Therefore,* no one may have the right to adjudicate upon the death of another human being.

Table 8: Comparison of two selected argumentative texts, one for each strategy, manually synthesized based on the units from Table 2. The italicized discourse markers have been added by the participants.

Similar holds for the *phrasing* of argumentative texts, or at least for the given task of adding discourse markers and connectives. In particular, Table 7 presents the proportion of the most frequent categories of these. Logos-oriented and pathos-oriented arguments are practically identical in this regard, even the most often used terms in each category match. Comparisons (especially contrasts with "but") as well as causal contingency markers dominate the applied phrasing operators.

Insights Exemplarily, Table 8 compares two arguments against the death penalty synthesized by different participants, one for each strategy. The theses differ in the emotional load rather than their framing. While the logos-oriented argument frames death penalty in terms of its potential deterrent effect and the execution of innocent people, the pathos-oriented puts full emphasis on the ability of humans to regret and change. The different numbers of frames lead to a slightly different phrasing with discourse markers. Matching our results, the arrangement of both arguments is the same on the abstraction level of unit types.

6 Conclusion

We propose a general model of synthesizing argumentation following rhetorical strategies in terms of Aristotle's means of persuasion: logos, ethos, pathos. The model idealizes the synthesis as the selection, arrangement, and phrasing of argumentative discourse units (ADUs). Before we develop computational approaches based on the model, this paper has evaluated its general adequacy in an experiment with human experts. The results provide evidence that humans agree significantly more when synthesizing argumentative texts following the same strategy. In addition, we found that the arrangement of the ADUs and the re-phrasing of their connections is hardly affected by the strategy at all. A study of the phrasing of the actual units is left to future work. In the long term, we envisage a system that is able to automatically generate *effective* argumentation. Such a system requires two main types of resources: (1) a large pool of decontextualized ADUs covering diverse topics, and (2) a sufficiently flexible set of select, arrange, and phrase operators along with information about their effectiveness for specific topics and about the means of persuasion they encode. Given corpora with respective annotations, both resources can be developed using existing natural language processing techniques. We see this as the next step towards our goal.

A Dataset for Building Code-Mixed Goal Oriented Conversation Systems

Suman Banerjee, Nikita Moghe, Siddhartha Arora and **Mitesh M. Khapra**
Indian Institute of Technology Madras, India

Abstract

There is an increasing demand for goal-oriented conversation systems which can assist users in various day-to-day activities such as booking tickets, restaurant reservations, shopping, *etc*. Most of the existing datasets for building such conversation systems focus on monolingual conversations and there is hardly any work on multilingual and/or code-mixed conversations. Such datasets and systems thus do not cater to the multilingual regions of the world, such as India, where it is very common for people to speak more than one language and seamlessly switch between them resulting in code-mixed conversations. For example, a Hindi speaking user looking to book a restaurant would typically ask, "Kya tum is *restaurant* mein ek *table book* karne mein meri *help* karoge?" ("Can you help me in booking a table at this restaurant?"). To facilitate the development of such code-mixed conversation models, we build a goal-oriented dialog dataset containing code-mixed conversations. Specifically, we take the text from the DSTC2 restaurant reservation dataset and create code-mixed versions of it in Hindi-English, Bengali-English, Gujarati-English and Tamil-English. We also establish initial baselines on this dataset using existing state of the art models. This dataset along with our baseline implementations is made publicly available for research purposes.

1 Introduction

Over the past few years, there has been an increasing demand for virtual assistants which can help users in a wide variety of tasks in several domains such as entertainment, finance, healthcare, e-commerce, *etc.* To cater to this demand, several commercial conversation systems such as Siri, Cortana, Allo have been developed. While these systems are still far from general purpose open domain chat, they perform reasonably well for certain goal-oriented tasks such as setting alarms/reminders, booking appointments, checking movie show timings, finding directions for navigation, *etc*. Apart from these commercial systems, there has also been significant academic research to advance the state of the art in conversation systems (Shang et al., 2015; Vinyals and Le, 2015; Yao et al., 2015; Li et al., 2016a; Li et al., 2016b; Serban et al., 2017). Most of this academic research is driven by publicly available datasets such as Twitter conversation dataset (Ritter et al., 2010), Ubuntu dialog dataset (Lowe et al., 2015), Movie subtitles dataset (Lison and Tiedemann, 2016) and DSTC2 restaurant reservation dataset (Henderson et al., 2014a). In this work, we focus on goal-oriented conversations such as the ones contained in the DSTC2 dataset.

Most of the datasets and state of the art systems mentioned above are monolingual. Specifically, all the utterances and responses in the conversations are in one language (typically, English) and there are no multilingual and/or code-mixed utterances/responses. However, in several multilingual regions of the world, such as India, it is natural for speakers to produce utterances and responses which are multilingual and code-mixed. For example, Table 1 shows real examples of how bilingual speakers from India talk when requesting someone to help them reserve a restaurant or book movie tickets. As it can

Table 1: Example code-mixed utterances in the specified languages.

be seen, when engaging in such informal conversations it is very natural for such speakers to use code-mixed utterances, mixing their native language with English. Apart from India, such code-mixing is also prevalent in other multilingual regions of the world, for example, Spanglish (Spanish-English), Frenglish (French-English), Porglish (Portuguese-English) and so on. To cater to such users, it is essential to create datasets containing code-mixed conversations and thus facilitate the development of code-mixed conversation systems.

With the above motivation, we build a dataset containing code-mixed goal-oriented conversations for four Indian languages. Specifically, we take every utterance from the DSTC2 restaurant reservation dataset and ask a mix of in-house and crowdsourced workers to create a corresponding code-mixed utterance involving their native language and English. We simply instructed the workers to (i) assume that they were chatting with a friend who spoke the same native language as them in addition to English, (ii) not try very hard to translate the sentence completely to their native language but feel free to switch to English whenever they wanted (just as they would in a normal conversation with a friend) and (iii) use Romanized text instead of the native language's script. The resulting dataset contains utterances of the type shown in Table 1. We found that 87.73% of the created utterances were code-mixed, 7.18% had only English words and 5.09% had only native language words. The four languages that we chose were Hindi, Bengali, Tamil and Gujarati which have 422M, 83M, 60M and 46M native speakers respectively.

Apart from reporting various statistics about this data (such as CM-index (Gambäck and Das, 2016) and I-index (Guzmán et al., 2016)), we also report some initial baselines by evaluating some state of the art approaches on the proposed dataset. Specifically, we evaluate a standard sequence-to-sequence model with an attention mechanism (Bahdanau et al., 2015) and a hierarchical recurrent encoder-decoder model (Serban et al., 2016). Our code implementing these models along with the dataset is available freely for research purposes[1]. To the best of our knowledge, this is the first conversation dataset containing code-mixed conversations and will hopefully enable further research in this area. In particular, since the data is 5-way parallel (English, Bengali, Hindi, Tamil, Gujarati) it would be useful for building jointly trained code-mixed models.

2 Related Work

Serban et al. (2015) report an excellent (and up-to-date) survey of existing dialog datasets. For brevity, we only mention some of the important points from their survey and refer the reader to the original paper for more details. To begin with, we note that existing dialog datasets can be categorized along 3 main dimensions. The first dimension is the modality of the dataset, *i.e.*, whether the dataset contains spoken conversations (Godfrey et al., 1992; Kim et al., 2016) or text conversations (Forsythand and Martell, 2007; Ritter et al., 2010; Lowe et al., 2015). The second dimension is whether the dataset contains goal-oriented conversations or open-ended conversations. A goal-oriented conversation typically involves chatting for the sake of completing a task such as the Dialog State Tracking Challenge (DSTC) datasets which involve tasks for reserving a restaurant (Henderson et al., 2014a), checking bus

Table 2: An example chat from the English version of DSTC2 dataset (Bordes and Weston, 2017).

schedules (Williams et al., 2013), collecting tourist information (Henderson et al., 2014b) and so on. Such datasets are also typically domain-specific. Open-ended conversations on the other hand involve general chat on any topic and there is no specific end task. Some popular examples of datasets containing such open-ended conversations are the Ritel Corpus (Rosset and Petel, 2006), NPS Chat Corpus (Forsythand and Martell, 2007), Twitter Corpus (Ritter et al., 2010), *etc*. The third dimension is whether the dataset contains human-human conversations or human-bot conversations. As the name suggests, human-bot conversation datasets contain conversations between humans and an existing conversation system (typically a domain-specific goal-oriented bot) (Williams et al., 2013; Henderson et al., 2014a; Henderson et al., 2014b). Human-human conversations, on the other hand, can contain spontaneous conversations between humans, as are typically observed in discussion forums (Walker et al., 2012), chat rooms (Forsythand and Martell, 2007), SMS messages (Chen and Kan, 2013) and so on. Human-human conversations can also contain scripted dialogs such as scripts of movies (Banchs, 2012), TV shows (Roy et al., 2014), *etc*. It is surprising that of the 63 conversation datasets developed in the past (Serban et al., 2015), none contain multilingual conversations. In particular, none of them contain code-mixed conversations from multilingual regions of the world. There is clearly a need to fill this gap and we believe that the dataset developed as a part of this work is a small step in that direction.

In general, the research community has been interested in developing datasets, tools and approaches for code-mixed content. This interest is largely triggered by the abundance of code-mixed content found in chats, emails, social media platforms, *etc*. In the context of such code-mixed content, existing works have looked at the problems of language identification (Nguyen and Dogruöz, 2013; Solorio et al., 2014; Barman et al., 2014; Molina et al., 2016), part-of-speech tagging (Barman et al., 2016; Ghosh et al., 2016; AlGhamdi et al., 2016), user profiling (Khapra et al., 2013), topic modeling (Rosner and Farrugia, 2007), information retrieval (Chakma and Das, 2016) and language modeling (Adel et al., 2013a; Adel et al., 2013b; Adel et al., 2015). However, to the best of our knowledge, ours is the first work on developing code-mixed conversation systems for goal-oriented dialogs.

3 Background: DSTC2 Restaurant Reservation Dataset

We build on top of the goal-oriented restaurant reservation dialog dataset which was released as part of the second Dialog State Tracking Challenge (DSTC2) (Henderson et al., 2014a). This dataset contains conversations between crowdsourced workers and existing dialog systems (bots). Specifically, the workers were asked to book a table at a restaurant with the help of a bot. These dialog systems consisted of modules like automatic speech recognizer, natural language interpreter, dialog manager, response generator and a speech synthesizer (Young, 2000). The dialog manager used polices which were either hand-crafted or learned by formulating the problem as a partially observable Markov decision process (POMDP) (Williams and Young, 2007). The speech input from the user was first converted to text and then fed to the dialog system. For this, the authors used two Automatic Speech Recognition (ASR) modules out of which one was artificially degraded in order to simulate noisy environments. The workers could request for restaurants based on 3 slots: *area* (5 possible values), *cuisine* (91 possible values) and *price range* (3 possible values). The workers were also instructed to change their goals and look for alternative *areas*, *cuisines* and *price ranges* in the middle of the dialog. This was done to account for the unpredictability in natural conversations. The conversations were then transcribed and the utterances were labeled with different dialog states. For example, each utterance was labeled with its semantic intent representation (*request[area], inform[area = north]*) and the dialog turns were labeled with annotations such as constraints on the slots (*cuisine = italian*), requested slots (*requested* = {*phone, address*}) and the method of search (*by_constraints, by_alternatives*). Such annotations are useful for domain-specific slot-filling based dialog systems.

Bordes and Weston (2017) argued that for various domains collecting such explicit annotations for every state in the dialog is tedious and expensive. Instead, they emphasized on building end-to-end dialog systems (as opposed to slot-filling based systems) by adapting this dataset and treating it as a simple sequence of utterance-response pairs (without any explicit dialog states associated with the utterances). In addition, the authors also created API calls which can be issued to an underlying Knowledge Base (KB) and appended the resultant KB triples to each dialog. Table 2 shows one small sample dialog from this adapted dataset along with the API calls. Notice that the API call uses the information of all the constraints specified by the user so far and then receives all triples from the restaurant KB which match the user's requirements. This dataset facilitated the development of models (Bordes and Weston, 2017; Seo et al., 2017; Williams et al., 2017; Eric and Manning, 2017) which just predict the bot utterances and API calls without explicitly tracking the slots. Table 3 reports the statistics of this dataset. In this work, we create code-mixed versions of this dataset in 4 different languages as described below.

4 Code-Mixed Dialog Dataset

In this section, we describe the process used for creating a new dataset containing code-mixed conversations. Specifically, we describe (i) the process used for extracting unique utterance templates from the original DSTC2 dataset, (ii) the process of creating code-mixed translations of these utterances with the help of in-house and crowdsourced workers and (iii) the process used for evaluating the collected conversations. Finally, we report some statistics about the dataset.

4.1 Extracting Unique Utterance Templates

We found that many utterances in the original English version of DSTC2 dataset (henceforth referred to as En-DSTC2) have the same sentence structure but only differ in the values of the *areas*, *cuisines*, *price ranges* and entities such as *restaurant names, addresses, phone numbers* and *post codes*. For example, consider these two sentences which only differ in the *area* and *cuisine*: (i) "Sorry, there is no *chinese* restaurant in the *north* part of town." and (ii) "Sorry, there is no *italian* restaurant in the *west* part of town". Both these sentences can be thought of as instantiations of the generic template: "Sorry, there is no [CUISINE] restaurant in the [AREA] part of town." wherein the placeholders [AREA] and [CUISINE] get replaced by different values. We used the KB provided by Bordes and Weston (2017) to find all the entities appearing in all the utterances and replaced them by placeholders such as: [AREA], [CUISINE], [PRICE], [RESTAURANT], [ADDRESS], [PHONE] and [POST_CODE]. Further, since the authors had mentioned that the KB provided was not perfect/complete, we did some manual inspection to find all such entities and came up with a list of 536 such entity words. After replacing these words with their respective placeholders we obtained 3590 unique English utterances.

4.2 Creating Code-Mixed Translations

According to Myers-Scotton (1993) code-mixing involves a native language which provides the morphosyntactic frame and a foreign language whose *linguistic units* such as *phrases, words* and *morphemes* are inserted into this morphosyntactic frame. The native language is called the *Matrix* while the foreign language is called the *Embedding*. Our work focuses on creating a conversation dataset wherein 4 different Indian languages, *viz.*, Hindi, Bengali, Gujarati and Tamil serve as the *Matrix* and English serves as the *Embedding*. We used a mix of in-house and crowdsourced workers to create a code-mixed version of the original DSTC2 dataset. For example, for Hindi and Gujarati, we did not have enough in-house speakers so we completely relied on crowdsourcing for creating the data but then used in-house workers to verify the collected data. For Bengali, all the data was created by in-house annotators who were native Bengali speakers and proficient in English. Lastly, for Tamil, roughly 40% of the data was created with the help of crowdsourced workers and the rest with the help of in-house workers. Irrespective of whether the workers were crowdsourced or in-house we used the same set of instructions as described below.

We instructed the annotators to assume that they were chatting with a friend who is a native speaker of Hindi (or Gujarati, Bengali, Tamil) but also speaks English well (typically, because English was the language in which the friend did most of his/her education). To explain the idea of code-mixing, we showed them example utterances where it was natural for the user to mix English words while chatting in the native language. They were then shown an English utterance from the DSTC2 dataset and asked to create its code-mixed translation in the native language keeping the above code-mixed examples in mind. They were asked to use Roman script irrespective of whether the word being used belongs to English or the native language (in particular, they were clearly instructed to not use the native language's script). As expected, we observed that while translating, the annotators tend to retain some difficult-to-translate and colloquially relevant English words as it is. The annotators were also clearly instructed to refrain from producing pure translations (*i.e.*, they were asked to not try hard to translate English words which they would typically not translate in an informal conversation). Also, the annotators were instructed to retain the placeholder words ([AREA], [CUISINE], *etc.*) as it is and not translate them.

We used Amazon Mechanical Turk (AMT) as the platform for crowdsourcing. Each Human Intelligence Task (HIT) required the user to give code-mixed translations of 5 utterances and was priced at $0.2. Once we collected the code-mixed translations of all the utterance templates that were extracted using the procedure described in the previous subsection, we then instantiated them into proper sentences by replacing the placeholders ([AREA], [CUISINE], *etc.*) with the corresponding entities as present in the original DSTC2 dataset. For every dialog in the original DSTC2 dataset, every utterance was then replaced by its code-mixed translation resulting in an end-to-end code-mixed conversation.

		In-house Workers	Evaluators
Avg. Age		25.2	24.6
Gender	**Female**	33.3%	25.0%
	Male	66.7%	75.0%
Highest Education	**Undergraduate**	25.0%	33.3%
	Graduate	41.7%	33.3%
	Postgraduate	33.3%	33.3%
English Medium Schooling	**Yes**	100%	100%
	No	0%	0%
Frequency of English usage	**Frequently**	75.0%	91.7%
	Occasionally	25.0%	8.3%
	Rarely	0%	0%
Frequency of native language usage	**Frequently**	100%	91.7%
	Occasionally	0%	8.3%
	Rarely	0%	0%

Table 4: Demographic details of the in-house workers and the human evaluators.

Datasets	Colloquialism	Intelligibility	Coherent
Hi-DSTC2	4.20	4.06	4.21
Be-DSTC2	4.07	4.05	4.11
Gu-DSTC2	3.66	3.60	3.76
Ta-DSTC2	4.17	3.96	3.93

Table 5: Average human ratings for different metrics.

4.3 Evaluating the Collected Dataset

We did evaluations at two levels. The first evaluation was at the level of utterances wherein if the code-mixed translation of an utterance was obtained via crowdsourcing, then we got this translation verified by in-house evaluators. The evaluators were asked to check if (i) the translation was faithful to the source sentence, (ii) the code-mixing was natural and not forced and (iii) all translations used Roman script and not the native language's script. Any utterance which was flagged as erroneous by the evaluator was again crowdsourced and a new translation was solicited from AMT workers. If a worker's utterances were flagged erroneous often then we barred him/her from doing any more tasks.

As mentioned in the previous section, once we collected such verified translations for all the utterance templates, we instantiated them and created complete end-to-end dialogs containing code-mixed utterances. Once the entire dialog was constructed, we conducted a separate human evaluation wherein we asked 12 in-house evaluators (3 evaluators per language) to read 100 code-mixed dialogs (entire dialogs as opposed to just some utterances) from each language and rate them on three metrics namely colloquialism, intelligibility and coherence on a scale of 1 (very poor) to 5 (very good) as defined below.

- **Colloquialism:** To check if the code-mixing was colloquial throughout the dialog and not forced.
- **Intelligibility:** To check if the entire dialog could be easily understood by a bilingual speaker who could speak the native language as well as English.
- **Coherence:** To check if the entire dialog looked coherent even though it was constructed by stitching together utterances which were independently translated and code-mixed (*i.e.*, while translating an utterance annotators did not know what their preceding and following utterances were).

These 100 dialogs were chosen randomly from across the entire dataset for each language. The evaluators used for this were different from the in-house annotators used to create the original translations in order to reduce the bias in evaluations. The average ratings given by the evaluators for each of the languages are shown in Table 5 and are encouraging. The demographic details of the in-house workers and evaluators are shown in Table 4.

4.4 Dataset Statistics and Analysis

For every word in the code-mixed corpus, we were able to identify whether it was a word from the native language or English or language agnostic (named entities). It was easy to do this because we had the vocabulary of the original English DSTC2 corpus as well as named entities (so any word which was not in the original DSTC2 vocabulary or a named entity was a word from the native language). We also manually verified this list of words marked as native words and corrected discrepancies if any (*i.e.*, we ensured that all the words which were marked as native words were actually native words). Note that the

	Hindi	Bengali	Gujarati	Tamil
Vocabulary Size	1676	1372	1858	2185
Code-Mixed English Vocabulary	386	360	387	424
Native Language Vocabulary	739	477	912	1214
Others Vocabulary	551	535	559	547
Unique Utterances	6549	6274	6417	6666
Utterances with code-mixed words	5750	5703	5643	5632

Average # of code-mixed utterances per dialog	12.11	14.28	11.80	12.96

Table 6: Statistics of the code-mixed dataset

cuisine names such as *Australian, Italian, etc.* have their own dedicated words in the native language. Table 6 summarizes various statistics about the dataset such as total vocabulary size, native language vocabulary size, *etc*. We refer to the original English dataset as En-DSTC2 and the Hindi, Bengali, Tamil and Gujarati code-mixed datasets created as a part of this work as Hi-DSTC2, Be-DSTC2, Ta-DSTC2 and Gu-DSTC2 respectively. Below, we make a few observations from Table 6.

The percentage of code-mixed English words in the vocabulary of Hi-DSTC2, Be-DSTC2, Gu-DSTC2 and Ta-DSTC2 are 23.03%, 26.24%, 20.83% and 19.40% respectively. From these English words, the most high frequency words across all the four versions of the dataset were *restaurant, food, town* and *serve*. Although these words have their own dedicated counterparts in all the other four languages, people colloquially use these code-mixed English words very often when talking about restaurants in their native language. The percentage of code-mixed utterances out of all the unique utterances in Hi-DSTC2, Be-DSTC2, Gu-DSTC2 and Ta-DSTC2 are 87.80%, 90.90%, 87.94% and 84.49% respectively (from Table 6). This shows that a significant portion of the dataset contains code-mixed utterances and very few utterances are in pure native languages or in pure English. This fact is also evident from the average number of code-mixed utterances per dialog in Table 6 compared to the average number of utterances per dialog in Table 3. We also calculated the number of utterances which contain k non-native words and then plotted a histogram (Figure 1) where the x-axis shows the number of k non-native words and the y-axis shows the number of utterances which had k non-native words. These histograms show a similar trend across all the languages. Apart from such intra-utterance code-mixing, we also noticed some intra-word code-mixing in mostly Bengali (*restauranter, towner*) and Tamil (*addressum, numberum, addressah*) versions of the dataset.

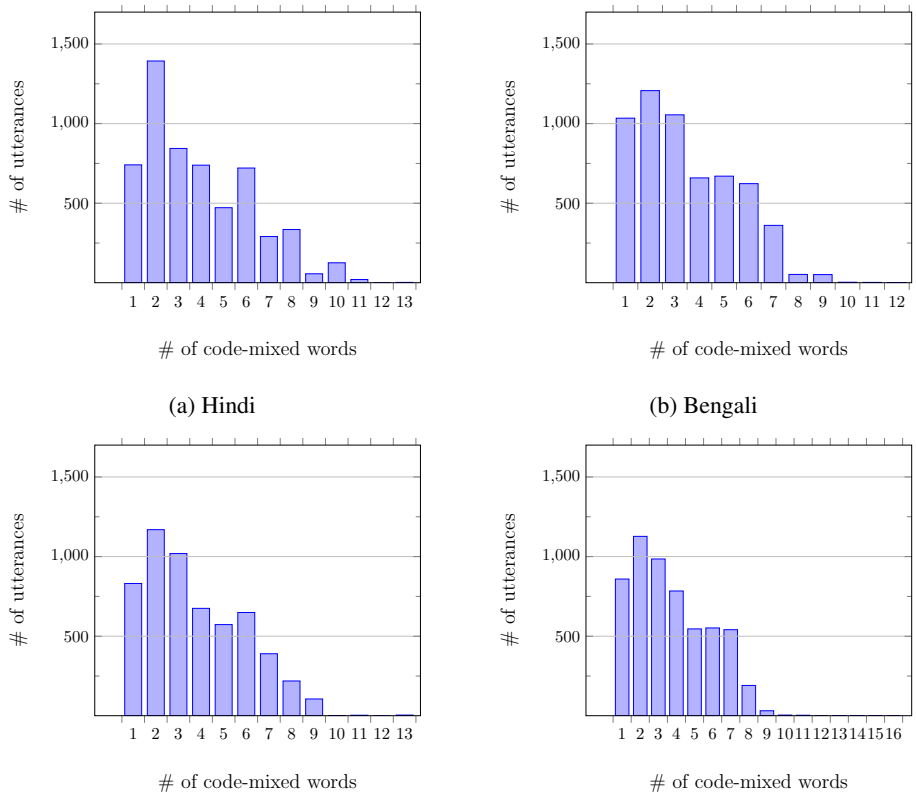
4.5 Quantitative Measures of Code-Mixing

Gambäck and Das (2016) introduced a measure to quantify the amount of code-mixing in a sentence as:

$$C_u(x) = \begin{cases} \frac{N(x) - \max\limits_{L_i \in \mathcal{L}} \{t_{L_i}\}}{N(x)} & : N(x) > 0 \\ 0 & : N(x) = 0 \end{cases} \quad (1)$$

Here, $\mathcal{L}$ is the set of all languages in the corpus, t_{L_i} is the number of tokens of language L_i in the given sentence x, $\max\limits_{L_i \in \mathcal{L}} \{t_{L_i}\}$ is the maximum number of tokens of a language L_i in the sentence x and $N(x)$ is the number of language-specific tokens in the sentence ($N(x)$ does not include named entities as they are language agnostic). The authors make a crucial assumption that $\arg\max\limits_{L_i \in \mathcal{L}} \{t_{L_i}\}$ is the *Matrix* language and hence the numerator of Equation 1 gives the number of foreign language tokens in x. This measure does not take into account the number of language switch points in a sentence (denoted by $P(x)$) and so the authors modify it further:

$$C_u(x) = 100 \cdot \frac{N(x) - \max\limits_{L_i \in \mathcal{L}} \{t_{L_i}\} + P(x)}{2N(x)} : (\textit{if}\, N(x) > 0) \quad (2)$$



(a) Hindi (b) Bengali

(c) Gujarati (d) Tamil

Figure 1: Histogram of the number of code mixed words in all the unique utterances for each language.

The code-mixing in the entire corpus can then be quantified by taking an average of the above measure across all sentences in the corpus:

$$C_{avg} = \frac{1}{U} \sum_{i=1}^{U} C_u(x_i) \tag{3}$$

where U is the number of sentences in the corpus. However, their main assumption that the language which has the maximum number of tokens in a sentence is the *Matrix* language, may not always hold. Consider a counter example: "Prezzo ek accha *restaurant* hain *in the north part of town* jo *tasty chinese food serve* karta hain." Here the word 'Prezzo' is a named entity and hence treated as a language independent token. The most frequent language (*italicized*) is English but the *Matrix* language is essentially Hindi. So we propose a small modification to their measure and replace $\max_{L_i \in \mathcal{L}}\{t_{L_i}\}$ by the following:

$$native(x) = \begin{cases} t_{L_n} & : t_{L_n} > 0 \\ N(x) & : t_{L_n} = 0 \end{cases} \tag{4}$$

where L_n is the native (*Matrix*) language of the utterance and t_{L_n} is the number of tokens of the native language in the utterance. Note that we know the native (*Matrix*) language of every utterance beforehand because of the manner in which the dataset was created. Gambäck and Das (2016) also pointed out that C_{avg} does not take the inter-utterance code-mixing and frequency of code-mixed utterances into account. To overcome this they proposed to use a term $\delta(x_i)$ which assigns a score of 1 if the *Matrix* language of x_i is different from that of x_{i-1} or a score of 0 if they are same or $i = 1$. Note that in our case $\delta(x_i)$ would mostly be 0 except for cases where x_i is a pure English utterance. The authors also used a term for the fraction of code-mixed utterances $(\frac{S}{U})$ in the corpus, where S is the total number of code-mixed utterances. We use a modified version of their final Code-Mixing index[2] by replacing the maximum

[2]We refer the reader to Gambäck and Das (2016) for the detailed derivation.

Language-pair	En-Be	En-Hi	En-Hi	En-Hi	En-Hi	En-Hi	En-Be	En-Gu	En-Ta
Dataset	TW (Jamatia)	TW (Jamatia)	FB (Jamatia)	FB+TW (Jamatia)	Vyas	Hi-DSTC2	Be-DSTC2	Gu-DSTC2	Ta-DSTC2
I-index	-	-	-	-	-	**0.04**	**0.04**	0.03	0.03
$\mathbf{C_{avg}}$	8.34	21.19	3.92	11.82	11.44	**32.12**	31.80	31.66	29.54

$\mathbf{C_c}$	25.14	64.38	16.76	38.53	31.31	73.31	76.27	71.63	**80.49**

Table 7: Comparison of the quantitative measures of code-mixing in the dataset.

function by $native(x)$:

$$C_c = \frac{100}{U}\left[\frac{1}{2}\sum_{i=1}^{U}\left(1 - \frac{native(x) + P(x)}{N(x)} + \delta(x)\right) + \frac{5}{6}S\right] \quad (5)$$

Similarly, Guzmán et al. (2016) introduced the I-index measure to quantify the integration of different languages in a corpus. This metric is much simpler and simply computes the number of switch points in the corpus. For example, if a corpus contains n words and there are k positions at which the language of $word_i$ is not the same as the language of $word_j$ then the I-index is given by $\frac{k}{n-1}$. We compute the I-index for every utterance in a dialog, then compute the average over all utterances in a dialog and finally report the average across all dialogs in the code-mixed corpus. These measures of our dataset are shown in Table 7 and are compared with that of the existing datasets (Jamatia et al., 2016; Vyas et al., 2014). Jamatia et al. (2016) collected the code-mixed text from Twitter (TW) and Facebook (FB) posts whereas Vyas et al. (2014) collected their dataset only from Facebook forums. Although the dataset of Vyas et al. (2014) show the highest inter-utterance code-mixing (δ), Hi-DSTC2 and Ta-DSTC2 show the highest level of overall code-mixing at the utterance level (C_{avg}) and the corpus level (C_c) respectively.

5 Baseline Models

We establish some initial baseline results on this code-mixed dataset by evaluating two different generation based models: (i) sequence-to-sequence with attention (Bahdanau et al., 2015) and (ii) Hierarchical Recurrent Encoder-Decoder (HRED) model (Serban et al., 2016). Due to lack of space we don't describe these popular models here but refer the reader to the original papers. Apart from the above models, models which fetch the correct response from a set of candidate responses such as Query Reduction Networks (Seo et al., 2017), Memory Networks (Bordes and Weston, 2017) and Hybrid Code Networks (Williams et al., 2017) have also been evaluated on En-DSTC2. However, it is difficult to get candidate responses for every domain in practice and hence we stick to generation based models.

5.1 Experimental Setup

We use the train, validation and test splits of Bordes and Weston (2017) mentioned in Table 3. We create training instances from the dialogs by creating pairs of $\{$*context, response*$\}$ where *response* is every even numbered utterance and *context* contains all the previous utterances. Thus, if a dialog has 10 utterances, we create 5 training instances from it. Similarly at the test time the model is given the *context* and it has to generate the *response*. For both the models, we used Adam optimizer (Kingma and Ba, 2015) to train the network with a mini batch size of 32. We used dropouts (Srivastava et al., 2014) of 0.25 and 0.35, initial learning rate of 0.0004 and Gated Recurrent Units (GRU) (Cho et al., 2014) with hidden dimensions of size 350. We used word embeddings of size 300 with Glorot initialization (Glorot and Bengio, 2010). We also clipped the gradients at a maximum norm of 10 to avoid exploding gradients.

5.2 Evaluation

We evaluate the performance of the above models using BLEU-4 (Papineni et al., 2002), ROUGE-1, ROUGE-2 and ROUGE-L (Lin, 2004) which are widely used to evaluate the performance of Natural Language Generation systems. We also compute the per utterance accuracy (exact match) by comparing

	SEQ2SEQ WITH ATTENTION					HRED				
Metrics	English	Hindi	Bengali	Gujarati	Tamil	English	Hindi	Bengali	Gujarati	Tamil
BLEU-4	56.6	54.0	56.8	53.8	62.1	57.8	54.1	56.7	54.1	60.7
ROUGE-1	67.2	62.9	67.4	64.7	67.8	67.9	63.3	67.1	65.3	67.1
ROUGE-2	55.9	52.4	57.5	54.8	56.3	57.5	52.6	56.9	55.2	55.6
ROUGE-L	64.8	61.0	65.1	62.6	65.6	65.7	61.5	64.8	63.2	65.1
Per response acc.	46.0	48.0	50.4	47.6	49.3	48.8	47.2	47.7	47.9	47.8
Per dialog acc.	1.4	1.2	1.5	1.5	1.3	1.4	1.5	1.6	1.6	1.0

Table 8: Performance of the baseline models on all the languages

the generated response with the ground truth response. The generated response is considered to be accurate only if it exactly matches the ground truth response. This is obviously a more strict metric for generation based models (Eric and Manning, 2017). We also compute the per dialog accuracy by matching all the generated responses in a dialog with all the ground truth responses for that dialog. This metric measures whether the model was able to produce the entire dialog correctly end-to-end and hence complete the goal. We summarize the performance of the two models in Table 8. We observe that the performance of these models is very similar across all the languages. We observe that the models are still far from 100% accuracy and there is clearly scope for further improvement.

6 Conclusion

Code-mixing is an emerging trend of communication in the multilingual regions. The community has already addressed this phenomenon by introducing challenges on POS-Tagging, Language Identification, Language Modeling, *etc* on the code-mixed corpora. However, the approaches to development of dialog systems still rely on monolingual conversation datasets. To alleviate this problem we introduced a goal-oriented code-mixed dialog dataset for four languages (Hindi-English, Bengali-English, Gujarati-English and Tamil-English respectively). The dataset was created using a mix of in-house and crowdsourced workers. All the utterances in the dataset were evaluated by in-house evaluators and the overall dialogs were also evaluated for colloquialism, intelligibility and coherence. On all these measures, the dialogs in our dataset received a high score. To facilitate further research on these datasets, we provide the implementation of two popular neural dialog models *viz.* sequence-to-sequence and HRED. The evaluation of these models suggest that there is a clear scope for development of new architectures which can understand and converse in code-mixed languages.

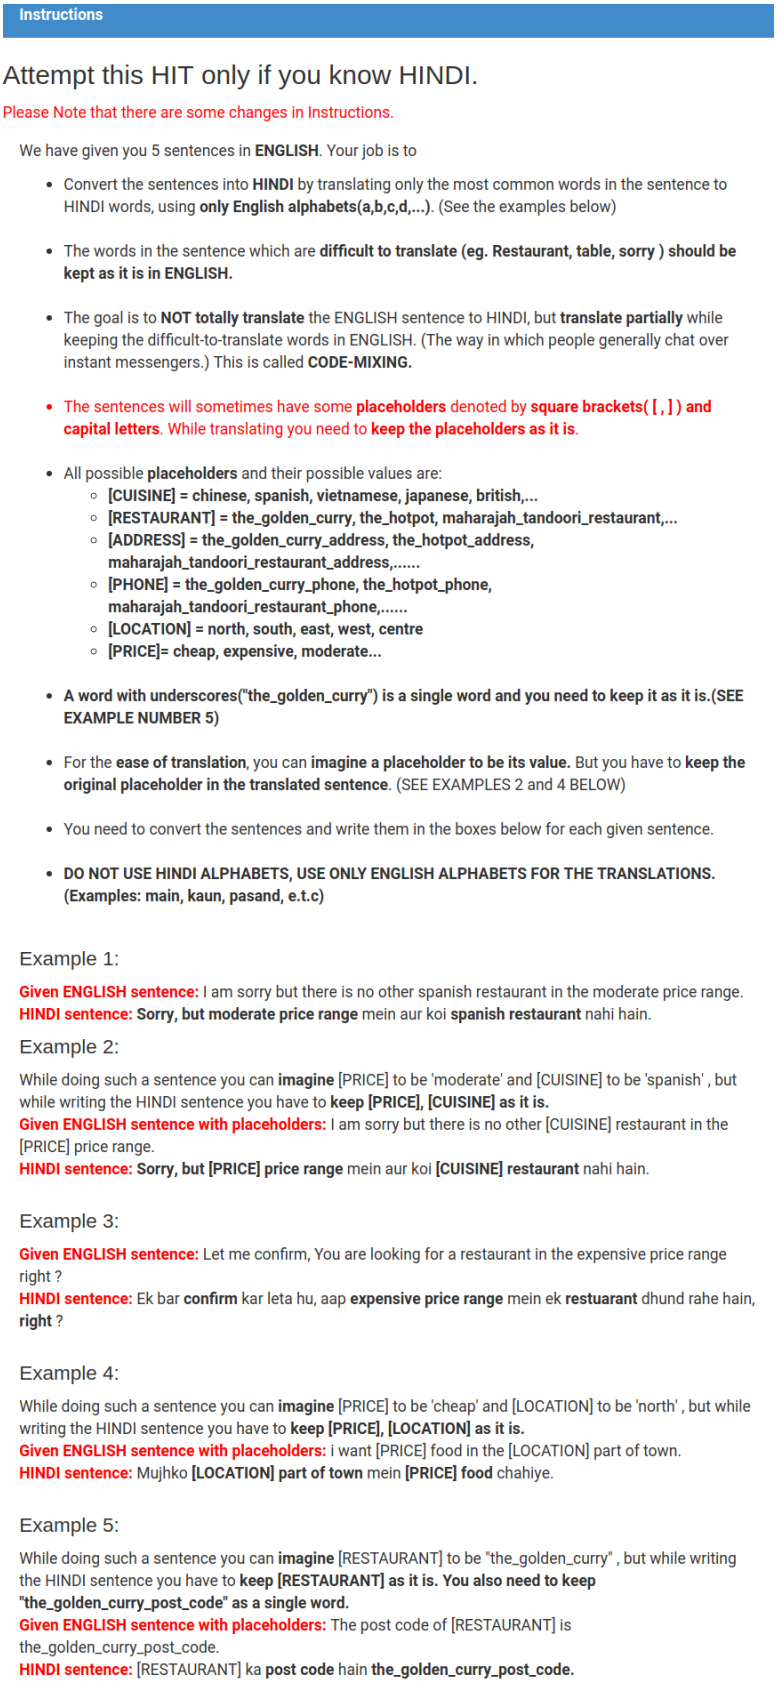
Appendix A. Instructions to Crowdsourced Workers



Instructions

Attempt this HIT only if you know HINDI.

Please Note that there are some changes in Instructions.

We have given you 5 sentences in **ENGLISH**. Your job is to

- Convert the sentences into **HINDI** by translating only the most common words in the sentence to HINDI words, using **only English alphabets(a,b,c,d,...)**. (See the examples below)
- The words in the sentence which are **difficult to translate (eg. Restaurant, table, sorry) should be kept as it is in ENGLISH.**
- The goal is to **NOT totally translate** the ENGLISH sentence to HINDI, but **translate partially** while keeping the difficult-to-translate words in ENGLISH. (The way in which people generally chat over instant messengers.) This is called **CODE-MIXING.**
- The sentences will sometimes have some **placeholders** denoted by **square brackets([,]) and capital letters**. While translating you need to **keep the placeholders as it is**.
- All possible **placeholders** and their possible values are:
  - **[CUISINE] = chinese, spanish, vietnamese, japanese, british,...**
  - **[RESTAURANT] = the_golden_curry, the_hotpot, maharajah_tandoori_restaurant,...**
  - **[ADDRESS] = the_golden_curry_address, the_hotpot_address, maharajah_tandoori_restaurant_address,.....**
  - **[PHONE] = the_golden_curry_phone, the_hotpot_phone, maharajah_tandoori_restaurant_phone,.....**
  - **[LOCATION] = north, south, east, west, centre**
  - **[PRICE]= cheap, expensive, moderate...**
- **A word with underscores("the_golden_curry") is a single word and you need to keep it as it is.(SEE EXAMPLE NUMBER 5)**
- For the **ease of translation**, you can **imagine a placeholder to be its value.** But you have to **keep the original placeholder in the translated sentence**. (SEE EXAMPLES 2 and 4 BELOW)
- You need to convert the sentences and write them in the boxes below for each given sentence.
- **DO NOT USE HINDI ALPHABETS, USE ONLY ENGLISH ALPHABETS FOR THE TRANSLATIONS. (Examples: main, kaun, pasand, e.t.c)**

Example 1:

Given ENGLISH sentence: I am sorry but there is no other spanish restaurant in the moderate price range.
HINDI sentence: **Sorry, but moderate price range** mein aur koi **spanish restaurant** nahi hain.

Example 2:

While doing such a sentence you can **imagine** [PRICE] to be 'moderate' and [CUISINE] to be 'spanish' , but while writing the HINDI sentence you have to **keep [PRICE], [CUISINE] as it is.**
Given ENGLISH sentence with placeholders: I am sorry but there is no other [CUISINE] restaurant in the [PRICE] price range.
HINDI sentence: **Sorry, but [PRICE] price range** mein aur koi **[CUISINE] restaurant** nahi hain.

Example 3:

Given ENGLISH sentence: Let me confirm, You are looking for a restaurant in the expensive price range right ?
HINDI sentence: Ek bar **confirm** kar leta hu, aap **expensive price range** mein ek **restuarant** dhund rahe hain, **right** ?

Example 4:

While doing such a sentence you can **imagine** [PRICE] to be 'cheap' and [LOCATION] to be 'north' , but while writing the HINDI sentence you have to **keep [PRICE], [LOCATION] as it is.**
Given ENGLISH sentence with placeholders: i want [PRICE] food in the [LOCATION] part of town.
HINDI sentence: Mujhko **[LOCATION] part of town** mein **[PRICE] food** chahiye.

Example 5:

While doing such a sentence you can **imagine** [RESTAURANT] to be "the_golden_curry" , but while writing the HINDI sentence you have to **keep [RESTAURANT] as it is. You also need to keep "the_golden_curry_post_code" as a single word.**
Given ENGLISH sentence with placeholders: The post code of [RESTAURANT] is the_golden_curry_post_code.
HINDI sentence: [RESTAURANT] ka **post code** hain **the_golden_curry_post_code.**

Sequence-to-Sequence Learning for Task-oriented Dialogue with Dialogue State Representation

Haoyang Wen, Yijia Liu, Wanxiang Che*, Libo Qin, Ting Liu
Research Center for Social Computing and Information Retrieval,
Harbin Institute of Technology, China
{hywen, yjliu, car, lbqin, tliu}@ir.hit.edu.cn

Abstract

Classic pipeline models for task-oriented dialogue system require explicit modeling the dialogue states and hand-crafted action spaces to query a domain-specific knowledge base. Conversely, sequence-to-sequence models learn to map dialogue history to the response in current turn without explicit knowledge base querying. In this work, we propose a novel framework that leverages the advantages of classic pipeline and sequence-to-sequence models. Our framework models a dialogue state as a fixed-size distributed representation and use this representation to query a knowledge base via an attention mechanism. Experiment on Stanford Multi-turn Multi-domain Task-oriented Dialogue Dataset shows that our framework significantly outperforms other sequence-to-sequence based baseline models on both automatic and human evaluation.

Title and Abstract in Chinese

面向任务型对话中基于对话状态表示的序列到序列学习

面向任务型对话中，传统流水线模型要求对对话状态进行显式建模。这需要人工定义对领域相关的知识库进行检索的动作空间。相反地，序列到序列模型可以直接学习从对话历史到当前轮回复的一个映射，但其没有显式地进行知识库的检索。在本文中，我们提出了一个结合传统流水线与序列到序列二者优点的模型。我们的模型将对话历史建模为一组固定大小的分布式表示。基于这组表示，我们利用注意力机制对知识库进行检索。在斯坦福多轮多领域对话数据集上的实验证明，我们的模型在自动评价与人工评价上优于其他基于序列到序列的模型。

1 Introduction

Task-oriented dialogue system attracts more and more attention with the success of commercial systems such as Siri, Cortana and Echo. It helps users complete specific tasks with natural language. Figure 1 shows a typical example of a task-oriented dialogue, where an agent provides with location information for a user. The requirements for the agents to accomplish users' demands usually involve querying the knowledge base (KB), like acquiring address from location information KB in Figure 1.

Typical machine learning approaches model the problem as a partially observable Markov Decision Process (POMDP) (Williams and Young, 2007; Young et al., 2013), where a pipeline system is introduced. The pipeline system consists of four components: natural language understanding (NLU, Tur and De Mori, 2011) , dialogue state tracking (Williams et al., 2013; Williams, 2012), dialogue policy learning (Young et al., 2010) and natural language generation (Wen et al., 2015). Taking the utterance in Figure 1 for example, NLU maps the utterance "`Address to the gas station`" into semantic slot "`POI type`". Dialogue state tracker keeps the probability of "`gas station`" close to 1 against other values of slot "`POI type`". Given a semantic frame as a dialogue state, which is the combination of distributions of these slots, dialogue policy learning generates the next pre-defined system action,

145 Amherst St	1 miles	coffee or tea place	Teavana	road block nearby
409 Bollard St	5 miles	grocery store	Willows Market	no traffic

Driver: Address to the gas station.
Car: Valero is located at 200 Alester Ave.
Driver: OK , please give me directions via a route that avoids all heavy traffic.
Car: Since there is a road block nearby, I found another route for you and I sent it on your screen.
Driver: Awesome thank you.

Figure 1: An example of a task-oriented dialogue that incorporates a knowledge base. The knowledge base will be changed based on different dialogue environment setting. Agents need to generate response based on current knowledge base.

which usually involves querying the knowledge base. The action is then converted to its natural language expression using natural language generation. Both natural language understanding and dialogue state tracking require a large amount of domain specific annotation for training, which is expensive to obtain. Besides, the design of actions and the explicit forms of semantic frames require a lot of knowledge from human experts, which are domain-specific as well.

Neural generative models, typically Seq2Seq models, have achieved success on machine translation (Sutskever et al., 2014; Bahdanau et al., 2014; Luong et al., 2015). This success spurs the interests to apply Seq2Seq models into dialogue systems. Seq2Seq models map dialogue history directly into the response in current turn, while requires a minimum amount of hand-crafting. However, conventional Seq2Seq doesn't model the exterior data retrieval explicitly, which makes it hard for Seq2Seq to generate information stored in KB like meeting time and address, but this kind of retrieval is easy to achieve for classic pipeline. To tackle with the problem, Eric and Manning (2017) use an additional copy mechanism to retrieve entities that occurs in both KB and dialogue history. Eric et al. (2017) further introduced retrieval from key-value KB where the model uses key representations to retrieve the corresponding values. However, not all KBs are presented in key-value forms. Besides, an important component of classic pipeline, dialogue state tracker, is not properly modeled, making it difficult to precisely retrieve from KB.

In this paper, we propose a novel framework that takes the advantages from both classic pipeline models and Seq2Seq models. We introduce dialogue states into Seq2Seq learning, but in a implicit way. Distributions in classic state tracking are modeled as a group of representation vectors computed by an attention-based network (Britz et al., 2017), which can be considered as a dialogue state representation that aggregates information for each slot. And training this representation doesn't require annotation of dialogue state tracking. Our model queries the KB entries in an attention-based method as well, so that the querying is differentiable, without domain-specific pre-defined action spaces. Meanwhile we compute the representation for KB using entry-level attention and aggregate the representation with dialogue state representation to form a memory matrix of dialogue history and KB information. While decoding, we perform an attention over memory and an attention over input, incorporating copying mechanism (Gu et al., 2016) that allows model to copy words from KBs to enhance the capability of retrieving accurate entities.

We evaluate the proposed framework on Stanford Multi-turn, Multi-domain Dialogue Dataset (Eric et al., 2017), to test the effectiveness of our framework and flexibility to apply to different domains. We compare our model with other Seq2Seq models and discovered that our model has outperformed other

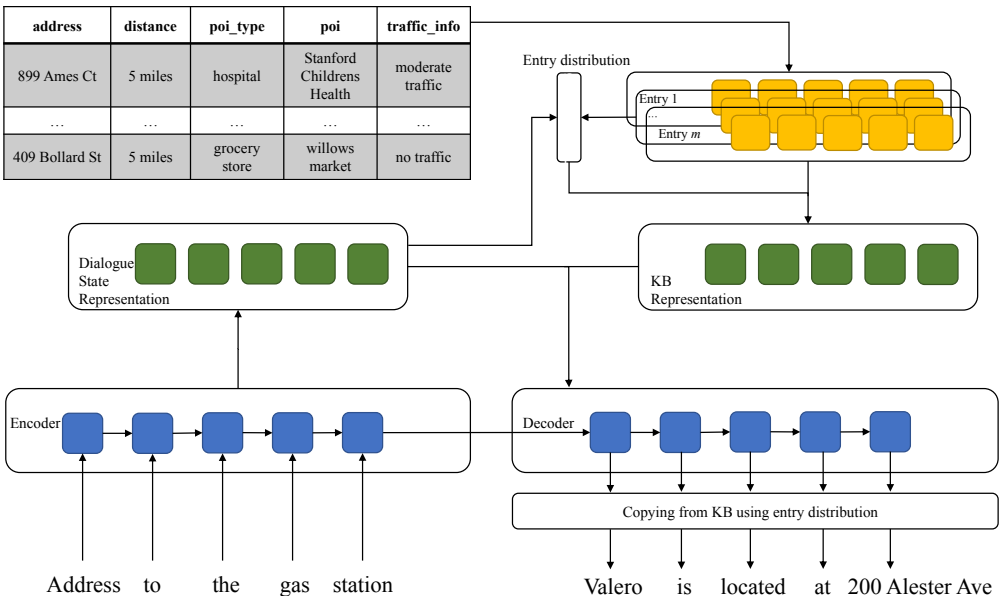

Figure 2: Proposed framework.

models on both automatic evaluation and human evaluation.

2 Proposed Framework

In this section, we describe a framework for task-oriented dialogue system. Our framework first encodes previous dialogue history, and computes dialogue state representation. Then our framework queries the table by attention and computes a matrix to represent information from previous history and KB. At last, the responses are generated using copying mechanism. The general architecture is demonstrated in Figure 2.

2.1 Encoder

Given a dialogue consisting of utterances from a user and an agent, our encoder encodes the whole dialogue history. We represent the dialogue history as a sequence of utterances. We encode the previous dialogue history as one single sequence consisting of each word in previous dialogue history and use $(x_1, x_2, \ldots, x_{n^{\text{IN}}})$ to denote the whole dialogue history word by word, where n^{IN} is the length of this sequence. Words are mapped to word embeddings and a long short-term memory network (LSTM) aggregates hidden representation over the sentence, denoted as $\boldsymbol{H}^{\text{ENC}} = \left[\boldsymbol{h}_1^{\text{ENC}}, \ldots, \boldsymbol{h}_{n^{\text{IN}}}^{\text{ENC}}\right]$ ($\boldsymbol{H}^{\text{ENC}} \in \mathbb{R}^{d \times n^{\text{IN}}}$, d is the dimensionality of a hidden state).

2.2 Dialogue State Representation

The dialogue state tracking component of a dialogue system interprets the previous dialogue history to a belief state (Williams et al., 2013), which consists of a group of probability distributions over values for each slot. The dialogue state tracking is the core component of pipeline model. It helps with retrieving values from KB and generating accurate entities. To introduce dialogue state into Seq2Seq learning, in this framework, we model representation of belief state, motivated by Britz et al. (2017). We do not compute the explicit probability distribution for each slot. Instead, a group of distributed representations is computed. In this paper, we assume each turn of the dialogue is associated with m slots and its dialouge state representation is a matrix $\boldsymbol{U}^{\text{IN}} = \left[\boldsymbol{u}_1^{\text{IN}}, \ldots, \boldsymbol{u}_m^{\text{IN}}\right] \in \mathbb{R}^{d \times m}$ whose columns represent corresponding distribution. We further assume that m equals to the number of columns in our KB. Each state representation $\boldsymbol{u}_k^{\text{IN}}$ is calculated by an attention over the whole representation of history:

$$\boldsymbol{u}_k^{\text{IN}} = \sum_{t=1}^{n^{\text{IN}}} a_k^{\text{IN}}(t)\, \boldsymbol{h}_t^{\text{ENC}},$$

where we assign each hidden state m different kinds of scores and perform a weighted average. The scores are computed by the following equations:

$$\begin{aligned} \textsc{ScoreIn}\left(\boldsymbol{w}_k^{\mathrm{A}}, \boldsymbol{h}_t^{\mathrm{ENC}}\right) &= \boldsymbol{w}_k^{A^T} \boldsymbol{h}_t^{\mathrm{ENC}}, \\ a_k^{\mathrm{IN}}(t) &= \frac{\exp\left(\textsc{ScoreIn}\left(\boldsymbol{w}_k^{\mathrm{A}}, \boldsymbol{h}_t^{\mathrm{ENC}}\right)\right)}{\sum_{t'} \exp\left(\textsc{ScoreIn}\left(\boldsymbol{w}_k^{\mathrm{A}}, \boldsymbol{h}_{t'}^{\mathrm{ENC}}\right)\right)}, \end{aligned}$$

$\boldsymbol{W}^A = [\boldsymbol{w}_1^A, \ldots, \boldsymbol{w}_m^A]$ is a parameter matrix in $\mathbb{R}^{d \times m}$.

2.3 Soft KB Attention

Table Encoder. In our framework, we compile the process of querying a KB entry into an attention network. The first step is to encode the tables. Each KB cell is represented as the concatenation of the column name embedding $\phi^{EMB}(f)$ and the cell value embedding $\phi^{EMB}(c)$. This representation is further fed into a $\tanh$ non-linearity and the final representation can be formalized as $\boldsymbol{c} = \tanh\left(\boldsymbol{W}^{\mathrm{C}}\left[\phi^{EMB}(c), \phi^{EMB}(f)\right]\right)$. The representation of the KB entry $\boldsymbol{C}_k$ is denote as $\boldsymbol{C}_k = [\boldsymbol{c}_{k,1}, ..., \boldsymbol{c}_{k,m}]$, consisting all its cell representations.

Entry and KB Representation. Conventionally, task-oriented dialogue systems interact with KB via carefully hand-crafted API calls, which are usually domain-specific and break the differentiability (Wen et al., 2017b). To make it differentiable, our framework applies a soft-attention over the KB entries and the attention value can be interpreted as the possibility that an entry will be used for decoding. We use the similarity between $\boldsymbol{C}_k$ and $\boldsymbol{U}^{\mathrm{IN}}$ to represent attention score for the k^{th} entry. The similarity is computed by the following equation:

$$\mathrm{sim}\left(\boldsymbol{C}_k, U^{\mathrm{IN}}\right) = \sum_{t=1}^{m} \boldsymbol{c}_{k,t} \cdot \boldsymbol{u}_t^{\mathrm{IN}},$$

where we sum the dot product between vectors in $\boldsymbol{C}_k$ and $\boldsymbol{U}^{\mathrm{IN}}$ respectively.

This similarity distribution is then converted into a probability distribution naturally using a softmax function. This probability distribution indicates the possibility to use entry e_k in the further response generation given previous dialogue history $\boldsymbol{x}_{<i}$:

$$p(e = e_k \mid \boldsymbol{x}_{<i}) = \frac{\exp\left(\mathrm{sim}\left(\boldsymbol{C}_k, U^{\mathrm{IN}}\right)\right)}{\sum_{k'} \exp\left(\mathrm{sim}\left(\boldsymbol{C}_{k'}, U^{\mathrm{IN}}\right)\right)}.$$

The information matrix from KB that is used for future generation can be computed as a weighted summation:

$$\boldsymbol{U}^{KB} = \sum_{t=1}^{|T|} p(e = e_t \mid \boldsymbol{x}_{<i}) \boldsymbol{C}_t,$$

where $\boldsymbol{U}^{\mathrm{KB}}$ is denoted as the information matrix, $|T|$ is the number of entries in this KB.

Since the dimensionalities of all parameters are not related to the size of knowledge base. it allows changing the KB on-the-fly. Besides, there is no need to define specific operations, which is required for using API calls to extract information. Since we model the entries directly, it is appropriate to extract information from non-entity-centric knowledge bases as well.

Finally, we combine these two kinds of information by concatenating corresponding vectors and feeding them into a linear layer with an activation function. Formally, we denote $\boldsymbol{U}^{\mathrm{CAT}}$ as the concatenation of $\boldsymbol{U}^{\mathrm{IN}}$ and $\boldsymbol{U}^{\mathrm{KB}}$. The two matrices are concatenated by concatenated corresponding vectors respectively. The process can be formulated as: $\boldsymbol{U} = \tanh\left(\boldsymbol{W}^{CAT}\boldsymbol{U}^{CAT}\right)$. The matrix $\boldsymbol{U}$ can be considered as a fix-sized memory representation over dialogue history and knowledge base.

2.4 Decoder

In this section, we will discuss the decoder that takes all previously calculated information to generate sentences. The vanilla Seq2Seq decoder generates a sequence of words recurrently based on the last hidden state of a encoder. We denote $\left(\boldsymbol{h}_1^{\text{DEC}}, \ldots, \boldsymbol{h}_{n^{\text{OUT}}}^{\text{DEC}}\right)$ as the hidden states of the decoder and $(y_1, \ldots, y_{n^{\text{OUT}}})$ as the output sentence. We will consider two kinds of information, that are information of dialogue history and information from KB. The model aggregates information via attention over KB representation and history representation.

Input Attention. The conventional attention mechanism is introduced to extend the decoder, where each hidden state in the encoder is assigned a score based on the current hidden state $\boldsymbol{h}_t^{\text{OUT}}$ at time step t, and then the context vector is computed by the weight summation (Luong et al., 2015). This process can be described by the following equations:

$$\begin{aligned}
\boldsymbol{c}_t^{\text{IN}} &= \sum_{i=1}^{n^{\text{IN}}} a_t^{\text{OUT}}(i)\, \boldsymbol{h}_i^{\text{ENC}}, \\
\textsc{ScoreOut}\left(\boldsymbol{h}_i^{\text{ENC}}, \boldsymbol{h}_t^{\text{DEC}}\right) &= \boldsymbol{v}^{\text{OUT}} \tanh\left(\boldsymbol{W}^{\text{OUT}}\left[\boldsymbol{h}_i^{\text{ENC}}, \boldsymbol{h}_t^{\text{DEC}}\right]\right). \\
a_t^{\text{OUT}}(i) &= \frac{\exp\left(\textsc{ScoreOut}\left(\boldsymbol{h}_i^{ENC}, \boldsymbol{h}_t^{\text{DEC}}\right)\right)}{\sum_{i'} \exp\left(\textsc{ScoreOut}\left(\boldsymbol{h}_{i'}^{\text{ENC}}, \boldsymbol{h}_t^{\text{DEC}}\right)\right)}.
\end{aligned}$$

Memory Attention. Besides the context vector through input attention, we also use another context vector from the attention over the fix-size memory matrix $\boldsymbol{U}$ and it's computed as:

$$\begin{aligned}
\boldsymbol{c}_t^{\text{MEM}} &= \sum_{i=1}^{m} a_t^{\text{MEM}}(i)\, \boldsymbol{u}_i, \\
\textsc{ScoreMem}\left(\boldsymbol{u}_i, \boldsymbol{h}_t^{\text{DEC}}\right) &= \boldsymbol{v}^{\text{MEM}} \tanh\left(\boldsymbol{W}^{\text{MEM}}\left[\boldsymbol{u}_i, \boldsymbol{h}_t^{\text{DEC}}\right]\right), \\
a_t^{\text{MEM}}(i) &= \frac{\exp\left(\textsc{ScoreMem}\left(\boldsymbol{u}_i, \boldsymbol{h}_t^{\text{DEC}}\right)\right)}{\sum_{i'} \exp\left(\textsc{ScoreMem}\left(\boldsymbol{u}_{i'}, \boldsymbol{h}_t^{\text{DEC}}\right)\right)}.
\end{aligned}$$

In practice, we use an additional context vector from encoder to calculate the dialogue state representation, which is different from the one that is used for the start of decoding.

The two kinds of context vectors and the current hidden state are used for decoding. We introduce a variant of copying mechanism (Gu et al., 2016) in order to retrieve entities from KB directly. We first compute a probability distribution over output vocabulary $\mathcal{V}$ and slot types $\mathcal{V}^{\text{SLOT}}$, given previous dialogue history $\boldsymbol{x}_{<i}$ and previous generated words $\boldsymbol{y}_{<t}$, which can be described as: $p\left(\widetilde{y}_t \mid \boldsymbol{x}_{<i}, \boldsymbol{y}_{<t}\right) = \text{softmax}\left(W^{\text{O}}\left[\boldsymbol{h}^{\text{DEC}}, \boldsymbol{c}^{\text{IN}}, \boldsymbol{c}^{\text{MEM}}\right]\right)$. The probability of generating a slot type represents the sum of probability of generating a slot value for this slot from KB. Since we have calculated the probability of using an entry in section 2.3, the probability of generating a word can be described as:

$$\begin{aligned}
p\left(y_t = y \mid \widetilde{y}_t, \boldsymbol{x}_{<i}, \boldsymbol{y}_{<t}\right) &= p\left(\widetilde{y}_t = y \mid \boldsymbol{x}_{<i}, \boldsymbol{y}_{<t}\right) \\
&\quad + \sum_{y^{\text{S}} \in \mathcal{V}^{\text{SLOT}}} p\left(\widetilde{y}_t = y^{\text{S}} \mid \boldsymbol{x}_{<i}, \boldsymbol{y}_{<t}\right) \sum_{k=1}^{|T|} \mathbb{1}\left\{e_k\left(y^{\text{S}}\right) = y\right\} p(e = e_k \mid \boldsymbol{x}_{<i}),
\end{aligned}$$

where $e_k\left(y^{\text{S}}\right)$ is the cell that is in slot (i.e. column) y^{S}. Note that the summation of probability over $\mathcal{V}$ is exactly 1 after the model copies entities from KB.

2.5 Training

Conventionally, we use negative log likelihood (NLL) for training to train a Seq2Seq model. Since there is no supervision for soft KB attention, and it is easy to get over-fitting when we only use NLL, we

	Weather	Navigation
Slot Types	location, date, highest temperature, lowest temperature and weather attribute	POI name, traffic info, POI type, address, distance

Table 1: Slot types for different domains.

apply policy gradient to improve the performance of soft KB attention as well. We consider the KB and fix-size memory representation from input as the environment in a reinforcement learning setting. There is only one action, which is defined as choosing a single entry from KB to help with generating response. Heuristically, the more entities in an entry appear in dialogue context, the higher possibility that this entry is used for generating response. Therefore, we consider the number of entities from an entry e that appear in previous dialogue history or current gold response as reward $R(e)$, and apply REINFORCE with baseline (Williams, 1992): $J_{RL} = -\mathbb{E}_{p(e|\boldsymbol{x}_{<i})}[R(e) - b]$, where b is a hyperparameter denoting the baseline reward. The joint loss is the combination of the NLL and loss from reinforcement learning, which is:

$$J = J_{NLL} + \lambda J_{RL}$$

where λ is a hyperpramater balancing the two factors. In practice, we first use J_{RL} only to train the soft KB attention and its encoder, without training for response generation, which will accelerate the convergence of Seq2Seq learning. We apply data augmentation to the original dataset as well, where we add delexicalised form responses into training data in order to force our model to generate slot types first and then retrieve entity from KB using copying mechanism. The delexicalised responses are generated by simple matching and replacing.

3 Experiment

In this section, we first introduce the details of experiment setting. Then we provide results and analyses of automatic evaluation and human evaluation in order to compare with other baseline models. Besides, we present ablation test to evaluate and analyze the function of different components in our framework. Finally, we provide visualization of dialogue state representation and case study.

3.1 Experiment Setting

We choose two KB-rich domains from Stanford Multi-turn Multi-domain Task-oriented Dialogue Dataset Eric et al. (2017), which are weather information retrieval and point-of-interest (POI) navigation (navigation). We first change the form of KB in weather information retrieval domain (weather). Eric et al. (2017) integrates the highest temperature, lowest temperature and weather information into a single weekday column due to their incapability of utilizing non-entity-centric KB. In this paper, we separate these information into three different column, and the slots of these two domains are provided in Table 3.

Our framework is trained separately in these two domains, using the same train/validation/test split sets as Eric et al. (2017). We do not map the entities in dialogue into its canonical form as what Eric et al. (2017) have done, since our framework extract entities directly from KB. And we evaluate our framework on exact entities as well.

Our framework is trained using the Adam optimizer (Kingma and Ba, 2014). The learning rate is 10^{-3}, λ for balancing two loss functions is 10^{-1}. We applied dropout (Srivastava et al., 2014) to the input and the output of LSTM, with a dropout rate at 0.75. We add the weight decay on the model. The coefficient of weight decay is 5×10^{-6}. The embedding size and all hidden size are 200. The number of epochs for training soft KB attention is 30 for both navigation and weather. Baseline b is 1.5 for both navigation and weather.

3.1.1 Baseline Models

We compare our model with two additional baselines beyond the Seq2Seq with attention, which includes:

- **Copy-augmented Sequence-to-Sequence Network.** This model is adapted from (Eric and Manning, 2017). It utilizes entities that appear in both previous dialogue history and KB. A hard copy mechanism for these entities is applied in this model.

- **Key-value Retrieval Network.** This model is adapted from Eric et al. (2017). It utilizes key-value forms to represent KBs. Key representations are used for an attention-based value retrieval. In weather information retrieval domain, although we have changed the KB into an non-entity-centric form, we still designate "`location`" slot as subject slot and we allow a key representation to retrieval multiple values. We convert inputs into canonical forms, while the outputs remain the same in order to compare with our model.

3.2 Automatic Evaluation

In this section, we provide two different automatic evaluations to compare with other baseline models. The results and analyses are provide in the following sections.

3.2.1 Evaluation Metrics

Entity F1 and BLEU score are used to evaluate our model. The entity F1 scores in both micro-average and macro-average manners are used to measure the difference between entities in the system and gold responses. Besides, we use BLEU to evaluate the quality of responses. Sharma et al. (2017) showed that BLEU has a comparatively strong correlation with human evaluation on task-oriented dialogue dataset. The BLEU score is computed from results with highest micro F1. To evaluate macro F1, we delete instances that neither gold nor generated response contains an entity.

3.2.2 Results and Analyses

Experiment results are illustrated in Table 2. The results show that our model outperforms other models in most of automatic evaluation metrics. In the navigation domain, compared to KV Net, we achieve 5.0 improvement on BLEU score, 37.1 improvement on Macro F1 and 27.4 improvement on Micro F1. Compared to Copy Net, we achieve 5.0 improvement on BLEU score, 41.2 improvement Macro F1 and 27.4 improvement on Micro F1. The results in navigation show our model's capability to generate more natural and accurate response than the Seq2Seq baseline models. In the weather domain, our model generates more accurate responses than our baseline models as well. The BLEU score is a little bit lower than Copy Net and Seq2Seq with attention. This is because the forms of responses are relatively limited in weather domain. Besides, the entities in inputs are highly probable to be mentioned in responses, such as "`location`". These two reasons indicate that the simpler models can capture this pattern more smoothly. The results that Seq2Seq with Attention performs better than Copy Net and KV Net also confirm this.

We also find that the KV Net's results are lower than that reported by Eric et al. (2017). We address this to the differences in the preprocessing, model training and evaluation metrics. In spite of the difference of evaluation metrics that we evaluate on exact entities rather than their canonical forms, the Micro F1 score of our model still outperforms what Eric et al. (2017) reported, which is 41.3 in navigation domain and which is evaluated on canonical forms. Our changes of the weather domain into non-entity-centric also influence its performance. This differences in results also indicate the robustness of our model when facing non-entity-centric KBs.

3.2.3 Ablation

In this section, we perform several ablation experiments to evaluate different components in our framework on the navigation domain. Results are shown in Table 3. The results demonstrate effectiveness of components of our model to the final performance.

Copying mechanism enables our framework to retrieve entities directly from KBs. Without copying mechanism, such retrieval is infeasible and our framework cannot produce values in KBs. The results show that it introduces more variability to the generation process if we do not use copying mechanism.

The reinforcement learning loss helps our framework to use correct KB entries so that improve the performance of generation. Without this reinforcement learning loss, the item selection process is only

Model	Navigation			Weather		
	BLEU	Macro F1	Micro F1	BLEU	Macro F1	Micro F1
Seq2Seq with Attention	8.3	15.6	17.5	**19.6**	56.0	53.5
Copy Net	8.7	20.8	23.7	17.5	52.4	53.1

Table 2: Automatic evaluation on test data. Best results are shown in bold. Generally, our framework outperforms other models in most automatic evaluation metrics.

Model	BLEU	Macro F1	Micro F1
our model	**13.7**	**62.0**	**56.9**
-copying	9.6	35.2	41.3
-RL	9.3	38.2	46.0

Table 3: Ablation experiment on navigation domain. -copy refers to a framework without copying. -RL refers to a framework without RL loss.

Model	Correct	Fluent	Humanlike
Copy Net	3.52	4.47	4.17
KV Net	3.61	4.50	4.20
our model	**4.21**	**4.65**	**4.38**
agreement	41.0	55.0	43.0

Table 4: Human evaluation of responses based on random selected previous dialogue history in test dataset. The agreement scores indicate the percentage of responses to which all three human experts give exactly the same scores.

supervised by log likelihood loss. We address the drop in performance to that our model overfits to the training data.

3.3 Human Evaluation

In this section, we provide human evaluation on our framework and other baseline models. We randomly generated 200 responses. These response are based on distinct dialogue history in navigation test data. We hire three different human experts to evaluate the quality of responses. Three dimensions are involved, which are correctness, fluency, and humanlikeness. Three human experts judged each dimension on a scale from 1 to 5. And each judgment indicates a relative score compared to standard response from test data. The results are illustrated in Table 4. The results show that our framework outperforms other baseline models on all metrics. The most significant improvement is from correctness, indicating that our model generates more accurate information that the users want to know.

3.4 Visualization and Case Study

We provide a visualization example to demonstrate the effectiveness of dialogue state representation. The visualization illustrates attention scores over the sentence for each slot. The blue-level of a cell indicates the attention score it represents. From this visualization, we can discover that our dialogue state representation matches slots with correct entities in sentence. For example, "`pizza_restaurant`" matches "`poi`" and "`poi_type`" correctly, "`4_miles`" matches "`address`" correctly. The visualization indicates the capability of our framework to track accurate information and integrate them into a fix-size matrix representation.

Finally, we provide a case study that consists of two conversations which are generated between our framework and a human and between Seq2Seq with Attention with human respectively. In this case, we find that our framework is able to generate correct information such as address and point-of-interest.

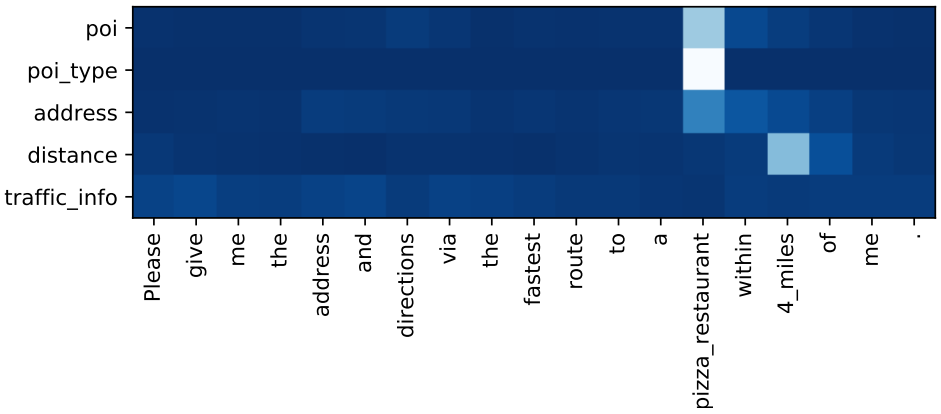

Figure 3: Visualization of dialogue state representation.

Car:	you 're welcome !

Figure 4: Case study. The dialogue in the left is generated from our framework, and that in the right is generated from Seq2Seq with Attention baseline.

Conversely, Seq2Seq with Attention is generated in a more random way. The comparison between these two dialogues illustrates the capability of our model to retrieve accurate entities and while in the same time generate natural response.

4 Related Work

The recent successes on neural networks spread across many natural language processing tasks, which also stimulate research on task-oriented dialogue system. The powerful distributed representation ability of neural networks makes task-oriented dialogue system end-to-end possible. Recently, Wen et al. (2017b) built a system that connects classic pipeline modules by a policy network training with a user simulator. Wen et al. (2017a) further introduced latent intention into end-to-end learning. However, their modules like belief tracker still needs to be trained separately before end-to-end training. In contrast to their work, our framework trained the state tracker jointly with the end-to-end dialogue training. Liu and

Lane (2017) built a turn-level LSTM to model the dialogue state and generate probability distribution for each slot. Bordes and Weston (2017) built a system by applying memory network to store the previous dialogue history. But the responses are retrieved from templates, which is significantly different from our neural generative responses. Another type of work tried to build an end-to-end system as a task completion dialogue system (Li et al., 2016; Li et al., 2017; Peng et al., 2017). These modeled are trained through an end-to-end fashion via reinforcement learning algorithm using the reward from user simulators. However, their dialogue responses are not generated from the dialogue history directly but from a set of pre-defined action and explicit semantic frames.

Our soft KB attention can be considered as a process to retrieve entries, which has been explored in many QA and dialogue work. One line of this research includes creating well-defined API calls to query the KB (Williams et al., 2017; Wen et al., 2017a). And another line of research tried to directly retrieve entities from knowledge base. Yin et al. (2016b) has built a system to encode all table cells and assign a score vector to each row. Our framework resembles the second line of research, but can generate multiple entities to form natural language responses. He et al. (2017) has built two symmetric dialogue agents with private knowledge, and has applied knowledge graph reasoning into Seq2Seq learning, which is distantly related with our framework. In the sense of the KB forms, Yin et al. (2016a) retrieved entities based on (*subject, relation, object*) triples. While Dhingra et al. (2017) applied a soft-KB lookup on an entity-centric knowledge base to compute the probability of that the user knows the values of slots, and has tried to model the posterior distributions over all slots. However, our framework doesn't require entity-centric knowledge base.

5 Conclusion

In this paper, we proposed a framework that leverages dialogue state representation, which is tracked by an attention-based methods. Our framework performed an entry-level soft lookup over the knowledge base, and applied copying mechanism to retrieve entities from knowledge base while decoding. This framework was trained in an end-to-end fashion with only the dialogue history, and get rid of other annotation. Experiments showed that our model outperformed other Seq2Seq models on both automatic and human evaluation. The visualization and case study demonstrated the effectiveness of dialogue state representation and entity retrieval.

Abstract

Current paper explores the use of multi-view learning for search result clustering. A web-snippet can be represented using multiple views. Apart from textual view cued by both the semantic and syntactic information, a complementary view extracted from images contained in the web-snippets is also utilized in the current framework. A single consensus partitioning is finally obtained after consulting these two individual views by the deployment of a multi-objective based clustering technique. Several objective functions including the values of a cluster quality measure evaluating the goodness of partitionings obtained using different views and an agreement-disagreement index, quantifying the amount of oneness among multiple views in generating partitionings are optimized simultaneously using AMOSA. In order to detect the number of clusters automatically, concepts of variable length solutions and a vast range of permutation operators are introduced in the clustering process. Finally a set of alternative partitionings are obtained on the final Pareto front by the proposed multi-view based multi-objective technique. Experimental results by the proposed approach on several bench-mark test datasets with respect to different performance metrics evidently establish the power of visual and text based views in achieving better search result clustering.

1 Introduction

Web search results clustering (SRC), also known as ephemeral clustering or post-retrieval clustering has garnered much attention in the past few decades for making web browsing easier for users. The key objective of SRC systems is: for a given query it can return some meaningful labeled clusters from a set of web documents (or web snippets) retrieved from a search engine. Recent years have witnessed a large number of attempts in solving this SRC problem (Di Marco and Navigli, 2013; Scaiella et al., 2012). Most of them have developed some clustering algorithms optimizing a single objective criteria (Osinski and Weiss, 2005; Zamir and Etzioni, 1998; Moreno et al., 2013). But a complex data set like set of web-snippets can be clustered into several alternative partitionings. Therefore to detect all possible partitionings containing clusters of different shapes automatically, application of multiobjective optimization (MOO) for solving the problem of clustering becomes prevalent (Maulik et al., 2011). In this context, Acharya et al. (Acharya et al., 2014) have proposed a multi objective optimization based approach for solving SRC problem by extracting both semantic and syntactic information present in web-snippets. Results attained by this approach outperformed the other existing single objective based approaches. Moreover a web-snippet can be represented using different views, for example semantic view, syntactic view. Recently, Wahid et al. (Wahid et al., 2014) have developed a multi-view based MOO clustering technique for search result clustering where multiple views are consulted for developing a consensus partitioning of available web-snippets.

Multimodal approaches have gained increased attention over the past few years. These models have been used in various applications: image captioning (You et al., 2016); sentiment analysis (Poria et al.,

Proceedings of the 27th International Conference on Computational Linguistics, pages 3793–3805
Santa Fe, New Mexico, USA, August 20-26, 2018.

2016); multimodal machine translation (Specia et al., 2016); visual question answering (Antol et al., 2015); combating human trafficking (Tong et al., 2017); and detection of Cyber-bullying (Zhong et al., 2016). In today's online environment, the strategic use of multimedia (image, video etc.) has become increasingly important part of creating a successful website. Visual information embedded in web documents provides right-angled information that is free of ambiguities of natural language. It can also improve search ranking and Search engine optimization (SEO) scores on many levels that contribute to search visibility, find-ability, user satisfaction, experience and engagement. As a result, use of multimedia content in web documents has become more dominant than text in recent years. Rich content of multimedia data, constructed in alliance with the information contained in different modalities, calls for new and innovative methods for better management of web search results.

In this paper, we hypothesize that high quality clustering can be obtained by representing different objective functions over different views of web documents and simultaneously optimizing them. In contrast to prior works which solely depend on information extracted from text we present a multi objective based multiview clustering algorithm which integrates both visual (images) and text content of web-documents for solving SRC problem. Experimental results show that this new multi-view approach significantly outperforms state-of-the-art unimodal approaches. We motivate this paper with a real example which

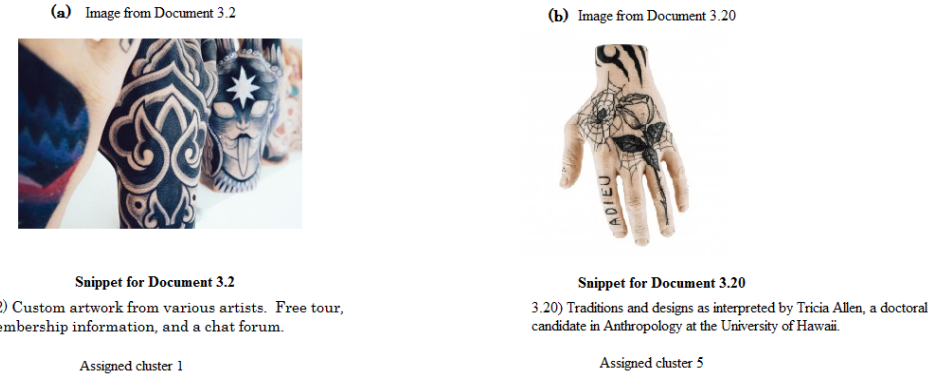

Figure 1: Example where text content differs but image information is same.

demonstrates the potential benefit of integrating visual information for better organization of web search results. Figure 1 shows results from state-of-the-art approach that depends only on text part of the web document for the web search query "3.1 Arts_Bodyart_Tattoo" in ODP-239 dataset. Even though it is clear from looking at the images that they should belong to same cluster, text snippets are not providing enough clues, causing it to appear in different clusters. It is evident from the example that there is complimentary information in the images that is either unavailable in the text or can be in contrast to the text. Our hypothesis is that we can improve SRC performance if we can capture this complimentary high-level visual information. We use pre-trained 19-layer VGG net (Simonyan and Zisserman, 2014) to extract high-level features directly from the image. After extracting the image features for all the images in our dataset, *image view* of each document is generated (Section 3.1). To generate the *textual view* of each document, we combine the benefits of both Word2Vec (Mikolov et al., 2013) and TF-IDF. While Word2Vec vectors are better at capturing the generalized meaning of each word, combining them together by assigning equal weight to all words of a document to generate its *textual view* is not ideal for our task. For example, words that contribute to the syntax rather than the meaning of a sentence should have lower impact on clustering algorithm compared to more specific rare words. Therefore, we scale each word vector by the corresponding TF-IDF weight for that word and generate the *textual view* following the approach in Section 3.1. Finally, we combine both views of the dataset by our multi-objective based multi-view clustering framework.

In order to draw conclusive remarks, we present an exhaustive evaluation where our multi objective based multi-view algorithm (MOO-Multiview-PBM) is compared to the most competitive text-based (endogenous) SRC algorithms: STC (Zamir and Etzioni, 1998), Bisecting Incremental K-means (BIK), LINGO (Osinski and Weiss, 2005), GK-means (Moreno et al., 2013), MOO-clus (Acharya et al., 2014)

and MMOEA (Wahid et al., 2014). Experiments are conducted on three different standard data sets (MORESQUE, ODP- 239 and AMBIENT) for two clustering evaluation metrics (F_{b^3} and F_1). Results show that MOO-Multiview-PBM exceeds all text-based approaches and solutions. In this paper, our main contributions are as follows: **a)** As far the best of our knowledge, this is the first attempt to solve SRC by using both textual & visual information; **b)** A new multi objective based multi-view clustering algorithm for SRC, that determines the number of clusters automatically; and **c)** Novel text representation of document in the context of SRC by combining the benefits of both word2vec and TF-IDF.

2 Related Work

2.1 SRC Algorithms

Suffix Tree Clustering (STC) algorithm proposed by Zamir and Etzioni (1998), is a clustering technique, that combines base clusters having maximum string overlaps based on web snippets represented as compact tries. Results showed improvements over K-means, agglomerative hierarchical clustering, buckshot, single-pass and fractionation algorithms, and this approach is a tough baseline to beat Moreno and Dias (2014). Later, authors of Osinski and Weiss (2005) presented an approach named LINGO which utilizes similar representation of strings as done in Zamir and Etzioni (1998). Initially frequent phrases were extracted based on suffix-arrays and later the group descriptions were matched with topics generated with latent semantic analysis. Documents were then assigned to their relevant groups. Carpineto et al. (2009) showed that the nature of the outputs obtained by SRC algorithms recommend the adoption of a meta clustering approach. The core idea is to combine the complementary results obtained from SOO (single objective) solutions. A novel approach that computes the agreement of two partitions of objects into varied clusters was proposed in this paper. This is done depending on the information content related to the series of decisions made by the partitions on single pairs of objects. OPTIMSRC results demonstrated that meta clustering is far better than individual clustering techniques. Moreno et al. (2013), adapted the K-means algorithm to a third-order similarity measure and proposed a stopping criterion that determines the optimal number of clusters automatically. Experiments were conducted on two standard data sets, MORESQUE (Navigli and Crisafulli, 2010) and ODP-239 (Carpineto and Romano, 2010), and showed significant improvement over all existing text-based SRC techniques developed by then.

Later, Acharya et al. (2014), first defined the SRC task as a multi-objective problem. They defined two objective functions (separability & compactness), that are optimized parallely with the help of AMOSA (Bandyopadhyay et al., 2008). Their evaluations outperformed knowledge-driven exogenous strategies (Scaiella et al., 2012), text-based endogenous SRC approaches and algorithms.

In another work, the multi-view clustering approach proposed by Wahid et al. (2014) used the search capability of multi-objective optimization for SRC. It is basically a cluster ensemble approach where the outputs of multiple clustering techniques like hierarchical clustering approaches and K-means are combined efficiently using NSGA-II (Deb et al., 2002) (non-dominated sorting genetic algorithm-II).

A considerable amount of works have also been proposed that uses exogenous information to solve the SRC problem. One such work is proposed by Scaiella et al. (2012) which uses Wikipedia articles to develop a bipartite graph and employs spectral clustering over it to discover relevant clusters. Recently, authors of Di Marco and Navigli (2013) presented an approach to incorporate word sense induction on the Web1T corpus (Brants and Franz, 2006) that improves SRC.

2.2 Multi-view Clustering

Multi-view data sets are frequent in real life because of the use of different modalities of data input and generation, viz., text, video and audio. The growth of multi-view data in real-world applications has increased the curiosity in multi-view learning (Sun, 2013). Multi-view clustering techniques try to explore the available multiple representations of data for obtaining a precise and robust partitioning of the data in contrast to single-view clustering. A two-view expectation maximization based clustering technique was developed by (Bickel and Scheffer, 2004). A two-view spectral clustering algorithm that generates a bipartite graph was developed by (De Sa, 2005). Another multi-view spectral clustering technique was proposed by (Kumar and Daumé, 2011). A convex mixture model based multi-view

clustering technique was proposed by (Tzortzis and Likas, 2009). The same authors later proposed a kernel-based weighted multi-view clustering technique (Tzortzis and Likas, 2012). A cluster ensemble based approach for multi-view clustering was proposed by (Xie and Sun, 2013). A new multi-view based K-means clustering technique was developed by (Cai et al., 2013) for large-scale data sets. (Wahid et al., 2014) have developed a cluster ensemble based technique to solve the multi-view clustering problem for web documents. Although it presented a multi-view based algorithm MMOEA for solving SRC problem but all the views (i.e., different representations of the data set) are related to semantic and syntactic contents of the web snippets.

3 Multiobjective Multi-view Approach for SRC

In this work we have proposed a multiobjective based multi-view approach, namely *MOO-Multiview-PBM* for solving the problem of search result clustering.

3.1 Generation of Different Views

In the current study we have used some standard data sets of SRC problem for the purpose of evaluation: AMBIENT, MORESQUE (Navigli and Crisafulli, 2010) and ODP-239 (Carpineto and Romano, 2010). For each of web-snippets present in the data set, we have generated two views as follows:

1. *The Textual view*: This view represents both syntactic and semantic information of a document given a particular query. This is generated by combining the document similarity matrix obtained from both word embedding and TF-IDF. Using word embedding each word in the vocabulary is represented by a vector of dimension 1×100. Document similarity matrix using word embedding is generated by Equation 1.

$$S_{emb}(\overline{d}_i, \overline{d}_j) = \frac{1}{\|d_i\|\|d_j\|} \sum_{r=1}^{\|d_i\|} \sum_{b=1}^{\|d_j\|} CosSim(w_i^r, w_j^b) \tag{1}$$

   Here, w_i^r (resp. w_j^b) represents the r^{th} (resp. b^{th}) word vector of document $\overline{d}_i$ (resp. $\overline{d}_j$). $\|d_i\|$ and $\|d_j\|$ denote the total number of words in documents $\overline{d}_i$ and $\overline{d}_j$, respectively. $CosSim(.,.)$ is the cosine similarity between two vectors. TF-IDF is generated using the following steps:

   (a) The terms in the documents are first extracted,

   (b) A document-term matrix is created. Here, a row, a column and a cell correspond to a document, a term, and the weighted value of a term for a document, respectively,

   (c) TF-IDF (a common weighting scheme) values are used to fill this matrix. Each cell contains the TF-IDF score of a term given a document.

   The cosine similarity is calculated between TF-IDF vectors of two documents to generate the $document \times document$ similarity matrix S_{tfidf}. Here $S_{tfidf}(\overline{d}_i, \overline{d}_j)$ contains cosine similarity between TF-IDF vectors of two documents, $\overline{d}_i$ and $\overline{d}_j$.
   The Final $document \times document$ similarity matrix, S_{text}, is generated by the equation:

$$S_{text}(\overline{d}_i, \overline{d}_j) = S_{emb}(\overline{d}_i, \overline{d}_j) \times S_{tfidf}(\overline{d}_i, \overline{d}_j), i, j = 1, \ldots, n \tag{2}$$

   Here n is the total number of documents.
2. *The Image view*: Images are extracted from each web document. We feed images to the pre-trained VGG19 network which computes a 4096 dimensional feature vector for every image that contains the activations of the hidden layer ('fc7') immediately before the VGG's object classifier. Given two image vectors img_i and img_j from two different web documents $\overline{d}_i$ and $\overline{d}_j$, respectively, the similarity between the documents is calculated by Equation 3.

$$S_{image}(\overline{d}_i, \overline{d}_j) = \frac{1}{\|d_i\|\|d_j\|} \sum_{r=1}^{\|d_i\|} \sum_{b=1}^{\|d_j\|} CosSim(img_i^r, img_j^b) \tag{3}$$

   Here, img_i^r (resp. img_j^b) represents the r^{th} (resp. b^{th}) image of the $\overline{d}_i$ (resp. $\overline{d}$) web document. $\|d_i\|$ and $\|d_j\|$ denote the total number relevant images present in $\overline{d}_i$ and $\overline{d}_j$, respectively.

3.2 String Representation and Archive Initialization

The first step of the proposed clustering approach is to initialize the Archive used in AMOSA (Bandyopadhyay et al., 2008) with some alternative diverse set of solutions. The solutions are generated randomly. Here each solution contains a set of cluster centroids (representative web-snippets) in order to represent the partitioning of web-snippets.

The number of cluster centroids encoded in a particular solution i, denoted by K_i, is selected randomly from the given range K_{min} to K_{max} as follows: $K_i = (rand()\text{mod}(K_{max} - 1)) + K_{min}$. For the purpose of initialization, K_i number of web-snippets are randomly selected from the data set and the corresponding indices are used as the initial cluster centers.

3.3 Formation of Clusters and Objective Function Calculations

After initializing the archive members with some randomly selected cluster centroids, the following steps are executed to compute different objective functions. The search capability of AMOSA can be utilized to simultaneously optimize these objective functions.

1. First, the set of representative web-snippets present in the string are extracted. Let the entire set be $\{\overline{C}_1, \overline{C}_2, \ldots, \overline{C}_K\}$ here $\overline{C}_i$ is the ith cluster representative. K is the number of clusters encoded in that particular string. *K*-medoids clustering is applied to the dataset using this set of cluster representatives for different views. In case of text-view, a particular document $\overline{d}_i$ is assigned to cluster t whose centroid has the maximum similarity value to $\overline{d}_i$ given by $t = argmax_{k=1,\ldots K} S_{text}(\overline{d}_i, \overline{C_k})$.Here $S_{text}(\overline{d}_i, \overline{C_k})$ is computed using Equation 2.

   In case of visual view, a particular document $\overline{d}_i$ is assigned to cluster t whose centroid has the maximum similarity value to $\overline{d}_i$. $t = argmax_{k=1,\ldots K} S_{image}(\overline{d}_i, \overline{C_k})$.Here $S_{image}(\overline{d}_i, \overline{C_k})$ is computed using Equation 3.

2. The PBM-index values are calculated for the final partitionings obtained using individual views. Let the values be denoted by PBM_v, $v = 1, 2$.

3. The adjoint matrix (A^v of size $n \times n$, where n is the number of documents) corresponding to view v is calculated as follows:

$$A^v_{ij} = 1 \text{ if } \overline{d}_i \text{ and } \overline{d}_j \text{ belong to the same cluster or } i = \text{j} \quad (4)$$

$$= 0 \quad \text{otherwise} \quad (5)$$

4. A new objective function *Agreement Index* is calculated as follows. This measures the agreement between the partitionings obtained using multiple views. The measure is calculated as follows:

   At a time two views are considered: $v1$ and $v2$. Let the corresponding adjoint matrices be A^{v1} and A^{v2}, respectively. The number of agreement (n_a) is calculated as follows: $n_a = \sum_{i=1}^{n} \sum_{j=1}^{n} I_{A^{v1}_{ij}, A^{v2}_{ij}}$, here

$$I_{A^{v1}_{ij}, A^{v2}_{ij}} = 1 \text{ if } A^{v1}_{ij} = A^{v2}_{ij} \quad (6)$$

$$= 0 \quad \text{otherwise}$$

   The number of disagreements (n_d) is calculated as follows: $n_d = n^2 - n_a$. *Agreement index* between these two views ($v1$, $v2$) is calculated as follows: $AI_{v1,v2} = \frac{n_a+1}{n_d+1}$. The values of 1 in the numerator and denominator are used as a normalization factor to avoid the problem of division by zero. The total *Agreement index* for the entire partitioning is calculated as follows:

$$AI = \frac{\sum_{j=1}^{m} \sum_{i=1, j \neq i}^{m} 2 \times AI_{v_j, v_i}}{m \times (m-1)}, \quad (7)$$

   where m is the available number of views.

5. The objective functions corresponding to a particular string are:
   $\{PBM_{text}, PBM_{image}, AI\}$ where PBM_{text} and PBM_{image} are the values of PBM-indices calculated on partitionings obtained using text based view and image based view, respectively.

3.4 Update of String

After the objective functions are calculated, a consensus partitioning is obtained which satisfies all the available views. The cluster centroids corresponding to this consensus partitioning are used to update the string of AMOSA.

- Let the partitioning obtained using two views be represented by π^1, π^2. Let us denote the jth cluster of view v as π_j^v. First some reordering is done among all the obtained partitionings so that there is a one-to-one correspondence between the cluster numbers of different partitionings.
- New cluster centroids $\overline{C}$, are selected among those documents which are present in the same cluster corresponding to both the views. Let common documents of cluster i in both the views be $\{\overline{d}_1^i, \ldots, \overline{d}_m^i\}$. Then the representative of this set, denoted by $\overline{C}_i$, is $\overline{d}_t$ where
$$t = argmax_{k=1}^{m} \frac{\sum_{j=1, j\neq k}^{m} \frac{S_{text}(\overline{d}_k^i, \overline{d}_j^i) + S_{image}(\overline{d}_k^i, \overline{d}_j^i)}{2}}{m-1}. \quad (8)$$
Here S_{final} and S_{image} are calculated using Equation 2 and 3, respectively.
- Next, the newly generated cluster centroids $\overline{C}_j, \quad j = 1, \ldots, K$ are used to obtain the final consensus partitioning as follows: $\pi_j = \{\forall \overline{d}_i \in S : Sim(\overline{d}_i, \overline{C}_j) > Sim(\overline{d}_i, \overline{C}_l) \text{ for } l = 1, \ldots, K, l \neq j\}$. Here, K is the number of clusters encoded in that solution.
$$Sim(\overline{d}_i, \overline{C}_j) = \frac{S_{text}(\overline{d}_i, \overline{C}_j) + S_{image}(\overline{d}_i, \overline{C}_j)}{2} \quad (9)$$
Here S_{final} and S_{image} are calculated using Equation 2 and 3, respectively. S denotes the set of all documents.
- Finally, the representatives of clusters $\pi_j, \quad j = 1 \ldots, K$ are calculated using Equation 8. These new cluster centroids $\overline{C}_j, \ j = 1, \ldots, K$ are used to replace the old centroids encoded in the string.

So, in order to obtain a consensus partitioning, initially the common points of different clusters present in different partitionings obtained using different views are identified. These points are further used to determine cluster centroids. The other points are assigned to the centroids having maximum similarity, calculated by Equation 9, to obtain a final consensus partitioning. These cluster centroids are used to update the given string.

3.5 Search Operators

In order to explore the search space efficiently using AMOSA, perturbation operations are introduced. These operators also help in generating some new solutions from the current solution which can further take part in the search process. For this purpose, three different perturbation operators are introduced. Below we describe three types of mutation operations in detail:

Mutation 1: In this operation each centroid is parsed individually and with some probability the existing document id in the centroid is replaced by a new document id which is selected from the document collection randomly [1].

Mutation 2: Here a cluster centroid is randomly selected and it is deleted from the string. Size of the string is reduced by 1.

Mutation 3: Here a web document is randomly chosen and the corresponding index is added to the string. Size of the string is increased by 1.

All the above mentioned three mutation operations are equi-probable. Any one of the above discussed mutation operators is applied on a particular solution to generate a new solution which can further participate in the process of AMOSA.

4 Results and Discussion

Results of different approaches are shown in Table 2 for all the data sets with respect to different performance metrics. From Table 2, it is evident that our proposed approach *MOO-Multiview-PBM* outperforms the results of *MOO-clus* (Acharya et al., 2014) by a margin of around $6.2\% - 6.5\%$ in terms

[1] existing document id may or may not get replaced by the new document id

of $F_{b^3} - measure$ and $7.0\% - 7.3\%$ in terms of $F1 - measure$ for both MORESQUE and ODP-239 datasets. Box plots of results obtained from combined $F1 - measure$ and combined $RandIndex$ over all three data sets (i.e., AMBIENT, MORESQUE and ODP-239) by our proposed method are reported in Figure 4. This is done to compare the performance of *MOO-Multiview-PBM* with MMOEA algorithm (Wahid et al., 2014). Although, AMBIENT has received less attention since the creation of ODP-239, we have included it to show a fair comparison of our results with the results from MMOEA (Wahid et al., 2014). In Figure 4, comparison with MMOEA (Wahid et al., 2014) is illustrated. *MOO-Multiview-PBM (word2vec*tfidf)* reports an average F1 measure and Rand Index values of 0.74 and 0.77, respectively, over all three datasets combined, which are similar to those obtained by MMOEA. Note that MMOEA is based on three views (Topics, terms and senses) and also utilized some external information like Wikipedia data during its processing. But our proposed method attains comparable results using information extracted only from the given datasets. No external information was used during the computation of our approach.

Table 1: Evaluation results in terms of $F1$ and F_{b^3} over MORESQUE and ODP239 data sets: Comparison of the proposed approach with state-of-the-art approaches.†→ Results are obtained by 10 consecutive runs of the algorithm and are statistically significant.

	F1	0.342	0.376	0.3814	0.3901	0.4031	0.4083

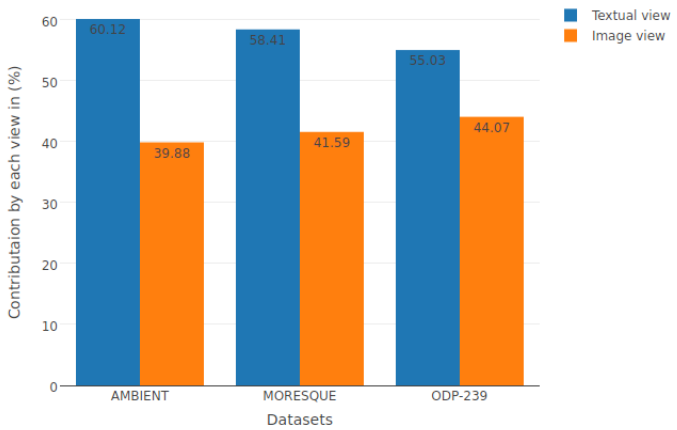

Figure 2: The following bar graph shows contribution by each view in the clustering process for different datasets.

We have implemented our proposed algorithm using two different versions of textual views. Initially we have used word embeddings (Mikolov et al., 2013) for the textual view and combined it with image view in our algorithm *MOO-Multiview-PBM(word2vec)*. Later we have used word embeddings and tf-idf vector together, described in Section 3.1, as textual view along with image view for our algorithm *MOO-Multiview-PBM(word2vec*tf-idf)*. Results in Table 2 show that *MOO-Multiview-PBM(word2vec*tf-idf)* achieves an improvement of $1.2\% - 1.8\%$ over *MOO-Multiview-PBM(word2vec)*. It substantiates our hypothesis that combining the benefits of both word2vec and TF-IDF can improve the search result clustering performance.

We have also quantified the influence of individual views in obtaining the final partitioning. The degree is expressed as follows:

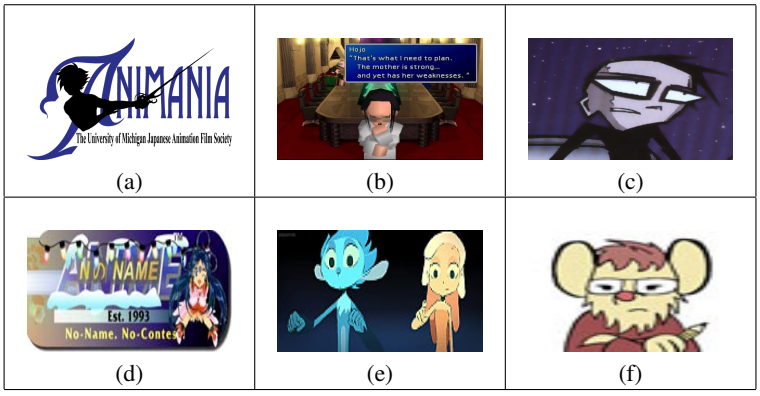
$$Degree_v = \frac{\|A^v \cap A^{\cup v}\|}{\|A^{\cup v}\|}$$

where A^v denotes the adjoint matrix (expressed in Equation 4) corresponding to the partitioning obtained using view v and $A^{\cup v}$ is the adjoint matrix corresponding to the consensus partitioning obtained by consulting all views. The contributions computed as above for different views are shown in Figure 2. It is observed that knowledge extracted from images has contributed on an average 41.58% in the clustering process (refer to Figure 2) for all three datasets.

As mentioned in Section 1 that only textual information is not sufficient for SRC clustering, here we have presented some examples where although these web snippets belong to the same cluster, their textual information widely vary whereas their corresponding image information classify them into the same cluster. In Table 3, we have listed some sample queries from ODP-239 datasets whose textual contents vary widely related to query. In Figure 3, we have shown corresponding images extracted from websites of above mentioned queries. It is evident from these examples that image information is more relevant to the query compared to the textual information.

Table 3: List of query results whose textual contents differ. **S#Id**: Subtopic Id. **R#Id**: Result Id.

S#Id	Subtopic	R#Id	Results	Figures
1.1	Arts	1.19	List of screenings, a few MP3s, and series information.	3a and 3d
	Animation	1.20	Events, news, forum, and newsletter.	3b and 3e
	Anime	1.21	History, constitution, showings, and tape library.	3c and 3f

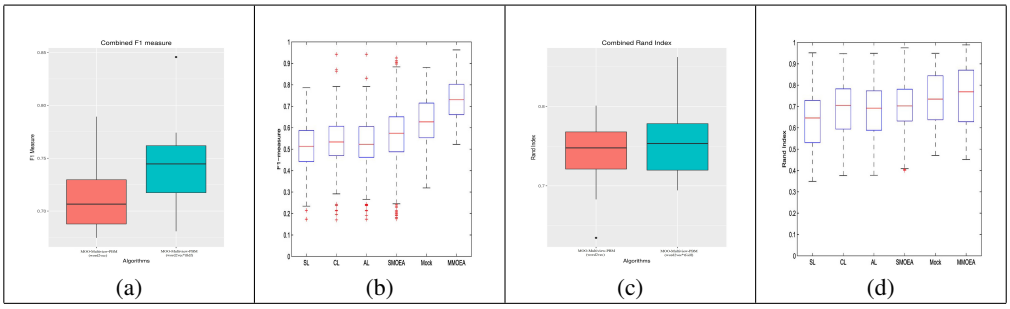


(a) (b) (c) (d) (e) (f)

Figure 3: Sample figures extracted from each query given in Table 3.

5 Error Analysis

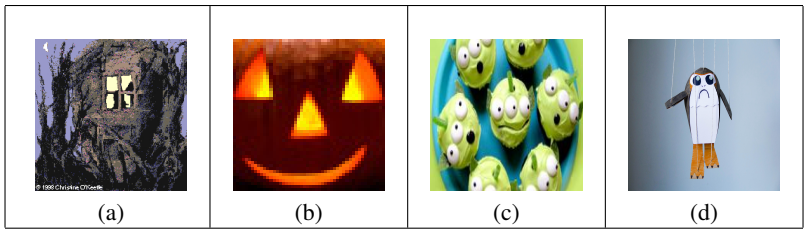
The errors made by our proposed method have been thoroughly analyzed. After a thorough manual analysis, it has been observed that misclassification occurred because of the following reasons. Firstly, from Table 4, it can be seen that there are many inactive web links from which we failed to extract images. For those instances only textual information from the snippets are used for classification. For example, in ODP-239 dataset results 2.54 and 2.65 belong to the same cluster in original labelling. Web links of both 2.54 and 2.65 are inactive, therefore only textual information is used for clustering.



(a) (b) (c) (d)

Figure 4: Boxplots of the best (a) F1-measure (c) Rand index values obtained for different queries combining all the data sets together after application of the proposed MOO-Multiview-PBM technique. Boxplots of the best (b) F1-measure (d) Rand index values obtained for different queries combining all the data sets together after application of MMOEA (taken from the paper (Wahid et al., 2014)).

But in these web snippets text varies widely, viz.,"Meeting schedules, contact information, calendar of events, ftm, mtf, soffa, information, articles, book catalog, and guestbook." in 2.65 and "Headline links from media sources worldwide." in 2.54, hence in predicted clustering solution both 2.54 and 2.65 belong to different clusters. Secondly, there are few instances where textual view and image view differ widely, consensus between these two views is very less hence leads to misclassification. For example, in ODP-239 dataset query 196.1 and 196.11 originally belong to the same cluster. But the text contents, viz.,"Fairy and monster identification list, free e-cards, customs, recipes, games, history, and links to other holiday pages." in 196.1 and "Includes crafts, recipes, costumes, games and activities, and party ideas. Also features autumn harvest party ideas with pumpkin crafts." in 196.11, and image contents of queries 196.1 (see Figures 5a and 5b) and 196.11 (see Figures 5c and 5d) differ widely hence no concrete consensus is drawn between the two views, therefore in predicted clustering solution they are misclassified.



(a) (b) (c) (d)

Figure 5: Sample figures extracted from queries in dataset ODP-239.

6 Conclusion

In the current study a multiobjective based multi-view clustering technique is developed for solving the problem of search result clustering (SRC). Views constructed over textual and visual information contained in web-snippets are considered. We have hypothesized that two web-snippets can be similar either with respect to content or with respect to images. These two views are exploited simultaneously in order to detect good-quality clustering of web-snippets. Three objective functions capturing the qualities of different partitions and a consensus function measuring the similarity between two partitions obtained using different views are simultaneously optimized using the search capability of a MOO process. Improved results on standard bench-mark data sets over state-of-the-art approaches support our hypothesis that use of multi-view information indeed helps in solving the SRC problem. In future we would like to exploit other views of web-snippets and incorporate it in our framework. Investigations of AMOSA as the underlying optimization strategy and PBM -index as the internal cluster validity index are also required to be carried out in future.

Appendix A. Objective Functions

PBM index: This is a popular cluster validity index proposed by Pakhira, Bandyopadhyay and Maulik (Pakhira et al., 2004). It outperforms most of the cluster validity indices in the literature in properly detecting the optimal partitioning. This index is defined as follows:

$$PBM(K) = (\frac{1}{K} \times \frac{\mathcal{E}_1}{\mathcal{E}_\mathcal{K}} \times D_K) \tag{10}$$

Here, K denotes the number of clusters, $\mathcal{E}_\mathcal{K} = \sum_{k=1}^{K}\sum_{j=1}^{n_k} dist(\overline{C}_k, \overline{d}_j^k)$ and $D_K = \max_{i,j=1}^{K} dist(\overline{C}_i, \overline{C}_j)$, where $\overline{C}_j$ denotes the centroid of the j^{th} cluster and $\overline{d}_j^k$ denotes the j^{th} web-snippet of the k^{th} cluster. n_k is the total number of web-snippets of the k^{th} cluster. The objective is to maximize the PBM-index. In case of text-view, $dist(\overline{C}_k, \overline{d}_j^k) = 1 - S_{text}(\overline{C}_k, \overline{d}_j^k)$, where S_{text} is calculated using Equation 2 and in case of image-view $dist(\overline{C}_k, \overline{d}_j^k) = 1 - S_{image}(\overline{C}_k, \overline{d}_j^k)$, where S_{image} is calculated using Equation 3. Similarly D_K value between two centroids is also calculated either using text-based similarity or image based similarity measure.

Appendix B. Experimental Setup

We perform web snippet tokenization and word vector generation using gensim library.[2] Word embeddings are obtained from the pre-trained Google news word embeddings.[3] Image features are extracted from the *FC7* layer of *VGG19* available in Keras library.[4] We executed our algorithm over three gold standard datasets: AMBIENT[5]; MORESQUE (Navigli and Crisafulli, 2010); and ODP-239 (Carpineto and Romano, 2010). Description of the datasets, total number of relevant images extracted for each query and number of active query links present in each data set are summarized in Table 4.

The parameters of our proposed algorithms are: $T_{min} = 0.01$, $T_{max} = 100$, $\alpha = 0.85$, $HL = 20$, $SL = 30$, $itr = 20$, $K_{max} = \sqrt{\#ofsamples}$ and $K_{min} = 2$. All these values have been determined after conducting a thorough sensitivity study (and those are in line with the approach proposed by (Acharya et al., 2014)).

Table 4: First part represents SRC gold standard data sets. Second part represents total number of relevant images extracted for each query and number of active query links present in each data set.

Datasets	**# of quaries**	**# of Subtopics Avg/Min/Max**	**# of Snippets**
AMBIENT	44	17.95/6/37	4400
MORESQUE	114	10 / 10 / 10	11400
ODP-239	239	6.7 / 2 / 38	25580

# of web links	**# of active web links**	**# of inactive web links**	**# of images in each quary Avg/Min/Max**
4400	4137	263	6 / 4 / 20
11400	10834	566	8/ 4 / 18
25580	19513	3067	6 / 3 / 25

Appendix C. Evaluation Metrics

An ideal SRC system should be represented by a unique cluster having all the relevant web pages inside. However, determining a unique and complete metric to evaluate the performance of a clustering algorithm is still an open problem (Amigó et al., 2013).

In order to measure the qualities of partitions obtained using different clustering techniques for these web search data sets, we have used three cluster quality measures, F_{b^3} measure (Amigó et al., 2009), F_1 measure (Crabtree et al., 2005) and Rand Index (Hubert and Arabie, 1985). In particular, F_{b^3} has been defined to evaluate completeness, cluster homogeneity, size-vs-quantity and rag-bag constraints. F_{b^3} is a function of $Precision_{b^3}(P_{b^3})$ and $Recall_{b^3}$ (R_{b^3}). All metrics are defined as follows:.

$$F_{b^3} = \frac{2 \times P_{b^3} \times R_{b^3}}{P_{b^3} + R_{b^3}}, P_{b^3} = \frac{1}{N}\sum_{j=1}^{K}\sum_{d_i \in \pi_j} \frac{1}{\mid \pi_i \mid} \sum_{d_l \in \pi_j} h^*(d_j, d_l),$$

$$R_{b^3} = \frac{1}{N}\sum_{j=1}^{K}\sum_{d_i \in \pi_j^*} \frac{1}{\mid \pi_i^* \mid} \sum_{d_l \in \pi_j^*} h^*(d_j, d_l)$$

here π_j is th j^{th} cluster and π_j^* is the gold standard of j^{th} cluster. $h(.,.)$ and $h^*(.,.)$ are defined in Equation 11.

[3] https://code.google.com/archive/p/word2vec/
[4] https://keras.io/
[5] http://credo.fub.it/ambient

$$h^*(d_j, d_l) = \begin{cases} 1 & \iff \exists i \quad : d_j \in \pi_i^* \wedge d_l \in \pi_i^* \\ 0 & \quad\quad\;\; : otherwise \end{cases}, h(d_j, d_l) = \begin{cases} 1 & \iff \exists i \quad : d_j \in \pi_i \wedge d_l \in \pi_i \\ 0 & \quad\quad\;\; : otherwise \end{cases} \tag{11}$$

Appendix D. Model Comparisons

In order to comprehensively evaluate the performance of our proposed approach *(MOO-Multiview-PBM)*, we listed some strong baseline approaches for comparison.

- **MOO-clus(Acharya et al., 2014):** This algorithm uses archived multi-objective simulated annealing framework to simultaneously optimize two objectives, compactness and separation, for clustering web snippets.
- **GK-means(Moreno et al., 2013):** This algorithm has adapted the K-means algorithm to a third-order similarity measure and proposed a stopping criterion to automatically determine the number of clusters.
- **Suffix Tree Clustering(STC)(Zamir and Etzioni, 1998):** It is an incremental, linear time algorithm which creates clusters based on phrases shared between documents.
- **LINGO(Osinski and Weiss, 2005):** In this method, initially the frequent phrases based on suffix-arrays are extracted and later matched the group description with topics obtained with latent semantic analysis.
- **MMOEA(Wahid et al., 2014):** This algorithm uses multiple views to generate different clustering solutions and then select a combination of clusters to form a final clustering solution.

Integrating Tree Structures and Graph Structures with Neural Networks to Classify Discussion Discourse Acts

Abstract

We proposed a model that integrates discussion structures with neural networks to classify discourse acts. Several attempts have been made in earlier works to analyze texts that are used in various discussions. The importance of discussion structures has been explored in those works but their methods required a sophisticated design to combine structural features with a classifier. Our model introduces tree learning approaches and a graph learning approach to directly capture discussion structures without structural features. In an evaluation to classify discussion discourse acts in Reddit, the model achieved improvements of 1.5% in accuracy and 2.2 in F_1 score compared to the previous best model. We further analyzed the model using an attention mechanism to inspect interactions among different learning approaches.

1 Introduction

With the recent growth of social news sites and debate portals, people today discuss various topics online. These discussions include valuable public opinions of crowds. However, automated analyses of them are often difficult, requiring understanding of textual contents and discussion structures. By extending approaches taken in the analysis of spoken dialogue acts (Stolcke et al., 2000; Bunt et al., 2010), there have been a number of attempts to analyze discussions with discourse acts. Discussions in emails (Cohen et al., 2004; Carvalho and Cohen, 2005; Carvalho and Cohen, 2006; Hu et al., 2009; Omuya et al., 2013), newsgroups (Wang et al., 2007), technical forums (Kim et al., 2010b; Wang et al., 2011; Bhatia et al., 2012; Liu et al., 2017) and social news (Zhang et al., 2017) are targeted in earlier studies. The automatic classification of these discourse acts can improve tasks like information access and summarization for discussions.

The importance of discussion structures for analyzing discourse acts has already been recognized in earlier studies. Relational features (Carvalho and Cohen, 2005), link features (Hu et al., 2009), and structural features (Wang et al., 2007; Kim et al., 2010a; Kim et al., 2010b; Wang et al., 2011; Bhatia et al., 2012; Zhang et al., 2017; Liu et al., 2017) are combined with a probabilistic graphical model, a structured prediction model, or sequential classification models. These approaches have achieved promising results in classifying discourse acts, but they require a sophisticated design to integrate structural features into a classification model. In this paper, we propose a model that integrates discussion structures with neural networks to classify discourse acts. Recently, neural networks have shown their effectiveness at capturing tree structures (Socher et al., 2011; Socher et al., 2014; Tai et al., 2015) and graph structures (Defferrard et al., 2016; Kipf and Welling, 2017). Our model introduces tree learning approaches and a graph learning approach to directly capture discussion structures without structural features to classify discourse acts.

Proceedings of the 27th International Conference on Computational Linguistics, pages 3806–3818
Santa Fe, New Mexico, USA, August 20-26, 2018.

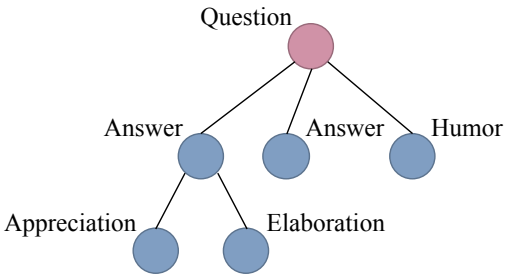

Figure 1: An example of a Reddit thread with discourse acts. The circles represent comments. An initial question is replied by answers and a humor. One of the answer is further replied by an appreciation and an elaboration.

Among the various targets that have been analyzed in earlier studies, we apply our models to the analysis of Reddit[1] discussions. Reddit is among the largest social news sites, hosting discussions of various topics. We aim to classify comments into 9 discourse acts of Zhang et al. (2017), namely *Answer*, *Elaboration*, *Question*, *Appreciation*, *Agreement*, *Disagreement*, *Humor*, *Announcement*, and *Negative Reaction*. Figure 1 illustrates an example of a Reddit thread with discourse acts. We chose Reddit discussions for two reasons. First, threads that comprise Reddit discussions have an explicit tree structure with reply relations as edges. Secondly, the publicly available dataset is larger than other datasets, which enables neural networks to learn tree structures and graph structures. We demonstrate that our model successfully learns discussion structures with tree learning approaches and a graph learning approach of neural networks.

The following are the contributions of this paper:

1. We propose a neural model with tree learning components and a graph learning component that can efficiently learn discussion structures.
2. We show that the proposed model outperforms earlier sequential learning approaches in a discourse act classification.
3. We analyze some components of the proposed model to ascertain the learned effective discussion structures.

In subsequent sections of the paper, we present related works in two criteria in Section 2. Section 3 describes the proposed model. Details of an experiment are reported in Section 4, with discussions in Section 5. Finally, Section 6 concludes the paper with a presentation of some future directions.

2 Related Works

2.1 Discourse Act Classification

The analysis of discussions attracted researchers to propose automated approaches to classify discourse acts. In earlier works, emails and forums were popularly targeted by several works. Cohen et al. (2004) annotated emails with speech acts and built a classifier with textual features for them. This work was extended by Carvalho and Cohen (2005) to combine relational features with a dependency-network-based collective classification model and by Carvalho and Cohen (2006) with an exploitation of n-gram features. Hu et al. (2009) also annotated emails with speech acts and trained a structured prediction classifier. Omuya et al. (2013) extended this work using per-class feature optimization and a cascade of classifiers. Kim et al. (2010b) tagged technical forums with dialogue acts and conducted an experiment on them using structural features and a sequential learner. Later, these dialogue acts were tackled by Wang et al. (2011) with a joint classification approach of discourse acts and link relations, and by Liu et al. (2017) with a sequential learner including an external memory. Bhatia et al. (2012) assigned dialogue acts to technical forums and evaluated classifiers using a variety of features including structural features.

The discourse acts of other targets were also explored in earlier works. Wang et al. (2007) evaluated a sequential learning technique with structural features of newsgroup argument codes. Kim et al. (2010a)

[1]https://www.reddit.com/

explored the classification of dialogue acts in chats with various features including structural ones with a sequential learner. Zhang et al. (2011) annotated tweets with speech acts and trained a classification model with word features and character features. These speech acts were examined further in Zhang et al. (2012) with semi-supervised learners including a graph-based label propagation. Ferschke et al. (2012) created a Wikipedia Talks corpus with dialog acts and trained a binary classifier with textual features and talk turn features. Zhang et al. (2017) annotated Reddit threads with discourse acts and designed sequential models with various features including structural features.

2.2 Reddit Analysis

Reddit, which has become a popular target for researchers for analyses of public opinion, consists of massive textual contents and visual contents with metadata that are readily accessible via an API. Within studies using Reddit as their data, automated analysis of the *karma score*, a post-level popularity of discussions in Reddit based on positive votes and negative votes of users, is widely studied. Jaech et al. (2015) proposed a karma score ranking task and used a pairwise classifier to rank them. Wei et al. (2016) designed a system that ranks comments based on karma scores as a reference to their persuasiveness. He et al. (2016) proposed a deep reinforcement learning architecture for the effective modeling of an online popularity prediction task. He et al. (2017) extended the model using a two-stage approach. Hessel et al. (2017) experimented on a relative popularity task using karma scores and demonstrated the effectiveness of multimodal features. Cheng et al. (2017) introduced a factored neural model that demonstrated improvements on predicting karma scores over standard document embedding methods. Zayats and Ostendorf (2018) presented a graph-structured neural architecture that outperformed a node-independent architecture in predicting karma scores.

Automatic analysis of targets other than karma scores were also investigated in earlier works analyzing Reddit discussions. The analysis of discourse acts (Zhang et al., 2017) is one such work, but some other attempts were also made. Buntain and Golbeck (2014) demonstrated the presence of answer-person roles and their identification with a supervised classifier. Tan et al. (2016) examined *ChangeMyView* subreddit to clarify the mechanism of persuasion and built a classifier for opinion malleability prediction. Lim et al. (2017) explored the estimation of relative user expertise through various content-agnostic approaches. Habernal et al. (2018) investigated ad hominem arguments and experimented with neural models for prediction.

2.3 Comparisons with Our Model

Our model, which we describe in Section 3 learns a discussion structure using tree learning approaches and a graph learning approach. The model processes textual information and structural information jointly within its architecture without structural features. For the classification of discourse acts, most earlier works used sequential learning approaches (Wang et al., 2007; Kim et al., 2010a; Kim et al., 2010b; Wang et al., 2011; Zhang et al., 2017; Liu et al., 2017). Carvalho and Cohen (2005) used a probabilistic graphical model, but it relied on relational features and pre-trained classifier trained with textual features. When we compare our model with Reddit analysis models, a close approach is taken in the model of Zayats and Ostendorf (2018). They extended Long short-term memory (LSTM) (Hochreiter and Schmidhuber, 1997) to accommodate graph structures to capture hierarchical and temporal conversations. However, their model includes designs for efficiently learning the popularity of Reddit. The popularity of a comment in Reddit is known to be associated strongly with the post timing and the post author (Jaech et al., 2015). We present in an experiment explained in Section 4 that a simple application of a popularity prediction model will not perform well on classifying discourse acts.

3 Model

Figure 2 illustrates the overview of our proposed model: Tree-LSTM GCN Hybrid. The model first encodes comments in a thread with an LSTM and max-pooling (Comment Encoder) to comment representations. The comment representations are then updated with tree-level LSTM processes (Parent-Branch Tree-LSTM and Child-Sum Tree-LSTM) and a graph-level convolutional networks process (GCN) to

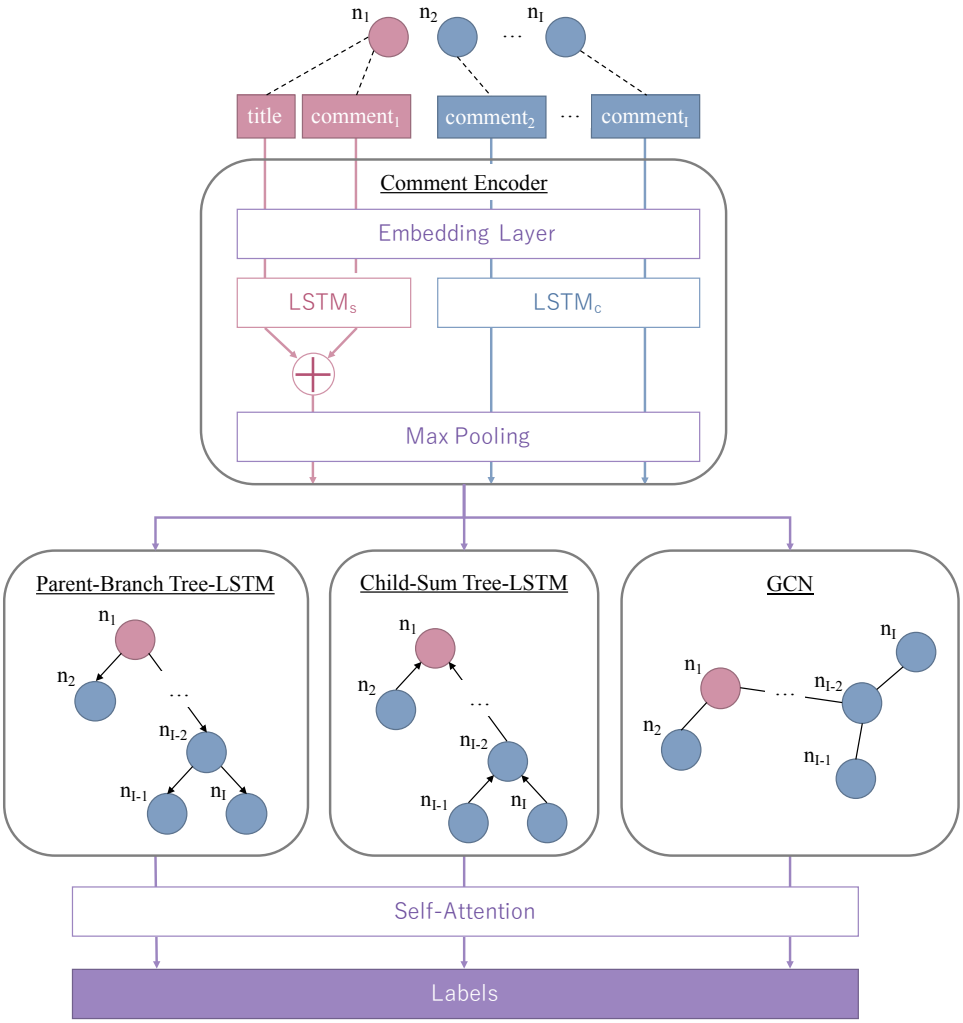

Figure 2: Overview of our proposed model: Tree-LSTM GCN Hybrid. In this model, comments in an input thread is encoded by Comment Encoder and then processed by tree processing components (Parent-Branch Tree-LSTM and Chid-Sum Tree-LSTM) and a graph processing component (GCN). Best viewed with colors.

introduce comment correlations. Finally, the updated comment representations are merged with an attention layer (Self-Attention) and are connected to labels with a fully-connected layer.

Comment Encoder

An input sequence consists of a title text $\boldsymbol{a}_{title}$ and comment texts $\boldsymbol{a}_{1...I}$. The words in these texts are embedded into $\boldsymbol{x}_{title}$ and $\boldsymbol{x}_{1...I}$ with an embedding matrix $\boldsymbol{E}$ in Embedding layer. Embedded inputs are then passed to bi-directional LSTM layers[2] to be processed using the following transition functions as

$$\boldsymbol{i}_t = \sigma\left(\boldsymbol{W}_i\boldsymbol{x}_t + \boldsymbol{U}_i\boldsymbol{h}_{t-1} + \boldsymbol{b}_i\right) \quad (1)$$
$$\boldsymbol{o}_t = \sigma\left(\boldsymbol{W}_o\boldsymbol{x}_t + \boldsymbol{U}_o\boldsymbol{h}_{t-1} + \boldsymbol{b}_o\right) \quad (2)$$
$$\boldsymbol{f}_t = \sigma\left(\boldsymbol{W}_f\boldsymbol{x}_t + \boldsymbol{U}_f\boldsymbol{h}_{t-1} + \boldsymbol{b}_f\right) \quad (3)$$
$$\tilde{\boldsymbol{c}}_t = \tanh\left(\boldsymbol{W}_c\boldsymbol{x}_t + \boldsymbol{U}_c\boldsymbol{h}_{t-1} + \boldsymbol{b}_c\right) \quad (4)$$
$$\boldsymbol{c}_t = \boldsymbol{i}_t \odot \tilde{\boldsymbol{c}}_t + \boldsymbol{f}_t \odot \boldsymbol{c}_{t-1} \quad (5)$$
$$\boldsymbol{h}_t = \boldsymbol{o}_t \odot \tanh\left(\boldsymbol{c}_t\right) \quad (6)$$

where $\boldsymbol{i}_t$ is an input gate, $\boldsymbol{o}_t$ is an output gate, $\boldsymbol{f}_t$ is a forget gate, $\tilde{\boldsymbol{c}}_t$ is a cell gate, $\boldsymbol{c}_t$ is a cell state, $\boldsymbol{h}_t$ is a hidden state, $\boldsymbol{W}_*$ and $\boldsymbol{U}_*$ are weight matrices, $\boldsymbol{b}_*$ are bias vectors, σ is a logistic sigmoid function,

[2]We prepared two separate LSTMs for an initial comment ($\mathrm{LSTM_s}$) and for later comments ($\mathrm{LSTM_c}$).

and $\odot$ is an element-wise multiplication operator. Bi-directional LSTM outputs are concatenated and processed with a max-over time process to obtain a comment representation $\boldsymbol{m} = \max\left(\overrightarrow{\boldsymbol{h}} \| \overleftarrow{\boldsymbol{h}}\right)$. For an initial comment, the title output ($\boldsymbol{h}_{title}$) and the comment output ($\boldsymbol{h}_1$) are added before the max-over time process as $\boldsymbol{m} = \max\left(\overrightarrow{\boldsymbol{h}}_{title} \| \overleftarrow{\boldsymbol{h}}_{title} \oplus \overrightarrow{\boldsymbol{h}}_1 \| \overleftarrow{\boldsymbol{h}}_1\right)$, where $\oplus$ is an element-wise addition operator.

Parent-Branch Tree-LSTM

This component allows a discourse act of a comment to be predicted with information from its parent. The comments representations are processed from the root to the leaves with LSTM. We conducted this process with a simple extension to LSTM by replacing a previous time state $\boldsymbol{h}_{t-1}$ in Eq. 1–4 with a parent state $\boldsymbol{h}_{parent}$. A comment can have multiple children. Therefore, $\boldsymbol{h}_{parent}$ are likely to be shared by multiple comments. For latter processes, $\boldsymbol{h}$ is used as an updated comment representation $\boldsymbol{r}_P$.

Child-Sum Tree-LSTM

This component allows a discourse act of a comment to be predicted with information from its children. The comments representations are processed from the leaves to the root with LSTM. We used Child-Sum Tree-LSTM (Tai et al., 2015) for this process. Child-Sum Tree-LSTM extends LSTM by expressing a state transition of children to parent with a summation. More specifically, a previous time state $\boldsymbol{h}_{t-1}$ in Eq. 1, 2, and 4 are replaced by previous child states $\tilde{\boldsymbol{h}}_t$, with updates to forget gate $\boldsymbol{f}_t$ (Eq. 3) and cell gate $\boldsymbol{c}_t$ (Eq. 5) by

$$\tilde{\boldsymbol{h}}_t = \sum_k \boldsymbol{h}_k \tag{7}$$

$$\boldsymbol{f}_{tk} = \sigma\left(\boldsymbol{W}_f \boldsymbol{m}_t + \boldsymbol{U}_f \boldsymbol{h}_k + \boldsymbol{b}_f\right) \tag{8}$$

$$\boldsymbol{c}_t = \boldsymbol{i}_t \odot \tilde{\boldsymbol{c}}_t + \sum_k \boldsymbol{f}_{tk} \odot \boldsymbol{c}_k \tag{9}$$

where $\boldsymbol{h}_k$ is a hidden state of a child and $\boldsymbol{c}_k$ is a cell state of a child. For latter processes, $\boldsymbol{h}$ is used as an updated comment representation $\boldsymbol{r}_C$.

GCN

This component allows a discourse act of a comment to be predicted with information from surrounding comments. The comments representations are processed with a convolution over a graph. For each node, the representations of the surrounding nodes are considered with a convolution filter. We used the graph convolution approach of Defferrard et al. (2016) which approximates a convolutional filter over a graph with Chebyshev expansion (Hammond et al., 2011). In this approach, input representations $\boldsymbol{h}_l$ are processed with the following transition functions as

$$\boldsymbol{h}_{l+1} = U g_\theta\left(\Lambda\right) U^T \boldsymbol{h}_l \tag{10}$$

$$g_{\boldsymbol{\theta}}\left(\Lambda\right) = \sum_k^{K-1} \boldsymbol{\theta}_k T_k(\tilde{\Lambda}) \tag{11}$$

where U is the Fourier basis of a normalized Laplacian in an input graph, $\boldsymbol{\theta}_k$ is a vector of Chebyshev coefficients, and $T_k(\tilde{\Lambda})$ is a Chebyshev polynomial of order k. This graph convolution process can be stacked easily to perform convolutions over a graph iteratively. We prepared two graph convolution processes with rectified linear unit (ReLU) as an intermediate activation as

$$\boldsymbol{r}_G = U g_\theta\left(\Lambda\right) U^T \mathrm{ReLU}\left(U g_\theta\left(\Lambda\right) U^T \boldsymbol{m}\right) \tag{12}$$

to obtain an updated comment representation $\boldsymbol{r}_G$.

Self-Attention

Outputs of three components are merged with an attention layer (Self-Attention) with a self-attentive style (Yang et al., 2016; Lin et al., 2017). A comment representation $\boldsymbol{s}_i$ is updated as a weighted sum of

$\boldsymbol{r}_{ji}$ with weight α_{ji} as

$$\boldsymbol{s}_i = \sum_{j \in \{P,C,G\}} \alpha_{ji} \boldsymbol{r}_{ji} \tag{13}$$

$$\alpha_{ji} = \frac{\exp\left(\boldsymbol{v}_\alpha^T \boldsymbol{u}_{ji}\right)}{\sum_{j' \in \{P,C,G\}} \exp\left(\boldsymbol{v}_\alpha^T \boldsymbol{u}_{j'i}\right)} \tag{14}$$

$$\boldsymbol{u}_{ji} = \tanh\left(\boldsymbol{W}_\alpha \boldsymbol{r}_{ji} + \boldsymbol{b}_\alpha\right) \tag{15}$$

where $\boldsymbol{v}_\alpha$ is a weight vector, $\boldsymbol{W}_\alpha$ is a weight matrix, and $\boldsymbol{b}_\alpha$ is a bias vector.

4 Experiment

4.1 Baselines

Rule 5-ACTS

We prepared a simple rule-based classifier as a non-machine learning baseline. Given a thread, an initial comment is classified as *Question* if it includes a question mark and as *Announcement* for another case. In later comments, a comment is classified as *Question* if it includes a question mark and as *Appreciation* if it includes "thank", "thanks", "thx", "thxs", or "tks", and as *Answer* or *Elaboration* for another case. In the *Answer* or *Elaboration* case, a comment is classified as *Answer* if it is preceded by a comment with *Question* and as *Elaboration* for another case. Note that comments are never classified with the remaining 4 acts (*Agreement*, *Disagreement*, *Humor*, and *Negative Reaction*) in this classifier.

CRF Vote

We implemented the best model in Zhang et al. (2017) as CRF Vote. This model decomposes a thread into root-to-leaf sequences. Features of content, punctuation, structure, author, thread, and community are extracted and used to train a Conditional Random Field (CRF) with Orthant-Wise Limited-memory Quasi-Newton training algorithm and L1 regularization. The strong effect of structural features were confirmed on an ablation test. In this model, a comment often receives multiple prediction labels since a thread is decomposed into sequences. In that case, the label of a comment is decided by a majority vote of the given labels.

LSTM-CRF Vote

We prepared a straightforward extension of CRF Vote combining Comment Encoder (Section 3), an LSTM layer, and a CRF layer. An architecture combining an LSTM and a CRF is known to be effective for sequential labeling tasks (Huang et al., 2015; Lample et al., 2016; Ma and Hovy, 2016). As in CRF Vote, a thread is first decomposed into root-to-leaf sequences. The decomposed sequences are then processed with Comment Encoder to obtain comment representations. The comment representations are then updated with an LSTM layer to introduce comment correlations. Finally, the updated comment representations are passed to a CRF layer to include label correlations. Like in CRF Vote, the label of a comment with multiple prediction labels is decided by a majority vote of the given labels.

Graph-LSTM

We implemented the graph-structured LSTM in Zayats and Ostendorf (2018) as Graph-LSTM. In this model, LSTM is extended to process parent–child relationships and sibling relationships in a Reddit thread. Relationships of these two kinds are introduced to LSTM by preparing a forget gate for hierarchical (reply) connections and a forget gate for timing (sibling) connections. An input to the extended LSTM is comments represented with concatenated word representation averages and submission context features. Submission context features include structural features such as graph locations and graph responses. This model is not designed for discourse acts, but it has shown superior performances for predicting the popularity of Reddit comments.

Discourse Act	Count	Initial Comment Rate
Answer	40,723	0.00%
Elaboration	18,513	0.00%
Question	17,105	41.32%
Appreciation	8,380	0.00%
Agreement	4,815	0.00%
Disagreement	3,263	0.00%
Humor	2,291	2.71%
Announcement	2,002	100.00%
Negative Reaction	1,773	0.00%

Table 1: Numbers of discourse acts and their initial comment rates in the dataset that we used in the experiment.

4.2 Dataset and Evaluation

To evaluate the proposed model and the baseline models, we used the dataset of Zhang et al. (2017)[3], which consists of 9,483 threads with 115,827 comments from 2,837 communities (subreddits). These comments are annotated with the following 10 discourse acts: *Answer*, *Elaboration*, *Question*, *Appreciation*, *Agreement*, *Disagreement*, *Humor*, *Announcement*, *Negative Reaction*, and *Other*. Following the setting of Zhang et al. (2017), we discarded the comments that have no majority annotation or which have *Other* as a majority annotation. We used the resulting 9,131 threads with 98,865 comments to evaluate our models. The numbers of respective discourse acts and their initial comment rates in the resulting dataset are presented in Table 1.

All models are evaluated with ten-fold cross validation following the setting of Zhang et al. (2017). Accuracy, precision, recall, and F_1 score are used for evaluation metrics. For neural models, the dataset is split into train:validation:test in the ratio of 8:1:1 for each fold to provide validation data. A best performing model in a validation data in terms of F_1 score is used to evaluate the corresponding test data.

4.3 Model Configurations

Pre-training of Word Representations

We pre-trained the word-embeddings using randomly sampled comments from Reddit dumps during 2006–2016[4,5]. We restricted communities to those which appeared in the dataset of Section 4.2, and extracted approximately 230M comments. For pre-training, we used word2vec (Mikolov et al., 2013) with the skip-gram algorithm of parameters dimension=100, learning rate=0.025, window size=5, negative sample size=5, and epoch=5. The pre-trained word representations are used in LSTM-CRF Vote, Graph-LSTM, and Tree-LSTM GCN Hybrid.

Hidden Unit Sizes and Maximum Number of Words

Several layers in our models have hidden units as their parameters. For LSTM layers, we have set hidden unit sizes to $\mathrm{LSTM}_s = 300$, $\mathrm{LSTM}_c = 300$, and the LSTM layer in LSTM-CRF Vote to 600. Parent-Branch Tree-LSTM, Child-Sum Tree-LSTM, and GCN also have hidden units. Their size were set to 600. Reddit comments are sometimes long consisting of thousands of words. We restricted the maximum number of words for each comment to speedup training. The maximum numbers were set to 400 for initial comments and 100 for later comments.

Optimization

We trained LSTM-CRF Vote, Graph-LSTM, and Tree-LSTM GCN Hybrid by stochastic gradient descent. As an optimization objective, the score of CRF is used for LSTM-CRF Vote and cross-entropy loss is used for Graph-LSTM and Tree-LSTM GCN Hybrid. The learning rate is selected from $\{0.01, 0.1\}$ using a validation data along with momentum=0.9 and gradient clipping=3.0 for parameters of stochastic

gradient descent. To avoid overfitting, we introduced dropout (Srivastava et al., 2014) with a rate of 0.5 to the LSTM layers of all models and the intermediate layer of GCN for regularization.

4.4 Result

Table 2 presents the evaluation results. For Tree-LSTM GCN Hybrid, we prepared models that used only a single component as Proposed (*component name*). Results show that our proposed model Tree-LSTM GCN Hybrid outperforms the previous best approach of Zhang et al. (2017) (CRF Vote) by 1.5% in accuracy and 2.2 in F_1 score. LSTM-CRF Vote also outperformed CRF Vote but in a smaller magnitude compared to Tree-LSTM GCN Hybrid. This result suggests the effectiveness of both the simple neural extension and the neural structural learning approaches[6]. Graph-LSTM performed moderately but lower than CRF Vote. This result implies that a popularity predictions and a discourse act classification differs even within Reddit. Rule 5-ACTS performed substantially lower than other machine learning models. This result indicates that simple rules are not enough to solve this task. For computational times, Tree-LSTM GCN Hybrid took approximately 21 hours to perform the ten-fold cross validation with an NVIDIA Titan X gpu. This is about five times slower to CRF Vote, which took approximately 4 hours on the evaluation with an Intel Core i7 cpu core.

Performances of the single component proposed models vary among active components. Results show that Parent-Branch Tree-LSTM performs best, with GCN slightly lower than Parent-Branch Tree-LSTM, and with Child-Sum Tree-LSTM scoring quite low. These results are intuitive because a discussion flow in a thread occurs from the root to the leaves with the chain of replies. GCN considers surrounding nodes in distance of two. Therefore, its performance suggests that the effect of distant comments is not strong to classify the discourse act of a comment.

5 Discussions

5.1 Strategy for Combining Three Components

Our proposed model combines three components to classify discourse acts. We analyzed attention probabilities in Self-Attention layer to see how Tree-LSTM GCN Hybrid merges the three components. Figure 3a shows the estimated probability density functions of all comments. As in the single component models in Section 4.4, Parent-Branch Tree-LSTM is most preferred in the model. However, the next preferred component is Child-Sum Tree-LSTM, which performed quite poorly as a single component model. This observation implies that the performance of an individual component might not relate directly to importance in a hybrid model. Figure 3b shows the estimated probability density functions of initial comments. Initial comments have no parents. Therefore, Child-Sum Tree-LSTM and GCN have stronger preference compared to the all comments case.

We further analyzed attention probabilities in terms of the number of replies. In the case of comments with none or a small number of replies, the probability density function shows a similar trend to the all

[6]We confirmed statistically significant improvements between Tree-LSTM GCN Hybrid and LSTM-CRF Vote for all four metrics with the confidence level of 0.05 by Fisher-Pitman permutation test. The improvements between LSTM-CRF Vote and CRF Vote were also statistically significant with the confidence level of 0.10 for accuracy and the confidence level of 0.05 for precision, recall, and F_1 score.

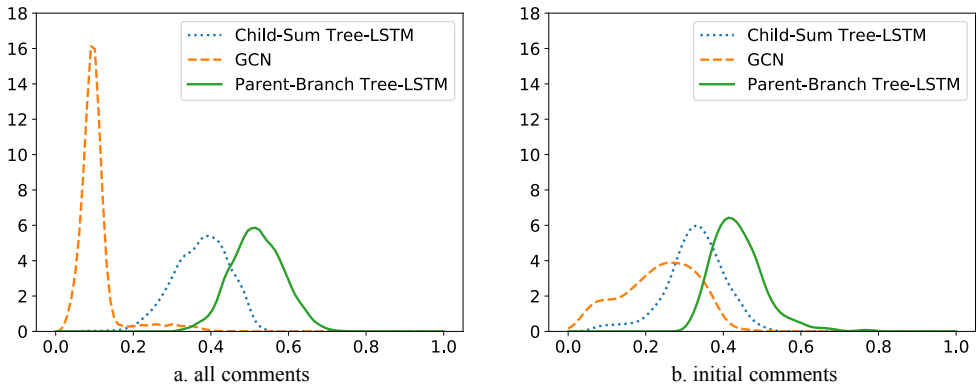

Figure 3: Estimated probability density functions of attention probabilities in the Self-Attention layer.

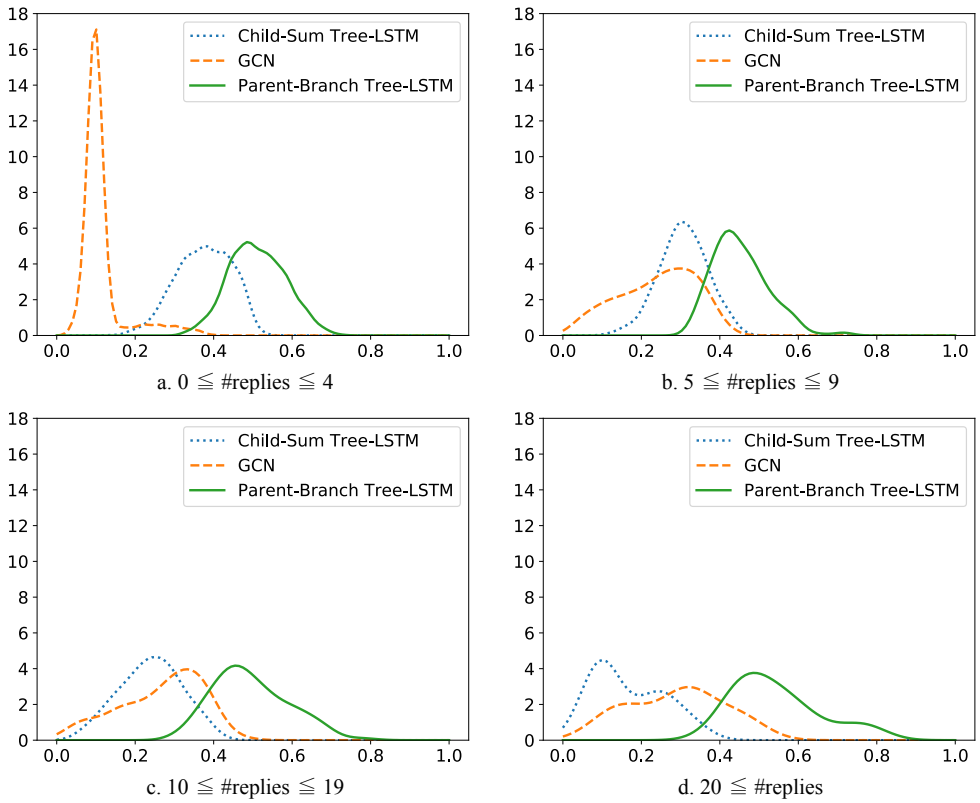

Figure 4: Estimated probability density functions in terms of the number of replies.

comments case (Figure 4a). The preference of Child-Sum Tree-LSTM and the preference of GCN become close in the case with a moderate number of replies (Figure 4b). The preference of GCN surpasses the preference of Child-Sum Tree-LSTM with larger numbers of replies (Figure 4c, 4d). These results imply that when there is a sufficient number of replies, considering nearby comments like in GCN is an effective approach for predicting discourse acts.

5.2 Strengths of Neural Models

In the experiment, we targeted 9 discourse acts for prediction. To clarify the effects of the proposed model, we analyzed the performances of each discourse act. Table 3 shows the detailed F_1 scores of Rule 5-ACTS, CRF Vote, LSTM-CRF Vote, Parent-Branch Tree-LSTM, and Tree-LSTM GCN Hybrid. The analysis shows that the neural models perform on par or better for most acts. Strong improvements in the neural models against CRF Vote are observed in *Disagreement*, *Humor*, and *Negative Reaction*.

Discourse Act	Rule 5-ACTS	CRF Vote	LSTM-CRF Vote	Parent-Branch Tree-LSTM	Tree-LSTM GCN Hybrid
Answer	0.685	0.884	0.892	0.897	0.900
Elaboration	0.325	0.647	0.657	0.660	0.667
Question	0.754	0.853	0.869	0.870	0.877
Appreciation	0.575	0.730	0.704	0.713	0.720
Agreement	0.000	0.460	0.458	0.462	0.475
Disagreement	0.000	0.219	0.280	0.259	0.299
Humor	0.000	0.180	0.285	0.269	0.290
Announcement	0.679	0.787	0.779	0.787	0.819
Negative Reaction	0.000	0.189	0.280	0.302	0.313

Table 3: F_1 scores for each discourse acts in selected baseline models and proposed models.

Model	Precision	Recall	F_1 score
Rule 5-ACTS	0.836	0.439	0.575
CRF Vote (Zhang et al., 2017)	0.794	0.676	0.730
LSTM-CRF Vote	0.721	0.689	0.704
Proposed (Parent-Branch Tree-LSTM)	0.722	0.703	0.713
Proposed (Tree-LSTM GCN Hybrid)	0.750	0.693	0.720

Table 4: Precisions, recalls, and F_1 scores of *Appreciation* in selected baseline models and proposed models.

These acts are less frequent than others (Table 1), and the improvements imply the strength of the neural models to capture infrequent characteristics.

The strength of the hybrid approach (Tree-LSTM GCN Hybrid) is observed in *Announcement* with an improvement of 3.2 in F_1 score. A unique characteristic of *Announcement* is that it only appears in initial comments (Table 1). Therefore, the strength of the hybrid approach supports the observation in Section 5.1 that Child-Sum Tree-LSTM and GCN are more preferred in initial comments. One exception where the proposed model did not work well is *Appreciation*. Table 4 shows the detailed evaluation values of *Appreciation*. In terms of precision, the non-neural models (Rule 5-ACTS and CRF Vote) performed better than the neural models. This analysis suggests that non-neural approaches have certain strength for classifying discourse acts that have strong linguistic clues (e.g. thank).

6 Conclusion

As described in this paper, we proposed a model that integrates discussion structures with neural networks to analyze discourse acts. Parent-Branch Tree-LSTM, Child-Sum Tree-LSTM, and GCN are used as components of the proposed model to capture discussion structures. Results show that, by combining the three components with a self-attentive process, improvements of 1.5% in accuracy and 2.2 in F_1 score are achieved compared to the previous best model. Interactions among the three components are also explored via analysis of attention probabilities in the self-attentive layer of the model. As future works of this study, we first plan to apply our model to discussion in different domains. Reddit comments have their strength in data size, but they are known to have strong association with non-textual attributes such as timing and authors. We are planning to expand our models to explore a more flexible architecture for analyzing discussions.

Abstract

In this paper, we present AnlamVer, which is a semantic model evaluation dataset for Turkish designed to evaluate word similarity and word relatedness tasks while discriminating those two relations from each other. Our dataset consists of 500 word-pairs annotated by 12 human subjects, and each pair has two distinct scores for similarity and relatedness. Word-pairs are selected to enable the evaluation of distributional semantic models by multiple attributes of words and word-pair relations such as frequency, morphology, concreteness and relation types (e.g., synonymy, antonymy). Our aim is to provide insights to semantic model researchers by evaluating models in multiple attributes. We balance dataset word-pairs by their frequencies to evaluate the robustness of semantic models concerning out-of-vocabulary and rare words problems, which are caused by the rich derivational and inflectional morphology of the Turkish language.

Title and Abstract in Turkish

AnlamVer: Anlambilimsel Model Ölçümleme Veri Kümesi - Kelime Benzerliği ve İlişkiselliği

Bu makalede, Türkçe için kelime benzerlik ve ilişkisellik görevlerini ayrı ayrı ölçümleyebilmek için tasarlanmış anlambilimsel bir model veri kümesi olan AnlamVer'i sunuyoruz. Veri kümemiz, 12 kişi tarafından her kelime çifti için ilişkisellik ve benzerlik puanları ayrı ayrı puanlanmış toplam 500 kelime çiftinden oluşmaktadır. Kelime çiftleri, dağılımsal anlambilimsel modelleri kelimelerin ve kelime çiftlerinin sıklık, morfoloji, somutluk ve ilişki tipleri (eş anlamlılık, karşıt anlamlılık vb.) gibi birden fazla niteliğine göre ölçümleyebilmek için seçilmiştir. Amacımız, anlambilimsel model araştırmacılarının modellerini birden fazla niteliğe göre ölçümleyerek içgörüler kazanmasını sağlamaktır. Veri kümesindeki kelime çiftleri, Türkçe'nin zengin türetimsel ve çekimsel yapısı kaynaklı sözlük-dışı ve seyrek-kelime problemlerine karşı anlambilimsel modellerin sağlamlığını ölçümleyebilmek amacıyla sıklık değerlerine göre dengelenmiştir.

1 Introduction

Unsupervised semantic modeling has recently gained a lot of attention in the NLP community due to the notion of high reusability of pre-trained models across a variety of higher level NLP tasks such as machine translation, word sense disambiguation and named entity recognition. Increasing computability of unsupervised distributional semantic modeling (DSM) methods enable researchers to increase the performance of NLP tasks by leveraging extracted semantic information from a high volume of unstructured texts at low costs. However, there are very few available methods and resources to evaluate semantic models intrinsically regardless of the higher level tasks' dynamics. Presenting word similarity and word relatedness (i.e., association) dataset AnlamVer, we aim at providing the semantic modeling field for Turkish with an intrinsic evaluation resource targeting morphology driven issues caused by the rich agglutinative nature of the language. We are not aware of the existence of such word similarity or

Proceedings of the 27th International Conference on Computational Linguistics, pages 3819–3836
Santa Fe, New Mexico, USA, August 20-26, 2018.

relatedness evaluation resources constructed for Turkish. In this paper, we describe design considerations and data collection guidelines we followed in the construction of such dataset as well as dataset statistics.

The main contributions of this paper include: (i) an introduction of a first word similarity and word relatedness evaluation dataset for a low-resource language Turkish[1], (ii) design considerations on the construction of a dataset where the main objective is balancing the words and the words-pairs by multiple morphological and semantic attributes, (iii) a novel analysis and visualization of a word similarity and relatedness dataset containing bi-dimensional values for each word-pair and, (iv) a publicly available web-based word similarity questionnaire software.[2]

2 Background and Design Motivations

Word similarity evaluation (i.e., wordsim) is one of the oldest intrinsic methods of semantic model assessment. For example, RG dataset Rubenstein and Goodenough (1965) is still being used today as one of the gold standards in the DSM research. Wordsim datasets are constructed by asking human subjects to assign numeric scores from 0 to 10 for every pre-selected word-pairs. In this section, we describe some issues of word similarity evaluation and design decisions we made to overcome such issues in our study.

2.1 Similarity and Relatedness Confusion

Linguistic Background

Linguists have been studying on statistical distributions of linguistic items (words) for a century. Although the distributional hypothesis *"words that occur in similar contexts, tend to have similar meanings"* is commonly traced back to Harris (1954), according to Sahlgren (2006), theoretical foundations of his distributional methodology go back to structuralist linguist Bloomfield (1887 - 1949) and Ferdinand de Saussure (1857 - 1913). De Saussure et al. (2011) pointed out that there can be distinctive functional roles of *signs* within the language system. He defined functional differences of linguistic elements in two (orthogonal) types which are widely studied with distributional relations in distributional semantics (DS) research today: *syntagmatic* and *paradigmatic*. Briefly, "words have a syntagmatic relation if they co-occur, and a paradigmatic relation if they share same neighbors" (Sahlgren, 2006). Paradigmatic words represent similar concepts or entities of the real world which are most likely substitutional in the context. One example is the synonyms like "clever" and "smart" in the sentence "She is very [clever | smart]." where two words are less likely to occur at the same sentence.

Lack of Distinction in Word Evaluation

Following the theoretical distinction of paradigmatic and syntagmatic relation types, one can easily apply such distinction to word evaluation by making the assumption that "similarity represents paradigmatic and relatedness represents syntagmatic type of relations.". However, semantic research has not paid as much attention to this distinction as necessary. Two most comprehensive DSM benchmark studies, Baroni et al. (2014) and Levy et al. (2015), reported model performances based on *wordsim* datasets such as RG (Rubenstein and Goodenough, 1965), WordSim-353 (Finkelstein et al., 2001) and MEN (Bruni et al., 2012). In their study, Hill et al. (2016) thoroughly describe the distinction between similarity and relatedness (i.e., sim-rel) caused limitation problems of such datasets. Hill et al. (2016) also define the criteria for evaluation datasets in three: representative, *clearly-defined*, consistent and reliable. Most wordsim datasets such as RG, MC (Miller and Charles, 1991), WordSim-353, and MEN do not satisfy clearly-defined criteria since their screen guidelines use both "similarity" and "relatedness", and "association" words in place of each others. One good example for guideline ambiguity is the following instructions from the WordSim-353 study: *"...please assign a numerical similarity score between 0 and 10 (0 = words are totally unrelated), 10 = words are VERY closely related..."*. Since our study aims to collect both similarity and relatedness scores from participants, we provided *clearly-defined* detailed instructions in the questionnaire screens (Figure 2).

[2]Source code and a demo application are publicly available at `http://www.gokhanercan.com/wsquest`

One Model Does Not Fit All

Agirre et al. (2009) detected the aforementioned sim-rel confusion and split the original WordSim-353 dataset into two datasets (WS-Rel and WS-Sim) by classifying word-pairs based on their relationship types. Thus, they solved the dataset's sim-rel distinction problem without re-scoring word-pairs.[3] They proposed two separate models for similarity and relatedness evaluation tasks. For example, they reported that the context-windows-based approach is better at capturing similarity (evaluated on WS-Sim) while the bag-of-words approach is at relatedness (evaluated on WS-Rel). Capturing the similarity seems arguably harder for *the distributional hypothesis* based unsupervised models compared to relatedness models. Examining the DSM benchmark study of Levy et al. (2015), average performances of all model configurations consistently perform the worst on the SimLex-999 similarity dataset (≈ 0.39) compared to relatedness (traditional wordsims) (≈ 0.70) datasets.[3] [4]

Similarly, Hill et al. (2016) focus only on similarity evaluation while clearly informing annotators about the sim-rel distinction in their SimLex-999 dataset work. In another dataset study, SimVerb-3500 (Gerz et al., 2016), only distributional verb semantics with a large scale (3,500 word-pairs) of verb similarity evaluation is considered. We observe that DSMs have been starting to be divided into more specific models (e.g., relatedness, similarity, antonymy), motivated by the better performance requirements of the higher-level tasks. As Faruqui et al. (2016) point out, intrinsic wordsim evaluation does not correlate well with extrinsic NLP tasks' evaluation results. Wordsim sim-rel confusion might be one of the reasons for this inconsistency. It is an open question whether a single pre-trained DSM can represent the semantics of a domain consistently across multiple higher-level tasks. We think that a *perfect* DSM would be a multi-model structure which could handle every specific relation types (e.g., relatedness, similarity, antonymy, hypernymy, meronymy) of the words with maximum performances. In this study, our dataset targets Turkish language specific DSMs with two main types of semantic relations (similarity and relatedness) by evaluating word-pairs on both at the same time. We are not aware of the existence of such dataset study for any language.

Sim-Rel Vector Space

Instead of splitting word-pairs into two distinct groups, we decided to get two scores for every word-pair: similarity and relatedness. By doing so, we can keep the dataset as a single unit while evaluating semantic models in two relation types. Two-dimensional structure of our evaluation data structure allows us to visualize the semantic space of the dataset through a scatter plot diagram we named "Sim-Rel vector space" (Figure 1).

Given x and y axes represent relatedness r and similarity s scores of each word-pair in the dataset respectively, and variables r and s (orthogonality of paradigmatic and syntagmatic relations) range from 0 and 10. Let SU similar-unrelated, SR similar-related, DU dissimilar-unrelated, DR dissimilar-related are categorical labels of possible semantic sub-spaces ss, $ss = f_1(r, s)$ function would be,

$$ss = f_1(r, s) = \begin{cases} \text{SU}, & \text{if } s \geq 5 \text{ and } r < 5 \\ \text{SR}, & \text{if } s \geq 5 \text{ and } r \geq 5 \\ \text{DU}, & \text{if } s < 5 \text{ and } r < 5 \\ \text{DR}, & \text{if } s < 5 \text{ and } r \geq 5 \end{cases}$$

And let $t = 2$ denotes a threshold variable that represents boundary point of relation-type-spaces where $synonym, antonym, irrelevant$ are categorical labels of possible semantic relation-types rt, $rt = f_2(r, s)$ function would be,

$$rt = f_2(r, s) = \begin{cases} \text{synonym}, & \text{if } 10 - t \leq s \text{ and } 10 - t \leq r \\ \text{antonym}, & \text{if } 10 - t \leq r \text{ and } s \leq t \\ \text{irrelevant}, & \text{if } t \geq r \text{ and } t \geq s \end{cases}$$

[3] Since participants scored under ambiguous guidelines, WS-Sim is not inherently a similarity dataset. See (Hill et al., 2016).

[4] Low scores on RW dataset are plausible because it targets OOV and rare words problems.

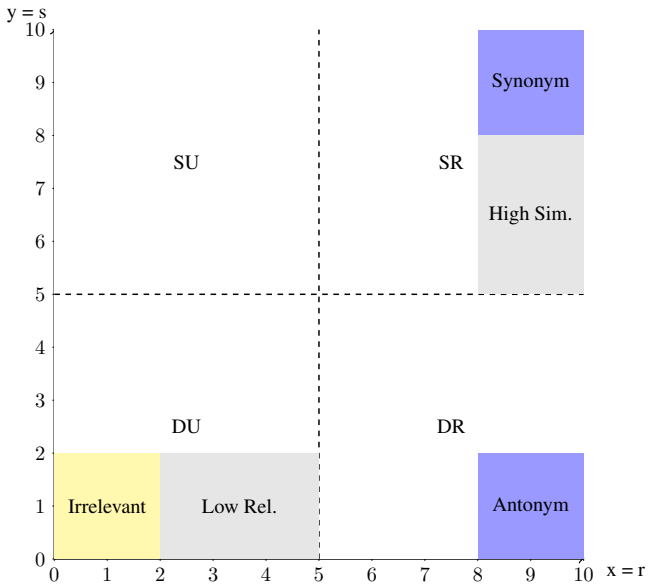

Figure 1: Sim-Rel vector space of word-pairs.

If we assume that participants are asked to score lower for similarity s (closer to 0) in the case of their antonym judgements for word-pairs, and asked to score higher (closer to 10) in the case of their synonym judgements[5], following the definition of the Sim-Rel vector space functions f_1 and f_2 above, followings can be inferred:

- A perfect DSM could assign word-pairs to every semantic sub-space ss with 100% accuracy.
- No word-pair instance is expected to be assigned to a similar-unrelated SU sub-space. Semantically, all highly similar word-pairs should also be highly related. For example, "car - automobile" word-pair is highly similar. Since they are very likely to share many common neighbors in their contexts, their relatedness score should be high, too.
- Word-pairs could be accepted as synonyms if their rt value is assigned to $synonym$ varying by the t parameter. The same rule applies to the $irrelevant$ value, too. We intuitively chose the threshold $t = 2$ value for Sim-Rel semantic space. We kept $t = 2$ same for all axes and relations for the sake of model and visualization simplicity. We leave the theoretical or empirical investigation of selection strategies of such threshold values for future work.
- Antonym-DR-overlapping problem: No DSM could perfectly assign rt as an $antonym$. Boundaries between the antonyms and dissimilar-related DR word-pairs are semantically ambiguous. Our bi-dimensional evaluation model cannot differentiate between the two. For example, word-pairs "tense - loose" and "red - rose" could get closer r and s scores while the first one can semantically be an antonym but the latter is obviously not. Asking to score lower for antonym judgements is a common method in *similarity* datasets (Hill et al., 2016) (Gerz et al., 2016). Storing two inherently different relation types' scores (synonym, antonym) in a single s variable is the root cause of the problem. It is the downside of our Sim-Rel vector space model. We leave the resolution of this problem for future work.

2.2 Out-Of-Vocabulary and Rare Words Problems

Turkish is an agglutinative language which has a highly inflectional and derivational morphology. The agglutinative nature allows forming new words by stringing stem, morphemes and suffixes together. In

[5]Scoring closer numbers to zero for antonyms is a common convention for similarity datasets (Hill et al., 2016), (Gerz et al., 2016).

Turkish, words are bound-morphemes, which means that there can be only one lexical stem (root) of a word. Since Turkish has many productional affixes (e.g., CHk, CA, CI, lHK, SHz, HmsH), theoretically unlimited surface words can be generated. Table 1 shows inflections and derivations of various words in morphologically decomposed forms where every word share the same lexeme "maymun" (monkey). In this study, all morphological decompositions are performed by the toolkit from Görgün and Yildiz (2011).

Word	Decomposition	Sense	Form	Frequency
maymun	maymun	monkey	root form	very
maymunları	maymun + lAr + sH	their monkeys	inflectional	medium
maymunsu	maymun + sI	ape, like monkeys	derivational (usual deviance)	rare
maymungilleri	maymun + gil + lAr + yH	family of monkeys, primades	derivational (acceptable deviance)	oov
maymuncuk	maymun + CHk	skeleton key, picklock (tool)	derivational (deviant)	rare

Table 1: Morphological decomposition of various words sharing the same lexeme.

Simple word-based models ignore the internal structure of words which reduces the model's capabilities and qualities. The main problem is zero (i.e., unseen, out-of-vocabulary) or low occurrence (i.e., rare words) of a testing word in the training corpus. Distributional semantics (DS) community has been developing more complex subword-level (i.e., compositional) models to overcome *out-of-vocabulary* (OOV) and *rare words* problems. DSMs for morphologically-rich languages must alleviate OOV and rare words problem to generalize better. RW dataset (Luong et al., 2013) provides word frequency (i.e., rareness) based evaluation strategy to compositional model developers. Similarly, we aim to balance our dataset's word-pool by words' frequencies to assess generalization powers of such models.

In addition to the traditional OOV and rare words evaluation strategy, we applied another concept that we named *made-up words* by injecting *novel* (i.e., made-up, fake) words into the word-pool of our dataset. Vecchi et al. (2017) applied this concept to their phrase-level models to test the model's creative capabilities (i.e., generalization power). The main idea is as follows: even if people hear a word for the first time and it might sound odd to them, people have the intuition to make sense of the intended meaning. Could DSMs do the same? In our subword-level case, we assume that Turkish affixes can change the meanings of the words in a consistent manner, which is called *acceptable semantic deviance*. For example, the word "maymungilleri" (family of monkeys) is a made-up word and it sounds odd to any native Turkish speaker (Table 1) in the first place. But almost every native speaker can understand what it's meant to some extent. This productivity feature of a language can be seen as a substantial model generalization potential for a researcher. However, the downside of the concept is that the assumption does not always hold as in the word "maymuncuk" (skeleton key, a tool) (Table 1). In this example, the word is derived from the root word (i.e., lexeme) "maymun" (monkey) by getting the affix "cHk" with a valid state transition but its *one sense's* meaning shifts to an entirely different space. It is a very challenging problem for compositional DSMs. Vecchi et al. (2017) name this type of semantically-lossy derivations as *deviants*.

2.3 Dataset Translation Issues

Before starting the dataset construction phase, we have considered translating the existing well-known wordsim datasets to Turkish. After completing MC dataset's translation, we conclude that constructing a new dataset would be more meaningful and reliable than translating the existing ones. The main reasons behind our decision can be summarized as follows:

1. Both words in the source word-pair map to the same single word in the target language: *"football - soccer"* $\rightarrow$ *"futbol - futbol"*.

2. A word in the source word-pair maps to a multi-word phrase: *"asylum - madhouse"* $\rightarrow$ *"tımarhane - akıl hastanesi"*. Traditional wordsim datasets and DSMs ignore phrases for the sake of model and evaluation simplicity. We left phrases out of the scope of this study.

3. Meaning shifts in translations require re-annotation from human resources for every word-pair. The human annotation stage is one of the costly parts of the study. [6]

4. We aim to balance words and word-pairs in as many attributes as possible such as word frequency, derivations, inflections, concreteness and relation types. Word frequencies and morphological features are pretty much language-dependent.

3 Dataset Design and Methodology

Design motivations we borrowed from the previous section can be summarized as follows: (i) collecting two-dimensional relatedness and similarity scores from participants while clearly-defining distinctions of such concepts, (ii) making it language-specific morphological dataset which can evaluate DSMs' generalization power concerning OOV, rare words and semantic deviance scenarios, and (iii) balancing the dataset by multiple morphological and semantic attributes as much as possible. Due to the time and budget limitations, we set the target dataset size of the project to 1.000 scores (500 word-pairs) as most of the wordsim datasets include fewer scores (SimLex-999=999, RG=65, M30, WordSim-353=353, RW=2,034, MEN=3,000). We planned dataset construction process in three stages: word candidates, word pool and word-pairs selections (Table 2).

	Stage 1	Stage 2	Stage 3
	1) Word Candidates (starts)	2) Word-Pool Selection	3) Word-Pairs Selection
Goals	1.1) Reusing existing resources	2.1) Balancing word attributes by estimations	3.3) Balancing word-pairs by estimations
Input	1.2) TKN (600) + MC (39)	2.2) Stage1 output (639) + new derivational words (99)	3.2) 320 Stage2 words
Process	1.3) Attaching frequencies, morphological tags	2.3) Filtering for balancing	3.3) Mapping pairs (every word used 2-5 times building word-pairs)
Output	1.4) 639 words	2.4) 320 words	3.4) 500 word-pairs (ends)

Table 2: Three stages of dataset construction.

3.1 Word Candidates Selections

TKN Dataset

Since Turkish is a low-resource language in NLP research, we aimed to re-use existing resources as much as possible. We investigated word candidates that already have some informative attributes. We used word norms "Türkçe Kelime Normları" (TKN) dataset (Tekcan and Göz, 2005) which is constructed for a psycholinguistics study. TKN consists of 600 Turkish words which are balanced in terms of *concreteness* (half concrete, half abstract) values. TKN's concreteness values are annotated by 100 voluntary university students. As in the English USF word norms dataset (Nelson et al., 2004), TKN words range between 1 and 7. Lower values denote more abstract and higher values denote more concrete concepts. For instance, the word "mutluluk" (happiness) takes 1.85 while the word "gül" (rose) 6.79. By choosing candidates from TKN, we enabled model developers to evaluate their models on various concreteness levels. Unfortunately, TKN contains very frequent and root-formed word dataset with 480 words in lexical root form where none of the 120 non-root form words are inflected.[7] Those limitations led us to add 99 words (with no concreteness values) manually on the next stage in order to achieve the balancing goal of the dataset.

[6] Considering human resources, questionnaire software and data pre/post-processing costs.

[7] 108 words having one derivations, 12 words having two derivations.

3.2 Word-pool Selections

Having 600 candidate words that are transferred from the first stage, our goal was to narrow down them to 320 words (word-pair candidates) while preserving our dataset balancing requirements. Table 3 shows word-pool grouping attributes along with the number of words and percentages.

Frequency-based Balancing

Considering the importance of OOV and rare words problems in modeling for morphologically rich and productive languages, our priority was to balance our word-pool based on word frequencies. RareWords dataset (Luong et al., 2013) addresses this issue by grouping words by their frequencies into four groups $(5-10, 10-100, 100-1000, 1000-10000)$. Since the RareWords dataset is designed for the English language (which is relatively less inflectional and productive than Turkish), researchers may assume that words with frequencies lower than five are most likely to be junk or non-English words. In our case, a single Turkish lexicon can take thousands of surface forms. Our own corpus coverage analysis shows that 47% of word types (277K) occur only once in the corpus, which is compatible with Boun Corpus word coverage statistics (Sak et al., 2011). Therefore, we couldn't ignore the words that have zero or less than five frequencies. We applied a different grouping strategy, where the first group is OOV (zero frequency) and rare words in five groups $RW1, RW2, RW3, RW4, RW5$. Table 3 displays how OOV and rare words (RW) groups are represented in the word-pool. We made the frequency analysis on Boun Corpus (Sak et al., 2011) which consists of roundly 3.2 million token types (i.e., vocabulary size). We defined frequency groups $(0-32, 32-320, 320-3200, 3200-32000, 32000-\infty)$ by using the $gr(n, voc, g)$ function below, where g is the number of groupings, n is the index of each group varying between 1 to g, and voc is the vocabulary size of the given corpus. The only exception is the minimum and maximum values of the first and last groups are fixed to 0 and ∞ respectively. Ampersand symbols (&) denotes string concatenations:

$$gr(n, voc, g) = (voc \times 10^{-(g-n+3)}) \text{ \& "-" \& } (voc \times 10^{-(g-n+2)})$$

3.3 Word Pair Selections

In the word-pair selection stage, we matched words from word-pool with each other to form new pairs. We defined a constraint that every word in the word-pool should occur in the matching word-pairs up to five times. The primary goal of this mapping stage was to find, 500 word-pair relations, which are balanced explicitly by new type attributes: estimated semantics relations are synonym, antonym, hypernym, meronym etc. We manually matched and estimated the semantic type of the relationships. For example, we manually picked two potentially similar words "otomobil" (automobile) and "araba" (car) from the pool and flagged them as a strong synonym potential. We defined 50 synonym, 50 antonym, 50 meronym, 50 hypernym relations. Similarly, we grouped word-pairs by estimated magnitudes (low, medium, high) of relatedness relations too. Table 4 shows the number of actual instances and percentages of such estimation-based groupings and morphological groupings of word-pairs. Finally, we ended up with 500 manually-selected, grouped word-pairs. Table 5 shows some sample annotated word-pair instances from the final dataset.

4 Questionnaire Design

4.1 Platform

We built a web-based application to collect data from human annotators. Participants were asked to score similarity and relatedness relationship for every 500 word-pairs. In total, every participant scored 1,000 answers for 500 word-pairs. We split the questionnaire into two sections. The first section starts with describing what similarity relation is, along with five examples with detailed descriptions. Similar to the Simlex-999 guidelines, we asked users to score low for antonyms and score high for synonyms. We described similarity as follows (showing first two sentences only):
"Two words are similar if they refer to the same thing, person, concept or action. Similar things share common concrete or abstract attributes. For example, 'tea' and 'coffee' are quite similar because both

	G0	G1	G2	G3	G4	G5	Total

are relaxing hot drinks gathered from nature and irreplaceable beverages for friendly conversations." Figure 2 shows a snapshot from the initial guideline screen for similarity annotation. When a participant presses the "ileri" (next) button, first word-pair page appears, asking to score 20 word-pairs per screen (Figure 3).

4.2 Participants

All 12 participants are native Turkish speakers who voluntarily participated in the questionnaire. Eight participants are female, and four participants are male. Both mean and median values of ages are 33.5

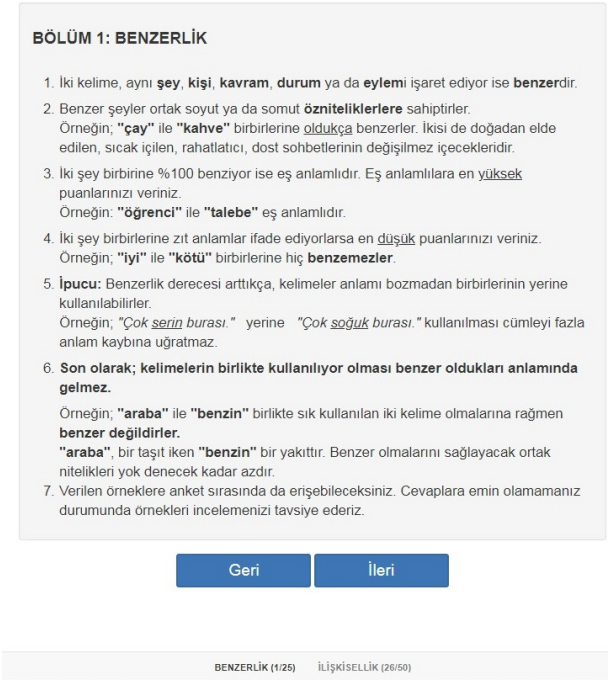

Figure 2: Similarity instructions page.

Figure 3: Word-pair annotation page.

with the standard deviation of 9.3. Nine participants are university graduates (seven participants with the master's degree), two participants are undergraduate, and a participant holds a high school degree. Participants were asked to join the questionnaire remotely using their web browsers by following the invitation link sent to their mailboxes. Questionnaire software WSQuest's[8] responsive layout support, allowed users to score quickly from mobile and tablet devices. They are asked to read user guidelines carefully since no participant had the prior knowledge about the flow of the annotation process, and word similarity and relatedness concepts. Initial guideline screen informed users that they could score the questionnaire freely at any time of the day in three days since questionnaire software allows users to continue their sessions easily as long as they keep the last completed URL of the software. Without giving any breaks, it took participants' 75 minutes on average to complete the entire questionnaire.

5 Dataset Analysis

Final (actual) similarity s and relatedness r values of the dataset seems consistent with our estimations. Under the aforementioned Sim-Rel vector space model assumptions and configuration, scatter plot of the average values of s and r yielded a visual similar to our expectations (Figure 4). Our observations about the actual data distribution as follows:

- SU subspace remain empty as expected. Participants proved that word-pairs cannot be similar and unrelated at the same time.
- Antonym-DR-overlapping problem holds. We observed very close word-pair values for antonym and DR word-pairs. For example, average s and r scores of "kırmızı - gül" (red - rose) word-pair are 1.16 and 7.16 respectively. On the other hand, an antonym-estimated word-pair "şeffaf - opak" (transparent - opaque) has exactly the same scores as the former one (see Table 5).
- Participants scored word-pairs that include made-up words normally as regular word-pairs. For example, annotators scored the word-pair "atatürkist - kemalci" (atatürk+İST - kemal+CH) as 8.75

[8]See appendices or `http://www.gokhanercan.com/wsquest` for complete user screen guidelines.

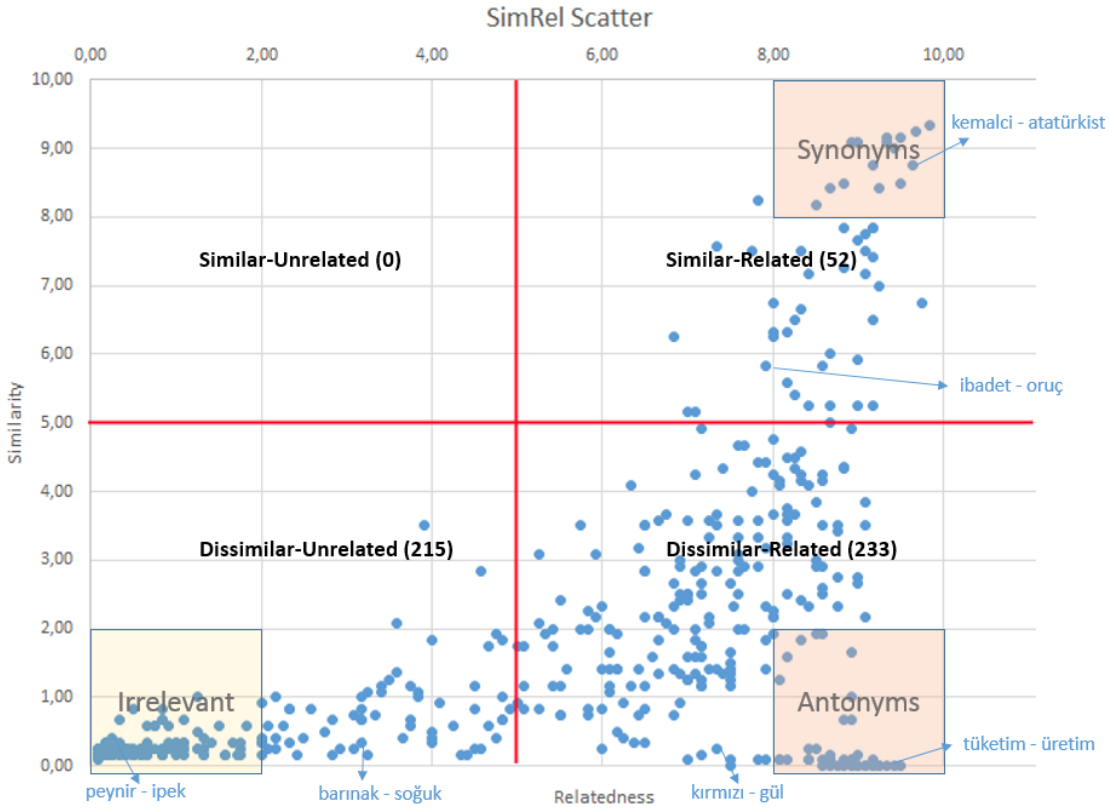

Figure 4: Scatter plot of the final (actual) dataset. Data-points denote participants' avg. Sim-Rel score of each word-pair where y axis is s and x axis is r. Member counts of $ss\{SU, SR, SU, DR\}$ semantic sub-spaces are in the parenthesis.

similar and 9.63 related (see Table 5) where neither of surface forms has the common usage in Turkish (OOV and RW1 respectively). Both İST and CH suffixes have usages to change words' meaning to "ideological adherence to a person/thing" where both names "Atatürk" and "Kemal" are parts of the name "Mustafa Kemal Atatürk" who is the founder of the Republic of Turkey.

5.1 Post-processing and Inter-annotator Argument

Since questionnaire includes many uncommon OOV and rare words pairs, it allows users to skip that word-pair empty if they don't have any idea about the meanings. However, null answering rate (0.1%) is quite lower than we expected. In order to calculate ranking correlations properly, we replaced null answers with the average score of all users' answers for that question. Among 16 participants, we do some post analysis on collected data. We detected that one participant achieved marginally low (0.32 min, 0.57 max) Spearman ranking correlation score compared to the other participants. After a little further investigation, we noticed that this participant had completed the test only in 25 minutes. It is three times faster than what we estimated for a high-quality annotation. Similarly, we increased the overall data quality by removing three more participant's answers too. After post-processing, we computed 0.748 average pairwise inter-annotator ($apia$) score where the highest pairwise correlation of users is 0.847, and the lowest one is 0.474. Even though dataset's $apia$ score is lower than we expected, 0.748 is still higher than the most word similarity datasets (WS-Sim=0.667, MEN=0.68, 0.67=SimLex-999). Based on the study of (Snow et al., 2008), more than ten annotators are statistically acceptable for word similarity evaluation task's reliability.

word1	word2	sim.	rel.	oov	conc.	ss	der#	inf#
otomobil (automobile)	araba (car)	9.16	9.33	no	6.87	SR (syn.)	0	0

gevşek (loose)	heykel (statue)	0.16	0.16	no	-	DU (irr.)	0	0
üşengen* (lazy)	yedigen (heptagon)	0.16	0.25	two	-	DU	2	0

Table 5: Sample word-pairs from the final dataset. Words with asterisks (*) are made-up words. (adh = adherent, conc = concreteness, ss = semantic sub-space, syn = synonyms, ant = antonyms, irr = irrelevant, der# = total derivations, inf# = total inflections)

6 Conclusion

We presented a semantic model evaluation dataset for the Turkish language. Turkish morphology requires complex semantic models to alleviate OOV and rare words problems. Since the dataset includes 13% OOV and 26% rare-word-pairs (RW1 and RW2), we think that it will be a challenging intrinsic evaluation task for DSM researchers. Hopefully, AnlamVer-evaluated distinct similarity and relatedness models correlate better with the higher level NLP tasks. For future work, we are planning to construct a bigger dataset, leveraging existing lexical resources such as Turkish WordNet (Ehsani et al., 2018) which already includes manually-annotated synonymy (i.e., synsets), antonymy and hypernymy relations.

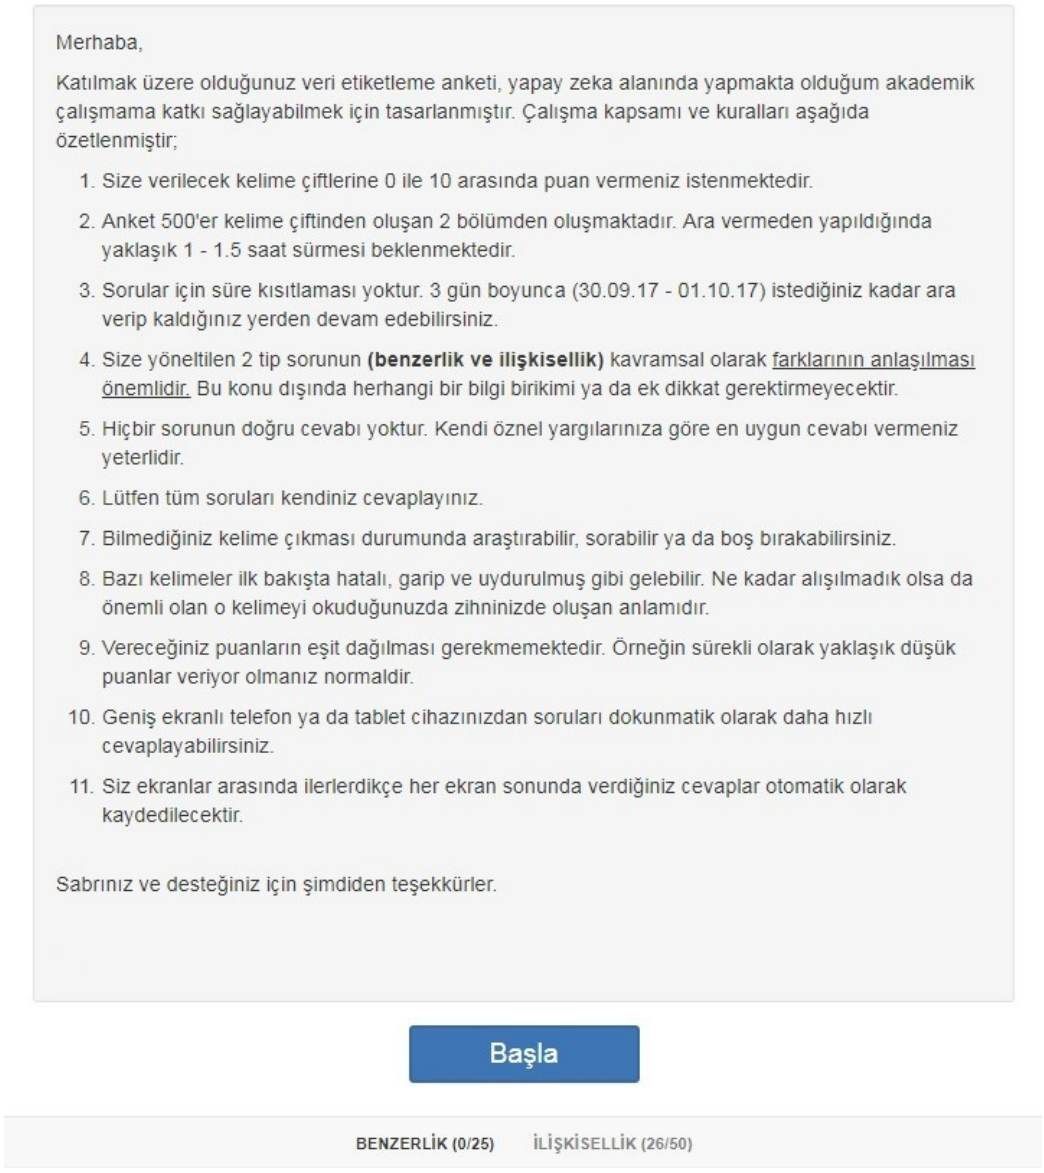
Appendices



Merhaba,
Katılmak üzere olduğunuz veri etiketleme anketi, yapay zeka alanında yapmakta olduğum akademik çalışmama katkı sağlayabilmek için tasarlanmıştır. Çalışma kapsamı ve kuralları aşağıda özetlenmiştir;
1. Size verilecek kelime çiftlerine 0 ile 10 arasında puan vermeniz istenmektedir.
2. Anket 500'er kelime çiftinden oluşan 2 bölümden oluşmaktadır. Ara vermeden yapıldığında yaklaşık 1 - 1.5 saat sürmesi beklenmektedir.
3. Sorular için süre kısıtlaması yoktur. 3 gün boyunca (30.09.17 - 01.10.17) istediğiniz kadar ara verip kaldığınız yerden devam edebilirsiniz.
4. Size yöneltilen 2 tip sorunun (benzerlik ve ilişkisellik) kavramsal olarak farklarının anlaşılması önemlidir. Bu konu dışında herhangi bir bilgi birikimi ya da ek dikkat gerektirmeyecektir.
5. Hiçbir sorunun doğru cevabı yoktur. Kendi öznel yargılarınıza göre en uygun cevabı vermeniz yeterlidir.
6. Lütfen tüm soruları kendiniz cevaplayınız.
7. Bilmediğiniz kelime çıkması durumunda araştırabilir, sorabilir ya da boş bırakabilirsiniz.
8. Bazı kelimeler ilk bakışta hatalı, garip ve uydurulmuş gibi gelebilir. Ne kadar alışılmadık olsa da önemli olan o kelimeyi okuduğunuzda zihninizde oluşan anlamıdır.
9. Vereceğiniz puanların eşit dağılması gerekmemektedir. Örneğin sürekli olarak yaklaşık düşük puanlar veriyor olmanız normaldir.
10. Geniş ekranlı telefon ya da tablet cihazınızdan soruları dokunmatik olarak daha hızlı cevaplayabilirsiniz.
11. Siz ekranlar arasında ilerlerdikçe her ekran sonunda verdiğiniz cevaplar otomatik olarak kaydedilecektir.
Sabrınız ve desteğiniz için şimdiden teşekkürler.
Başla
BENZERLİK (0/25)
İLİŞKİSELLİK (26/50)

BÖLÜM 1: BENZERLİK

1. İki kelime, aynı **şey**, **kişi**, **kavram**, **durum** ya da **eylem**i işaret ediyor ise **benzer**dir.
2. Benzer şeyler ortak soyut ya da somut **özniteliklerlere** sahiptirler.
   Örneğin; **"çay"** ile **"kahve"** birbirlerine oldukça benzerler. İkisi de doğadan elde edilen, sıcak içilen, rahatlatıcı, dost sohbetlerinin değişilmez içecekleridir.
3. İki şey birbirine %100 benziyor ise eş anlamlıdır. Eş anlamlılara en yüksek puanlarınızı veriniz.
   Örneğin: **"öğrenci"** ile **"talebe"** eş anlamlıdır.
4. İki şey birbirlerine zıt anlamlar ifade ediyorlarsa en düşük puanlarınızı veriniz.
   Örneğin; **"iyi"** ile **"kötü"** birbirlerine hiç **benzemezler**.
5. **İpucu:** Benzerlik derecesi arttıkça, kelimeler anlamı bozmadan birbirlerinin yerine kullanılabilirler.
   Örneğin; *"Çok serin burası."* yerine *"Çok soğuk burası."* kullanılması cümleyi fazla anlam kaybına uğratmaz.
6. **Son olarak; kelimelerin birlikte kullanılıyor olması benzer oldukları anlamında gelmez.**

   Örneğin; **"araba"** ile **"benzin"** birlikte sık kullanılan iki kelime olmalarına rağmen **benzer değildirler.**
   "araba", bir taşıt iken **"benzin"** bir yakıttır. Benzer olmalarını sağlayacak ortak nitelikleri yok denecek kadar azdır.
7. Verilen örneklere anket sırasında da erişebileceksiniz. Cevaplara emin olamamanız durumunda örnekleri incelemenizi tavsiye ederiz.

BÖLÜM 2: İLİŞKİSELLİK

1. Bu bölümde aynı kelime çiftlerini **ilişkisellik** derecesi bakımından değerlendirmeniz beklenmektedir.
2. İlişkisellik bir önceki bölümdeki benzerliğe oranla çok daha kolay belirlenebilmektedir.
3. Yüksek ilişkili kelimeler birbirleri ile alakalıdırlar ve sıklıkla benzer bağlamlar içinde kullanılırlar. Örneğin; **"benzin"** ile **"araba"** kelimeleri benzer bağlamlar içinde kullanıldıklarından oldukça ilişkilidirler.
4. Kelimelerin yüksek ilişkili olabilmesi için ortak özniteliklerinin olmasına ihtiyaç yoktur. Örneğin; **"kahve"** ve **"fincan"** çiftinde, biri içecek diğeri eşya olmasına rağmen çift oldukça ilişkilidir ve hatta birbirlerini hatırlatırlar. Bununla beraber; **"faiz"** ve **"fincan"** kelimelerinin ilişkileri oldukça azdır.
5. Benzer ve zıt anlamlı kelimelerin ilişki seviyeleri de genellikle yüksektir. Örneğin; *"İyi kötü ve çirkin."* cümlesinden anlaşılacağı gibi "iyi" ve "kötü" benzer bağlamlarda kullanılırlar. **"iyi"** ve **"kötü"** oldukça ilişkilidirler. Aynı şekilde; benzer anlamlı **"öğrenci"** ve **"talebe"** kelimeleri de benzer bağlamlarda sık geçerler ve oldukça ilişkilidirler.
6. Verilen örneklere anket sırasında da erişebileceksiniz. Cevaplara emin olamamanız durumunda örnekleri incelemenizi tavsiye ederiz.

Abstract

The aim of this paper is to argue for a coherent Universal Dependencies approach to the core vs. non-core distinction. We demonstrate inconsistencies in the current version 2 of UD in this respect – mostly resulting from the preservation of the argument–adjunct dichotomy despite the declared avoidance of this distinction – and propose a relatively conservative modification of UD that is free from these problems.

1 Introduction

Universal Dependencies (UD; Nivre et al. 2016) has recently become a *de facto* standard for the representation of dependency treebanks. An important feature of UD is that it attempts *not* to represent the argument–adjunct distinction. This is stated explicitly in the paper introducing UD (Nivre et al. 2016: 1661): "The scheme [...] makes a distinction between core arguments (e.g., subject and object) and other dependents, but does not attempt to distinguish complements vs. adjuncts" (recall that *complements* are non-subject arguments), and it is confirmed on the current official UD webpage:[1] "[The UD taxonomy] does not make a distinction between adjuncts (general modifiers) versus oblique arguments (arguments said to be selected by a head but not expressed as a core argument)." This decision is not justified in Nivre et al. 2016, but it is briefly motivated on the UD webpage (cf. fn. 1): "[T]he argument/adjunct distinction is subtle, unclear, and frequently argued over. For instance, syntacticians at certain times have argued for various obliques to be arguments, while at other times arguing that they are adjuncts, particularly for certain semantic roles such as oblique instruments or sources. We take the distinction to be sufficiently subtle (and its existence as a categorical distinction sufficiently questionable) that the best practical solution is to eliminate it."

This view goes against the theoretical-linguistic received wisdom – linguistic theories invariably assume a fundamental argument–adjunct dichotomy (AAD). However, it has been repeatedly observed that AAD has been flawed ever since its conception: the three criteria for distinguishing arguments from adjuncts given by Tesnière (1959) – the father of modern valency theory – are pairwise incompatible (Vater 1978a, 1978b, Przepiórkowski 1999). Multiple tests proposed since then have often been inconsistent with linguists' intuitions about AAD (and with each other) and short-lived; as cautiously noted by Tutunjian and Boland (2008, 633), "[t]he sheer number of [purported argument/adjunct] tests underlines the fact that no single test is entirely satisfactory". The existence of such a universal dichotomy is also called into doubt by typologists (see, e.g., Croft 2001: 272–280 and Haspelmath 2014). We have argued recently that even those theories which put much emphasis on the argument–adjunct distinction have not proposed any operational way to distinguish these two classes (Przepiórkowski 2016a, 2017b). On the constructive side, we have demonstrated that a relatively modest modification of some assumptions of Lexical Functional Grammar (LFG; Bresnan 1982, Dalrymple 2001, Bresnan et al. 2015) results in a theory that does not assume AAD at any level of representation and in any theory-internal mechanisms

(Przepiórkowski 2016b, 2017a; Patejuk and Przepiórkowski 2016). This means that neither syntax nor compositional semantics necessarily presuppose AAD. Hence, given that AAD is both non-operational and unnecessary, the avoidance of AAD is a very attractive feature of UD, one that should be consistently implemented and preserved.

Unfortunately, UD does not consistently follow the policy expressed in the quotes evoked at the beginning of this section. The main aim of this paper is to identify those aspects of UD which do preserve AAD and to propose a modified version of the current standard which consistently eschews this ill-defined dichotomy. In particular, we demonstrate that the presence of some vestiges of AAD in UD results in serious inconsistencies in the current classification of dependents as core or non-core – a dichotomy which is fundamental for UD.

2 Argument–Adjunct Dichotomy in UD

The declared UD avoidance of any reference to AAD is consistently implemented in the case of broadly nominal (that is, also prepositional) dependents of verbs. For example, in the case of English, nominal subjects (`nsubj`) may be defined as those dependents which agree with verbs, nominal objects (`obj`) – as those bare nominal (NP) dependents which normally occur immediately after the verb, and nominal indirect objects (`iobj`) – as those NP dependents which normally occur immediately after the direct object. The actual UD definitions of `nsubj`, `obj` and `iobj` are different and somewhat internally inconsistent (cf. §4.2), but the point remains that no reference to AAD is made here. All other broadly nominal non-predicative dependents – including prepositional (PP) dependents – are classified as obliques (`obl`). This way the phrase *at the restaurant*, when it is a dependent of a (non-copula) verb, is always marked as oblique, whether it is an argument (e.g., *I looked at the restaurant*) or an adjunct (e.g., *I fell at the restaurant*) according to the advocates of AAD. Hence, there is no argument–adjunct dichotomy lurking in the process of deciding whether a typical broadly nominal dependent of a verb is core or non-core. Below we will show that the situation is very different in the case of clausal dependents of verbs – both 'closed' (usually finite) and 'open' (controlled, often infinitival) – and in the case of secondary predicates.

2.1 Closed Clausal Dependents

Ordinary (non-controlled) subordinate clauses which are dependents of verbs are marked in UD either as `csubj`, if they are subjects, or as `ccomp`, if they are not subjects but should still be classified as core, or as `advcl`, if they are non-core. Let us assume that it is possible to recognise `csubj` dependents (e.g., in English, as immediately pre-verbal clauses), but how should other clausal dependents be split into core (i.e., `ccomp`) and non-core (i.e., `advcl`)? Current guidelines do not make this clear, saying the following about `ccomp`: "A clausal *complement* of a verb or adjective is a dependent clause which is a core argument. That is, it functions *like an object* of the verb, or adjective"[2] (emphasis ours). The first sentence, making reference to the notion of *complement* (i.e., non-subject argument), explicitly relies on AAD: complement clauses are marked as `ccomp`, adjunct clauses – as `advcl`. The second sentence, making reference to the notion of *object*, could in principle avoid AAD, if there were independent criteria of deciding when a clausal dependent "functions like an object". Since no such criteria are provided in UD guidelines, UD practitioners implicitly rely on AAD and classify dependent clauses as `ccomp` when they seem to be (non-subject) arguments, and as `advcl` – when they seem to be adjuncts.

It might seem then that both sentences have the same effect, but in fact they differ. On the first – broader – view, complement clauses are treated as core, but they are not necessarily assumed to be objects. That is, it is possible for a single head to have an `obj` dependent and a `ccomp` dependent. On the second – narrower – view, complement clauses are (direct) objects, so – given that a head may have at most one (direct) object dependent – it is not possible for a single head to have both an `obj` dependent and a `ccomp` dependent. In fact, such a check is implemented in the UD validating script, UDAPY, and the accompanying validation web page states this explicitly: "No predicate can have more than one direct object. Ccomp counts as direct object."[3]

[2] `http://universaldependencies.org/u/dep/ccomp.html`
[3] `http://universaldependencies.org/svalidation.html`

Both approaches are found in UD (release 2.1) treebanks. The broader view is implemented, *inter alia*, in the Latvian LVTB treebank and in the English EWT treebank (the latter henceforth abbreviated to $\text{UD}^{\text{EN}}_{\text{EWT}}$), where in both cases about 1% of utterances contain a head with an `obj` and a `ccomp` dependent; one of the 160 such cases in $\text{UD}^{\text{EN}}_{\text{EWT}}$ is:

(1) Apparently the City *informed* [them]$_{\texttt{obj}}$ [that no permit is required]$_{\texttt{ccomp}}$.

On the other hand, some treebanks – including the Finnish TDT treebank and the Polish SZ treebank ($\text{UD}^{\text{PL}}_{\text{SZ}}$, for short) – take the stronger position: if two dependents compete for the status of the direct object, only one of them may be labelled as `obj` or `ccomp`, and the other one is given the status of indirect object, `iobj`. As indirect objects are assumed to be nominal, never clausal, `ccomp` always wins the competition for the direct object status, so the nominal is marked as `iobj`. But this has very unwelcome consequences, as it forces some most prototypical direct objects to be reanalysed as indirect objects only because the verb also subcategorises for a clause. This is illustrated with example (2) from $\text{UD}^{\text{PL}}_{\text{SZ}}$, where the verb *spytało* 'asked' combines with the numeral subject *kilka osób* 'several people', the accusative nominal *mnie* 'me' and the subordinate clause *czy jestem...*, lit. 'whether I am...'.

(2) Kilka osób *spytało* [mnie]$_{\texttt{iobj}}$, [czy jestem dzięki feminizmowi szczęśliwsza]$_{\texttt{ccomp}}$.
several people asked me.ACC whether am thanks feminism.DAT happier.NOM
'Some people have asked me whether feminism made me happier.'

Since the subordinate clause is marked as `ccomp`, *mnie* 'me' must be (and is) marked as an indirect object, `iobj`, contrary to linguistically motivated definitions of direct objects in Polish. On the view prevailing in contemporary grammars of Polish, the only reasonable definition of direct objects in Polish is as those dependents which become subjects under passivisation – and *mnie* 'me' above satisfies this definition. A more traditional view refers to accusative bare nominal complements – and *mnie* 'me' satisfies this definition as well. In fact, when the same verb, SPYTAĆ 'ask', occurs in $\text{UD}^{\text{PL}}_{\text{SZ}}$ with an accusative complement but without a clausal complement, the accusative nominal is marked as `obj`, as in the following sentence:

(3) Chciał [ją]$_{\texttt{obj}}$ *spytać* [o wiele rzeczy]$_{\texttt{obl}}$.
wanted her.ACC ask.INF about many things
'He wanted to ask her about many things.'

Note that *mnie* 'me' in (2) and *ją* 'her' in (3) bear exactly the same semantic role with respect to the two forms of the verb SPYTAĆ 'ask' and have the same grammatical properties (passivisability, grammatical case, etc.), so this is a clear case of intra-linguistic annotation inconsistency.

One line of defence could be that there are two valency frames for SPYTAĆ 'ask' witnessed in these two examples and that the accusative complement – while having the same semantic role – is assigned different grammatical functions in these frames. Consider, however, the attested[4] example (4), which involves a coordination of a nominal dependent with the preposition O 'about' and a clausal dependent with the complementiser CZY 'whether'. Such examples make it clear that the accusative phrases in (2)–(3) occupy the same position within the same valency frame, in which another position may be realised either as a subordinate clause, as in (2), or as a prepositional phrase with the preposition O 'about', as in (3), or as a coordination of such two realisations, as in (4).[5,6]

(4) ...należy więc *spytać* [lekarza]$_{?}$ [[o rekomendowane leczenie]$_{\texttt{obl}}$ i [czy
ought.IMPS so ask.INF doctor.ACC about recommended treatment and whether
można się spodziewać wypadania włosów]$_{\texttt{ccomp}}$].
may.IMPS RM expect falling_out hair
'...so one should ask the doctor about the recommended treatment and whether one should expect hair to fall out.'

Let us summarise. Two views on what it means to be a (non-subject) core clausal dependent are present

[4] `http://www.handsomemen.pl/wlosy,lysienie,wypadanie_wlosow_u_dzieci.html`

[5] Since the accusative dependent of SPYTAĆ 'ask' is claimed to be `iobj` in (2) and `obj` in (3), it is not clear – on the approach discussed here – what its label should be in (4); hence the question mark.

[6] Note that, unlike in the English translation, the second conjunct cannot be analysed as a dependent of the preposition *o* 'about'.

in UD guidelines. The broader view makes an explicit reference to AAD and defines ccomp as any non-subject clausal argument. The narrower view defines ccomp as a clausal object, but – given the lack of an independent definition of such clausal objects – this also boils down in practice to assuming AAD and treating all non-subject clausal arguments as ccomp. Moreover, the narrower view, as currently implemented, is linguistically naïve and leads to violations of annotation consistency. In §4, we propose a solution that may be viewed as a variant of the narrower view, but one that does not make reference to AAD and does not lead to annotation inconsistencies.

2.2 Open Clausal Dependents

While ccomp marks non-subject 'closed' clausal arguments, xcomp is used, *inter alia* (see §2.3 below), to label so-called 'open' non-subject core clauses, i.e., clausal dependents with obligatorily controlled subject, as in the English example from $\text{UD}^{\text{EN}}_{\text{EWT}}$: "So [Bush]$_{\text{nsubj}}$ *stopped* [flying]$_{\text{xcomp}}$." Just as in the case of ccomp, the xcomp relation is understood differently in different treebanks. In $\text{UD}^{\text{EN}}_{\text{EWT}}$, xcomp dependents are again understood broadly, as any open complements, and they do not compete with prototypical direct objects. For example, *asked* in the following (partial) sentence has an obj dependent and an xcomp dependent: "I *asked* [them]$_{\text{obj}}$ [to change it]$_{\text{xcomp}}$…". On the other hand, in $\text{UD}^{\text{PL}}_{\text{SZ}}$, the prototypical (passivisable, accusative) direct object *je* 'them' of the verb *uczą* 'teach' in (5) is marked as an indirect object, probably due to the presence of an xcomp dependent of the same verb, which wins the competition for the direct object position:

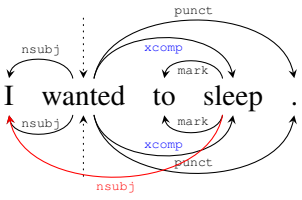
(5) …*uczą* [je]$_{\text{iobj}}$ [zjeżdżać na racicach]$_{\text{xcomp}}$.
teach.3.PL them.ACC slide.INF on hooves
'…they teach them to slide on their hooves.'

Again, in both cases reference is made to AAD: non-subject open dependents are marked as xcomp if they are arguments, and as advcl – if they are adjuncts. And, again, the narrower view goes against the linguistically-motivated definitions of *direct object* and results in annotation inconsistency, as illustrated by (6), where the corresponding (passivisable, accusative) dependent *nas* 'us' is marked as a direct object, obj, while the iobj label is used for the taught material, *tego* 'this' (which semantically corresponds to the xcomp dependent *zjeżdżać na racicach* 'slide on hooves' in (5)).

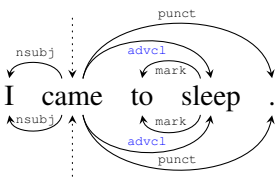
(6) [Tego]$_{\text{iobj}}$ [nas]$_{\text{obj}}$ *uczy* [Boże Słowo]$_{\text{nsubj}}$.
this.GEN us.ACC teach.3.SG god's.NOM word.NOM
'God's Word teaches us that.'

Note that, unlike in the case of 'closed' clausal dependents, a different label (xcomp vs. advcl here, ccomp vs. advcl there) is not the only difference between the two analyses. If an 'open' clausal dependent is analysed as core, i.e., as xcomp, there is an additional secondary nsubj edge in the enhanced representation, as in (7). Such a secondary edge is missing if the dependent is analysed as non-core, as in (8). But since core vs. non-core distinction relies on AAD, this means that the structure of the resulting dependency graph depends on the dichotomy that UD claims to eschew.

(7)



(8)



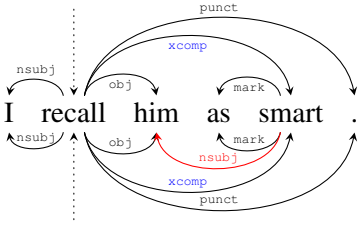
2.3 Secondary Predicates

Finally, AAD is also preserved in UD in the treatment of secondary predicates, as in the English "I recall him as smart and genial" (from the iWeb corpus, https://corpus.byu.edu/iweb/). Should the depictive dependent, *smart and genial*, be analysed as an argument of *recall*, or as its adjunct? Valency dictionaries do not agree about this (see Appendix A). As is made clear in the description of the xcomp label,[7] secondary predicates analysed as arguments are xcomp dependents of the verb, with an enhanced

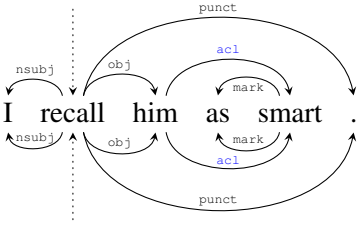
[7] http://universaldependencies.org/u/dep/xcomp.html

nsubj relation to the nominal they predicate of, as in (9). However, those analysed as adjuncts are acl dependents of the nominal elements they predicate of, as in (10).

(9)

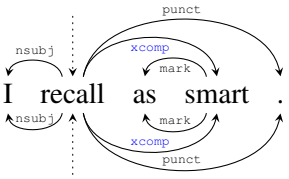


(10)

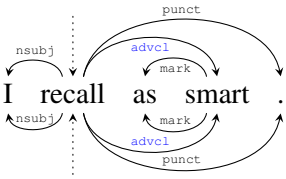


Moreover, if the subject of predication is missing or realised non-locally, as in "(This is the man) I recall as smart", the secondary predicate is still an xcomp dependent of the verb, if it is analysed as an argument (cf. (11)), but it is marked with a third dependency label, advcl, if it is analysed as an adjunct (cf. (12)). Hence, in the case of secondary predicates, the resulting structures depend on the ill-defined AAD even more than in the case of 'open' clausal dependents, again, despite the declared avoidance of this dichotomy in UD.

(11)



(12)



2.4 Summary of AAD in UD

While UD avows to forsake AAD, the core vs. non-core distinction boils down to the argument–adjunct dichotomy at least in the case of clausal dependents of verbs – both 'closed' (clausal, often finite) and 'open' (controlled, often infinitival) – and in the case of secondary predicates. While this dichotomy is vague and controversial, the resulting dependency representations differ sharply, depending on the classification of the relevant constituent as an argument or an adjunct. The following section shows that these vestiges of AAD in UD also make it impossible to coherently classify certain dependents as core or non-core.

3 Core vs. Non-Core Distinction in UD

The fact that non-subject core *nominal* dependents are understood very narrowly – as bare nominal direct objects and perhaps indirect objects – while non-subject core *clausal* dependents may be understood more broadly – as any clausal complements – leads to some serious inconsistencies.

Consider the verb ASK. In sentences such as "We asked the president about the hunt for Osama bin Laden", the prepositional phrase *about the hunt for Osama bin Laden* will receive the obl – i.e., non-core – dependency label (this is the annotation of such dependents of ASK in $\text{UD}^{\text{EN}}_{\text{EWT}}$). On the other hand, in the sentence "We asked the president whether Americans are safe at home", the subordinate interrogative clause, being an argument, is a core dependent, so it will be annotated as ccomp (again, this is the annotation of such subordinate clause dependents of ASK in $\text{UD}^{\text{EN}}_{\text{EWT}}$). If so, what is the coreness status of the coordinate dependent of *asked* in the following example from the iWeb corpus?

(13) At the White House, we *asked* the president [[whether Americans are safe at home]$_{\texttt{ccomp}}$ and [about the hunt for Osama bin Laden]$_{\texttt{obl}}$].

At the moment, UD's reply is inconsistent: the broadly nominal second conjunct of this coordinate structure is a non-core dependent of the verb, and the clausal first conjunct is a core dependent of the verb. On the natural assumption that whole dependents should be classified as core or non-core (see Appendix B), and that the coordinate structure *whether Americans are safe at home and about the hunt for Osama bin Laden* is such a dependent of *asked*, the coreness status of this dependent is incoherent.

It is easy to provide an arbitrary technical solution of this conceptual problem: the coreness of a coordinate dependent could be resolved by fiat to the coreness of the first conjunct. So, in (13), the coordinate structure would be ruled as core, given that the first conjunct is a ccomp – i.e., core – dependent

of *asked*. The arbitrariness of this technical solution is made clear by the fact that, by adopting it, the coreness of a coordinate structure depends on the order of conjuncts. Thus, in "We asked the president about the hunt for Osama bin Laden and whether Americans are safe at home", the coordinate dependent would be classified as non-core, because the first conjunct is now an `obl` dependent of *asked*.

This problem is not limited to dependents of ASK; similar examples may be found in corpora, which involve other heads and other kinds of coordinated dependents, including the following, again from iWeb:

(14) Dennis is an important voice of moderation who *worries* [[whether Colorado has adequate water reserves]$_{\texttt{ccomp}}$, and [about the future of family farms]$_{\texttt{obl}}$].

(15) Mr. Bernhardt *told* him [[about the "mediandisease" virus]$_{\texttt{obl}}$ and [that Adrian's blood analysis showed that he was virus free]$_{\texttt{ccomp}}$].

(16) We *counsel* them [[about the dangers of giving birth]$_{\texttt{obl}}$ and [that their baby might be born infected]$_{\texttt{ccomp}}$].

Neither is the problem limited to English; a Polish example of this kind is in fact given above – see (4). There, the prepositional oblique (non-core) dependent *o rekomendowane leczenie* 'about recommended treatment' of the verb *spytać* 'ask' is coordinated with the clausal (core) dependent *czy można się spodziewać wypadania włosów* 'whether one should expect hair to fall out'.

Similar inconsistency involves `xcomp` dependents: they are core, but they may fill the same position as non-core dependents, as in the following attested[8] example:

(17) Campbell made two visits to the home of domestic abuse victim Miss A, during which he *asked* her [[for a kiss]$_{\texttt{obl}}$ and [to go on a date with him]$_{\texttt{xcomp}}$].

Again, *for a kiss* would currently be classified as a non-core `obl` and *to go on a date with him* is a typical `xcomp` (also in $\text{UD}^{\text{EN}}_{\text{EWT}}$), i.e., a core dependent, so the status of the coordinate phrase as a core or non-core dependent of *asked* is inconsistent.

4 Proposal

4.1 Basic Idea

The basic idea follows directly from the discussion of the previous sections. Since there are no generally accepted objecthood criteria of clausal dependents of verbs, only those clausal dependents should be treated as objects which may be coordinated with nominal – i.e., uncontroversial – objects. Similarly, clausal dependents which may be coordinated with broadly nominal obliques – especially, prepositional phrases – should be classified as non-core. On this approach, the clausal dependent of the Polish verb SPYTAĆ 'ask', as in (2), where it is marked as `ccomp`, should be classified as non-core, because it may be coordinated with a prepositional oblique, as in (4). (Note that the obstacle to treating the passivisable accusative *mnie* 'me' in (2) as a direct object would then disappear.) Similarly, given coordination facts such as (13), the clausal dependent of the English ASK in constructions involving an NP object (cf. *the president* in (13) and in its variants discussed in the main text) would also be classified as non-core, as it may also be coordinated with a prepositional oblique. The same holds for appropriate 'closed' clausal dependents of verbs in (14)–(16). Also some 'open' dependents, hitherto marked as `xcomp`, would have to be classified as non-core, on the basis of data such as (17).

The question arises whether, on this approach, there are any clausal dependents left that would have to be classified as objects rather than as obliques. The answer is yes: it is clear that some clausal dependents must be analysed as direct objects. Take the following classic example (Sag et al. 1985: 165):

(18) Pat *remembered* [[the appointment]$_{\texttt{obj}}$ and [that it was important to be on time]$_{\texttt{ccomp}}$].

In the simpler "Pat remembered the appointment", the NP *the appointment* is an uncontroversial direct object. Hence, the coordinate phrase *the appointment and that it was important to be on time* in the above sentence must also be considered the direct object.[9] If so, it must be concluded that the direct object position of the verb REMEMBER may be realised as either an NP or a clause. But this in turn

[8] `https://www.liverpoolecho.co.uk/news/liverpool-news/police-officer-attempted-kiss-vulnerable-13615076`

[9] Sag et al. 1985 convincingly argue that unlike category coordination cannot be explained away as ellipsis.

implies that the subordinate clause in "Pat remembered that it was important to be on time" should also be considered a direct object. Note that this conclusion does not lead to undesired consequences of the kind discussed in §§2.1–2.2 above: the NP and the clause do not compete for the status of direct object, as only one of them (or a single coordinate phrase) may occur with REMEMBER: *"Pat remembered the appointment that it was important to be on time". Obviously, such constructions are not limited to linguistic papers, as the following examples from the iWeb corpus testify:

(19) I do *remember* [[a lot of wine bottles]$_{\texttt{obj}}$ and [that Felix spoke almost nothing]$_{\texttt{ccomp}}$].

(20) Well, my initial reaction was, I have to *assume* [[the worst]$_{\texttt{obj}}$ and [that he's really going to take his life]$_{\texttt{ccomp}}$].

(21) One guy who had a registered one really didn't *know* [[the law]$_{\texttt{obj}}$ and [that he had to register the gun in this state]$_{\texttt{ccomp}}$].

Neither are they limited to English, as illustrated by the following Polish example (from the National Corpus of Polish; `http://nkjp.pl/`; Przepiórkowski et al. 2011, 2012):

(22) Milena *widzi* [[dewastację]$_{\texttt{obj}}$ oraz [że to coś wyciekające paskudzi
Milena.NOM sees devastation.ACC and that this something oozing soils
dywan]$_{\texttt{ccomp}}$]...
carpet
'Milena sees the devastation and that the oozing thing is soiling the carpet...'

Again, the same reasoning may be applied to 'open' clausal dependents, `xcomp`, as the following attested examples illustrate:[10]

(23) She *wants* [[a career in virtual reality]$_{\texttt{obj}}$, and [to perhaps even found her own company]$_{\texttt{xcomp}}$].

(24) Homeless people *need* [[a work ethic]$_{\texttt{obj}}$ and [to be self-reliant]$_{\texttt{xcomp}}$], Bender said.

(25) He *remembers* [[the cocktail napkins]$_{\texttt{obj}}$, and [to serve the ladies first]$_{\texttt{xcomp}}$].

Exactly such constructions in Polish are analysed in Patejuk and Przepiórkowski 2014, on the basis of the classic (Kallas 1993: 123) example (26).

(26) *Chcę* [[pić]$_{\texttt{xcomp}}$ i [papierosa]$_{\texttt{obj}}$].
want drink.INF and cigarette.ACC
'I want to drink and (I want) a cigarette.'

Hence, according to the current proposal, all the examples cited in this section, (18)–(26), show that the relevant heads (marked in italics) may combine with clausal dependents "functioning like objects".

There are two immediate consequences of this basic proposal. First, since some obligatorily controlled – i.e., 'open' – clausal dependents (e.g., the infinitival dependent of some uses of ASK; cf. (17)) are now analysed as non-core, it would be useful to distinguish such 'open' oblique clauses from 'closed' oblique clauses, just as 'open' object-like clauses (`xcomp`) are distinguished from 'closed' object-like clauses (`ccomp`). For the time being we retain the label `advcl` for the 'closed' oblique clauses and we introduce the label `xadvcl` for 'open' oblique clauses. In Appendix C, we provide independent motivation for such 'open' obliques, and also for 'open' – obligatorily controlled – subjects, called `xsubj` for now. Thus, we propose to extend the repertoire of basic dependents of verbs from (27) to (28).

(27)

	subject	object	non-core
nominal	`nsubj`	`obj/iobj`	`obl`
clausal	`csubj`	`ccomp`	`advcl`
open		`xcomp`	

(28)

	subject	object	non-core
nominal	`nsubj`	`obj/iobj`	`obl`
clausal	`csubj`	`ccomp`	`advcl`
open	`xsubj`	`xcomp`	`xadvcl`

Second, while some clausal dependents retain their status as core (cf. (18)–(26)), many clausal dependents which are prototypical arguments according to the advocates of AAD will now be analysed as non-core. While this may be perceived as a disadvantage of the current proposal, it is in fact its advantage, as it increases the internal consistency of UD: the treatment of broadly nominal dependents is

[10] The first example is taken from `https://www.usatoday.com/story/sponsor-story/xq/2017/04/03/high-school-wants-revolutionize-learning-technology/99985812/`, the other – from the iWeb corpus.

fully analogous. There, only very few of traditional arguments are assigned the status of core dependents: subjects, bare nominal direct objects and perhaps bare nominal indirect objects. The whole class of prototypical – but prepositional – arguments, as in "*wait* [for somebody]$_{\texttt{obl}}$", "*rely* [on somebody]$_{\texttt{obl}}$", "*nibble* [at something]$_{\texttt{obl}}$", etc., is relegated to obliques, together with prototypical adjuncts.[11] We see no reason not to adopt the same solution in the verbal domain: apart from closed and open subjects (`csubj`, `xsubj`) and objects (`ccomp`, `xcomp`), all other clausal dependents should be relegated to the respective classes of 'clausal obliques', i.e., `advcl` and `xadvcl`. If this solution seems difficult to accept at first, it is only because of the unfortunate names UD assigns to such 'clausal obliques', names which suggest their necessarily adverbial character; in §4.3, we will propose a more adequate naming scheme.

Let us take stock of the proposal so far. Unlike in the current UD practice, we propose to take seriously the stance expressed in the UD guidelines that (non-subject) core clausal dependents "function like an object" and mark as `ccomp` and `xcomp` only those 'closed' and 'open' clausal dependents which may be coordinated with uncontroversial – nominal – objects. The other (non-subject) 'closed' and 'open' clausal dependents should be marked as `advcl` and `xadvcl` (but see §4.3 below). But apart from making precise the recommendation that (non-subject) core clausal dependents should "function like objects", this proposal has a number of other advantages. First, it removes explicit and implicit references to AAD in the treatment of clausal dependents of verbs. Second, it is free from inconsistency problems with the previous narrow understanding of core clausal dependents (nominal direct objects reanalysed as indirect objects because of the presence of a clausal dependent). Third, it is free from the problem of the incoherent coreness status of certain coordinate dependents.

4.2 Direct and Indirect Objects Revisited

The above subsection concentrated on obliques and on uncontroversial direct objects. What about indirect objects? Can clausal dependents be coordinated with indisputable indirect objects and, hence, be claimed to "function like indirect objects"? The answer depends on a particular understanding of the distinction between direct and indirect objects. The current UD practice follows the linguistic tradition: indirect objects are those NPs in double object constructions which bear the semantic role of a recipient or a benefactor. Thus, in (29), from $\text{UD}^{\text{EN}}_{\text{EWT}}$, the NP *you* immediately following the verb is the indirect object, and the next NP, *a voice mail*, is the direct object:

(29) I *left* [you]$_{\texttt{iobj}}$ [a voice mail]$_{\texttt{obj}}$ on Friday.

If so, there are probably no clausal dependents that should be analysed as indirect objects – with the possible exception of free relatives, it is difficult to imagine such a clausal dependent bearing the semantic role of a recipient or a benefactor. So, for example, in the attested[12] (30), the 'closed' clausal conjunct should be analysed as a direct object, because the nominal conjunct, *balance*, is marked as a direct object (and the preceding NP, *me*, is marked as an indirect object):

(30) Mother Nature *taught* [me]$_{\texttt{iobj}}$ [[balance]$_{\texttt{obj}}$, and [that regular pattern interrupts can negate radical change]$_{\texttt{ccomp}}$].

Similarly for the 'open' clausal conjunct in the following attested sentence (from Patejuk and Przepiórkowski 2014):

(31) My uncle said to hell with that and *taught* [me]$_{\texttt{iobj}}$ [[karate]$_{\texttt{obj}}$, and [to fire weapons]$_{\texttt{xcomp}}$].

However, as is often the case with linguistic tradition, this traditional view confuses different levels of linguistic representation, namely, semantic roles and (syntactic) grammatical functions. As discussed at length in Andrews 2007, grammatical functions correlate with semantic roles, but – in the end – the precise scope of particular grammatical functions must be defined intra-linguistically, on the basis of such 'coding strategies' as case marking, agreement and word order, as well as on the basis of diathesis alternations (especially, passivisation). In the case of English, case marking and agreement do not distinguish the two NPs in double object constructions, but word order potentially does: on the simplest definition of direct objects – as those NPs which necessarily (apart from well-defined constructions, such

[11] Similarly in the case of arguments which are not nominal or clausal at all, as in "behaving *in some way*" or "treating somebody *in some way*"; they are assigned the `advmod` label (also in $\text{UD}^{\text{EN}}_{\text{EWT}}$, despite being arguments on most accounts).

[12] `http://thedeliverymag.com/10-things-mother-nature-taught-me-about-motherhood/`

as topicalisation, heavy NP shift, etc.) immediately follow the verb – it is the pronoun *me* that should be analysed as the direct object in the two examples above. This stance is strongly supported by another grammatical property that such initial – immediately post-verbal – NPs in ditransitive constructions share with prototypical direct objects in monotransitive constructions, namely, they normally passivise in all varieties of English, unlike the non-initial NPs, which passivise only in some varieties and under certain conditions: "I was taught balance by Mother Nature" vs. %"Balance was taught me by Mother Nature" (where % indicates limited acceptability). Hence, as also argued in Andrews 2007: 184–188 with reference to passivisation facts, it is the first post-verbal NP – the recipient or benefactor – that should be considered the direct object in double object constructions in languages such as English.

Note that the UD guidelines are actually inconsistent about the status of the immediately post-verbal NP in double object constructions. While the fragment on indirect objects[13] defines them with reference to the semantic roles of recipient and benefactive, the fragment about direct objects[14] defines a (direct) object as "[t]ypically, [...] the noun phrase that denotes the entity acted upon or which undergoes a change of state or motion (the proto-patient)." These two definitions are often in conflict, as in the case of "My uncle taught me karate", where *me* is a much better candidate for the recipient or benefactive role than *karate*, so it should be classified as `iobj`, but it is also clearly an "entity acted upon", "which undergoes a change of state", so it should be classified as `obj`.

Given the arguments in Andrews 2007 and the inconsistency of current UD guidelines, we assume that the immediately post-verbal NP in English double object constructions is the direct object. Unfortunately, Andrews is not very clear about the status of the NP following the direct object, but he generally denies the possibility of indirect objects in English: "In English, Bantu, and many other languages..., we do not seem to find even *prima facie* plausible candidates for an indirect object grammatical relation" (Andrews 2007: 190). If so, perhaps the notion of core dependents should be limited to subjects and (direct) objects, and all other broadly nominal dependents – not only PPs but also the NPs following direct objects – should be treated as oblique. In fact, within LFG, this view is argued for in Alsina 1996 and Patejuk and Przepiórkowski 2016. On this view, the above two examples should be labelled as follows:

(32) Mother Nature *taught* [me]$_{\texttt{obj}}$ [[balance]$_{\texttt{obl}}$, and [that regular pattern interrupts can negate radical change]$_{\texttt{advcl}}$].

(33) My uncle said to hell with that and *taught* [me]$_{\texttt{obj}}$ [[karate]$_{\texttt{obl}}$, and [to fire weapons]$_{\texttt{xadvcl}}$].

Constraining cores to subjects and normally immediately post-verbal direct objects would also explain the following facts (Nathan Schneider, p.c.), otherwise somewhat awkward for the basic proposal presented in the previous subsection:

(34) He *told* [me]$_{\texttt{obj}}$ [[an idea]$_{\texttt{obl}}$ and [that he thought it was viable]$_{\texttt{advcl}}$].

(35) He *told* [me]$_{\texttt{obj}}$ [[about an idea]$_{\texttt{obl}}$ and [that he thought it was viable]$_{\texttt{advcl}}$].

The labels indicated in these examples reflect the constrained understanding of cores: in both cases both conjuncts are oblique, so the whole coordinate dependent is oblique. However, on the standard UD view, (34) involves a coordination of a direct object *an idea* and a finite clause, which – for this reason – must also be analysed as core. But (35) indicates that such a finite clause is oblique, as it is coordinated with the oblique *about an idea*. Hence, in the sentence "He told me that the idea was viable", the clausal dependent should be analysed as core on the basis of (34) and as oblique on the basis of (35). On the view advocated here, this potential problem for the current proposal is avoided: when a post-verbal NP (i.e., the direct object) is present, the following clause is treated as non-core.

In fact, there is additional evidence that there is a valency frame of TELL with a syntactic position which may be realised by an NP, a PP or a clause: not only is it possible to coordinate an NP and a clause, as in (34), or a PP and a clause, as in (35), but it is also possible to coordinate an NP and a PP directly, as in the following examples from the iWeb corpus (simplified here):

(36) I *told* her [[the story]$_{\texttt{obl}}$ and [about my own experiences]$_{\texttt{obl}}$].

(37) I... *told* them [[the situation]$_{\texttt{obl}}$ and [about the expungement]$_{\texttt{obl}}$]...

[13] `http://universaldependencies.org/u/dep/iobj.html`

[14] `http://universaldependencies.org/u/dep/obj.html`

This supports the decision to treat both realisations – bare nominal and prepositional – as oblique (given that only subjects and direct objects are core).

4.3 Limited Reintroduction of AAD

Of course, any proposal to relegate to the obliques various dependents treated so far as core only increases the sometimes perceived need to distinguish between argument-like obliques and adjunct-like obliques. To accommodate this desire, we propose to adopt a version of the solution presented in Zeman 2017, namely, to optionally subtype non-core dependents into 'arguments' – `obl:arg`, `advcl:arg` and `xadvcl:arg` – and 'adjuncts' (no `:arg` suffix), but with an important proviso that this subtyping should be optional and treebank-specific. Linguists have not made much progress since Tesnière's 1959 three pairwise-incompatible criteria, so particular languages and treebanks should be free in applying such subtyping or not and, if so, they should be free in deciding how they understand this distinction.

In summary, we propose the system of basic ad-verbal dependency relations in (38) (complemented by `vocative`, `expl`, etc.). Given the proposal in Appendix C of renaming labels in a way that makes more clear the orthogonality of grammatical function (`subj`, `obj` and `obl`) and grammatical category and 'openness' status (`n`, `c`, `x`), this table translates into the more transparent table (39).

(38)

	subject	object	non-core	
			(arg)	adj
nominal	nsubj	obj	obl:arg	obl
clausal	csubj	ccomp	advcl:arg	advcl
open	xsubj	xcomp	xadvcl:arg	xadvcl

(39)

	subject	object	non-core	
			(arg)	adj
nominal	subj:n	obj:n	obl:n:arg	obl:n
clausal	subj:c	obj:c	obl:c:arg	obl:c
open	subj:x	obj:x	obl:x:arg	obl:x

5 Conclusion

In this paper, we identified two rather fundamental problems in the current (version 2) UD schema: reliance on AAD despite declared avoidance of this dichotomy and the resulting inconsistent approach to the core vs. non-core distinction (most conspicuous in unlike category coordination). We aimed at a relatively conservative modification of the schema – cf. (38) and the less conservative but more transparent (39) – that solves these problems, as well as the problem discussed in Appendix C, namely, the lack of support for obligatorily controlled subjects and obliques. The crux of the proposal is the definition of (non-subject) core clausal dependents as "functioning like objects" according to the coordination test. We also considered the possibility of constraining the notion of core dependents to subjects and direct objects, and we accommodated for the proposal of Zeman 2017 to allow for a – treebank-specific – distinction between argument-like and adjunct-like obliques. We strongly believe that adopting these proposals will increase both intra-lingual and inter-lingual consistency of UD treebanks and, hence, of multiple tasks currently relying on dependency parsing.

Acknowledgements

Apart from the three anonymous reviewers, the following people – while not necessarily agreeing with all or any of the proposals in this paper – have provided valuable comments on the previous version of the paper and/or on some of its ideas discussed on the UD forum and at the Oslo Center for Advanced Study at the Norwegian Academy of Science and Letters, during the authors' fellowship there: Bill Croft, Dan Flickinger, Dag Haug, Sylvain Kahane, Marie-Catherine de Marneffe, Joakim Nivre, Stephan Oepen, Martha Palmer, Nathan Schneider and Amir Zeldes. The research reported here is partially supported by the Polish Ministry of Science and Higher Education within the CLARIN ERIC programme 2016–2018 (`http://clarin.eu/`).

Appendices

A Depictive Dependent of RECALL

The argument/adjunct status of various depictive dependents is perhaps even more controversial than that of other types of dependents. The Valency Dictionary of English (Herbst et al. 2004) mentions the depictive dependent introduced by *as* in the case of the verb REMEMBER (and illustrates it with "I *remember* her as pretty and sort of tallish"), but not in the case of RECALL. On the other hand, this type of dependent is considered an argument (or core) of both verbs in both FrameNet (Ruppenhofer et al. 2016) (both verbs evoke the `Remembering_experience` frame) and in PropBank (Kingsbury and Palmer 2002) (rolesets `remember.01` and `recall.02`).[15] Moreover, neither dictionary mentions the possibility of an *as*-less depictive in the case of REMEMBER, as in "I look at Macie [...] and try to *remember* him young" (abridged from the iWeb corpus). Given the level of uncertainty about the argument/adjunct status of such secondary predicates, UD representations should not differ dramatically depending on their AAD classification. But – as discussed in the main text and illustrated in (9)–(12) – they currently do. Appendix C proposes a solution that minimises such differences – see (48)–(51) there.

B Coordination of (Un)Like Grammatical Functions

The system of relations adopted in Universal Dependencies is a "mixed functional-structural system".[16] The core vs. non-core distinction is a very coarse-grained functional distinction: some grammatical functions – especially, subject and direct object – are core, other are non-core.

While linguists do not any longer believe that only the same syntactic categories may be coordinated, and many examples of unlike category coordination are given in the main text, they assume that – apart from some well-defined exceptions to be discussed below – only the same grammatical functions may be coordinated. For example, in the ditransitive construction, the direct object cannot normally be coordinated with the other NP argument: *"John gave Mary and a book". As core grammatical functions are different from non-core grammatical functions, this means that core dependents cannot normally be coordinated with non-core dependents. In other words, coordinating a core dependent and a non-core dependent would result in the coordination of different grammatical functions, contrary to the overwhelming generalisation that only the same grammatical functions may be coordinated.

There are two classes of exceptions to this generalisation, both very constrained empirically. The first (pointed to us by Amir Zeldes, p.c.) is sylleptic zeugma, as in:

(40) He *made* [[his apologies]$_{\texttt{obj}}$ and [for the door]$_{\texttt{obl}}$].

Such constructions, in which the two conjuncts invoke two different meanings of the head, have a metalinguistic feel and they are easy to distinguish from genuine coordination.

The second exception is the so-called lexico-semantic coordination (Sannikov 1979, 1980), occurring mainly in Slavic and in some neighbouring languages (Paperno 2012), as in the following sentence from the National Corpus of Polish (cited here after Patejuk and Przepiórkowski 2012b: 463):[17]

(41) *Obiecać* można [[wszystko]$_{\texttt{obj}}$ i [wszystkim]$_{\texttt{iobj}}$].
promise.INF may everything.ACC and everyone.DAT
'One may promise everything to everyone.'

As discussed in Patejuk and Przepiórkowski 2012a, 2012b and in Paperno 2012, such constructions are limited to certain classes of pronouns and quantifiers, including question pronouns (so-called *wh*-words), negative pronouns (so-called *n*-words) and pronominal-like words expressing existential or universal quantifiers (the latter illustrated in (41)). Again, such exceptional constructions are easily distinguished from run-of-the-mill cases of coordination, where the sameness of grammatical functions is preserved.

[15] VerbNet (Kipper et al. 2000, Kipper et al. 2006) does not seem to contain the relevant meaning of RECALL, so it is not discussed here.

[16] `http://universaldependencies.org/u/overview/syntax.html`

[17] The labels `obj` and `iobj` reflect how this example would be annotated in Polish UD treebanks.

C Open Dependents in UD

UD assumes that obligatory control only targets object-like core dependents, and not subjects or obliques. This is a reasonable first approximation, but cross-lingual facts show that it is ultimately false.

First, obligatory control into subjects, while rare, occurs in languages as diverse as Balinese and Polish. For example, Arka and Simpson 1998 argue convincingly that in the Balinese (42), in which the main verb *orahin* 'ask' is in the so-called objective voice (OV), the sequence *teka mai prajani* 'come here immediately' is the subject of this main verb and that its own subject (i.e., the subject of *teka* 'come') is obligatorily controlled by another dependent of the main verb, *Nyoman*.

(42) teka mai prajani ane orahin tiang Nyoman
come here immediately REL OV.ask 1 Nyoman
'Coming here immediately is what I asked Nyoman to do.'

While in Balinese control into subject clauses is related to the phenomenon of objective voice, in Polish it is a matter of lexical properties of some copular constructions (Patejuk and Przepiórkowski 2018) as well as, possibly, some (very rare) verbs, especially, UDAĆ SIĘ 'succeed in, manage', as in the following example from $\text{UD}^{\text{PL}}_{\text{SZ}}$:[18]

(43) Nie udało im się uruchomić ciągnika.
NEG manage.3.SG.N them.DAT RM start.INF tractor.GEN
'They didn't succeed in starting the tractor.'

Such examples involve strict (not partial, etc.; Landau 2013) obligatory control into the infinitival clause. Moreover, the infinitival clause should be analysed as the subject here; while it triggers the 3rd person singular neuter 'default agreement' (Dziwirek 1990) with the verb, expected when the subject is non-nominative or lacks case altogether (Przepiórkowski 1999), full subject–verb agreement is witnessed when the infinitival phrase is replaced by a nominative phrase:

(44) Nie udał im się rozruch ciągnika.
NEG manage.3.SG.M them.DAT RM start.NOM.SG.M tractor.GEN
'They didn't succeed in starting the tractor.'

Current UD guidelines do not make it possible to adequately handle control into subjects in languages such as Balinese or Polish: as controlled core dependents, such infinitival phrases should perhaps be marked as `xcomp`, but since they are subjects, they should actually be marked as `csubj`.[19]

In Polish, there are also clausal dependents which are obligatorily controlled despite being prototypical adjuncts. Such dependents are headed by adverbial participles, sometimes called converbs, as in (45), where the implicit subject of the participle *patrząc* 'looking' is obligatorily controlled by *hrabia* 'count', the subject of the main verb *przysiadł* 'sat down'.

(45) Hrabia przysiadł, bezmyślnie patrząc przed siebie.
count.NOM.SG.M sat.3.SG.M thoughtlessly looking before self
'The count sat down, looking ahead thoughtlessly.'

Again, according to the current guidelines, such obligatorily controlled adverbial participial clauses may either be marked as `advcl`, losing information about control, or as `xcomp`, wrongly promoting such clauses to the status of core dependents. Recognising such open adverbial clauses is a natural step in UD: just as the `xcomp` relation is based on the eponymous grammatical function in LFG, so a new relation could be added to UD based on LFG's XADJUNCT function.

Let us note that the above considerations make clear an elegant symmetry between different kinds of dependents, one that is missing in the current UD system: just as there are three kinds of object-like dependents – nominal (`obj` and perhaps `iobj`), 'closed' clausal (`ccomp`) and 'open' – controlled – clausal (`xcomp`), the same tripartite distinction should be made within subjects and within obliques. In the case of subjects, the distinction is currently made between nominal subjects (`nsubj`) and broadly verbal subjects (`csubj`), but the examples above show that a subclass of controlled subjects should be

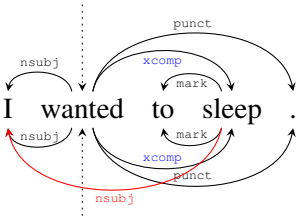
[18] The particle SIĘ is the so-called 'reflexive marker', RM, which – as in this case – is an inherent part of the verb, without any anaphoric meaning. NEG in (43) stands for 'negative marker'.

[19] In $\text{UD}^{\text{PL}}_{\text{SZ}}$, the infinitival clause in (43) is marked as an `xcomp`, thus losing information that it is the subject.

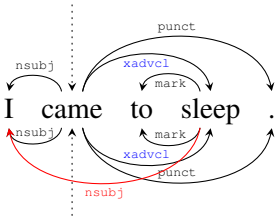
carved out of csubj – let us call this subclass xsubj. Similarly, the current class of modifier clauses should be split into closed modifier clauses – let us still call them advcl – and obligatorily controlled modifiers, say, xadvcl. This leads to the repertoire of basic dependents of verbs given in (28) in the main text.

The addition of these two relations has the effect of narrowing down the scope of csubj and advcl so that open dependents fall out of these (and into xsubj and xadvcl, respectively). Obviously, all open dependents – not just xcomp – are now expected to involve additional enhanced dependencies, indicating the relation between their covert subjects and some dependents of the higher predicate (usually, object or subject). This means that the difference between dependency representations (7)–(8) will now be reduced to the difference in label name:

(46)

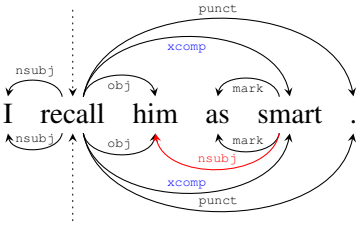


(47)

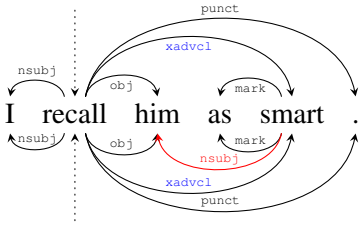


One welcome consequence of this proposal is that the representation of secondary predicates is uniform now: object-like secondary predicates still bear the xcomp relation, but oblique-like secondary predicates always bear the xadvcl relation to the verb now, rather than bearing the acl relation to the predicated nominal, if it is present, and the advcl relation to the verb, otherwise. Also, in both cases an enhanced relation points at the subject of secondary predication (if locally present). Thus, the analysis is essentially the same, whether the secondary predicate is considered core or non-core, with the only difference being the name of one dependency label (xcomp or xadvcl); the following representations should be compared to (9)–(12) in the main text.

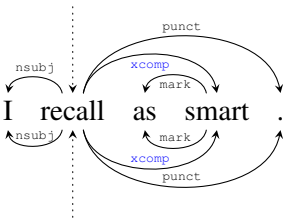
(48)



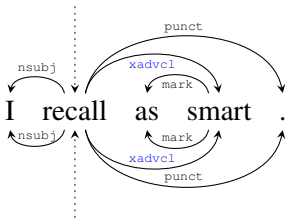
(49)



(50)



(51)



The symmetry between the three types of dependents – nominal, 'closed' clausal and 'open' clausal – can be made more conspicuous by renaming the labels as in (52).[20] However, these new names still mix two different types of information: grammatical function (subj, obj and obl) and grammatical category and 'openness' status (n, c, x). We propose to separate these two orthogonal types of information and make the bare grammatical function the main label of dependency relation, with categorial and 'openness' information given as subtypes, as in (53).

[20]The distinction between direct and indirect objects, if needed (see §4.2), could then be handled via a subtype to the nobj relation, e.g., nobj:sec.

(52)

	subject	object	non-core
nominal	nsubj	nobj	nobl
clausal	csubj	cobj	cobl
open	xsubj	xobj	xobl

(53)

	subject	object	non-core
nominal	subj:n	obj:n	obl:n
clausal	subj:c	obj:c	obl:c
open	subj:x	obj:x	obl:x

Given this last naming scheme, the relation of the whole coordinate structure to its head becomes clear, even in the case of unlike category coordination. For example, the two conjuncts in (54) (based on (13) in the main text) are obl:c and obl:n, so the whole coordinate structure could be labelled as obl, and similarly for (55), (56) and (57) (based on (17), (19) and (24) in the main text).

(54) At the White House, we *asked* the president [[whether Americans are safe at home]$_{\texttt{obl:c}}$ and [about the hunt for Osama bin Laden]$_{\texttt{obl:n}}$]$_{\texttt{obl}}$.

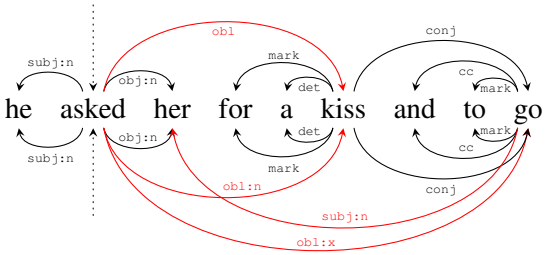
(55) Campbell made two visits to the home of domestic abuse victim Miss A, during which he *asked* her [[for a kiss]$_{\texttt{obl:n}}$ and [to go on a date with him]$_{\texttt{obl:x}}$]$_{\texttt{obl}}$.

(56) I do *remember* [[a lot of wine bottles]$_{\texttt{obj:n}}$ and [that Felix spoke almost nothing]$_{\texttt{obj:c}}$]$_{\texttt{obj}}$.

(57) Homeless people *need* [[a work ethic]$_{\texttt{obj:n}}$ and [to be self-reliant]$_{\texttt{obj:x}}$]$_{\texttt{obj}}$, Bender said.

Once the syntactic category of a dependent is expressed by a subtype, an unlike category coordination dependent could bear a relation which does not mention such a subtype. For example, the representation of the relevant fragment of (55) could be as in (58).

(58)



As in the case of the previous dependency structures, the differences between the basic representation (at the top) and the enhanced representation (at the bottom) are marked in red. Thus, while the enhanced representation contains dependency edges from *asked* to particular conjuncts, labelled as obl:n (*for a kiss*) and obl:x (*to go*), the basic representation contains just one edge labelled as obl. Additionally, the enhanced representation contains the explicit control information in the form of the subj:n dependency from the second conjunct to the controller *her*. This way it is possible to represent in UD the possibility of "control into selected conjuncts", somewhat problematic for some linguistic theories (Patejuk and Przepiórkowski 2014).

Abstract

We study German affixoids, a type of morpheme in between affixes and free stems. Several properties have been associated with them – increased productivity; a bleached semantics, which is often evaluative and/or intensifying and thus of relevance to sentiment analysis; and the existence of a free morpheme counterpart – but not been validated empirically. In experiments on a new data set that we make available, we put these key assumptions from the morphological literature to the test and show that despite the fact that affixoids generate many low-frequency formations, we can classify these as affixoid or non-affixoid instances with a best F1-score of 74%.

1 Introduction

In this work, we study a subset of complex German words that includes many hapaxes, namely items that have as one of their morphological components a so-called **affixoid** or semi-affix. Examples of affixoid formations include *Gesetzeshengst* 'jobsworth, stickler for the letter of the law' [lit. 'law/legal stallion'] or *Mentalitätsmonster* 'person with laser focus' [lit. 'mentality monster']. The class of affixoid morphemes sits in between affixes and stems. While various criteria have been proposed to identify affixoids (Schmidt, 1987), at least the following three are widely taken for granted (ten Hacken, 2000; Elsen, 2009): (i) increased productivity; (ii) semantic bleaching/decreased semantic specificity; and (iii) an etymological and formal link to an existing free stem. The first two criteria are applied by comparing the affixoid to its corresponding free stem. For instance, in *Weingott* 'deity of wine', *Gott* is a free morpheme occurring with its regular meaning; in *Gitarrengott* 'guitar god', *Gott* is an affixoid: the whole word does not refer to a deity but to a talented human guitar player. Such evaluative or intensifying meanings are a hallmark of affixoids (Meibauer, 2013). The last of the three criteria distinguishes affixoids from affixes, which by definition occur only bound to other morphemes. For example, German *-heit*, whose English cognate is *-hood* as in *falsehood*, is an affix: there is no longer a related free form. By contrast, German *-gott* is an affixoid since there is a related free form *Gott*, cognate with English *god*.

Research on affixoids has been centered on Germanic languages like German, Dutch and Swedish (Ascoop and Leuschner, 2006; Booij, 2005; Booij and Hüning, 2014; Norde and Van Goethem, 2014). However, we believe affixoids are not an exclusive feature of these languages. They are likely to arise in other languages with productive compounding. For English, for instance, there is little to no systematic research but arguably *quality* (as in *quality press/furniture/diamonds* but not in *quality management*) and *nut* (as in *health/math/trivia nut* but not in *pecan nut*) can be considered English affixoids. Even for languages on which there is more research, that work is typically focused on the theoretical relevance of assuming a category of affixoids that is distinct from affixes on the one hand and compounds on the other. Very little quantitative work using corpus data has been done to, for instance, study the level of productivity for different affixoid candidates or to substantiate the intuition that most affixoid uses carry evaluative meanings. Our work thus fills an empirical gap in the theoretical discussion.

In addition, we are interested in studying affixoids for the purposes of sentiment analysis. On the one hand, theoretical linguistic work that notes the expressive function of affixoids such as Meibauer

Proceedings of the 27th International Conference on Computational Linguistics, pages 3853–3865
Santa Fe, New Mexico, USA, August 20-26, 2018.

(2013) suggests this. On the other hand, it is known from prior research on sentiment analysis that hapax words in general are often subjective (Wiebe et al., 2004). As we show in §3, affixoids tend to generate many (near-)hapax forms, which meshes with observations on their productivity in the morphological literature and the general expectation about the Zipfian distribution of word frequencies. Since hapaxes, by definition, cannot be readily analyzed based on their distribution in corpora, it would be very useful if we could make use of their intrinsic properties to classify such forms as affixoid uses (and therefore likely subjective) or not.

The main task that we set ourselves in this paper is morpheme sense disambiguation: we want to classify complex forms containing possible affixoids as to whether the morphemes in question really occur as affixoids with special meanings or as regular morphemes with their full, common semantics. We frame this task as a binary classification problem. The major contributions of our paper are:

- a gold standard annotation of complex forms containing potential affixoids, which make publicly available[1];
- empirical validation of claims regarding the association between intensification / evaluation and affixoid meanings;
- a detailed examination of various novel features that have been devised to detect the presence of an affixoid in a complex form.

2 Related work

Recently, Ruppenhofer et al. (2017) studied the problem of how well the polarity of complex words, including both compounds and derived forms, can be predicted based on its components and the word's morphological structure. They found that, while on core vocabulary – defined as items listed in the PolArt dictionary (Klenner et al., 2009) and highly likely to be listed in GermaNet (Hamp and Feldweg, 1997), the German WordNet resource – classification accuracy was as high as 85%, performance was severely degraded on more colloquial, domain-specific and linguistically creative forms taken from Wiktionary[2] and the Wortwarte[3] neologism project. Note that this research did not distinguish true compounds from complex forms involving affixoids.

Similar research was carried out earlier by Moilanen and Pulman (2008) who evaluated how well it was possible to classify unknown English words into one of three polarity classes based on morphological analysis. Compared to these prior efforts, our task is narrower as we do not deal with derivation and do not predict polarity for the complex entries. Our data is also more focused since we have only complex forms containing exactly two nouns and the second components of our data represent only 7 different lemmas. And importantly, our data are low frequency words in distinction to Ruppenhofer et al. (2017), whose main data set looked at higher-frequency core vocabulary.

In another line of research, several studies have tackled the problem of classifying senses as either *objective* or *subjective*. For English Su and Markert (2009) and Gyamfi et al. (2009) tackled this task on data from WordNet. Subjective entries are ones that possess polarity, that is, they could in further analysis be classified as either positive or negative. This task is similar to ours in the sense that a simple binary categorization of items is sought. However, there are key differences. First, our classification targets lemmas not word senses. That is, we assume that the complex lemmas are monosemous or have a clearly dominant sense in our data.[4] Second, the distinction *objective* versus *subjective* does not fully line up with the distinction *non-affixoid* use versus *affixoid* use. A complex form may contain the affixoid candidate in its regular objective sense but the other component may make the whole word subjective. An example of this kind is *Lieblings|hai* 'favorite shark'. Finally, since our complex forms are unlikely to be listed in lexical resources, we will usually lack information such as glosses, supersenses or example sentences for them.

[1] https://github.com/josefkr/affixoids

[2] https://de.wiktionary.org

[3] http://wortwarte.de/

[4] This assumption can be made plausible by the observations that longer words have more specific meanings than shorter ones, and that they tend to have fewer meanings than their head words, and fewer meanings than their components do on average (Altmann, 2002).

In another strand of research involving German morphology and sentiment analysis, Wiegand et al. (2016) developed an approach to classify the first element of German compounds as expressing either the source or target of evaluation, or neither, relative to the second element, if in the first step of analysis the second element was determined to be subjective. As do we, those authors focused on noun-noun compounds and they did not address polarity classification. However, their approach targets higher frequency words as it relies on the availability of sufficient corpus data to enable the use of distributional similarity. For our dataset, we cannot directly model the distributional properties of our complex items.

3 Data

Data creation. German has both nominal affixoids – items that are related to nouns (e.g. *Affen|tempo*, 'high speed' [lit. 'ape speed']) – and adjectival affixoids – items that are related to adjectives (e.g. *unheils|schwanger* 'ominous' [lit. 'pregnant with doom']).[5] Here, we concentrate on nominal affixoids. Two subtypes of nominal affixoids exist, depending on the position of the nominal affixoid in the complex word. *Affe*, as in *Affentempo*, is a prefixoid as it occurs as the first item in the compound-like complex word, whereas *Gott* is a suffixoid as it occurs as the second item in complex formations such as *Gitarrengott* 'guitar god'. To make the best use of our resources for annotation, we focus on suffixoids here as we believe that addressing suffixoids and prefixoids at the same time may not be helpful. Consider that for many suffixoid candidates, a suffixoid use is recognizable by the fact that the referent of the whole word is not a hyponym of the suffixoid in its basic meaning. For instance, a *Kredithai* 'loan shark' is not a shark. With prefixoids, this is usually different, as they tend to add evaluation or intensification but do not change the class of referent. A *Scheißauto* 'shit car' is still a car.

No pre-compiled resource is available that lists all suffixoids and the complex words in which they figure. We therefore first compiled a set of 60 possible suffixoids from the literature on morphology (Motsch, 2004; Erben, 2006; Elsen, 2009; Elsen, 2011; Fleischer et al., 2012) and then looked for complex forms containing them in the 1.7-billion deWaC web corpus (Baroni et al., 2009).[6] We queried the corpus for complex forms whose lemma ended in one of the suffixoids and where the suffixoid was preceded by at least four letters. The latter condition was imposed to rule out complex forms where the first part is a simple prefix. Further, we allowed only for complex forms spelled as contiguous strings as standard German orthography does not allow open compounds. E.g. the German word for *hammerhead shark* cannot be spelled as *Hammer Hai* using two white space-separated tokens.

The extracted forms were then semi-manually filtered for remaining errors. We used the SMOR morphological segmentation tool (Schmid et al., 2004; Faaß et al., 2010) to detect cases that did not represent simple noun-noun combinations. We excluded instances that were not compliant with standard German orthography, for instance, due to spelling errors or incorrect tokenization. We eliminated duplicates that differed only in whether the two parts of the complex form were written contiguously or separated by a hyphen. Thus, we for instance kept *Hammerhai* but not *Hammer-Hai* 'hammerhead shark'.

To keep the overall effort manageable, we selected seven items from our pool of suffixoids for annotation and subsequent use in our experiments. We chose these for two reasons. First, we did not want items that were extremely biased towards either affixoid or non-affixoid uses. For instance, more than 99% of the formations for *Dreck* 'dirt' and *Junkie* 'junkie, addict' are suffixoid formations. Second, we wanted items for which a sizable number of complex forms exist in our corpus. This criterion ruled out, for instance, *Base* 'female cousin' because most forms found in the corpus were false positives involving compounds using the homographic English noun *base* as a head, rather than intended German forms such as *Klatschbase* 'telltale/chatterbox'. Table 1 gives some basic descriptive information about the items. The complex forms of these 7 items will represent the raw data for our gold standard (*see also supplementary material*). In total, there are 1788 of such complex forms.

[5] Our literature survey did not throw up any German verbal affixoids. This is not unexpected since German also has very limited compounding involving verbs. They can only occur as modifiers in compounds with nominal or adjectival heads as in *Bratpfanne* 'frying pan' or *waschecht* 'colorfast' [lit. 'wash-true'] (Olsen, 2000).

[6] We also found 40 possible nominal prefixoids in the literature we reviewed. Note that these lists are not necessarily complete: the items discussed in the linguistic literature are discovered through introspection rather than in a data-driven way.

	basic sense	# senses	intensifying	polar	freq	freq. rank
Bolzen	bolt	4	Y	Y	115	34632.5

-könig	290	370	53	0	713
total	492	1174	115	7	1788

Table 2: Affixoid and non-affixoid uses (gold)

	dlexdb		GermaNet		Wiktionary		SentiMerge	
	all	aff	all	aff	all	aff	all	aff
-bolzen	17 (16.5)	1	1 (1.0)	0	1	0	4	0
-bruder	41 (22.4)	4	3 (1.6)	0	2	0	1	0
-gott	133 (28.1)	10	21 (4.4)	2	7	2	3	0
-hai	13 (19.1)	3	7 (10.3)	1	3	0	10	1
-hengst	23 (20.7)	7	2 (1.8)	1	0	0	3	1
-kaiser	25 (18.5)	3	1 (2.8)	0	1	0	0	0
-könig	177 (24.8)	54	19 (2.6)	5	14	0	6	1
total	429 (24.0)	82	54 (3.0)	9	28 (1.6)	2	27 (1.5)	3

Table 3: Coverage by lexical resources (absolute and %)

Table 3 shows that only 429 items (24.0%) of the 1788 forms in the gold standard are covered by the dlexdb lexical database (Heister et al., 2011), 54 (3.0%) are covered by GermaNet 11.0, and only 28 (1.6%) by Wiktionary. SentiMerge (Emerson and Declerck, 2014), the largest German sentiment lexicon with close to 100k entries, covers 27 (1.5%) forms. By contrast, 93% of the 9300 items in Ruppenhofer et al. (2017)'s main data set were covered by dlexdb, and 88.4% by GermaNet. Finally, Table 3 shows that of the formations included in the various resources, the majority are non-affixoid cases. Inclusion in a resource thus is not a very useful feature as it is only predictive of the majority class.

Figure 1 illustrates that the token frequencies for the complex forms with *König* 'king' as its second component have a largely Zipfian distribution: there are many complex forms with very low token frequencies (in fact, mostly their frequency is 1), whereas there are very few complex forms with high token frequencies. While we cannot show it here for lack of space, the shape of the distribution is the same for all the suffixoid candidates. Note further that the numbers shown in Table 2 do not delimit the productivity of these suffixoids. Consider that, for instance, in a collection of 120 million tweets, we found 905 complex forms for *König*, of which only 226 overlapped with the 713 forms found in the deWaC corpus.

Annotation of the affixoid vs. non-affixoid distinction. Most of the data was annotated by one of the authors. To assess how well human annotators agree on the distinction between affixoid uses and non-affixoid uses, two of the authors performed an annotation experiment on 200 randomly chosen instances of the total set of 1788 complex forms. The annotators could label each complex form as Y (only affixoid uses or predominantly affixoid uses), N (only non-affixoid uses or predominantly non-affixoid uses) and

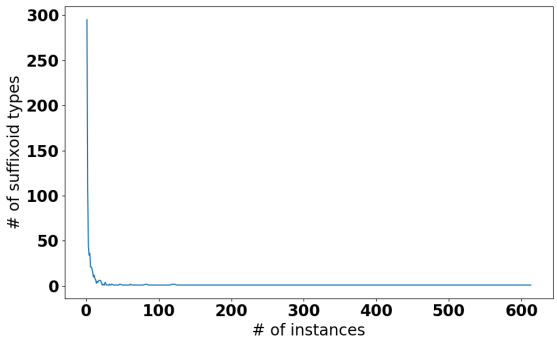

Figure 1: Frequency spectrum for *König* 'king'

	Y	N	B	total
Y	43	1	1	45
N	12	116	3	131
B	16	2	6	24
total	71	119	10	200

Figure 2: Annotator confusion matrix

B (both types of use likely). The annotators achieved a Cohen's kappa (Cohen, 1960) value of 0.67, which amounts to substantial agreement according to Landis and Koch (1977). As the confusion matrix in Figure 2 shows, the majority of errors are 'milder' cases where one annotator considers one type of use dominant whereas the other considers both types of uses plausible.

4 Features

4.1 Automatic features

We first explore features that can be extracted automatically from corpora and resources, which is the most realistic setting. (We discuss our handling of missing values in §4.2).

Suffixoid. Since the suffixoid candidates differ in how frequently they do in fact occur as affixoids and also differ in their evaluative meanings, it makes sense to capture which suffixoid in particular occurs in a complex form. We define a binary indicator variable for each suffixoid.

Frequency. There exists a significant body of research in quantitative linguistics on the productivity of morphological processes. But works on the productivity of compounding such as Altmann (2002) or Krott et al. (1999) do not make a distinction between affixoid formations and true compounds and therefore there are no prior results on their similarities and differences in regards to productivity: the assumption of increased productivity for affixoids has, to our knowledge, not been empirically validated. For our set suffixoids, we used Baayen's `languageR` R-package to compare, the lexical richness of compound formations to that of affixoid formations, per affixoid candidate and for pooled data. We found no consistent differences in terms of vocabulary growth curves, vocabulary growth rates or type-token ratios (Baayen, 2005). This result notwithstanding, we want to see if frequency information about the components and the complex forms could help us distinguish between the two kinds of complex forms. One relevant intuition that we had in this regard is that the complex forms of affixoidal uses may tend to have lower frequencies than complex forms representing regular compounds. Table 4 shows that for most items this seems to be borne out, although the difference is not statistically significant, with the exception of *-hai*. However, for *-könig* the reverse situation holds in a statistically significant way: the frequencies of affixoid formations are higher than those of the non-affixoid formations.

	affixoid	non-affixoid	p-value of t-test
-hai	37.50	12.41	**0.01**
-kaiser	3.40	6.64	0.13
-bolzen	4.21	4.36	0.93
-hengst	4.03	8.40	0.27
-könig	4.92	16.23	**0.00**
-bruder	1.88	6.04	0.39
-gott	10.07	19.90	0.36

Table 4: Frequency differences between affixoid and non-affixoid formations

Compositionality. This feature measures the compositionality of the complex word. The intuition is as follows. In regular compounds, the meaning of the complex form is more or less compositionally

derived from the meaning of the components. However, since affixoid uses of the morphemes in question go along with bleached meanings, the semantics of a complex word containing an affixoid use should be harder to model compositionally. Following Schulte im Walde et al. (2013), we represent each component as well as the complex word as vectors. As our measure of compositionality, we determine the cosine similarity between the sum of the component vectors and the vector of the complex word.

We used fastText (Bojanowski et al., 2016) in its default setting to train word embeddings on the SdeWaC-corpus (Faaß and Eckart, 2013), which contains about 880 million tokens and is a cleaned up version of the deWaC corpus (Baroni et al., 2009). The choice of fastText was motivated by the fact that fastText computes vectors for words by adding up the vectors for n-grams found in the words, which allows us to produce vectors for words not seen in the training data. Since many of our complex forms are (near-)hapaxes, this is a crucial benefit of fastText.

Pointwise mutual information. We use Pointwise mutual information (Church and Hanks, 1990) to capture the level of association between the two components of the complex word. The expectation is that the components of regular compounds exhibit higher PMI-scores than the components of a complex word involving an affixoid. This is motivated by Tellenbach (1985)'s observation that for complex forms containing an affixoid use, paraphrases containing the morpheme in question as a free word are unlikely. By contrast, compositional compounds are often paraphrased using their components. As an example, the compositional compound *Perserkönig* is readily paraphrased as *König der Perser* 'king of the Persians', whereas *Gitarrenkönig* is less likely to be paraphrased as *König der Gitarre* 'king of the guitar'. Even aside from paraphrasing, it seems more likely that *Perser* and *König* occur together in a text as they share the context of governance than it does that *Gitarre* and *König* co-occur.

GermaNet supersenses. As in the English WordNet (Miller, 1995), GermaNet's synsets are associated with supersenses that define high-level categorizations such as `Human`, `Animal`, `Artifact`, or `Group`. A lexical unit in GermaNet can be associated with one or more of its supersenses. Accordingly, we define three series of indicator variables that capture whether any sense of the complex form, the first component or the second component exhibits a particular supersense. We refer to all these features as *supersenses_bag*. This feature group is motivated by the observation that with several of our suffixoid candidates, the semantic types of the first component and the complex form tends to provide good evidence on whether the complex word will be an affixoidal use or not. For instance, the first component *Haflinger* in *Haflinger|hengst* refers to a breed of horses and the complex form is a regular compound. By contrast, the first component *Büro* 'office' of *Büro|hengst* refers to either an `Artifact` or a `Group` and the complex form represents an affixoidal use meaning something like 'pencil pusher'. Moreover, the complex form *Haflingerhengst* also has the supersense `Animal`, whereas *Bürohengst* has the supersense `Human`. Because for this particular set of suffixoid candidates differences between the second component and the complex word's supersenses may be particularly important, we experiment with an alternative set of supersense features (*supersenses_diffs*): we use a series of indicator variables that code whether the second component and the complex word differ in their value for a given supersense.[7]

Polarity. Since affixoid uses are likely to have evaluative meanings, we explore whether this is reflected in the polarity of the two components and the complex form. We extract polarity information for all three from SentiMerge (Emerson and Declerck, 2014). With 96,918 entries, it is to date the largest available polarity lexicon for German. SentiMerge was created by harmonizing and combining three smaller lexicons (PolArt (Klenner et al., 2009); GermanPolarityClues (Waltinger, 2010); and SentiWS (Remus et al., 2010)) using a Bayesian probabilistic model.

Psycholinguistic features. If available, we extract psycholinguistic ratings along four dimensions for the whole word and its components. This type of feature has been successfully used in various tasks, such as identifying metaphors (Turney et al., 2011; Klebanov et al., 2014); studying persuasion (Tan et al., 2016); sarcasm detection (Bamman and Smith, 2015); and, most similar to us, polarity prediction for complex words (Ruppenhofer et al., 2017). The first dimension places words on a scale from abstract to concrete (**abstconc**). Abstract words refer to things that we cannot perceive directly with

[7]Note that for other suffixoids not covered here such as *Papst* (lit. 'pope', suffixoid 'expert') and *Nest* (lit. 'nest', affixoid 'den/hideout') there is no difference at all between the supersenses of the second component and the complex word.

our senses (*integer*, *politics*, ...) whereas concrete words refer to things we can perceive (*sound*, *scent*, ...). The second dimension concerns imageability (**img**). A large subset of concrete words have a high imageability. These words refer to things that we can actually see (*chestnut*, *police jeep*, ...). The third rating dimension is valence (**val**), which measures the pleasantness of a word (*gift* vs. *punishment*). The final dimension, **arousal**, represents the intensity of emotion caused by a stimulus (*alert* vs. *calm*).[8] We obtain affective ratings from the resource of Köper and Schulte im Walde (2016). It provides information on 350k words and is far more comprehensive than the affective norm data of Kanske and Kotz (2010) or Lahl et al. (2009). It is also much larger than commonly used polarity lexicons for German such as PolArt (Klenner et al., 2009) or GermanPolarityClues (Waltinger, 2010).

Emotion. Since emotion information is commonly used in sentiment-related classification tasks (e.g. Tang et al. (2014), Sulis et al. (2016)), we wanted to see to what extent emotion information could benefit our task. For this purpose, we use the NRC Word-Emotion Association Lexicon (EmoLex) for English which was created by Mohammad and Turner (2013) using a crowdsourcing approach. EmoLex contains binary associations of words with the eight basic emotions (joy, sadness, anger, fear, disgust, surprise, trust, anticipation) of Plutchik (1962) . Although the German version of the lexicon was produced using machine translation, we use it here because we do not have a similarly large natively produced resource available for German. The German EmoLex covers 9630 lemmas. For each complex form, we extract the emotions associated with the overall word and do likewise for the first and the second components.

4.2 Missing value imputation

With features derived from resources (polarity, psycholinguistic ratings, emotion, supersenses and PMI), we face the problem that there are gaps in coverage. Various strategies are conceivable to fill in missing values. The first one we considered is to substitute for a word that is not covered that word which is most similar to it according to cosine similarity among the fastText vectors and which is covered by the resource. A second approach we considered is to use the mean value for the feature in question. A third approach uses the median. A fourth option is to use the modal value. Our experiments showed that for our SVM classifier, the choice of imputation strategy does not result in any statistically significant differences in results. We thus report results based on the first strategy, which is based on cosine similarity.

4.3 Manual feature annotations

In order to be able to explore to what extent the notions of intensification and evaluation correlate with the use of our target morphemes as either affixoids or regular morphemes, we added further annotations to our complex forms. We labeled them manually with respect to the features listed below. Based on the theoretical literature, they should be very predictive for our affixoid classification task.[9]

- Polarity of complex word: does the item have positive, negative or neutral polarity?
- High intensity of complex word: does the complex word express high intensity? *Temperamentsbolzen* 'highly temperamental person': yes; *Metallbolzen* 'metal bolt': no.
- Evaluativity of complex word: does the complex word mostly carry either a positive or negative evaluation? *Bürohengst* 'pencil pusher': yes; *Haflingerhengst* 'Haflinger stallion': no.
- Head Intensity: does the head (i.e. the potential affixoid) contribute an intensifying meaning to the overall word? *Charmebolzen* 'highly charming person': yes; *Riesenbolzen* 'giant bolt': no.
- Head Polarity: does the head of the complex word contribute an evaluating meaning to the overall word? *Fußballgott* 'footballing god': yes; *Wettergott* 'weather god': no.

5 Experiments

5.1 Automatically extracted features

Our experimental set-up is as follows. We perform a 5-fold cross validation. Our data is initially randomized before we defined folds that are held constant across all experiments. For our experiments,

[8] Valence and arousal are part of (Osgood et al., 1957)'s well-known theory of emotions.

[9] We tested agreement only for polarity of the complex word. Here, two annotators achieved a kappa of 0.86 on a random sample of 200 items.

we convert the instances of B(oth) to instances of Y, i.e. affixoid uses. The seven instances that the annotators had left as unsure are excluded from the experiments. We use the automatically extractable features discussed in §4.1. As our classifier, we use SVM (Vapnik, 1995), as implemented by SVM^{light} (Joachims, 1998). Note that we experimented with the cost-factor, by which training errors on positive examples (i.e. examples of class Y) outweight errors on negative examples (i.e. examples of class N). However, modifying it only helped in the lowest-performing configurations where we would otherwise perform exactly like the majority baseline. Table 5 reports results for the different features obtained with the default settings of SVM^{light}. The majority baseline we report represents a classifier that always predicts non-affixoid as this is the majority class for each suffixoid and the dataset as a whole.

		Y *(i.e. affixoid use)*			N *(i.e. non-affixoid use)*			all

Table 5: Results for classification experiments per feature group; setting: 5-fold CV

The bag of supersenses is the best feature group and notably better than paying attention only to differences between second component and complex word in terms of supersenses.

5.2 Automatic features in balanced setting

The difference in performance between the two classes that we found when using all data (cf. §5.1) might be due either to the class imbalance or come about because the majority class N is inherently easier to learn. In order to tease this apart, we here repeat the previous experiment using all features in a 5-fold cross-validation setting, however this time with a balanced dataset of 970 items. The dataset is constructed so that each fold contains the same number of instances per suffixoid and those instances are themselves balanced equally across the affixoid and non-affixoid classes.[10] As Table 6 shows, with balanced data we can obtain much more balanced performance on the two classes. And despite the fact that we are using only 54.3% of the available data, the overall F1-score (0.73) is more or less tied with the result obtained on all data (0.74).

		Y			N			all

Table 6: Results for classification experiment on balanced data using all features; setting: 5-fold CV

5.3 Feature ablation experiments

Table 7 shows an ablation experiment using all data. We remove one particular feature from the entire feature set at a time. The table shows that the performance decreases only marginally for most removed features, which indicates that most features encode information. The largest performance drop is caused by removing supersenses, which suggests that this is the feature with the most unique information.

Since the supersense feature is both the strongest individual feature (cf. Table 5) and also the feature encoding most unique information (cf. Table 7), we further examined this feature by listing the top 10 supersenses according to χ^2 ranking as shown in Table 8. The most predictive supersenses are predominantly those of the first component of the compound or those of the (complex) compound form itself. This first component is very helpful, for instance, for *König*. Its non-affixoid uses (e.g. *Sarazenenkönig* 'king of the Saracens') mostly co-occur with a first component denoting a `Location` or a nationality

[10] These latter two constraints result in only 970 items being used rather than 984, if we simply used all 492 instances of class Y and added as many instances from class N.

		Y			N			all		
	Acc	P	R	F1	P	R	F1	P	R	F1

Table 7: Ablation experiments where one feature is removed from the entire feature set

(Human) whereas its affixoid uses typically involve Events (e.g. *Tanzkönig* 'dancing king') or artifacts or objects (e.g. *Schotterkönig* 'king of gravel'). The importance of the supersense of the whole word arises in relation to the supersense of the second component. When the two differ for some of the affixoid candidates, the meaning of the whole word is usually only metaphorically related to the second component. For instance, while *Hai* 'shark' and *Hengst* 'stallion' refer to Animals in their basic meaning, complex forms in which they occur as affixoids refer to Humans. Similarly, *Bolzen* refers to an Artifact but complex forms containing an affixoid use of it refer to Humans.

rank	χ^2 score	supersense	rank	χ^2 score	supersense
1	97.76	second_component::Artifact	6	26.86	first_component::Event
2	65.01	first_component::Human	7	18.90	complex_form::Food
3	58.29	first_component::Creation	8	13.81	first_component::Food
4	48.59	first_component::Artifact	9	13.59	complex_form::Feeling
5	33.43	complex_form::Human	10	12.75	first_component::Time

Table 8: Top 10 supersense features according to χ^2 ranking

5.4 Cross-affixoid generalization

Using the automatic features, we experiment with a setting where we train on the instances of all but one affixoid candidate and then test on the instances of the reamining affixoid. For this experiment, we leave out the lexical suffixoid feature. Table 9 shows the results.

		Y			N			all		
test set	Acc	P	R	F1	P	R	F1	P	R	F1
bolzen	0.68	0.57	0.12	0.20	0.69	0.95	0.80	0.63	0.54	0.58
bruder	0.72	0.11	0.17	0.14	0.86	0.80	0.83	0.49	0.49	0.49
gott	0.75	0.51	0.36	0.42	0.80	0.88	0.84	0.66	0.62	0.64
hai	0.74	0.47	0.44	0.45	0.82	0.84	0.83	0.64	0.64	0.64
hengst	0.73	0.45	0.17	0.25	0.76	0.93	0.83	0.61	0.55	0.58
kaiser	0.72	0.67	0.19	0.30	0.72	0.96	0.82	0.69	0.57	0.63
könig	0.52	0.00	0.00	0.00	1.00	0.52	0.68	0.50	0.26	0.34

Table 9: Results for cross-affixoid classification, training on six affixoids, testing on the remaining one; all features except suffixoid

The results show lower performance than in the cross-validation setting where we had instances of all affixoids in the train and the test folds. For *könig* the results drop down as low as the majority baseline in the present setting. However, the low result is very likely also heavily driven by the fact that the instances of *könig* make up close to 40% of our whole dataset. In other words, when testing on *könig*, we use only 60% of the dataset to train on. On the other hand, we also see lower results on affixoids such as *bolzen* that are much less frequent than *könig* and for which we use more training instances in the present generalization setting than we did in the cross-validation setting in §5.1. This suggests that overall cross-affixoid generalization may be somewhat limited.

5.5 Gold-quality manual features

The final experiment we perform is a simple one: we use the manual features described in §4.3 and try to predict whether the complex form is an affixoid formation or not.

Table 10 shows that all features are highly predictive, with intensifying function of the suffixoid being the best. The results confirm that affixoids can be defined in terms of intensification and evaluation.

		Y			N			all		
	Acc	P	R	F1	P	R	F1	P	R	F1
suffixoid intensity	0.96	0.93	0.97	0.95	0.98	0.96	0.97	0.96	0.96	0.96
suffixoid evaluation	0.93	0.92	0.87	0.89	0.93	0.96	0.95	0.93	0.92	0.92
word polarity	0.89	0.78	0.97	0.86	0.98	0.85	0.91	0.88	0.91	0.90
word intensity	0.89	0.76	0.98	0.86	0.99	0.84	0.91	0.87	0.91	0.89
word evaluation	0.89	0.78	0.97	0.86	0.98	0.85	0.91	0.88	0.91	0.90

Table 10: Results for classification on all data using manual features; setting: 5-fold cross-validation

6 Error analysis

Table 11 shows confusion matrices per suffixoid candidate and for all data cumulatively for the best setting in our automatic experiments (cf. Table 5), in which all features were used in 5-fold cross validation. The breakdown per suffixoid candidate reveals that the overall performance is strongly influenced by *König*, which in particular contributes the bulk of the recall of true affixoid formations.

	Bolzen		Bruder		Gott		Hai		Hengst		König		Kaiser		**all**	
	Y	N	Y	N	Y	N	Y	N	Y	N	Y	N	Y	N	Y	N
Y	11	23	1	23	28	91	1	15	2	27	266	77	10	32	319	288
N	0	70	1	156	13	341	2	47	4	77	88	282	5	87	113	1060

Table 11: Confusion matrices on all data for the *all features* setting; gold: rows, predicted: columns

Table 12 below shows the confusion matrix for the experiment with a balanced data set reported in §5.2. As was to be expected based on the scores in Table 6, the performance across the different suffixoids is now much better. We can thus conclude that the difference in performance between the two classes that we found when using all data is largely owed to the class imbalance and that the distinction between affixoid formations and non-affixoid formations can in principle be learned for suffixoids other than *König*.

	Bolzen		Bruder		Gott		Hai		Hengst		König		Kaiser		**all**	
	Y	N	Y	N	Y	N	Y	N	Y	N	Y	N	Y	N	Y	N
Y	24	6	12	8	61	14	12	3	20	5	231	59	20	10	380	105
N	14	16	10	10	26	49	8	7	13	12	77	213	11	19	159	326

Table 12: Confusion matrices on balanced data for the *all features* setting; gold: rows, predicted: columns

7 Conclusion

In this paper we studied German complex forms containing suffixoid candidates. To do so, we constructed a new data set with 1788 items distributed about 7 potential affixoid candidates, which we make available to the research community. In one set of experiments we validated the high correlation between evaluative and intensifying semantics and affixoid status that has always been assumed by theoretical work but not demonstrated. In another experiment, we tackled the task of classifying our complex forms as affixoids formations or regular compounds. Being able to do so successfully can be useful for sentiment analysis, as the affixoid uses are typically evaluative. The task is difficult, though, as we have little reliable information about the complex forms available due to their low frequency. Still, we achieved best results of 74% F1-score using a custom set of features, among which supersenses had the most impact.

In future work, we plan on pursuing lines of research that we needed to leave open here. First, we would like to cover more suffixoid candidates and also extend this work to prefixoid formations. Second, we want to tackle affixoids that occur in complex adjectival forms. Finally, once we have annotated data for further affixoid candidates in hand, we would like to explore if it is possible to identify morphemes that have affixoid uses from properties of their formations, including their frequency distribution, and distinguish them from morphemes that only participate in regular compounds. Since so far affixoids have been identified based on human introspection, we do not know how many of them actually exist in German or other languages.

Acknowledgements

Michael Wiegand and Rebecca Wilm were partially supported by the German Research Foundation (DFG) under grants WI 4204/2-1 and RU 1873/2-1. We would also like to thank Ulrich Heid for the inspiration to study affixoids.

Abstract

We provide a detailed overview of the various approaches that were proposed to date to solve the task of Open Information Extraction. We present the major challenges that such systems face, show the evolution of the suggested approaches over time and depict the specific issues they address. In addition, we provide a critique of the commonly applied evaluation procedures for assessing the performance of Open IE systems and highlight some directions for future work.

1 Introduction

Information extraction (IE) turns the unstructured information expressed in natural language text into a structured representation (Jurafsky and Martin, 2009) in the form of relational tuples consisting of a set of arguments and a phrase denoting a semantic relation between them: $\langle arg1; rel; arg2 \rangle$. Traditional approaches to IE focus on answering narrow, well-defined requests over a predefined set of target relations on small, homogeneous corpora. To do so, they take as input the target relation along with hand-crafted extraction patterns or patterns learned from hand-labeled training examples (e.g., Agichtein and Gravano (2000), Brin (1999), Riloff and Jones (1999)). Consequently, shifting to a new domain requires the user to not only name the target relations, but also to manually define new extraction rules or to annotate new training data by hand. Thus, those systems rely on extensive human involvement. In order to reduce the manual effort required by IE approaches, Banko et al. (2007) introduced a new extraction paradigm: Open IE. Unlike traditional IE methods, Open IE is not limited to a small set of target relations known in advance, but rather extracts all types of relations found in a text. In that way, it facilitates the domain-independent discovery of relations extracted from text and scales to large, heterogeneous corpora such as the Web. Hence, Banko et al. (2007) identified three major challenges for Open IE systems:

Automation. Open IE systems must *rely on unsupervised extraction strategies*, i.e. instead of specifying target relations in advance, possible relations of interest must be automatically detected while making only a single pass over the corpus. Moreover, the manual labor of creating suitable training data or extraction patterns must be reduced to a minimum by requiring only a small set of hand-tagged seed instances or a few manually defined extraction patterns.

Corpus Heterogeneity. Heterogeneous datasets form an obstacle for profound linguistic tools such as syntactic or dependency parsers, since they commonly work well when trained and applied to a specific domain, but are prone to produce incorrect results when used in a different genre of text. Furthermore, Named Entity Recognition (NER) is unsuitable to target the variety and complexity of entity types on the Web. As Open IE systems are intended for *domain-independent usage*, such tools should be avoided in favor of shallow parsing methods such as part-of-speech (POS) taggers.

Efficiency. In order to *readily scale to large amounts of text*, Open IE systems must be computationally efficient. Enabling fast extraction over huge datasets, shallow linguistic features, like POS tags, are to be preferred over deep features that are derived from parse trees.

Proceedings of the 27th International Conference on Computational Linguistics, pages 3866–3878
Santa Fe, New Mexico, USA, August 20-26, 2018.

These criteria were first implemented in the Open IE system TEXTRUNNER, which was presented together with the task definition in Banko et al. (2007). This seminal work triggered a lot of research effort in this area, resulting in a multitude of proposed approaches that often did not strictly adhere to these initial guidelines. For example, to date, Open IE systems are commonly evaluated on rather small-scale, domain-dependent corpora. In addition, recent approaches frequently rely on the output of a dependency parser to identify extraction patterns, thereby hurting the domain-independence and efficiency assumptions.

2 Open IE Systems

A large body of work on the task of Open IE has been described since its introduction by Banko et al. (2007). Existing Open IE approaches make use of a set of patterns in order to extract relational tuples from a sentence, each consisting of argument phrases and a phrase that expresses a semantic relation between them. Such extraction patterns are either hand-crafted or learned from automatically labeled training data, as shown below.

2.1 Learning-based Systems

The line of work on Open IE begins with TEXTRUNNER (Banko et al., 2007), a self-supervised learning approach consisting of three modules. First, given a small sample of sentences from the Penn Treebank, the learner applies a dependency parser to heuristically identify and label a set of extractions as positive and negative training examples. This data is then used as input to a Naive Bayes classifier which learns a model of trustworthy relations using unlexicalized POS and noun phrase (NP) chunk features. The self-supervised nature mitigates the need for hand-labeled training data, and unlexicalized features help scale to the multitudes of relations found on the Web. The second component, the extractor, then generates candidate tuples by first identifying pairs of NP arguments and then heuristically designating each word in between as part of a relation phrase or not. Next, each candidate extraction is presented to the classifier, whereupon only those labeled as trustworthy are kept. Restricting to the use of shallow features in this step makes TEXTRUNNER highly efficient. Finally, a redundancy-based assessor assigns a probability to each retained tuple based on the number of sentences from which each extraction was found, thus exploiting the redundancy of information in Web text and assigning higher confidence to extractions that occur multiple times.

WOE (Wu and Weld, 2010) also learns an open information extractor without direct supervision. It makes use of Wikipedia as a source of training data by bootstrapping from entries in Wikipedia infoboxes, i.e. by heuristically matching infobox attribute-value pairs with corresponding sentences in the article. This data is then used to learn extraction patterns on both POS tags (WOE^{pos}) and dependency parses (WOE^{parse}). Former extractor utilizes a linear-chain Conditional Random Field (CRF) to train a model of relations on shallow features which outputs certain text between two NPs when it denotes a relation. Latter approach, in contrast, makes use of dependency trees to build a classifier that decides whether the shortest dependency path between two NPs indicates a semantic relation. By operating over dependency parses, even long-range dependencies can be captured. Accordingly, when comparing their two approaches, Wu and Weld (2010) show that the use of dependency features results in an increase in precision and recall over shallow linguistic features, though, at the cost of extraction speed, hence negatively affecting the scalability of the system.

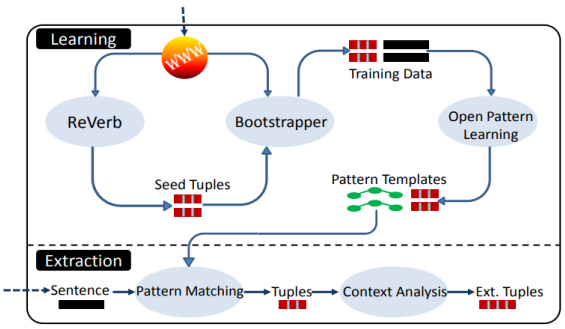

Figure 2: OLLIE's system architecture (Mausam et al., 2012). OLLIE begins with seed tuples from REVERB, uses them to build a bootstrap learning set, and learns open pattern templates. These are applied to individual sentences at extraction time.

OLLIE (Mausam et al., 2012) follows the idea of bootstrap learning of patterns based on dependency parse paths. However, while WOE relies on Wikipedia-based bootstrapping, OLLIE applies a set of high precision seed tuples from its predecessor system REVERB (see section 2.2) to bootstrap a large training set over which it learns a set of extraction pattern templates using dependency parses (see Figure 2). In contrast to previously presented systems that fully ignore the context of a tuple and thus extract propositions that are not asserted as factual, but are only hypothetical or conditionally true, OLLIE includes a context-analysis step in which contextual information from the input sentence around an extraction is analyzed to expand the output representation by adding attribution and clausal modifiers, if necessary, and thus increasing the precision of the system (see extractions (1) and (2) in Figure 1; for details, see section 2.4). Moreover, OLLIE is the first Open IE approach to identify not only verb-based relations, but also relationships mediated by nouns and adjectives (see extractions (3) and (4) in Figure 1). In that way, it expands the syntactic scope of relational phrases to cover a wider range of relation expressions, resulting in a much higher yield (at comparable precision) as compared to previous systems.

More recently, Yahya et al. (2014) proposed ReNoun, an Open IE system that entirely focuses on the extraction of noun-mediated relations. Starting with a small set of high-precision seed facts relying on manually specified lexical patterns that are specifically tailored for NPs, a set of dependency parse patterns for the extraction of noun-based relations is learned with the help of distant supervision (Mintz et al., 2009). These patterns are then applied to generate a set of candidate extractions which are assigned a confidence score based on the frequency and coherence of the patterns producing them.

2.2 Rule-based Systems

The second category of Open IE systems make use of hand-crafted extraction rules. This includes REVERB (Fader et al., 2011), a shallow extractor that addresses three common errors of hitherto existing Open IE systems: the output of such systems frequently contains a great many of uninformative extractions (i.e. extractions that omit critical information), incoherent extractions (i.e. extractions where the relational phrase has no meaningful interpretation) and overly-specific relations that convey too much information to be useful in further downstream semantic tasks. REVERB improves over those approaches by introducing a syntactic constraint that is expressed in terms of a simple POS-based regular expres-

sion (see Figure 3), covering about 85% of verb-based relational phrases in English text, as a linguistic analysis has revealed. In that way, the amount of incoherent and uninformative extractions is reduced. Moreover, in order to avoid overspecified relational phrases, a lexical constraint is presented which is based on the idea that a valid relational phrase should take many distinct arguments in a large corpus. Besides, while formerly proposed approaches start with the identification of candidate argument pairs, REVERB follows a relation-centric approach by first determining relational phrases that satisfy above-mentioned constraints, and then finding a pair of NP arguments for each such phrase. An example output produced by ReVerb can be seen in Figure 1 (6-7).

Whereas previously mentioned Open IE systems focus on the extraction of binary relations, commonly leading to extraction errors such as incomplete, uninformative or erroneous propositions, KRAKEN (Akbik and Löser, 2012) is the first approach to be specifically built for capturing complete facts from sentences by gathering the full set of arguments for each relational phrase within a sentence, thus producing tuples of arbitrary arity. The identification of relational phrases and their corresponding arguments is based on hand-written extraction rules over typed dependency parses.

$V \mid VP \mid VW^*P$
V = verb particle? adv?
W = (noun | adj | adv | pron | det)
P = (prep | particle | inf. marker)

Figure 3: ReVerb's POS-based regular expression for reducing incoherent and uninformative extractions.

EXEMPLAR (Mesquita et al., 2013) applies a similar approach for extracting n-ary relations, using hand-crafted patterns based on dependency parse trees to detect a relation trigger and the arguments connected to it. Based on the task of Semantic Role Labeling (SRL), whose key idea is to classify semantic constituents into different semantic roles (Christensen et al., 2010), it assigns each argument its corresponding role (such as subject, direct object or prepositional object).

A more abstract approach, PROPS, was suggested by Stanovsky et al. (2016), who argue that it is hard to read out from a dependency parse the complete structure of a sentence's propositions, since, amongst others, different predications are represented in a non-uniform manner and proposition boundaries are not easy to detect. Therefore, they introduce a more semantically-oriented sentence representation that is generated by transforming a dependency parse tree into a directed graph which is tailored to directly represent the proposition structure of an input sentence. Consequently, extracting propositions from this novel output format is straightforward. The conversion of the dependency tree into the proposition structure is carried out by a rule-based converter.

PredPatt (White et al., 2016) follows a similar approach. It employs a set of non-lexicalized rules defined over Universal Dependency (UD) parses (Marneffe et al., 2014) to extract predicate-argument structures. In doing so, PredPatt constructs a directed graph, where a special dependency ARG is built between the head token of a predicate and the head tokens of its arguments, while the original UD relations are preserved within predicate and argument phrases. As PredPatt uses language-agnostic patterns on UD structures, it is one of the few Open IE systems that work across different languages.

2.3 Clause-based Systems

Aiming to improve the accuracy of Open IE approaches, more recent work is based on the idea of incorporating a sentence re-structuring stage whose goal is to transform complex sentences, where relations are spread over several clauses or presented in a non-canonical form, into a set of syntactically simplified independent clauses that are easy to segment into Open IE tuples. An example of such a paraphrase-based Open IE approach is ClausIE (Del Corro and Gemulla, 2013), which exploits linguistic knowledge about the grammar of the English language to map the dependency relations of an input sentence to clause constituents. In that way, a set of coherent clauses presenting a simple linguistic structure is derived from the input. Then, the type of each clause is determined by combining knowledge of properties of verbs (with the help of domain-independent lexica) with knowledge about the structure of input clauses. Finally, based on its type, one or more propositions are generated from each clause, each representing different pieces of information. The basic set of patterns used for this task is shown in Table 1.

In the same vein, Schmidek and Barbosa (2014) propose a strategy to break down structurally com-

	Pattern	Clause type	Example	Derived clauses
S_1:	SV_i	SV	AE died.	(AE, died)
S_2:	SV_eA	SVA	AE remained in Princeton.	(AE, remained, in Princeton)
S_3:	SV_cC	SVC	AE is smart.	(AE, is, smart)
S_4:	$SV_{mt}O$	SVO	AE has won the Nobel Prize.	(AE, has won, the Nobel Prize)
S_5:	$SV_{dt}O_iO$	SVOO	RSAS gave AE the Nobel Prize.	(RSAS, gave, AE, the Nobel Prize)
S_6:	$SV_{ct}OA$	SVOA	The doorman showed AE to his office.	(The doorman, showed, AE, to his office)
S_7:	$SV_{ct}OC$	SVOC	AE declared the meeting open.	(AE, declared, the meeting, open)

Table 1: Basic patterns for proposition extraction (Del Corro and Gemulla, 2013). S: Subject, V: Verb, C: Complement, O: Direct object, A: Adverbial, V_i: Intransitive verb, V_c: Copular verb, V_e: Extended-copular verb, V_{mt}: Monotransitive verb, V_{dt}: Ditransitive verb, V_{ct}: Complex-transitive verb

plex sentences into simpler ones by decomposing the original sentence into its basic building blocks via chunking. The dependencies of each two chunks are then determined (one of "connected", "disconnected" or "dependent") using either manually defined rules over dependency paths between words in different chunks or a Naive Bayes classifier trained on shallow features, such as POS tags and the distance between chunks. Depending on their relationships, chunks are combined into simplified sentences, upon which the extraction process is carried out.

Angeli et al. (2015) present Stanford Open IE, an approach in which a classifier is learned for splitting a sentence into a set of logically entailed shorter utterances by recursively traversing its dependency tree and predicting at each step whether an edge should yield an independent clause or not. In order to increase the usefulness of the extracted propositions for downstream applications, each self-contained clause is then maximally shortened by running natural logic inference over it. In the end, a small set of 14 hand-crafted patterns are used to extract a predicate-argument triple from each utterance. An illustration of this approach is depicted in Figure 4.

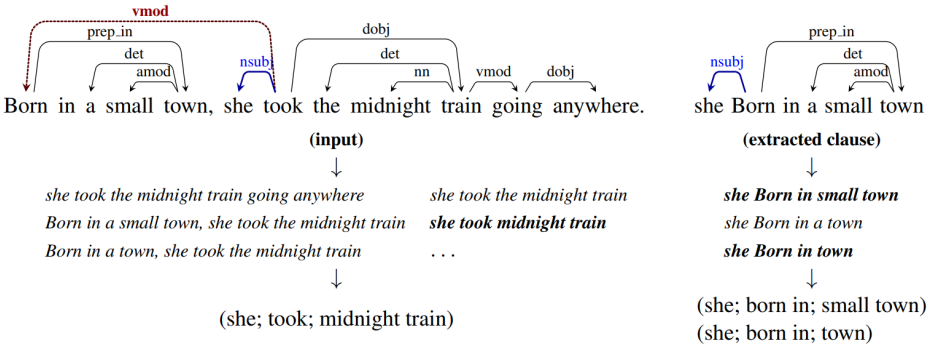

Figure 4: An illustration of Stanford Open IE's approach. From left to right, a sentence yields a number of independent clauses. From top to bottom, each clause produces a set of entailed shorter utterances, and segments the ones which match an atomic pattern into a relational triple (Angeli et al., 2015).

2.4 Systems Capturing Inter-Proposition Relationships

Aforementioned Open IE systems lack the expressiveness needed for a proper interpretation of complex assertions, since they ignore the context under which a proposition is complete and correct. Thus, they do not distinguish between information asserted in a sentence and information that is only hypothetical or conditionally true. For example, extracting the relational tuple ⟨*the earth*; *is the center of*; *the universe*⟩ from the sentence *"Early scientists believed that the earth is the center of the universe."* would be inappropriate, since the input is not asserting it, but only noting that is was believed by early scientists (Mausam, 2016). To properly handle such cases, OLLIE attempts a first solution by additionally extracting an attribution context, denoting a proposition that is reported or claimed by some entity:

(⟨*the earth*; *be the center of*; *the university*⟩;
`AttributedTo` *believe*; *Early astronomers*)

In that way, it extends the default Open IE representation of $\langle arg_1, rel, arg_2 \rangle$ with an extra field. Besides, OLLIE pays attention to clausal modifiers, such as:

(⟨*Romney*; *will be elected*; *President*⟩;
`ClausalModifier` *if*; *he wins five key states*)

Both types of modifiers are identified by matching patterns with the dependency parse of the sentence. Clausal modifiers are determined by an adverbial-clause edge and filtered lexically (the first word of the clause must match a list of cue terms, e.g. *if*, *when*, or *although*), while attribution modifiers are identified by a clausal-complement edge whose context verb must match one of the terms given in VerbNet's list of common verbs of communication and cognition (Mausam et al., 2012). A similar output is produced by OLLIES's successor OPENIE4 (Mausam, 2016), which combines SRLIE (Christensen et al., 2010) and RELNOUN (Pal and Mausam, 2016). Former is a system that converts the output of a SRL system into an Open IE extraction by treating the verb as the relational phrase, while taking its role-labeled arguments as the Open IE argument phrases related to the relation. Latter, in contrast, represents a rule-based Open IE system that extracts noun-mediated relations, thereby paying special attention to demonyms and compound relational nouns. In addition, OPENIE4 marks temporal and spatial arguments by assigning them a T or S label, respectively. Lately, its successor OPENIE 5.0 was released[1]. It integrates BONIE (Saha et al., 2017) and OpenIEListExtractor[2]. While the former focuses on extracting tuples where one of the arguments is a number or a quantity-unit phrase, the latter targets the extraction of propositions from conjunctive sentences.

Similar to OLLIE, Bast and Haussmann (2013), who explore the use of contextual sentence decomposition (CSD) for Open IE, advocate to further specify propositions with information on which they depend. Their system CSD-IE is based on the idea of paraphrasing-based approaches described in section 2.3. Using a set of hand-crafted rules over the output of a constituent parser, a sentence is first split into sub-sequences that semantically belong together, forming so-called "contexts". Each such context now contains a separate fact, yet it is often dependent on surrounding contexts. In order to preserve such inter-proposition relationships, tuples may contain references to other propositions. However, as opposed to OLLIE, where additional contextual modifiers are directly assigned to the corresponding relational tuples, Bast and Haussmann (2013) represent contextual information in the form of separate, linked propositions. To do so, each extraction is given a unique identifier that can be used in the argument position of an extraction for a later substitution with the corresponding fact by a downstream application. An example for an attribution is shown below (Bast and Haussmann, 2013):

#1: ⟨*The Embassy*; *said*; *that #2*⟩

#2: ⟨*6,700 Americans*; *were*; *in Pakistan.*⟩

Another current approach that captures inter-proposition relationships is proposed by Bhutani et al. (2016), who present a nested representation for Open IE that is able to capture high-level dependencies, allowing for a more accurate representation of the meaning of an input sentence. Their system NESTIE uses bootstrapping over a dataset for textual entailment to learn both binary and nested triple representations for n-ary relations over dependency parse trees. These patterns can take on the form of binary triples $\langle arg_1; rel; arg_2 \rangle$ or nested triples such as $\langle \langle arg_1; rel; arg_2 \rangle; rel_2; arg_3 \rangle$ for n-ary relations. Using a set of manually defined rules, contextual links between extracted propositions are inferred from the dependency parse in order to generate a nested representation of assertions that are complete and closer in meaning to the original statement. Similar to OLLIE, contextual links are identified as clausal complements, conditionals and relation modifiers. Linked propositions are represented by arguments that refer to the corresponding propositions using identifiers, e.g. (Bhutani et al., 2016):

#1: ⟨*body*; *appeared to have been thrown*; ∅⟩

#2: ⟨#1; *from*; *vehicle*⟩

or another example based on the following sentence:

[1] `https://github.com/dair-iitd/OpenIE-standalone`
[2] `https://github.com/swarnaHub/OpenIEListExtractor`

"*After giving 5,000 people a second chance at life, doctors are celebrating the 25th anniversary of Britain's first heart transplant.*"

#1: ⟨*doctors*; *are celebrating*; *the 25th anniversary of Britain's first heart transplant*⟩

#2: ⟨*doctors*; *giving*; *second chance at life*⟩

#3: ⟨#1; *after*; #2⟩

MinIE (Gashteovski et al., 2017), another recent Open IE system, is built on top of ClausIE, a system that was found to often produce overly specific extractions. Such overly specific constituents that combine multiple, potentially semantically unrelated propositions in a single relational or argument phrase generally hurt the performance of downstream semantic applications, such as question answering or textual entailment. In fact, those approaches benefit from extractions that are as compact as possible. Therefore, MinIE aims to minimize both relational and argument phrases by identifying and removing parts that are considered overly specific. For this purpose, MinIE provides four different minimization modes which differ in their aggressiveness, thus allowing to control the trade-off between precision and recall. Moreover, it semantically annotates extractions with information about polarity, modality, attribution and quantities instead of directly representing it in the actual extractions, as the following example shows (Gashteovski et al., 2017):

"*Pinocchio believes that the hero Superman was not actually born on beautiful Krypton.*"

#1: ⟨*Superman*; *was born actually on*; *beautiful Krypton*⟩
Annotation: factuality, (- [not], certainty), attribution (Pinocchio, +, possibility [believes])

#2: ⟨*Superman*; *was born on*; *beautiful Krypton*⟩
Annotation: factuality, (- [not], certainty), attribution (Pinocchio, +, possibility [believes])

#3: ⟨*Superman*; *"is"*; *hero*⟩
Annotation: factuality, (+, certainty)

with + and - signifying positive and negative polarity, respectively.

In that way, the output generated by MinIE is further reduced to its core constituents, producing maximally shortened, semantically enriched extractions.

To further enhance the expressiveness of extracted propositions and sustain their interpretability in downstream artificial intelligence tasks, Cetto et al. (2018) propose Graphene, an Open IE framework that uses a set of hand-crafted simplification rules to transform complex natural language sentences into clean, compact structures by removing clauses and phrases that present no central information from the input and converting them into stand-alone sentences. In that way, a source sentence is transformed into a hierarchical representation in the form of core facts and accompanying contexts (Niklaus et al., 2016). In addition, inspired by the work on Rhetorical Structure Theory (Mann and Thompson, 1988), a set of syntactic and lexical patterns is used to identify the rhetorical relations by which core sentences and their associated contexts are connected in order to preserve their semantic relationships and return a set of semantically typed and interconnected relational tuples (see extractions (15-17) in Figure 1). Graphene's extraction workflow is illustrated in Figure 5.

3 Evaluation

Though a multitude of systems for Open IE have been developed over the last decade, a clear formal specification of what constitutes a valid relational tuple is still missing. This lack of a well-defined, generally accepted task definition prevented the creation of an established, large-scale annotated corpus serving as a gold standard dataset for an objective and reproducible cross-system comparison. As a consequence, to date, Open IE systems were predominantly evaluated by hand on small-scale corpora that consist of only a few hundred sentences, thereby ignoring one of the fundamental goals of Open IE: scalability to large amounts of text. Moreover, none of the datasets that were used for assessing the

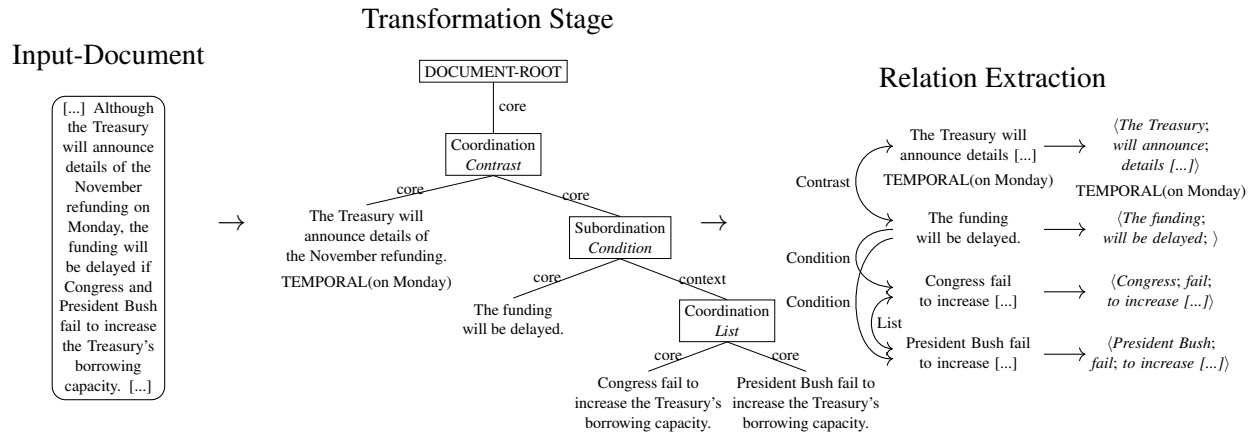

Figure 5: Graphene's extraction workflow for an example sentence (Cetto et al., 2018).

performance of different systems is widely agreed upon. As can be seen in Table 2, the corpora compiled by Del Corro and Gemulla (2013), Xu et al. (2013), Fader et al. (2011) and Banko et al. (2007) are occasionally re-used. However, new datasets are still collected, hindering a fair comparison of the proposed approaches. Besides, although Open IE methods are targeted at being domain independent and able to cope with heterogeneous datasets, the corpora used in the evaluation process are restricted to the news, Wikipedia and Web domains for the most part. Accordingly, no clear statement about the portability of the approaches to various genres of text is possible. In addition, most evaluation procedures described in the literature focus on precision-oriented metrics, while either completely ignoring recall or using some kind of proxy, such as yield, i.e. the total number of extractions labeled as correct, or coverage, i.e. the percentage of text from the input that is contained in at least one of the extractions. Hence, the absence of a standard evaluation procedure makes it hard to replicate and compare the performance of different Open IE systems. Table 2 provides a detailed overview of both the datasets and measures used for intrinsically evaluating the various approaches described above, while Table 3 shows the tasks that were used for an extrinsic evaluation of a small set of Open IE systems.

In order to address aforementioned difficulties, Stanovsky and Dagan (2016) recently made a first attempt in standardizing the Open IE evaluation by providing a large gold benchmark corpus. It is based on a set of consensual guiding principles that underly most Open IE approaches proposed so far, as they have identified. Those principles cover the core aspects of the task of Open IE, allowing for a clearer formulation of the problem to be solved. The three key features to consider are the following:

Assertedness. The assertedness principle states that extracted propositions should be asserted by the original sentence. Usually, instead of inferring propositions out of implied statements, e.g. the tuple ⟨*Sam*; *convinced*; *John*⟩ out of ⟨*Sam*; *succeeded in convincing*; *John*⟩, Open IE systems tend to extract the full relational phrase (⟨*Sam*; *succeeded in convincing*; *John*⟩), incorporating matrix verbs ("*succeeded*") and other elements, such as negotiations or modals (e.g. ⟨*John*; *could not join*; *the band*⟩).

Minimal Propositions. In order to serve for semantic tasks, it is beneficial for Open IE systems to extract compact, self-contained propositions that do not combine several unrelated facts. Therefore, systems should aim to generate valid propositions with minimal spans for both relation and argument slots, while preserving the meaning of the input. As an example, the coordination in the sentence "*Bell distributes electronic and building products*" should ideally yield the two propositions: ⟨*Bell*; *distributes*; *electronic products*⟩ and ⟨*Bell*; *distributes*; *building products*⟩.

Completeness and Open Lexicon. The completeness and open lexicon principle aims to extract all relations that are asserted in the input text. This principle was one of the fundamental ideas that have been introduced in the work of Banko et al. (2007) together with the Open IE terminology. In their work, the Open IE task was defined as a domain-independent task which extracts all possible

Table 3: Extrinsic evaluation approaches.

relations from heterogeneous corpora, instead of only extracting a set of pre-specified classes of relations. The majority of current Open IE systems realize this challenge by considering all possible verbs as potential relations. Accordingly, their scope is often limited to the extraction of verbal predicates, while ignoring relations mediated by more complex syntactic constructs, such as nouns or adjectives.

Realizing that above-mentioned requirements are subsumed by the task of Question Answering (QA) driven Semantic Role Labeling (SRL) (He et al., 2015), Stanovsky and Dagan (2016) converted the annotations of a QA-SRL dataset to an Open IE corpus, resulting in more than 10,000 extractions over 3,200 sentences from Wikipedia and the Wall Street Journal.

In addition, Schneider et al. (2017) presented RelVis, another benchmark framework for Open IE that allows for a large-scale comparative analysis of Open IE approaches. Besides Stanovsky and Dagan (2016)'s benchmark suite, it comprises the n-ary news dataset proposed in Mesquita et al. (2013), Banko et al. (2007)'s Web corpus and the Penn sentences from Xu et al. (2013). Similar to the toolkit proposed in Stanovsky and Dagan (2016), RelVis supports a quantitative evaluation of the performance of Open IE systems in terms of precision, recall and F_2-score. In addition, it facilitates a manual qualitative error analysis. For this purpose, six common error classes are distinguished to which inaccurate extractions can be assigned: (1) wrong boundaries, where the relational or argument phrase is either too long or too small; (2) redundant extraction, where the proposition asserted in an extraction is already expressed in another extraction; (3) uninformative extraction, where critical information is omitted; (4) missing extraction, i.e. a false negative, where either a relation is not detected by the system or the argument-finding heuristics choose the wrong arguments or none argument at all; (5) wrong extraction, where no meaningful interpretation of the proposition is possible; and (6) out of scope extraction, where a system yields a correct extraction that was not recognized by the authors of the gold dataset.

4 Open Research Questions

Even after more than one decade of research in the area of Open IE, there are still a lot of open research questions. As shown in Section 3, to date, there is only very little work on evaluating and comparing results among different Open IE systems in a large-scale, objective and reproducible fashion. Instead, most approaches use proprietary datasets over small, domain-dependent corpora. Stanovsky and Dagan (2016) and Schneider et al. (2017) recently made the first move to standardize the evaluation of Open IE by proposing benchmark frameworks that operate on a larger scale. However, apart from Cetto et al. (2018), neither benchmarking toolkit has been adopted yet in the Open IE community.

Moreover, most Open IE approaches focus on the English language, leaving aside other languages. Notable exceptions are Falke et al. (2016), who investigate the portability of the PROPS system to German, and Gamallo and Garcia (2015), who propose a multilingual system covering English, Spanish, Portuguese and Galician. Besides, due to the use of language-agnostic patterns over UD parses, PredPatt works across languages, though its performance was only evaluated on English texts. Hence, the applicability and transferability of previously proposed Open IE approaches to other languages than English represents an interesting direction for future work.

Finally, the problem of canonicalizing relational phrases and arguments has been hardly addressed so far. However, normalizing extractions would be highly beneficial for downstream semantic tasks, such as textual entailment or knowledge base population. Besides, coreference resolution, another field that has largely been ignored to date, may assist those tasks with the interpretation of the extracted propositions.

5 Conclusion

We presented an overview of the various methods that were proposed to solve the task of Open IE. We classified them into the four categories of learning-based, rule-based, clause-based systems and approaches capturing inter-proposition relationships, thereby showing their evolution over time, as well as the specific problems they tackle. Moreover, we described the approaches that were used to assess the performance of the proposed Open IE systems, while depicting the gaps in the evaluation procedures that are commonly applied to date. Finally, we identified directions for future work.

Design Challenges and Misconceptions in Neural Sequence Labeling

Jie Yang, Shuailong Liang, Yue Zhang
Singapore University of Technology and Design
{jie_yang, shuailong_liang}@mymail.sutd.edu.sg
yue_zhang@sutd.edu.sg

Abstract

We investigate the design challenges of constructing effective and efficient neural sequence labeling systems, by reproducing twelve neural sequence labeling models, which include most of the state-of-the-art structures, and conduct a systematic model comparison on three benchmarks (i.e. NER, Chunking, and POS tagging). Misconceptions and inconsistent conclusions in existing literature are examined and clarified under statistical experiments. In the comparison and analysis process, we reach several practical conclusions which can be useful to practitioners.

1 Introduction

Sequence labeling models have been used for fundamental NLP tasks such as POS tagging, chunking and named entity recognition (NER). Traditional work uses statistical approaches such as Hidden Markov Models (HMM) and Conditional Random Fields (CRF) (Ratinov and Roth, 2009; Passos et al., 2014; Luo et al., 2015) with handcrafted features and task-specific resources. With advances in deep learning, neural models have given state-of-the-art results on many sequence labeling tasks (Ling et al., 2015; Lample et al., 2016; Ma and Hovy, 2016). Words and characters are encoded in distributed representations (Mikolov et al., 2013) and sentence-level features are learned automatically during end-to-end training. Many existing state-of-the-art neural sequence labeling models utilize word-level Long Short-Term Memory (LSTM) structures to represent global sequence information and a CRF layer to capture dependencies between neighboring labels (Huang et al., 2015; Lample et al., 2016; Ma and Hovy, 2016; Peters et al., 2017). As an alternative, Convolution Neural Network (CNN) (LeCun et al., 1989) has also been used for its ability of parallel computing, leading to an efficient training and decoding process.

Despite them being dominant in the research literature, reproducing published results for neural models can be challenging, even if the codes are available open source. For example, Reimers and Gurevych (2017b) conduct a large number of experiments using the code of Ma and Hovy (2016), but cannot obtain comparable results as reported in the paper. Liu et al. (2018) report lower average F-scores on NER when reproducing the structure of Lample et al. (2016), and on POS tagging when reproducing Ma and Hovy (2016). Most literature compares results with others by citing the scores directly (Huang et al., 2015; Lample et al., 2016) without re-implementing them under the same setting, resulting in less persuasiveness on the advantage of their models. In addition, conclusions from different reports can be contradictory. For example, most work observes that stochastic gradient descent (SGD) gives best performance on NER task (Chiu and Nichols, 2016; Lample et al., 2016; Ma and Hovy, 2016), while Reimers and Gurevych (2017b) report that SGD is the worst optimizer on the same datasets.

The comparison between different deep neural models is challenging due to sensitivity on experimental settings. We list six inconsistent configurations in literature, which lead to difficulties for fair comparison.
• **Dataset**. Most work reports sequence labeling results on both CoNLL 2003 English NER (Tjong Kim Sang and De Meulder, 2003) and PTB POS (Marcus et al., 1993) datasets (Collobert et al., 2011; Huang et al., 2015; Ma and Hovy, 2016). Ling et al. (2015) give results only on POS dataset, while some

papers (Chiu and Nichols, 2016; Lample et al., 2016; Strubell et al., 2017) report results on the NER dataset only. dos Santos et al. (2015) conducts experiments on NER for Portuguese and Spanish.

Most work uses the development set to select hyperparameters (Lample et al., 2016; Ma and Hovy, 2016), while others add development set into training set (Chiu and Nichols, 2016; Peters et al., 2017). Reimers and Gurevych (2017b) use a smaller dataset (13862 vs 14987 sentences). Different from Ma and Hovy (2016) and Liu et al. (2018), Huang et al. (2015) choose a different data split on the POS dataset. Liu et al. (2018) and Hashimoto et al. (2017) use different development sets for chunking.

• **Preprocessing**. A typical data preprocessing step is to normize digit characters (Chiu and Nichols, 2016; Lample et al., 2016; Yang et al., 2016; Strubell et al., 2017). Reimers and Gurevych (2017b) use fine-grained representations for less frequent words. Ma and Hovy (2016) do not use preprocessing.

• **Features**. Strubell et al. (2017) and Chiu and Nichols (2016) apply word spelling features and Huang et al. (2015) further integrate context features. Collobert et al. (2011) and Huang et al. (2015) use neural features to represent external gazetteer information. Besides, Lample et al. (2016) and Ma and Hovy (2016) use end-to-end structure without handcrafted features.

• **Hyperparameters** including learning rate, dropout rate (Srivastava et al., 2014), number of layers, hidden size etc. can strongly affect the model performance. Chiu and Nichols (2016) search for the hyperparameters for each task and show that the system performance is sensitive to the choice of hyperparameters. However, existing models use different parameter settings, which affects the fair comparison.

• **Evaluation**. Some literature reports results using mean and standard deviation under different random seeds (Chiu and Nichols, 2016; Peters et al., 2017; Liu et al., 2018). Others report the best result among different trials (Ma and Hovy, 2016), which cannot be compared directly.

• **Hardware environment** can also affect system accuracy. Liu et al. (2018) observes that the system gives better accuracy on NER task when trained using GPU as compared to using CPU. Besides, the running speeds are highly affected by the hardware environment.

To address the above concerns, we systematically analyze neural sequence labeling models on three benchmarks: CoNLL 2003 NER (Tjong Kim Sang and De Meulder, 2003), CoNLL 2000 chunking (Tjong Kim Sang and Buchholz, 2000) and PTB POS tagging (Marcus et al., 1993). Table 1 shows a summary of the models we investigate, which can be categorized under three settings: (i) character sequence representations ; (ii) word sequence representations; (iii) inference layer. Although various combinations of these three settings have been proposed in the literature, others have not been examined. We compare all models in Table 1, which includes most state-of-the-art methods. To make fair comparisons, we build a unified framework[1] to reproduce the twelve neural sequence labeling architectures in Table 1. Experiments show that our framework gives comparable or better results on reproducing existing works, showing the practicability and reliability of our analysis for practitioners. The detailed comparison and analysis show that (i) Character information provides a significant improvement on accuracy; (ii) Word-based LSTM models outperforms CNN models in most cases; (iii) CRF can improve model accuracy on NER and chunking but does not on POS tagging. Our framework is based on PyTorch with batched implementation, which is highly efficient, facilitating quick configurations for new tasks.

[1]Our code has been released at `https://github.com/jiesutd/NCRFpp`.

2 Related Work

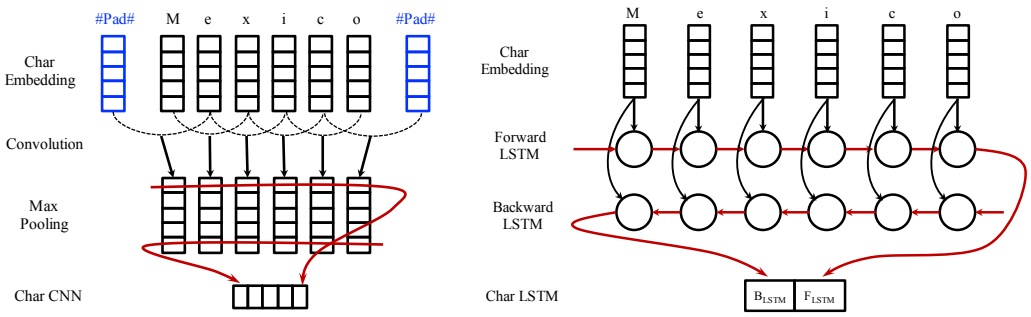
Collobert et al. (2011) proposed a seminal neural architecture for sequence labeling. It captures word sequence information with a one-layer CNN based on pretrained word embeddings and handcrafted neural features, followed with a CRF output layer. dos Santos et al. (2015) extended this model by integrating character-level CNN features. Strubell et al. (2017) built a deeper dilated CNN architecture to capture larger local features. Hammerton (2003) was the first to exploit LSTM for sequence labeling. Huang et al. (2015) built a BiLSTM-CRF structure, which has been extended by adding character-level LSTM (Lample et al., 2016; Liu et al., 2018), GRU (Yang et al., 2016), and CNN (Chiu and Nichols, 2016; Ma and Hovy, 2016) features. Yang et al. (2017a) proposed a neural reranking model to improve NER models. These models achieve state-of-the-art results in the literature.

Reimers and Gurevych (2017b) compared several word-based LSTM models for several sequence labeling tasks, reporting the score distributions over multiple runs rather than single value. They investigated the influence of various hyperparameters and configurations. Our work is similar in comparing different neural architectures under unified settings, but differs in four main aspects: 1) Their experiments are based on a BiLSTM with handcrafted word features, while our experiments are based on end-to-end neural models without human knowledge. 2) Their system gives relatively low performances on standard benchmarks[2], while ours can give comparable or better results with state-of-the-art models, rendering our observations more informative for practitioners. 3) Our findings are more consistent with most previous work on configurations such as usefulness of character information (Lample et al., 2016; Ma and Hovy, 2016), optimizer (Chiu and Nichols, 2016; Lample et al., 2016; Ma and Hovy, 2016) and tag scheme (Ratinov and Roth, 2009; Dai et al., 2015). In contrast, many results of Reimers and Gurevych (2017b) contradict existing reports. 4) We conduct a wider range of comparison for word sequence representations, including all combinations of character CNN/LSTM and word CNN/LSTM structures, while Reimers and Gurevych (2017b) studied the word LSTM models only.

3 Neural Sequence Labeling Models

Our neural sequence labeling framework contains three layers, i.e., a character sequence representation layer, a word sequence representation layer and an inference layer, as shown in Figure 1. Character information has been proven to be critical for sequence labeling tasks (Chiu and Nichols, 2016; Lample et al., 2016; Ma and Hovy, 2016), with LSTM and CNN being used to model character sequence information ("Char Rep."). Similarly, on the word level, LSTM or CNN structures can be leveraged to capture long-term information or local features ("Word Rep."), respectively. Subsequently, the inference layer assigns labels to each word using the hidden states of word sequence representations.

[2]Based on their detailed experiment report (Reimers and Gurevych, 2017a), the F1-scores on CoNLL 2003 NER task are generally less than 90%, while *state-of-the-art* results are around 91%.



(a) Character CNN. (b) Character LSTM.

Figure 2: Neural character sequence representations.

3.1 Character Sequence Representations

Character features such as prefix, suffix and capitalization can be represented with embeddings through a feature-based lookup table (Collobert et al., 2011; Huang et al., 2015; Strubell et al., 2017), or neural networks without human-defined features (Lample et al., 2016; Ma and Hovy, 2016). In this work, we focus on neural character sequence representations without hand-engineered features.

Character CNN. Using a CNN structure to encode character sequences was firstly proposed by Santos and Zadrozny (2014), and followed by many subsequent investigations (dos Santos et al., 2015; Chiu and Nichols, 2016; Ma and Hovy, 2016). In our experiments, we take the same structure as Ma and Hovy (2016), using one layer CNN structure with *max-pooling* to capture character-level representations. Figure 2(a) shows the CNN structure on representing word "Mexico".

Character LSTM. Shown as Figure 2(b), in order to model the global character sequence information of a word "Mexico", we utilize a bidirectional LSTM on the character sequence of each word and concatenate the *left-to-right* final state F_{LSTM} and the *right-to-left* final state B_{LSTM} as character sequence representations. Liu et al. (2018) applied one bidirectional LSTM for the character sequence over a sentence rather than each word individually. We examined both structures and found that they give comparable accuracies on sequence labeling tasks. We choose Lample et al. (2016)'s structure as its character LSTMs can be calculated in parallel, making the system more efficient.

3.2 Word Sequence Representations

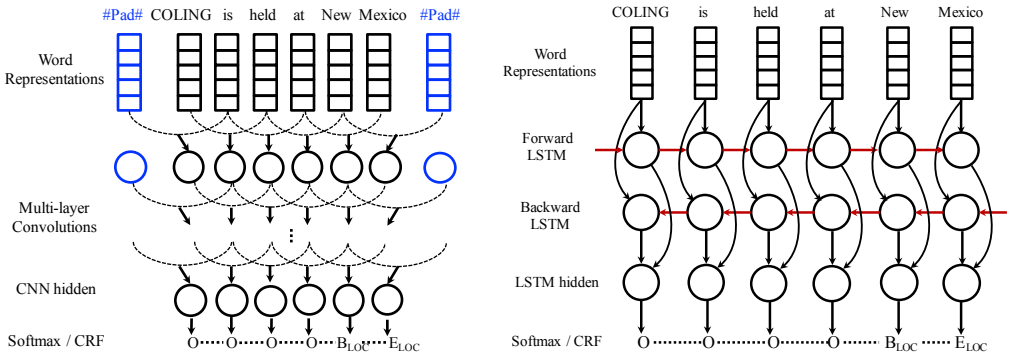
Similar to character sequences in words, we can model word sequence information through LSTM or CNN structures. LSTM has been widely used in sequence labeling (Lample et al., 2016; Ma and Hovy, 2016; Chiu and Nichols, 2016; Huang et al., 2015; Liu et al., 2018). CNN can be much faster than LSTM due to the fact that convolution calculation can be parallel on the input sequence (Collobert et al., 2011; dos Santos et al., 2015; Strubell et al., 2017).

Word CNN. Figure 3(a) shows the multi-layer CNN on word sequence, where words are represented by embeddings. If a character sequence representation layer is used, then word embeddings and character sequence representations are concatenated for word representations. For each CNN layer, a window of size 3 slides along the sequence, extracting local features on the word inputs and a ReLU function (Glorot et al., 2011) is followed. We follow Strubell et al. (2017) by using 4 CNN layers. Batch normalization (Ioffe and Szegedy, 2015) and dropout (Srivastava et al., 2014) are applied following each CNN layer.

Word LSTM. Shown in Figure 3(b), word representations are fed into a forward LSTM and backward LSTM, respectively. The forward LSTM captures the word sequence information from left to right, while the backward LSTM extracts information in a reversed direction. The hidden states of the forward and backward LSTMs are concatenated at each word to give global information of the whole sequence.

3.3 Inference Layer

The inference layer takes the extracted word sequence representations as features and assigns labels to the word sequence. Independent local decoding with a linear layer mapping word sequence representations



(a) Word CNN. (b) Word LSTM.

Figure 3: Neural word sequence representations.

to label vocabulary and performing softmax can be quite effective (Ling et al., 2015), while for tasks that with strong output label dependency, such as NER, CRF is a more appropriate choice. In this work, we examine both softmax and CRF as inference layer on three sequence labeling tasks.

4 Experiments

We investigate the main influencing factors to system accuracy, including the character sequence representations, word sequence representations, inference algorithm, pretrained embeddings, tag scheme, running environment and optimizer; analyzing system performances from the perspective of decoding speed and accuracies on in-vocabulary (IV) and out-of-vocabulary (OOV) entities/chunks/words.

4.1 Settings

Data. The NER dataset has been standardly split in Tjong Kim Sang and De Meulder (2003). It contains four named entity types: PERSON, LOCATION, ORGANIZATION, and MISC. The chunking task is evaluated on CoNLL 2000 shared task (Tjong Kim Sang and Buchholz, 2000). We follow Reimers and Gurevych (2017a) by using sections 15-18 of Wall Street Journal (WSJ) for training, section 19 as development set and section 20 as test set. For the POS tagging task, we use the WSJ portion of Peen Treebank, which has 45 POS tags. Following previous works (Toutanova et al., 2003; Santos and Zadrozny, 2014; Ma and Hovy, 2016; Liu et al., 2018), we adopt the standard splits by using sections 0-18 as training set, sections 19-21 as development set and sections 22-24 as test set. No preprocessing is performed on either dataset except for normalizing digits. The dataset statistics are listed in Table 2.

Hyperparameters. Table 3 shows the hyperparameters used in our experiments, which mostly follow Ma and Hovy (2016), including the learning rate $\eta = 0.015$ for word LSTM models. For word CNN based models, a large η leads to convergence problem. We take $\eta = 0.005$ with more epochs (200) instead. GloVe 100-dimension (Pennington et al., 2014) is used to initialize word embeddings and character embeddings are randomly initialized. We use mini-batch stochastic gradient descent (SGD) with a decayed learning rate to update parameters. For NER and chunking, we the BIOES tag scheme.

Evaluation. Standard precision (P), recall (R) and F1-score (F) are used as the evaluation metrics for NER and chunking; token accuracy is used to evaluate the performance of POS tagger. Development datasets are used to select the optimal model among all epochs, and we report scores of the selected model on the test dataset. To reduce the volatility of the system, we conduct each experiment 5 times under different random seeds, and report the *max, mean,* and *standard deviation* for each model.

4.2 Results

Tables 4, 5 and 6 show the results of the twelve models on NER, chunking and POS datasets, respectively. Existing work has also been listed in the tables for comparison. To simplify the description, we use "CLSTM" and "CCNN" to represent character LSTM and character CNN encoder, respectively. Similarly, "WLSTM" and "WCNN" represent word LSTM and word CNN structure, respectively.

Dataset		Train	Dev	Test	Label

word LSTM epochs	100	word CNN epochs	200

Table 3: Hyperparameters.

As shown in Table 4, most NER work focuses on WLSTM+CRF structures with different character sequence representations. We re-implement the structure of several reports (Chiu and Nichols, 2016; Ma and Hovy, 2016; Peters et al., 2017), which take the CCNN+WLSTM+CRF architecture. Our reproduced models give slightly better performances. The results of Lample et al. (2016) can be reproduced by our CLSTM+WLSTM+CRF. In most cases, our "Nochar" based models underperform their corresponding prototypes (Huang et al., 2015; Strubell et al., 2017), which utilize the hand-crafted features.

Table 5 shows the results of the chunking task. Peters et al. (2017) give the best reported single model results (95.00±0.08), and our CLSTM+WLSTM+CRF gives a comparable performance (94.93±0.05). We re-implement Zhai et al. (2017)'s model in our Nochar+WLSTM but cannot reproduce their results, this may because that they use grid search for hyperparameter selection. Our Nochar+WCNN+CRF can give comparable results with Collobert et al. (2011), even ours does not include character information.

The results of the POS tagging task is shown in Table 6. The results of Lample et al. (2016), Ma and Hovy (2016) and Yang et al. (2017b) can be reproduced by our CLSTM+WLSTM+CRF and CCNN+WLSTM+CRF models. Our WLSTM based models give better results than WLSTM+CRF based models, this is consistent with the fact that Ling et al. (2015) take CLSTM+WLSTM without CRF layer but achieve the best POS accuracy. Santos and Zadrozny (2014) build a pure CNN structure on both character and word level, which can be reproduced by our CCNN+WCNN models.

Based on above observations, most results in the literature are reproducible. Our implementations can achieve the comparable or better results with state-of-the-art models. We do not fine-tune any hyperparameter to fit the specific task. Results on Table 4, 5 and 6 are all under the same hyperparameters, which demonstrates the generalization ability of our framework.

4.3 Network settings

Character LSTM vs Character CNN. Unlike the observations of Reimers and Gurevych (2017b), in our experiments, character information can significantly ($p < 0.01$)[3] improve sequence labeling models (by comparing the row of Nochar with CLSTM or CCNN on Table 4, 5 and 6), while the difference between CLSTM and CCNN is not significant. In most cases, CLSTM and CCNN can give comparable results under different frameworks and different tasks. CCNN gives the best NER result under the WLSTM+CRF framework, while CLSTM gets better NER results in all other configurations. For chunking and POS tagging, CLSTM consistently outperforms CCNN under all settings, while the difference is statistically insignificant ($p > 0.2$). We conclude that the difference between CLSTM and CCNN is small, which is consistent with the observation of Reimers and Gurevych (2017b).

Word LSTM vs Word CNN. By comparing the performances of WLSTM+CRF, WLSTM with WCNN+CRF, WCNN on the three benchmarks, we conclude that word-based LSTM models are significantly ($p < 0.01$) better than word-based CNN models in most cases. It demonstrates that global word context information is necessary for sequence labeling.

Softmax vs CRF. Models with CRF inference layer can consistently outperform the models with softmax layer under all configurations on NER and chunking tasks, proving the effectiveness of label dependency information. While for POS tagging, the local softmax based models give slightly better accuracies while the difference is insignificant ($p > 0.2$).

[3]We use *t-test* to calculate the p value, reporting the highest p value when giving the conclusions on multiple configurations.

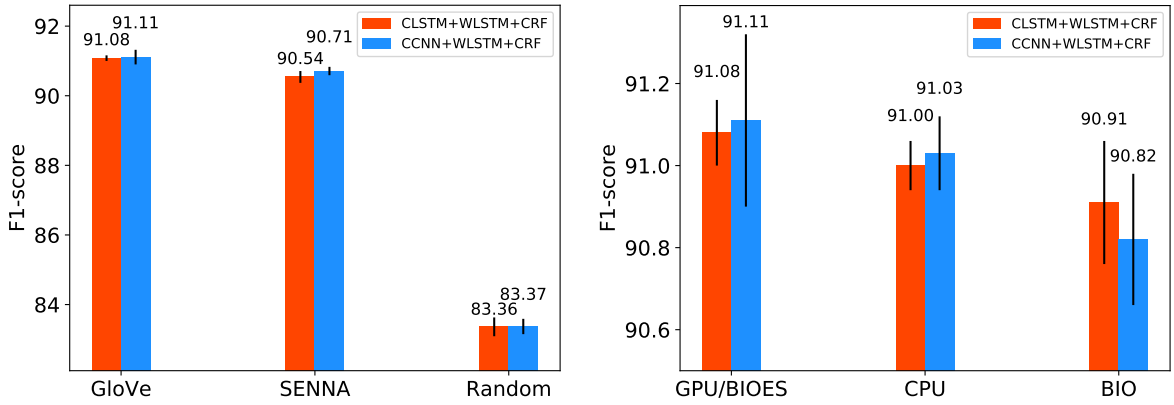
(2016) on the corresponding dataset. (Y-17)‡ use GRU for character and word sequence representations; here we regard GRU as a variant of LSTM.



(a) Pretrained embeddings.

(b) Tag scheme and running environment.

Figure 4: Performance comparison on the CoNLL 2003 NER task.

4.4 External factors

In addition to model structures, external factors such as pretrained embeddings, tag scheme, and optimizer can significantly influence system performance. We investigate a set of external factors on the NER dataset with the two best models: CLSTM+WLSTM+CRF and CCNN+WLSTM+CRF.

Pretrained embedding. Figure 4(a) shows the F1-scores of the two best models on the NER test set with two different pretrained embeddings, as well as the random initialization. Compared with the random initialization, models using pretrained embeddings give significant improvements ($p < 0.01$). The GloVe 100-dimension embeddings give higher F1-scores than SENNA (Collobert et al., 2011) on both models, which is consistent with the observation of Ma and Hovy (2016).

Tag scheme. We examine two different tag schemes: BIO and BIOES (Ratinov and Roth, 2009). The results are shown in Figure 4(b). In our experiments, models using BIOES are significantly ($p < 0.05$) better than BIO. Our observation is consistent with most literature (Ratinov and Roth, 2009; Dai et al., 2015). Reimers and Gurevych (2017b) report that the difference between the schemes is insignificant.

Running environment. Liu et al. (2018) observe that neural sequence labeling models can give better results on GPU rather than CPU. We conduct repeated experiments on both GPU and CPU environments. The results are shown in Figure 4(b). Models run on CPU give a lower mean F1-score than models run on GPU, while the difference is insignificant ($p > 0.2$).

Optimizer. We compare different optimizers including SGD, Adagrad (Duchi et al., 2011), Adadelta (Zeiler, 2012), RMSProp (Tieleman and Hinton, 2012) and Adam (Kingma and Ba, 2014). The results are shown in Figure 5[5]. In contrast to Reimers and Gurevych (2017b), who reported that SGD is the worst optimizer, our results show that SGD outperforms all other optimizers significantly ($p < 0.01$), with a slower convergence process during training. Our observation is consistent with most literature (Chiu and Nichols, 2016; Lample et al., 2016; Ma and Hovy, 2016).

4.5 Analysis

Decoding speed. We test the decoding speeds of the twelve models on the NER dataset using a Nvidia GTX 1080 GPU. Figure 6 shows the decoding times on 10000 NER sentences. The CRF inference layer severely limits the decoding speed due to the left-to-right inference process, which disables the parallel decoding. Character LSTM significantly slows down the system. Compared with models without character information, adding character CNN representations does not affect the decoding speed too much but can give significant accuracy improvements (shown in Section 4.3). Due to the support of parallel computing, word-based CNN models are consistently faster than word-based LSTM models, with close accuracies, leading to large utilization potential in practice.

[5]We fine-tune the learning rates for Adagrad, Adadelta, RMSProp and Adam, and report the best results in the figure.

Table 7: Results for OOV analysis.

OOV error. We conduct error analysis on in-vocabulary and out-of-vocabulary words with the CRF based models[6]. Following Ma and Hovy (2016), words in the test set are divided into four subsets: in-vocabulary words, out-of-training-vocabulary words (OOTV), out-of-embedding-vocabulary words (OOEV) and out-of-both-vocabulary words (OOBV). For NER and chunking, we consider entities or chunks rather than words. The OOV entities and chunks are categorized following Ma and Hovy (2016).

Table 7 shows the performances of different OOV splits on three benchmarks. The top three rows list the performances of word-based LSTM CRF models, followed by the word-based CNN CRF models. The results of OOEV in NER keep 100% because of there exist only 8 OOEV entities and all are recognized correctly. It is obvious that character LSTM or CNN representations improve OOTV and OOBV the most on both WLSTM+CRF and WCNN+CRF models across all three datasets, proving that the main contribution of neural character sequence representations is to disambiguate the OOV words. Models with character LSTM representations give the best IV scores across all configurations, which may be because character LSTM can be well trained on IV data, bringing the useful global character sequence information. On the OOVs, character LSTM and CNN gives comparable results.

5 Conclusion

We built a unified neural sequence labeling framework to reproduce and compare recent state-of-the-art models with different configurations. We explored three neural model design decisions: character sequence representations, word sequence representations, and inference layer. Experiments show that character information helps to improve model performances, especially on disambiguating OOV words. Character-level LSTM and CNN structures give comparable improvements, with the latter being more efficient. In most cases, models with word-level LSTM encoders outperform those with CNN, at the expense of longer decoding time. We observed that the CRF inference algorithm is effective on NER and chunking tasks, but does not have the advantage on POS tagging. With controlled experiments on the NER dataset, we showed that BIOES tags are better than BIO. Besides, pretrained GloVe 100d embedding and SGD optimizer give significantly better performances compared to their competitors.

[6]We choose the models that give the median performance on the test set for conducting result analysis.

Abstract

In this paper, we analyze several neural network designs (and their variations) for sentence pair modeling and compare their performance extensively across eight datasets, including paraphrase identification, semantic textual similarity, natural language inference, and question answering tasks. Although most of these models have claimed state-of-the-art performance, the original papers often reported on only one or two selected datasets. We provide a systematic study and show that (i) encoding contextual information by LSTM and inter-sentence interactions are critical, (ii) Tree-LSTM does not help as much as previously claimed but surprisingly improves performance on Twitter datasets, (iii) the Enhanced Sequential Inference Model (Chen et al., 2017) is the best so far for larger datasets, while the Pairwise Word Interaction Model (He and Lin, 2016) achieves the best performance when less data is available. We release our implementations as an open-source toolkit.

1 Introduction

Sentence pair modeling is a fundamental technique underlying many NLP tasks, including the following:

- Semantic Textual Similarity (STS), which measures the degree of equivalence in the underlying semantics of paired snippets of text (Agirre et al., 2016).
- Paraphrase Identification (PI), which identifies whether two sentences express the same meaning (Dolan and Brockett, 2005; Xu et al., 2015).
- Natural Language Inference (NLI), also known as recognizing textual entailment (RTE), which concerns whether a hypothesis can be inferred from a premise, requiring understanding of the semantic similarity between the hypothesis and the premise (Dagan et al., 2006; Bowman et al., 2015).
- Question Answering (QA), which can be approximated as ranking candidate answer sentences or phrases based on their similarity to the original question (Yang et al., 2015).
- Machine Comprehension (MC), which requires sentence matching between a passage and a question, pointing out the text region that contains the answer. (Rajpurkar et al., 2016).

Traditionally, researchers had to develop different methods specific for each task. Now neural networks can perform all the above tasks with the same architecture by training end to end. Various neural models (He and Lin, 2016; Chen et al., 2017; Parikh et al., 2016; Wieting et al., 2016; Tomar et al., 2017; Wang et al., 2017; Shen et al., 2017a; Yin et al., 2016) have declared state-of-the-art results for sentence pair modeling tasks; however, they were carefully designed and evaluated on selected (often one or two) datasets that can demonstrate the superiority of the model. The research questions are as follows: Do they perform well on other tasks and datasets? How much performance gain is due to certain system design choices and hyperparameter optimizations?

Proceedings of the 27th International Conference on Computational Linguistics, pages 3890–3902
Santa Fe, New Mexico, USA, August 20-26, 2018.

To answer these questions and better understand different network designs, we systematically analyze and compare the state-of-the-art neural models across multiple tasks and multiple domains. Namely, we implement five models and their variations on the same PyTorch platform: InferSent model (Conneau et al., 2017), Shortcut-stacked Sentence Encoder Model (Nie and Bansal, 2017), Pairwise Word Interaction Model (He and Lin, 2016), Decomposable Attention Model (Parikh et al., 2016), and Enhanced Sequential Inference Model (Chen et al., 2017). They are representative of the two most common approaches: **sentence encoding models** that learn vector representations of individual sentences and then calculate the semantic relationship between sentences based on vector distance and **sentence pair interaction models** that use some sorts of word alignment mechanisms (e.g., attention) then aggregate inter-sentence interactions. We focus on identifying important network designs and present a series of findings with quantitative measurements and in-depth analyses, including (i) incorporating inter-sentence interactions is critical; (ii) Tree-LSTM does not help as much as previously claimed but surprisingly improves performance on Twitter data; (iii) Enhanced Sequential Inference Model has the most consistent high performance for larger datasets, while Pairwise Word Interaction Model performs better on smaller datasets and Shortcut-Stacked Sentence Encoder Model is the best performaning model on the Quora corpus. We release our implementations as a toolkit to the research community.[1]

2 General Framework for Sentence Pair Modeling

Various neural networks have been proposed for sentence pair modeling, all of which fall into two types of approaches. The sentence encoding approach encodes each sentence into a fixed-length vector and then computes sentence similarity directly. The model of this type has advantages in the simplicity of the network design and generalization to other NLP tasks. The sentence pair interaction approach takes word alignment and interactions between the sentence pair into account and often show better performance when trained on in-domain data. Here we outline the two types of neural networks under the same general framework:

- **The Input Embedding Layer** takes vector representations of words as input, where pretrained word embeddings are most commonly used, e.g. GloVe (Pennington et al., 2014) or Word2vec (Mikolov et al., 2013). Some work used embeddings specially trained on phrase or sentence pairs that are paraphrases (Wieting and Gimpel, 2017; Tomar et al., 2017); some used subword embeddings, which showed improvement on social media data (Lan and Xu, 2018).
- **The Context Encoding Layer** incorporates word context and sequence order into modeling for better vector representation. This layer often uses CNN (He et al., 2015), LSTM (Chen et al., 2017), recursive neural network (Socher et al., 2011), or highway network (Gong et al., 2017). The sentence encoding type of model will stop at this step, and directly use the encoded vectors to compute the semantic similarity through vector distances and/or the output classification layer.
- **The Interaction and Attention Layer** calculates word pair (or n-gram pair) interactions using the outputs of the encoding layer. This is the key component for the interaction-aggregation type of model. In the PWIM model (He and Lin, 2016), the interactions are calculated by cosine similarity, Euclidean distance, and the dot product of the vectors. Various models put different weights on different interactions, primarily simulating the word alignment between two sentences. The alignment information is useful for sentence pair modeling because the semantic relation between two sentences depends largely on the relations of aligned chunks as shown in the SemEval-2016 task of interpretable semantic textual similarity (Agirre et al., 2016).
- **The Output Classification Layer** adapts CNN or MLP to extract semantic-level features on the attentive alignment and applies softmax function to predict probability for each class.

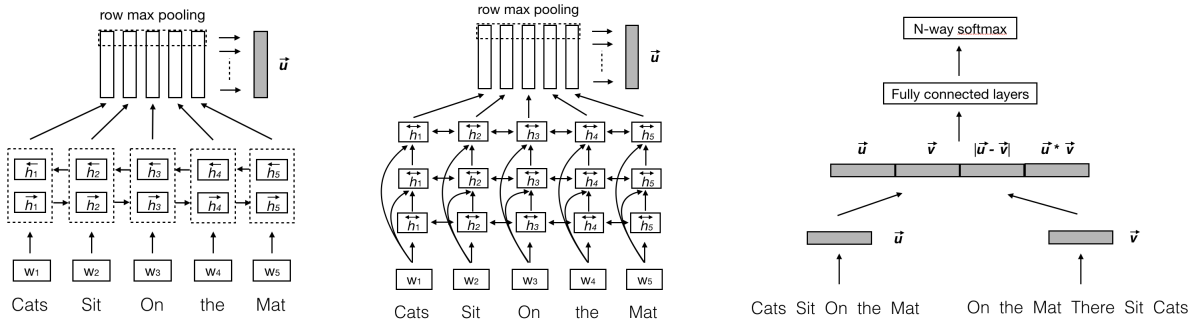
[1]The code is available on the authors' homepages and GitHub: `https://github.com/lanwuwei/SPM_toolkit`

3 Representative Models for Sentence Pair Modeling

Table 1 gives a summary of typical models for sentence pair modeling in recent years. In particular, we investigate five models in depth: two are representative of the sentence encoding type of model, and three are representative of the interaction-aggregation type of model. These models have reported state-or-the-art results with varied architecture design (this section) and implementation details (Section 4.2).

Models	Sentence Encoder	Interaction and Attention	Aggregation and Classification
(Shen et al., 2017b)	Directional self-attention network	-	MLP
(Choi et al., 2017)	Gumbel Tree-LSTM	-	MLP
(Wieting and Gimpel, 2017)	Gated recurrent average network	-	MLP
SSE (Nie and Bansal, 2017)	Shortcut-stacked BiLSTM	-	MLP
(He et al., 2015)	CNN	multi-perspective matching	pooling + MLP
(Rocktäschel et al., 2016)	LSTM	word-by-word neural attention	MLP
(Liu et al., 2016)	LSTM	coupled LSTMs	dynamic pooling + MLP
(Yin et al., 2016)	CNN	attention matrix	logistic regression
DecAtt (Parikh et al., 2016)	-	dot product + soft alignment	summation + MLP
PWIM (He and Lin, 2016)	BiLSTM	cosine, Euclidean, dot product + hard alignment	CNN + MLP
(Wang and Jiang, 2017)	LSTM encodes both context and attention	word-by-word neural attention	MLP
ESIM (Chen et al., 2017)	BiLSTM (Tree-LSTM) before and after attention	dot product + soft alignment	average and max pooling + MLP
(Wang et al., 2017)	BiLSTM	multi-perspective matching	BiLSTM + MLP
(Shen et al., 2017a)	BiLSTM + intra-attention	soft alignment + orthogonal decomposition	MLP
(Ghaeini et al., 2018)	dependent reading BiLSTM	dot product + soft alignment	average and max pooling+MLP

Table 1: Summary of representative neural models for sentence pair modeling. The upper half contains sentence encoding models, and the lower half contains sentence pair interaction models.



(a) InferSent (b) SSE (c) Classification Layer

Figure 1: **Sentence encoding models** focus on learning vector representations of individual sentences and then calculate the semantic relationship between sentences based on vector distance.

3.1 The Bi-LSTM Max-pooling Network (InferSent)

We choose the simple Bi-LSTM max-pooling network from InferSent (Conneau et al., 2017):

$$\overleftrightarrow{\boldsymbol{h}}_i = BiLSTM(\boldsymbol{x}_i, \overleftrightarrow{\boldsymbol{h}}_{i-1}) \tag{1}$$

$$\boldsymbol{v} = max(\overleftrightarrow{\boldsymbol{h}}_1, \overleftrightarrow{\boldsymbol{h}}_2, ..., \overleftrightarrow{\boldsymbol{h}}_n) \tag{2}$$

where $\overleftrightarrow{\boldsymbol{h}}_i$ represents the concatenation of hidden states in both directons. It has shown better transfer learning capabilities than several other sentence embedding models, including SkipThought (Kiros et al., 2015) and FastSent (Hill et al., 2016), when trained on the natural language inference datasets.

3.2 The Shortcut-Stacked Sentence Encoder Model (SSE)

The Shortcut-Stacked Sentence Encoder model (Nie and Bansal, 2017) is a sentence-based embedding model, which enhances multi-layer Bi-LSTM with skip connection to avoid training error accumulation, and calculates each layer as follows:

$$\overleftrightarrow{\boldsymbol{h}}_i^k = BiLSTM(\boldsymbol{x}_i^k, \overleftrightarrow{\boldsymbol{h}}_{i-1}^k) \tag{3}$$

$$\boldsymbol{x}_i^1 = \boldsymbol{w}_i \quad (k=1), \qquad \boldsymbol{x}_i^k = [\boldsymbol{w}_i, \overleftrightarrow{\boldsymbol{h}}_i^{k-1}, \overleftrightarrow{\boldsymbol{h}}_i^{k-2}, ..., \overleftrightarrow{\boldsymbol{h}}_i^1] \quad (k>1) \tag{4}$$

$$\boldsymbol{v} = max(\overleftrightarrow{\boldsymbol{h}}_1^m, \overleftrightarrow{\boldsymbol{h}}_2^m, ..., \overleftrightarrow{\boldsymbol{h}}_n^m) \tag{5}$$

where $\boldsymbol{x}_i^k$ is the input of the kth Bi-LSTM layer at time step i, which is the combination of outputs from all previous layers, $\overleftrightarrow{\boldsymbol{h}}_i^k$ represents the hidden state of the kth Bi-LSTM layer in both directions. The final sentence embedding $\boldsymbol{v}$ is the row-based max pooling over the output of the last Bi-LSTM layer, where n denotes the number of words within a sentence and m is the number of Bi-LSTM layers ($m = 3$ in SSE).

3.3 The Pairwise Word Interaction Model (PWIM)

In the Pairwise Word Interaction model (He and Lin, 2016), each word vector $\boldsymbol{w}_i$ is encoded with context through forward and backward LSTMs: $\overrightarrow{\boldsymbol{h}}_i = LSTM^f(\boldsymbol{w}_i, \overrightarrow{\boldsymbol{h}}_{i-1})$ and $\overleftarrow{\boldsymbol{h}}_i = LSTM^b(\boldsymbol{w}_i, \overleftarrow{\boldsymbol{h}}_{i+1})$. For every word pair $(\boldsymbol{w}_i^a, \boldsymbol{w}_j^b)$ across sentences, the model directly calculates word pair interactions using cosine similarity, Euclidean distance, and dot product over the outputs of the encoding layer:

$$D(\overrightarrow{\boldsymbol{h}}_i, \overrightarrow{\boldsymbol{h}}_j) = [cos(\overrightarrow{\boldsymbol{h}}_i, \overrightarrow{\boldsymbol{h}}_j), \|\overrightarrow{\boldsymbol{h}}_i - \overrightarrow{\boldsymbol{h}}_j\|, \overrightarrow{\boldsymbol{h}}_i \cdot \overrightarrow{\boldsymbol{h}}_j] \tag{6}$$

The above equation not only applies to forward hidden state $\overrightarrow{\boldsymbol{h}}_i$ and backward hidden state $\overleftarrow{\boldsymbol{h}}_i$, but also to the concatenation $\overleftrightarrow{\boldsymbol{h}}_i = [\overrightarrow{\boldsymbol{h}}_i, \overleftarrow{\boldsymbol{h}}_i]$ and summation $\boldsymbol{h}_i^+ = \overrightarrow{\boldsymbol{h}}_i + \overleftarrow{\boldsymbol{h}}_i$, resulting in a tensor $\mathbf{D}^{13 \times |sent1| \times |sent2|}$ after padding one extra bias term. A "hard" attention is applied to the interaction tensor to build word alignment: selecting the most related word pairs and increasing the corresponding weights by 10 times. Then a 19-layer deep CNN is applied to aggregate the word interaction features for final classification.

3.4 The Decomposable Attention Model (DecAtt)

The Decomposable Attention model (Parikh et al., 2016) is one of the earliest models to introduce attention-based alignment for sentence pair modeling, and it achieved state-of-the-art results on the SNLI dataset with about an order of magnitude fewer parameters than other models (see more in Table 5) without relying on word order information. It computes the word pair interaction between $\boldsymbol{w}_i^a$ and $\boldsymbol{w}_j^b$ (from input sentences s_a and s_b, each with m and n words, respectively) as $e_{ij} = F(\boldsymbol{w}_i^a)^T F(\boldsymbol{w}_j^b)$, where F is a feedforward network; then alignment is determined as follows:

$$\boldsymbol{\beta}_i = \sum_{j=1}^{n} \frac{exp(e_{ij})}{\sum_{k=1}^{n} exp(e_{ik})} \boldsymbol{w}_j^b \qquad\qquad \boldsymbol{\alpha}_j = \sum_{i=1}^{m} \frac{exp(e_{ij})}{\sum_{k=1}^{m} exp(e_{kj})} \boldsymbol{w}_i^a \tag{7}$$

where $\boldsymbol{\beta}_i$ is the soft alignment between $\boldsymbol{w}_i^a$ and subphrases $\boldsymbol{w}_j^b$ in sentence s_b, and vice versa for $\boldsymbol{\alpha}_j$. The aligned phrases are fed into another feedforward network G: $\boldsymbol{v}_i^a = G([\boldsymbol{w}_i^a; \boldsymbol{\beta}_i])$ and $\boldsymbol{v}_j^b = G([\boldsymbol{w}_j^b; \boldsymbol{\alpha}_j])$ to generate sets $\{\boldsymbol{v}_i^a\}$ and $\{\boldsymbol{v}_j^b\}$, which are aggregated by summation and then concatenated together for classification.

3.5 The Enhanced Sequential Inference Model (ESIM)

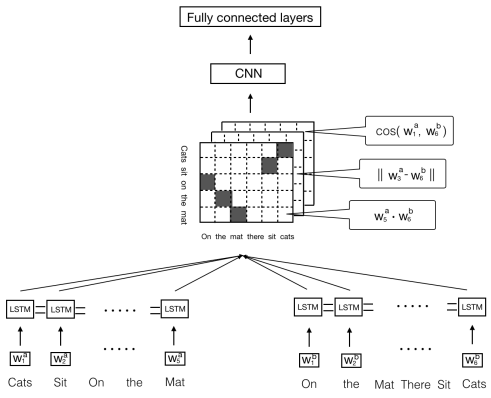
The Enhanced Sequential Inference Model (Chen et al., 2017) is closely related to the DecAtt model, but it differs in a few aspects. First, Chen et al. (2017) demonstrated that using Bi-LSTM to encode sequential contexts is important for performance improvement. They used the concatenation $\overline{\boldsymbol{w}}_i = \overleftrightarrow{\boldsymbol{h}}_i = [\overrightarrow{\boldsymbol{h}}_i, \overleftarrow{\boldsymbol{h}}_i]$ of both directions as in the PWIM model. The word alignment $\boldsymbol{\beta}_i$ and $\boldsymbol{\alpha}_j$ between $\overline{\boldsymbol{w}}^a$ and $\overline{\boldsymbol{w}}^b$ are calculated the same way as in DecAtt. Second, they showed the competitive performance of recursive architecture with constituency parsing, which complements with sequential LSTM. The feedforward function G in DecAtt is replaced with Tree-LSTM:

$$\boldsymbol{v}_i^a = TreeLSTM([\overline{\boldsymbol{w}}_i^a; \boldsymbol{\beta}_i; \overline{\boldsymbol{w}}_i^a - \boldsymbol{\beta}_i; \overline{\boldsymbol{w}}_i^a \odot \boldsymbol{\beta}_i]) \tag{8}$$

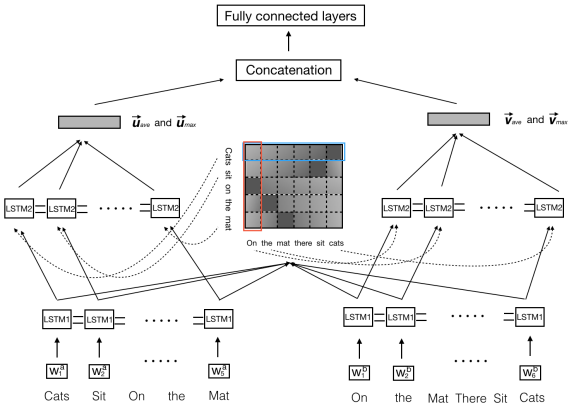
$$\boldsymbol{v}_j^b = TreeLSTM([\overline{\boldsymbol{w}}_j^b; \boldsymbol{\alpha}_j; \overline{\boldsymbol{w}}_j^b - \boldsymbol{\alpha}_j; \overline{\boldsymbol{w}}_j^b \odot \boldsymbol{\alpha}_j]) \tag{9}$$

Third, instead of using summation in aggregation, ESIM adapts the average and max pooling and concatenation $\boldsymbol{v} = [\boldsymbol{v}_{ave}^a; \boldsymbol{v}_{max}^a; \boldsymbol{v}_{ave}^b; \boldsymbol{v}_{max}^b]$ before passing through multi-layer perceptron (MLP) for classification:

$$\boldsymbol{v}_{ave}^a = \sum_{i=1}^{m} \frac{\boldsymbol{v}_i^a}{m}, \qquad \boldsymbol{v}_{max}^a = \max_{i=1}^{m} \boldsymbol{v}_i^a, \qquad \boldsymbol{v}_{ave}^b = \sum_{j=1}^{n} \frac{\boldsymbol{v}_j^b}{n}, \qquad \boldsymbol{v}_{max}^b = \max_{j=1}^{n} \boldsymbol{v}_j^b \tag{10}$$



(a) PWIM



(b) ESIM$_{seq}$ (DecAtt is similar and simpler.)

Figure 2: **Sentence pair interaction models** use different word alignment mechanisms before aggregation.

4 Experiments and Analysis

4.1 Datasets

We conducted sentence pair modeling experiments on eight popular datasets: two NLI datasets, three PI datasets, one STS dataset and two QA datasets. Table 2 gives a comparison of these datasets:

- **SNLI** (Bowman et al., 2015) contains 570k hypotheses written by crowdsourcing workers given the premises. It focuses on three semantic relations: the premise entails the hypothesis (entailment), they contradict each other (contradiction), or they are unrelated (neutral).
- **Multi-NLI** (Williams et al., 2017) extends the SNLI corpus to multiple genres of written and spoken texts with 433k sentence pairs.

Dataset	Size		Example and Label	
SNLI	train	550,152	s_a: *Two men on bicycles competing in a race.* s_b: *Men are riding bicycles on the street.*	**entailment**
	dev	10,000		neutral
	test	10,000		contradict
Multi-NLI	train	392,703	s_a: *The Old One always comforted Ca'daan, except today.* s_b: *Ca'daan knew the Old One very well.*	entailment
	dev	20,000		**neutral**
	test	20,000		contradict
Quora	train	384,348	s_a: *What should I do to avoid sleeping in class?* s_b: *How do I not sleep in a boring class?*	**paraphrase**
	dev	10,000		non-paraphrase
	test	10,000		
Twitter-URL	train	42,200	s_a: *Letter warned Wells Fargo of "widespread" fraud in 2007.* s_b: *Letters suggest Wells Fargo scandal started earlier.*	**paraphrase**
	dev	-		non-paraphrase
	test	9,324		
PIT-2015	train	11,530	s_a: *Ezekiel Ansah w the 3D shades Popped out lens* s_b: *Ezekiel Ansah was wearing lens less 3D glasses*	**paraphrase**
	dev	4,142		non-paraphrase
	test	838		
STS-2014	train	7,592	s_a: *Then perhaps we could have avoided a catastrophe.* s_b: *Then we might have been able to avoid a disaster.*	score $[0, 5]$
	dev	-		**4.6**
	test	3,750		
WikiQA	train	8,672	s_a: *How much is 1 tablespoon of water?* s_b: *In Australia one tablespoon (measurement unit) is 20 mL.*	**true**
	dev	1,130		false
	test	2,351

Table 2: Basic statistics and examples of different datasets for sentence pair modeling tasks.

- **Quora** (Iyer et al., 2017) contains 400k question pairs collected from the Quora website. This dataset has balanced positive and negative labels indicating whether the questions are duplicated or not.
- **Twitter-URL** (Lan et al., 2017) includes 50k sentence pairs collected from tweets that share the same URL of news articles. This dataset contains both formal and informal language.
- **PIT-2015** (Xu et al., 2015) comes from SemEval-2015 and was collected from tweets under the same trending topic. It contains naturally occurred (i.e. written by independent Twitter users spontaneously) paraphrases and non-paraphrases with varied topics and language styles.
- **STS-2014** (Agirre et al., 2014) is from SemEval-2014, constructed from image descriptions, news headlines, tweet news, discussion forums, and OntoNotes (Hovy et al., 2006).
- **WikiQA** (Yang et al., 2015) is an open-domain question-answering dataset. Following He and Lin (2016), questions without correct candidate answer sentences are excluded, and answer sentences are truncated to 40 tokens, resulting in 12k question-answer pairs for our experiments.
- **TrecQA** (Wang et al., 2007) is an answer selection task of 56k question-answer pairs and created in Text Retrieval Conferences (TREC). For both WikiQA and TrecQA datasets, the best answer is selected according to the semantic relatedness with the question.

4.2 Implementation Details

We implement all the models with the same PyTorch framework.[2][3] Below, we summarize the implementation details that are key for reproducing results for each model:

- **SSE:** This model can converge very fast, for example, 2 or 3 epochs for the SNLI dataset. We control the convergence speed by updating the learning rate for each epoch: specifically, $lr = \frac{1}{2^{\frac{epoch\_i}{2}}} * init\_lr$, where $init\_lr$ is the initial learning rate and $epoch\_i$ is the index of current epoch.

[2]InferSent and SSE have open-source PyTorch implementations by the original authors, for which we reused part of the code.
[3]Our code is available at: `https://github.com/lanwuwei/SPM_toolkit`

- **DecAtt:** It is important to use gradient clipping for this model: for each gradient update, we check the L2 norm of all the gradient values, if it is greater than a threshold b, we scale the gradient by a factor $\alpha = b/L2\_norm$. Another useful procedure is to assemble batches of sentences with similar length.
- **ESIM:** Similar but different from DecAtt, ESIM batches sentences with varied length and uses masks to filter out padding information. In order to batch the parse trees within Tree-LSTM recursion, we follow Bowman et al.'s (2016) procedure that converts tree structures into the linear sequential structure of a shift reduce parser. Two additional masks are used for producing left and right children of a tree node.
- **PWIM:** The cosine and Euclidean distances used in the word interaction layer have smaller values for similar vectors while dot products have larger values. The performance increases if we add a negative sign to make all the vector similarity measurements behave consistently.

4.3 Analysis

4.3.1 Re-implementation Results vs. Previously Reported Results

Table 3 and 4 show the results reported in the original papers and the replicated results with our implementation. We use accuracy, F1 score, Pearson's r, Mean Average Precision (MAP), and Mean Reciprocal Rank (MRR) for evaluation on different datasets following the literature. Our reproduced results are slightly lower than the original results by $0.5 \sim 1.5$ points on accuracy. We suspect the following potential reasons: (i) less extensive hyperparameter tuning for each individual dataset; (ii) only one run with random seeding to report results; and (iii) use of different neural network toolkits: for example, the original ESIM model was implemented with Theano, and PWIM model was in Torch.

4.3.2 Effects of Model Components

Herein, we examine the main components that account for performance in sentence pair modeling.

How important is LSTM encoded context information for sentence pair modeling?
Regarding DecAtt, Parikh et al. (2016) mentioned that "intra-sentence attention is optional"; they can achieve competitive results without considering context information. However, not surprisingly, our experiments consistently show that encoding sequential context information with LSTM is critical. Compared to DecAtt, ESIM shows better performance on every dataset (see Table 4 and Figure 3). The main difference between ESIM and DecAtt that contributes to performance improvement, we found, is the use of Bi-LSTM and Tree-LSTM for sentence encoding, rather than the different choices of aggregation functions.

Why does Tree-LSTM help with Twitter data?
Chen et al. (2017) offered a simple combination (ESIM$_{seq+tree}$) by averaging the prediction probabilities of two ESIM variants that use sequential Bi-LSTM and Tree-LSTM respectively, and suggested "parsing information complements very well with ESIM and further improves the performance". However, we found that adding Tree-LSTM only helps slightly or not at all for most datasets, but it helps noticably with the two Twitter paraphrase datasets. We hypothesize the reason is that these two datasets come from real-world tweets which often contain extraneous text fragments, in contrast to SNLI and other datasets that have sentences written by crowdsourcing workers. For example, the segment "*ever wondered ,*" in the sentence pair *ever wondered , why your recorded #voice sounds weird to you?* and *why do our recorded voices sound so weird to us?* introduces a disruptive context into the Bi-LSTM encoder, while Tree-LSTM can put it in a less important position after constituency parsing.

How important is attentive interaction for sentence pair modeling? Why does SSE excel on Quora?
Both ESIM and DecAtt (Eq. 7) calculate an attention-based soft alignment between a sentence pair, which was also proposed in (Rocktäschel et al., 2016) and (Wang and Jiang, 2017) for sentence pair modeling, whereas PWIM utilizes a hard attention mechanism. Both attention strategies are critical for model performance. In PWIM model (He and Lin, 2016), we observed a 1$\sim$2 point performance drop after

Model	SNLI	Multi-NLI	Quora	Twitter-URL	PIT-2015	STS-2014	WikiQA	TrecQA

Table 4: Replicated results with our reimplementation in PyTorch across multiple tasks and datasets. The best result in each dataset is denoted by a **bold** typeface, and the second best is denoted by an underline.

removing the hard attention, 0∼3 point performance drop and ∼25% training time reduction after removing the 19-layer CNN aggregation. Likely without even the authors of SSE knowing, the SSE model performs extraordinarily well on the Quora corpus, perhaps because Quora contains many sentence pairs with less complicated inter-sentence interactions (e.g., many identical words in the two sentences) and incorrect ground truth labels (e.g., *What is your biggest regret in life?* and *What's the biggest regret you've had in life?* are labeled as non-duplicate questions by mistake).

4.3.3 Learning Curves and Training Time

Figure 3 shows the learning curves. The DecAtt model converges quickly and performs well on large NLI datasets due to its design simplicity. PWIM is the slowest model (see time comparison in Table 5) but shows very strong performance on semantic similarity and paraphrase identification datasets. ESIM and SSE keep a good balance between training time and performance.

[3]This number was reported in (Tomar et al., 2017) by co-authors of DecAtt (Parikh et al., 2016).
[4]This number was reproduced by Williams et al. (2017).
[5]This number was generated by InferSent traind on SNLI and Multi-NLI datasets.

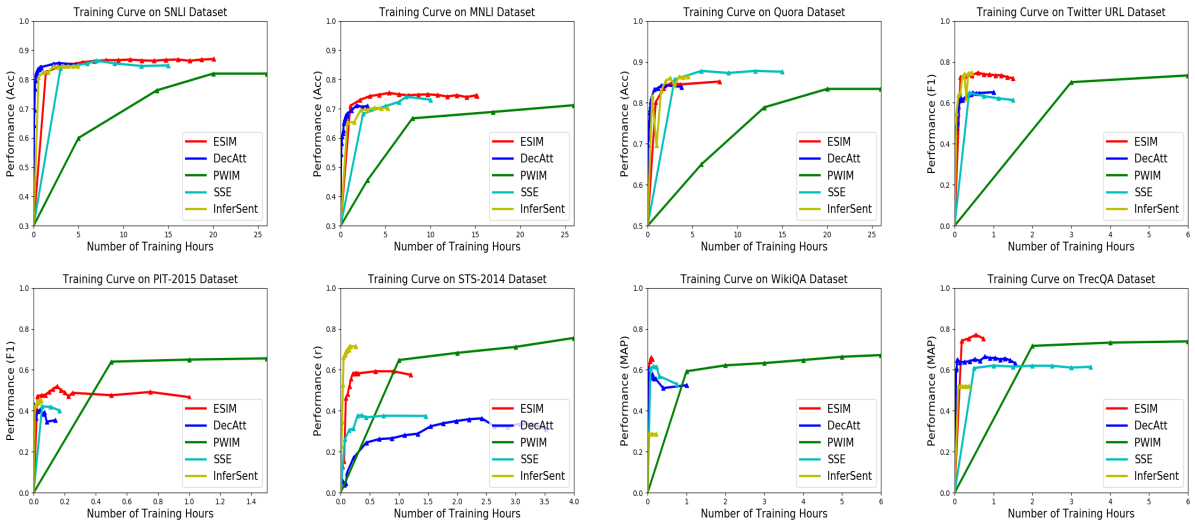

Figure 3: Training curves of ESIM, DecAtt, PWIM, SSE and InferSent models on eight datasets.

	InferSent	**SSE**	**DecAtt**	**ESIM$_{seq}$**	**ESIM$_{tree}$**	**PWIM**

Avg epoch time (seconds) / sentence pair	0.005	0.032	0.0006	0.013	0.016	0.60
Ratio compared to DecAtt model	$\times$8	$\times$53	1	$\times$22	$\times$26	$\times$1000

Table 5: Average training time per sentence pair in the Twitter-URL dataset (similar time for other datasets).

4.3.4 Effects of Training Data Size

As shown in Figure 4, we experimented with different training sizes of the largest SNLI dataset. All the models show improved performance as we increase the training size. ESIM and SSE have very similar trends and clearly outperform PWIM on the SNLI dataset. DecAtt shows a performance jump when the training size exceeds a threshold.

4.3.5 Categorical Performance Comparison

We conducted an in-depth analysis of model performance on the Multi-domain NLI dataset based on different categories: text genre, sentence pair overlap, and sentence length. As shown in Table 7, all models have comparable performance between matched genre and unmatched genre. Sentence length and overlap turn out to be two important factors – the longer the sentences and the fewer tokens in common, the more challenging it is to determine their semantic relationship. These phenomena shared by the state-of-the-art systems reflect their similar design framework which is symmetric at processing both sentences in the pair, while question answering and natural language inference tasks are directional (Ghaeini et al., 2018). How to incorporate asymmetry into model design will be worth more exploration in future research.

4.3.6 Transfer Learning Experiments

In addition to the cross-domain study (Table 7), we conducted transfer learning experiments on three paraphrase identification datasets (Table 6). The most noteworthy phenomenon is that the SSE model performs better on Twitter-URL and PIT-2015 when trained on the large out-of-domain Quora data than the small in-domain training data. Two likely reasons are: 1) the SSE model with over 29 million parameters is data hungry and 2) SSE model is a sentence encoding model, which generalizes better across domains/tasks than sentence pair interaction models. Sentence pair interaction models may encounter difficulties on Quora, which contains sentence pairs with the highest word overlap (51.5%) among all datasets and often causes

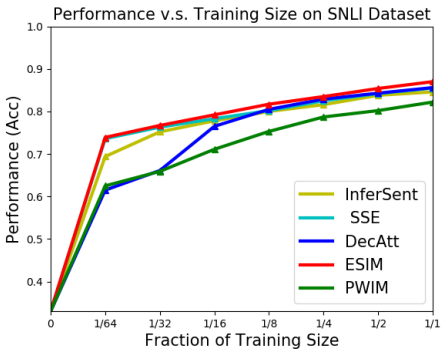

Figure 4: Performance vs. training size (log scale in x-axis) on SNLI dataset.

the interaction patterns to focus on a few key words that differ. In contrast, the Twitter-URL dataset has the lowest overlap (23.0%) with a semantic relationship that is mainly based on the intention of the tweets.

5 Conclusion

We analyzed five different neural models (and their variations) for sentence pair modeling and conducted a series of experiments with eight representative datasets for different NLP tasks. We quantified the importance of the LSTM encoder and attentive alignment for inter-sentence interaction, as well as the transfer learning ability of sentence encoding based models. We showed that the SNLI corpus of over 550k sentence pairs cannot saturate the learning curve. We systematically compared the strengths and weaknesses of different network designs and provided insights for future work.

Abstract

Most previous work in unsupervised semantic modeling in the presence of metadata has assumed that our goal is to make latent dimensions *more* correlated with metadata, but in practice the exact opposite is often true. Some users want topic models that highlight differences between, for example, authors, but others seek more subtle connections across authors. We introduce three metrics for identifying topics that are highly correlated with metadata, and demonstrate that this problem affects between 30 and 50% of the topics in models trained on two real-world collections, regardless of the size of the model. We find that we can predict which words cause this phenomenon and that by selectively subsampling these words we dramatically reduce topic-metadata correlation, improve topic stability, and maintain or even improve model quality.

1 Introduction

Unsupervised semantic models are a popular and useful method for inferring low-dimensional representations of large text collections. Examples of such models include latent semantic analysis (Deerwester et al., 1990) and word embeddings (Bengio et al., 2003), but for this work we will focus on statistical topic models (Hofmann, 1999; Blei et al., 2002), which are used to infer word distributions that correspond to recognizable themes. In practice, collections are often constructed by combining documents from multiple sources, which may have distinctive style and vocabulary. This heterogeneity of sources leads to a serious but rarely studied problem: the strongest, most prominent patterns in a collection may simply repeat the known structure of the corpus. Instead of finding informative, cross-cutting themes, models simply repeat the distinctive vocabulary of the individual sources. The model in this case is "correct" in that it has detected the strongest dimensions of variation, but it tells us nothing we did not already know.

As a motivating example, we focus on models trained on novels, where it is known that inferred topics are often simply names of characters and settings (Jockers, 2013). The words *Harry*, *Ron*, and *Hermione* look to the algorithm like the basis of an ideal topic because they occur very frequently together but not in other contexts. But this topic only tells us which books within a larger corpus are part of the *Harry Potter* series; themes like friendship, adolescence, and magic remain hidden. This phenomenon is not limited to fiction: we also include a case study of opinions from US state supreme courts. Unlike examples from fiction, Maine and Utah both exist in the same universe, but exhibit specific regional term use.

We begin by demonstrating that the problem of overly source-specific topics is both substantial and measurable. We present three metrics that provide related but distinct views of source specificity. These metrics are orthogonal to existing metrics of topic semantic quality: uselessly source-specific topics are often still highly coherent and meaningful. These metrics are also inversely related to commonly-used document classification evaluations. Learning 20 newsgroup-specific topics from 20 Newsgroups may be informative as an evaluation, but in practice users are rarely unaware of such structure.

Finally, we present a simple but effective method for reducing the prevalence of source-specific topics. This method relies on probabilistically subsampling words that correlate with known source metadata, and

Proceedings of the 27th International Conference on Computational Linguistics, pages 3903–3914
Santa Fe, New Mexico, USA, August 20-26, 2018.

is related to subsampling methods that have been highly effective in word embeddings (Mikolov et al., 2013; Levy et al., 2015). The best of the proposed methods substantially reduces source-specific topics, increases topic differentiation without increasing model complexity, and improves topic stability.

2 Related Work

The common assumption of prior work on metadata-aware topic modeling has been that metadata provides valuable hints that can be used to improve topics. Several methods use document metadata to influence document-level topic distributions. The author-topic model (Rosen-Zvi et al., 2004), relational topic model (Chang and Blei, 2009), and labeled LDA (Ramage et al., 2009) extend LDA by directly incorporating a particular type of metadata (e.g. author information, document links, user-generated tags) into the model. Others, like factorial LDA (Paul and Dredze, 2012), Dirichlet-multinomial regression topic models (Mimno and McCallum, 2008), and structural topic models (Roberts et al., 2014) incorporate more general categories of metadata. All of these aim to *increase* dependence between topics and metadata. In contrast, our goal is to make topics *independent* of specified metadata.

Other research makes topic-word distributions sensitive to document-level metadata. The special words with background model (Chemudugunta et al., 2006) incorporates document-specific word distributions into LDA, while cross-collection LDA (Paul, 2009) incorporates collection level word distributions. The topic-aspect model (Paul and Girju, 2010) extends LDA to include a mixture of aspects of documents such that aspects affect all topics similarly. Although these models may be able to sequester author-specific words, there is no reason to expect that those words will not also drag along general, cross-cutting words.

In this paper we focus on ways to explicitly identify words that bias topics towards a specific metadata tag and modify the input corpus for an algorithm to reduce their effect. Researchers have often dismissed this sort of data curation as unprincipled and heuristic "preprocessing." More recent work (Denny and Spirling, 2016; Boyd-Graber et al., 2014) emphasizes that *meta-algorithms* for data preparation can greatly affect the intrinsic model quality and human interpretability of topic models.

3 Collections and Models

We collected two real-world corpora that combine text from multiple distinct sources: science fiction novels and U.S. state supreme court opinions.[1]

Science Fiction (SCI-FI). We selected 1206 science fiction novels by 245 authors based on award nominations and curated book lists hosted on Worlds Without End.[2] We consider each author as a source, and treat collaborations as distinct sources. We augmented the corpus with other established authors to increase the diversity of author gender and ethnicity. The novels span from the early 1800s to the present day. Most of these works are currently protected by copyright, so rather than full text we obtained page-level word frequency statistics from the HathiTrust Research Center's Extracted Features Dataset (Capitanu et al., 2016). This data indicates, for example, that page 227 of *Dune* contains one instance of the word *storm* as a noun. Following previous work (Jockers, 2013) we divide volume-length works into page-level segments, omitting headers and footers.

Corpus	Authors	Docs	Types	Avg Len
SCI-FI	245	327K	132K	153
COURTS	50	52K	89K	1039

Table 1: Corpus statistics for the number of authors, documents, and word types, as well as average document length. Document and word type counts are listed in thousands (K).

U.S. State Supreme Courts (COURTS). Each U.S. state has a supreme court that decides appeals for decisions made by lower state courts. In this collection each document is a court opinion, written by the court after the completion of a case, summarizes the case and judgment. We treat each state court as a source, expecting that courts use geographically specific language (e.g. Colorado, Denver, Colo., Boulder)

[1] Coda and data is available at `https://github.com/laurejt/authorless-tms`.

[2] `https://www.worldswithoutend.com/lists.asp`

that is not relevant to the legal content of opinions. We examine court opinions for all 50 state supreme courts for cases filed from 2012 through 2016.[3]

Data Preparation. We apply the same initial treatment to both corpora. Tokens are three or more letter characters with possible internal punctuation (excluding em- and en-dashes). Words are lower-cased. To deal with globally frequent terms, we remove words used by more than 25% of documents in a corpus. To reduce the computational burden of a large vocabulary, we remove words occurring in fewer than five documents. We remove all documents with fewer than 20 tokens. This process removes 706 pages and 9192 court opinions from our starting science fiction and state courts corpora.

We train LDA models using Mallet (McCallum, 2002) with hyperparameter optimization occurring every 20 intervals after the first 50. We set the number of topics to be on the same order as the number of sources, so for SCI-FI we use $K \in [125, 250, 375]$ and for COURTS we use $K \in [25, 50, 75]$.

4 Evaluating Topic-Author Correlation

We introduce three ways to measure the source-specificity of topics. For concreteness we will use the terms "source" and "author" interchangeably, but a document's source could be any categorical variable. We want to identify topics that are used by relatively few authors, and more specifically topics whose "meaning" is unduly influenced by the contributions of relatively few authors.

Given a collection of D documents written by A authors such that each document d is written by a single author a, we train an LDA topic model with K topics. Then for each word token i in document d we have both a word type w_{id} and a posterior distribution over its token-level topic assignment z_{di}. For clarity of presentation we can assume a single topic assignment for each token and view the corpus as a data table with three columns: word type w, topic z, and author a. By summing over rows of this table we can define marginal count variables for authors $N(a)$ and topics $N(k)$ as well as joint count variables for the count of a word in a topic $N(w, k)$, a topic in an author $N(k, a)$, and a word in a topic in an author $N(w, k, a)$. A maximum likelihood estimate of the probability of word w given topic k is $P(w \mid k) = \frac{N(w,k)}{N(k)}$.[4]

We note that these statistics must be defined at the token level. As in Mimno and Blei (2011) we are looking for violations of the assumption that $\Pr(w \mid k) = \Pr(w \mid d, k)$. Gibbs sampling algorithms typically preserve token-level information in the form of sampling states, but EM-based algorithms often preserve only document-topic distributions θ_d and topic-word distributions ϕ_k. We can estimate the posterior distribution over topic assignments for each token in document d with word type w as $\Pr(z \mid d, k) \propto \sum_k \phi_k(w)\theta_d(k)$, and generate sparse representations by sampling from this distribution.

Author Entropy. We begin by measuring a topic's author diversity—how evenly its tokens are spread across authors—using the conditional entropy of authors given a topic (Eq. 1). Topics whose tokens are largely concentrated within a few authors will have low entropy, while topics more evenly spread across many authors will have high entropy. With asymmetric hyperparameter optimization we find that the most frequent topics (large α_k) have high author entropy, but topics with high author entropy can have a wide range of frequencies: topics can be both rare and well-distributed.

$$H(A \mid k) = \sum_a \Pr(a \mid k) \log_2 \Pr(a \mid k) = \sum_a \frac{N(a,k)}{N(k)} \log_2 \frac{N(a,k)}{N(k)} \quad (1)$$

While author entropy provides a general sense of author diversity, it does not take into account the expression of topics by authors. Content-based evaluation is especially important because many collections are not well balanced across authors. The fact that a topic is not balanced across authors does not necessarily imply that it is problematic. A novel about the voyages of a ship captain may contain a large proportion of words about sea travel and ships, while a novel that contains one minor character who is a ship captain may contain a small proportion of the same language, used in the same way. We therefore

[3] https://www.courtlistener.com

[4] We do not use Dirichlet smoothing for the purposes of this work for simplicity and to make more reliable comparisons across varying vocabulary sizes. Results using smoothing are similar.

need to be able to distinguish two cases: first, a topic that is consistent across authors but that is used at different rates by different authors, and second, a topic that is not only used at different rates but has different contents across authors. In the first case we can accurately use a topic to "stand for" a particular concept of interest, while in the second case we would get a false impression of the contents of documents, because the expression of the topic in the minority authors differs from the topic as a whole.

To differentiate expected author imbalance from pathological cases, we calculate Jensen-Shannon divergence between a topic's word distribution as estimated from the full collection $\Pr(w|k)$ and two distributions that have been transformed to reduce the influence of the most prominent authors. If the topic has low author correlation then there will be little divergence between the original distribution and its transformation. This method mimics a technique for identifying "junk" topics by AlSumait et al. (2009).

Minus Major Author. The first transformed distribution M (Eq. 2) recalculates the probability of words based on all documents *except* those written by the majority author. If a topic is consistent across authors then the presence or absence of its largest author contribution (labeled a_{major}) should have little effect on the topic's word distribution. The larger the resulting divergence, the more influence the major author has over the topic. Unlike author entropy, this technique does not inherently favor balanced distributions of authors; a very author-imbalanced (low entropy) topic can still have a low minus major author divergence if the dominating author's contribution agrees with the remaining topic tokens.

$$\Pr(w \mid M_k) = \Pr(w \mid \neg a_{major}, k) = \frac{N(w,k) - N(w, a_{major}, k)}{N(k) - N(a_{major}, k)} \tag{2}$$

Balanced Authors. The second transformed distribution B (Eq. 3) treats the contribution of each author equally, no matter how many words in that topic the author produces. The minus-major metric is most sensitive to the case where a single author dominates a topic, but does not handle the case where a small group of authors dominates. Using the balanced transformation we measure the similarity of each author contribution. The larger the resulting divergence between the original and transformed word distributions, the larger the variance in contributing author token usage.

$$\Pr(w \mid B_k) \propto \sum_a \Pr(w \mid k, a) = \sum_a \frac{N(w,k,a)}{N(k,a)} \tag{3}$$

We check the validity of our metrics by evaluating topic models trained on SCI-FI for a wide range of topic sizes (125–1000). As seen in Figure 1, all three measures produce bimodal distributions for all topic sizes, combining highly author-specific topics and more general cross-cutting ones. The proportion of cross-cutting topics remains fairly constant across topic sizes: for all of these models, over 50% of topics fall in the source-specific range. We emphasize that source-specific topics are not necessarily "bad". If the structure of the corpus were not known, these topics would provide a highly useful and coherent insight into that structure. But if, as is typical, the structure *is* known, more than half of the statistical capacity of these models is wasted learning distributions that simply reiterate known structure, regardless of the number of topics.

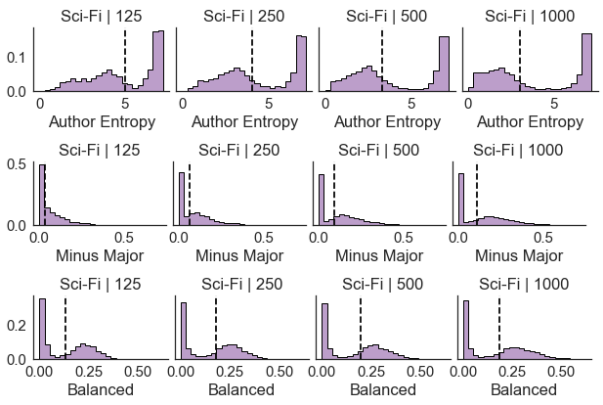

Figure 1: Author entropy, minus major author divergence, and balanced author divergence for topics in topic models trained on SCI-FI. Dashed lines indicate medians. Increasing the number of topics in a model does not reduce the proportion of author-specific topics.

While all three measurements produce similarly shaped distributions, they do not always agree in detail. Table 2 shows example topics that provide intuition for these differences. At the extremes, Topic A is a general, cross-cutting topic while Topic G is dramatically author-specific. While all three metrics score well for Topics A and B, in Topic B the word

Topic	Entropy	Minus Major	Balanced	Top Words
A	6.79	0.00067	0.017	school professor work university years research science students student college study class year history scientific theory young new field physics
B	6.67	0.0047	0.032	doctor paul hospital nurse patient medical patients doctors room ward bed drugs treatment clinic drug case mental sick therapy medicine

Table 2: Topics from a 250-topic model trained on SCI-FI and their corresponding measures of author entropy, minus major author, and balanced authors. Underlined values indicate poor quality scores and bolded terms indicate word types with low (< 1) author entropy within the topic.

paul seems out of place, but it is common enough in several authors that its word-level author entropy is not low. Topics E and G both score poorly in all three metrics, and both are highly specific to single authors (Isaac Asimov and Anne McCaffrey). But while G is clearly and exclusively names and settings, E contains the common terms *robot*, *robots*, and *human*, and could be confused for a general topic on artificial intelligence.

The metrics are also enlightening when they disagree. Topic C has high author entropy, but only because it mixes highly author-specific words from several different authors. Since each author's contribution differs from the others it scores poorly on the two content-based metrics. Topic D is partially about Mars, but also contains author-specific character names from stories set on Mars. No single author dominates, but the contributions of each author look different. Topic F is so highly correlated with Ray Bradbury that its entropy is low and it looks different when his contribution is removed, but its words are sufficiently general that Bradbury's use of the topic is close to the other authors' (minimal) use.

5 Contextual Probabilistic Subsampling

In this section we present interventions that predict the effect of words and contexts, and modify an input corpus to reduce the number of overly author-specific topics in resulting models. We hypothesize that this problem is due to *burstiness* (Doyle and Elkan, 2009): words that are globally rare, but locally frequent. Dampening the author-specificity of individual word types may reduce their connection to document sources. We therefore evaluate context-specific subsampling prior to modeling, with parameters defined based on tail probabilities of word-specific parametric models.

In selecting this particular approach we follow three design principles that we believe maximize use in actual practice. First, we want interventions to be minimal and have the least possible disruption to current work processes. We therefore choose to focus on meta-algorithms for data preparation that are compatible with but independent from existing, widely implemented inference algorithms. Second, we want any user-specified parameter choices to be simple and intuitive. Although we find that entropy is a useful diagnostic metric, information theoretic metrics such as mutual information are difficult for non-experts to interpret correctly, and critical values can differ widely across collections and dimensionalities. Third, we want both the choice of interventions and the effects of interventions to be transparent to users. We initially considered methods such as adversarially trained autoencoders, but we find that directly subsampling words is much faster, simpler, and easier to explain.

Identifying Author Specific Terms. The simplest way to find author-specific terms is to find terms unique to an author. The SCI-FI collection contains an unusual number of author-specific coinages, but words used by many authors can still be highly correlated with a particular author. We therefore estimate parametric distributions for each term and compare author-specific term proportions to this

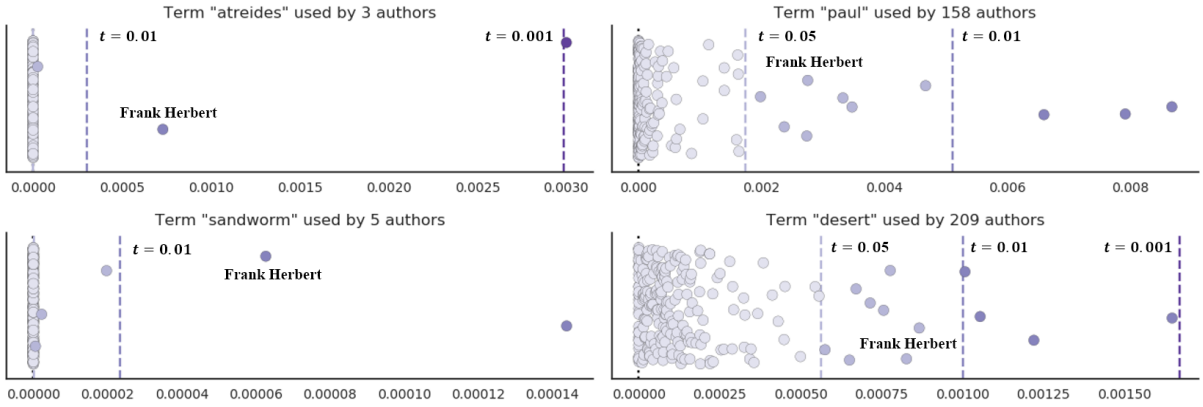

Figure 2: Reasonable threshold values t flag both rare words (left) and common words being used in author-specific ways (right). Each point represents the relative frequency of a term (x-axis) for an author (y-axis) in SCI-FI.

distribution. For each word type w, we calculate the sample mean $\bar{x}_w$ and variance s_w^2 and construct a gamma distribution Γ_w with shape $k = \bar{x}_w^2/s_w^2$ and rate $\theta = s_w^2/\bar{x}_w$. Similar to a significance test, given a user-specified probability threshold t we can define a critical term proportion value under Γ_w

$$\Pr[\Gamma_w \leq f_w^*] \leq 1 - t. \tag{4}$$

A word w is thus considered too specific to an author a if a's usage is too unlikely to occur according to Γ_w. Specifically, this occurs when the frequency $f_{w,a}$ is larger than the cutoff frequency f_w^* defined in Eq. 3. This method satisfies our design goals of simplicity and transparency: the threshold is intuitive and can be adjusted to change how aggressively words are flagged for curation.

Figure 2 shows two character names and nouns from Frank Herbert's *Dune*, where one name and noun are rare and the others are frequent. We see that the rare words *atreides* and *sandworm* are significant to Frank Herbert for $t = 0.01$: there is essentially no "normal" level of use of these words in other authors. Herbert also uses the more common terms *paul* and *desert* more than expected, but to a lesser extreme.

Determining Stop Rates. How we choose to dampen author-specific words is as important as how we detect them. If we globally removed these words using a traditional stoplist, we would lose a substantial portion of the vocabulary. A more sophisticated approach is to construct a stoplist for each author. In this case, words are only removed from contexts in which they are statistically overrepresented. For rare terms, where there is no middle ground between significant use and no use at all, this contextual treatment is effectively the same as a traditional stoplist. But for a word with more widespread use, that word would disappear only from contexts with abnormally high usage.

While this technique avoids erasing the majority of a collection's vocabulary, it leads to a paradoxical situation where a word that is thematically central to a work occurs *less* frequently in that work than in other works. Entirely removing *desert* from Frank Herbert or *robot* from Isaac Asimov would reduce the model's ability to identify relevant themes.

To find a middle ground, we use probabilistic subsampling to reduce outlier author use to something more in line with the collection's overall usage. We use the same threshold t to set subsampling rates. For a word type w and author a the probability of stopping a token of type w in a is

$$\Pr(\text{Stop } w \text{ in } a) = 1 - f_w^*/f_{w,a}. \tag{5}$$

The threshold t specifies when an author's use of a word is too extreme for our model Γ_w. If we reduce these outlier frequencies to their corresponding cutoff frequencies f_w^*, they will be set to the largest below-threshold frequency dictated by Γ_w. We construct our subsampling rates such that in expectation new author frequencies will equal their corresponding threshold frequency from the original distribution.[5]

[5]Iteratively reevaluating Γ_w leads to an unstable "race to the bottom."

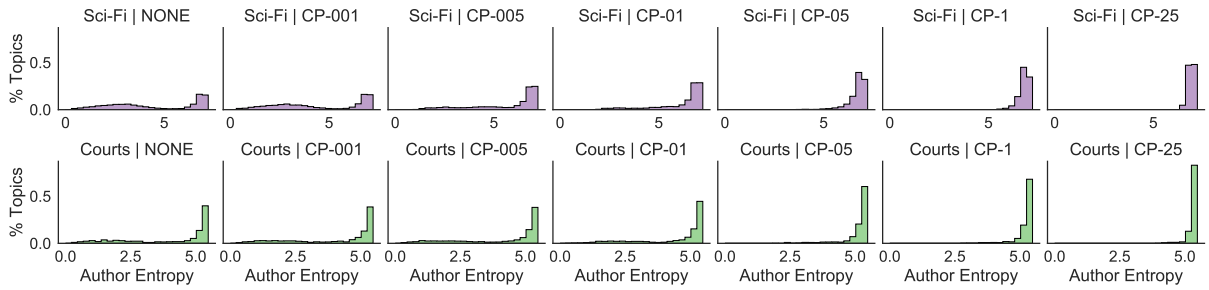

Figure 3: Increasing the threshold t for contextual probabilistic (CP) subsampling results in more topics with high dispersion over authors.

6 Results

Unless otherwise noted, we refer to models with a topic size of 250 for SCI-FI and 50 for COURTS, and set the hyperparameter t of context-based methods to 0.05. We refer to a treatment with no intervention beyond standard stopword removal as **NONE**. We compare these models to three classes of curation methods, each with varying parameters. **AF-[n]** removes all terms that are used by at most n authors. **C-[t]** removes any term from author a's context whose frequency $f_{w,a}$ exceeds significance threshold t with respect to distribution Γ_w. **CP-[t]** subsamples terms according to Eq. 5. We train 10 runs with random initializations for each parameter setting.

Subsampling reduces topic-metadata correlation. We begin by measuring how well the curation techniques reduce the formation of author-correlated topics. We find that while removing words with low author frequency has little effect (not shown), contextual methods greatly reduce the formation of "bad" topics according to all three measures. As expected, the value of the threshold t affects performance of the context-based methods. In Figure 3, we see that lowest values of t are ineffective; $t = 0.001$ is hardly distinguishable from NONE and $t = 0.005$ is on par with low author frequency stoplists. We observe that settings of $t \geq 0.05$ perform very well, and choose this value as a default in our public code release.

Subsampling before inference does more than change the appearance of topics, it changes the content of the inferred topics. To test whether subsampling after inference has the same effect we construct ten additional models by *post hoc* stopping the 250-topic trained models for NONE-treated SCI-FI to match token-for-token the CP-05 curated versions. We find that *post-hoc* removal has little effect on topic-metadata correlation; over twenty percent of topics are dominated by a single author with the worst having 96.4% of tokens contributed by one author.

Semantic quality is preserved. We define author-specificity as a property orthogonal to model quality: there is nothing fundamentally wrong with a topic full of character names outside the context of specific user needs. But ideally in reducing the prevalence of overly author-specific topics we would replace them with equally meaningful ones. We measure semantic quality of topics using Mimno et al. (2011)'s topic coherence metric as reported by Mallet. This metric measures the tendency for the most probable (top) words of a topic to cooccur. A topic k with m top words $w_{k,1}, \ldots, w_{k,m}$ has topic coherence

$$\sum_i \sum_{j<i} \log \frac{D(w_i, w_j)}{D(w_i)} + \beta, \tag{6}$$

where D represents the number of documents containing a word or word pair and β is the LDA hyperparameter for topic-word smoothing. Large negative values indicate that the top words of a topic seldom cooccur, while values close to zero indicate that the top words frequently coccur.

We find that despite substantial changes in topic content, corpus modification has no consistent effect on the semantic quality of topics. In Figure 4, we find that all curation methods except CP-001 have significantly higher mean topic coherence than NONE for SCI-FI. Contextual methods with $t \geq 0.05$ have the highest coherence. For COURTS, topic coherence is maintained across treatments, except for the most aggressive interventions C-05 and C-1.

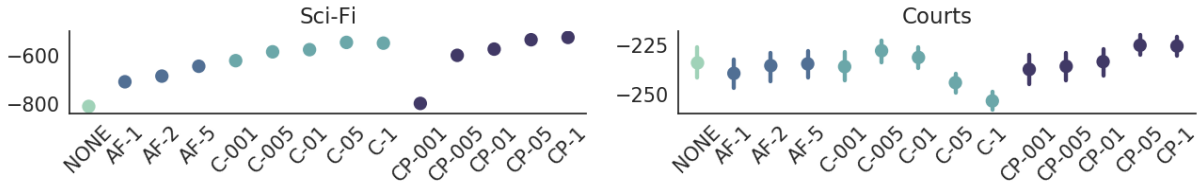

Figure 4: Contextual probabilistic subsampling improves mean topic coherence for SCI-FI despite the removal of frequent words. Coherence degrades under context curation for COURTS.

Corpus damage is reduced. All things being equal, we want to modify the input collection minimally, both in terms of vocabulary and actual document content. Figure 5 confirms that contextual curation has the highest type and token loss across corpora, because it completely removes all instances of a word type in a context. This may partially explain the dramatic loss of model quality for these specific treatments.

Contextual probabilistic subsampling removes more tokens than author frequency cut-offs, but better preserves the vocabulary. For thresholds $t \leq 0.01$, contextual probabilistic subsampling removes fewer word types than any of the author frequency cut-off methods. However, there is less agreement across corpora for $t \geq 0.05$. For SCI-FI, these methods remove more types than AF-5, while the reverse is true for COURTS. This discrepancy might arise from differences in the relative size of collection sources—some authors write more than others, some courts issue more opinions—and vocabulary use.

Subsampling affects more than names. Character names are the most prominent motivating example for this work, so it is reasonable to ask whether named-entity tagging or even a simple part-of-speech (POS) filter would be sufficient. To check whether we are just removing proper nouns, we compare the frequency of four general POS categories: common nouns, proper nouns, verbs, and adjectives. These make up 37%, 10%, 27%, 13% of all tokens respectively in SCI-FI. Figure 6 shows the proportion of tokens removed from each category for each curation method. Unsurprisingly, proper nouns make up a large proportion in all cases, but contextual methods also remove substantial numbers of tokens across all word groups.

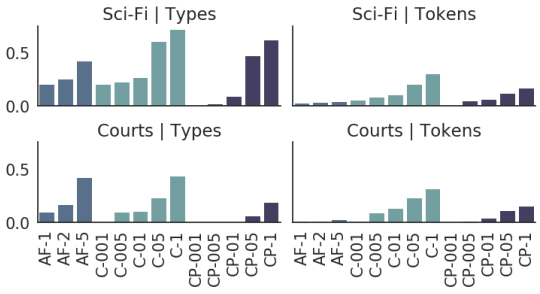

Figure 5: Proportional loss of removed word types and tokens. Contextual probabilistic subsampling does substantially less damage than contextual curation.

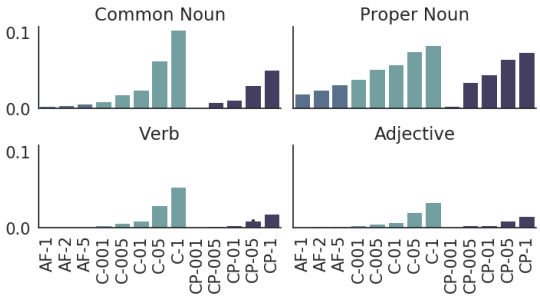

Figure 6: Proportion of SCI-FI tokens removed across part-of-speech groups. Contextual methods remove tokens from all groups.

Subsampling increases stability and specificity. We find that removing author-specific terms using contextual probabilistic subsampling greatly mitigates the formation of author-correlated topics, but what do these models learn instead? Are they augmenting the set of uncorrelated topics found within the untreated models, or are they perhaps identifying entirely new structure? More importantly, what are the characteristics of the newly formed or persisting author-correlated topics? To answer these questions, we perform pairwise comparisons of the topic-word distributions from different models using Jensen-Shannon divergence to find the most likely of topic correspondences. By linking these topics together, we can gain a sense of which topics persist across treatments, which are refined or split, and which are lost entirely. We focus on SCI-FI since it has larger models, but we will highlight similar analysis for COURTS.

Before making any inter-treatment comparisons, we examine topic stability internally within each

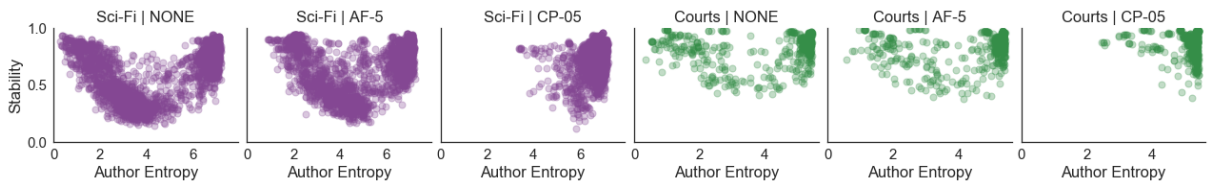

Figure 7: Topic Stability and Entropy for SCI-FI ($K = 250$) and COURTS ($K = 50$). AF-5 has little effect. Many of the low-entropy topics avoided by CP-05 are highly unstable.

treatment. We define stability as the average similarity between a topic and its nearest equivalent from each of the nine other trained models for a treatment. More formally, the stability of topic k_i from the ith instance of a model is

$$\text{Stability}(k_i) = 1 - \frac{1}{9} \sum_{j \neq i} \min_{k_j} JSD(P(w \mid k_i), P(w \mid k_j)) \tag{7}$$

where JSD is Jensen-Shannon divergence. A topic stability close to one implies that a topic persists across runs, while a value close to zero implies that a topic is *ephemeral*—observed once and unlikely to be seen again across random initializations.

High stability does not imply author-specificity. In Figure 7, we see that the most stable topics tend to have either maximal or minimal author entropy, while the most unstable topics have middling values. The unstable topics tend to capture a mixture of disjoint structures as we saw in topics C and D from Table 2. This also occurs (but to a lesser extent) in COURTS with topics containing many distinct regional terms (S1: *s.w oklahoma tenn kan ind n.e indiana app tennessee o.s*) or containing a mixture of a general and state-specific concept (S2: *school wyo miss wyoming mississippi ann education students hill student*). Thus, the most stable topics are the most apparent by being very context specific or most cross-cutting.

Now that we have evaluated the stability of topics under the baseline NONE treatment, we can use minimum divergence to align those topics with topics trained under the CP-05 subsampling treatment. Unstable NONE topics are generally very distant from their nearest CP-05 counterparts. Of our example topics in Table 2, C and D are the most unstable at 0.39 and 0.42 respectively. Topic C diverges heavily (0.87) from its closest CP-05 match, while aspects of D are echoed in its nearest match *sand desert rock mountains mountain dust land surface plain water* (0.53). COURTS topic S2 is also more distantly associated (0.63) with an education/administration topic: *board school commission administrative agency plan department board's education regulations*. Over 95% of NONE topics with high stability and high author entropy are linked to a CP-05 topic with divergence less than 0.5. Topic A has a close match (*professor university college student students research school science work years*) at 0.23. A appears to have become more specific in CP-05 by splitting into two additional topics that echo other aspects, namely teaching children (0.54) and scientific research (0.55).

The case of stable, low entropy NONE topics is harder to interpret. While half of these topics are far from their CP-05 match (> 0.7), 16% have divergences of less than 0.4. Topic G matches well to *lord hold between master queen star enough turns high good* (0.3) which is both very stable and CP-05's lowest author entropy topic (64.1% from Anne McCaffrey).[6] While these topics have not been prevented entirely, they have been largely mitigated.

The topics in CP-05 that are the most dissimilar from topics within NONE demonstrate that this treatment adds differentiation. We find that overall 50% of CP-05 topics have a large divergence (> 0.7) with the NONE topics. Some of these divergent topics consist of names, but these groupings might indicate regional or temporal naming patterns. In other cases, we encounter new and interesting topics such as an authentic robots topic (*machine robot machines robots human mechanical metal brain men built*), which matches to both a general computer topic and example topic E (Asimov). We also find a new topic on magic and witchcraft (*magic ghost demon evil witch demons power spell magician ghosts*) whose

[6]The topic is common words used in specific ways: a *hold* is a fortified settlement, dragons teleport by going *between*.

closest match is a general religion topic *god gods religion world religious ancient temple people faith these*. In fact, the term *witch* never appears as a top-20 term for any topic within the 250-topic NONE models. These topics may appear for NONE when we increase the topic size to $K = 1000$, but at the cost of a much larger model and with no guarantee against intruding character names.

Subsampling produces cross-cutting topics. While our topics score well quantitatively, how humanly interpretable and useful are the resulting topics? Are they actually cross-cutting in nature? We address these questions by more closely examining topics generated by the CP-05 subsampling treatment. We can explore the collection by sorting authors and individual novels within topics.

The highest frequency topics from the *NONE* treatment are largely preserved by *CP-05*. These topics by their nature are very cross-cutting and filled with frequent, general words. Despite this extreme generality they can provide a way to analyze passages representing high-level discourse concepts such as inquiry (*why asked ask answer question want questions should does because*) and the description of events and time (*during such most these course because happened effect period result*).

The mid-frequency topics are more concretely thematic in nature. We find a topic describing empire, politics, and history (*empire world power people war new government history political under*) which is associated with Doris Lessing's *Canopus in Argos* series, Isaac Asimov's *Foundation* series, and Kim Stanley Robinsons's *The Years of Rice and Salt*. In line with the science fiction genre, these novels focus on expansive future and alternative histories. We also find a topic on language (*language words english speak word understand spoke speech languages talk*). The most prominent authors in the topic—Robert A. Heinlein, Robert Silverberg, and Poul Anderson—are among the five most prolific authors in SCI-FI, which suggests the generality of the topic. Notably the most prominent volumes are by none of these authors: *Babel-17* by Samuel R. Delany, *Native Tongue* by Suzette Haden Elgin, and *Changing Planes* by Ursula K. Le Guin. All three include the social and political language as a major plot point. These three works are fundamentally tied confirming that this topic embodies a cross-cutting linguistic theme.

Looking more closely at the lower frequency robots topic (*machine robot machines robots human mechanical metal brain men built*), we find that it is both topically cohesive and cross-cutting. The five most-represented authors all have works heavily related to artificial intelligence: Isaac Asimov, Robert Silverberg, Stanisław Lem, Clifford D. Simak, and Philip K. Dick. The most-represented volumes tell a similar story with *Men and machines* by Robert Silverberg, *The complete robot* by Isaac Asimov, and *The Humanoids* by Jack Williamson holding the top three ranks. Reassuringly, there are well-represented novels by less-represented authors such as *The Starchild Trilogy* by Fredrick Pohl and Jack Williamson. The low frequency of this topic is surprising given the presence in the collection of robot-related novels, especially works by Isaac Asimov. This discrepancy revealed that an Asimov-specific topic (*human being law might must such without may robot beings*) has persisted. Many authors receive a non-negligible token representation, but Asimov's token count is still a factor of ten larger than the second most prominent author (Robert A. Heinlein).

7 Conclusion

We present a formal definition of the problem of overly source-specific topics, three evaluation metrics to measure the degree of source-specificity, and a simple text curation meta-algorithm that dramatically reduces the number of source-specific topics. This approach has immediate practical application for the many collections that combine multiple distinct sources, but it also has important theoretical implications.

We view this work as a preliminary step towards predictive theories of latent semantics, beyond purely descriptive models. Despite ample practical evidence that interventions such as stoplist curation can have significant effects, most previous work has focused on algorithms for identifying a single "optimal" low-dimensional semantic representation. Our results indicate that there are potentially many interventions in text collections that each have distinct but predictable effects on the results of algorithms. Just as biologists use multiple stains to view different aspects of microorganisms using the same microscope, users of text mining algorithms should be able to choose multiple distinct text treatments, each with its own predictable effects, to meet distinct user needs.

Abstract

Multi-label classification is an important yet challenging task in natural language processing. It is more complex than single-label classification in that the labels tend to be correlated. Existing methods tend to ignore the correlations between labels. Besides, different parts of the text can contribute differently to predicting different labels, which is not considered by existing models. In this paper, we propose to view the multi-label classification task as a sequence generation problem, and apply a sequence generation model with a novel decoder structure to solve it. Extensive experimental results show that our proposed methods outperform previous work by a substantial margin. Further analysis of experimental results demonstrates that the proposed methods not only capture the correlations between labels, but also select the most informative words automatically when predicting different labels.[1]

1 Introduction

Multi-label classification (MLC) is an important task in the field of natural language processing (NLP), which can be applied in many real-world scenarios, such as text categorization (Schapire and Singer, 2000), tag recommendation (Katakis et al., 2008), information retrieval (Gopal and Yang, 2010), and so on. The target of the MLC task is to assign multiple labels to each instance in the dataset.

Binary relevance (BR) (Boutell et al., 2004) is one of the earliest attempts to solve the MLC task by transforming the MLC task into multiple single-label classification problems. However, it neglects the correlations between labels. Classifier chains (CC) proposed by Read et al. (2011) converts the MLC task into a chain of binary classification problems to model the correlations between labels. However, it is computationally expensive for large datasets. Other methods such as ML-DT (Clare and King, 2001), Rank-SVM (Elisseeff and Weston, 2002), and ML-KNN (Zhang and Zhou, 2007) can only be used to capture the first or second order label correlations or are computationally intractable when high-order label correlations are considered.

In recent years, neural networks have achieved great success in the field of NLP. Some neural network models have also been applied in the MLC task and achieved important progress. For instance, fully connected neural network with pairwise ranking loss function is utilized in Zhang and Zhou (2006). Kurata et al. (2016) propose to perform classification using the convolutional neural network (CNN). Chen et al. (2017) use CNN and recurrent neural network (RNN) to capture the semantic information of texts. However, they either neglect the correlations between labels or do not consider differences in the contributions of textual content when predicting labels.

In this paper, inspired by the tremendous success of the sequence-to-sequence (Seq2Seq) model in machine translation (Bahdanau et al., 2014; Luong et al., 2015; Sun et al., 2017), abstractive summarization (Rush et al., 2015; Lin et al., 2018), style transfer (Shen et al., 2017; Xu et al., 2018) and other domains, we propose a sequence generation model with a novel decoder structure to solve the MLC task. The proposed sequence generation model consists of an encoder and a decoder with the attention

Proceedings of the 27th International Conference on Computational Linguistics, pages 3915–3926
Santa Fe, New Mexico, USA, August 20-26, 2018.

mechanism. The decoder uses an LSTM to generate labels sequentially, and predicts the next label based on its previously predicted labels. Therefore, the proposed model can consider the correlations between labels by processing label sequence dependencies through the LSTM structure. Furthermore, the attention mechanism considers the contributions of different parts of text when the model predicts different labels. In addition, a novel decoder structure with global embedding is proposed to further improve the performance of the model by incorporating overall informative signals.

The contributions of this paper are listed as follows:

- We propose to view the MLC task as a sequence generation problem to take the correlations between labels into account.
- We propose a sequence generation model with a novel decoder structure, which not only captures the correlations between labels, but also selects the most informative words automatically when predicting different labels.
- Extensive experimental results show that our proposed methods outperform the baselines by a large margin. Further analysis demonstrates the effectiveness of the proposed methods on correlation representation.

The whole paper is organized as follows. We describe our methods in Section 2. In Section 3, we present the experiments and make analysis and discussions. Section 4 introduces the related work. Finally in Section 5 we conclude this paper and explore the future work.

2 Proposed Method

We introduce our proposed methods in detail in this section. First, we give an overview of the model in Section 2.1. Second, we explain the details of the proposed sequence generation model in Section 2.2. Finally, Section 2.3 presents our novel decoder structure.

2.1 Overview

First of all, we define some notations and describe the MLC task. Given the label space with L labels $\mathcal{L} = \{l_1, l_2, \cdots, l_L\}$, a text sequence $\boldsymbol{x}$ containing m words, the task is to assign a subset $\boldsymbol{y}$ containing n labels in the label space $\mathcal{L}$ to $\boldsymbol{x}$. Unlike traditional single-label classification where only one label is assigned to each sample, each sample in the MLC task can have multiple labels. From the perspective of sequence generation, the MLC task can be modeled as finding an optimal label sequence $\boldsymbol{y}^*$ that maximizes the conditional probability $p(\boldsymbol{y}|\boldsymbol{x})$, which is calculated as follows:

$$p(\boldsymbol{y}|\boldsymbol{x}) = \prod_{i=1}^{n} p(y_i|y_1, y_2, \cdots, y_{i-1}, \boldsymbol{x}) \tag{1}$$

An overview of our proposed model is shown in Figure 1. First, we sort the label sequence of each sample according to the frequency of the labels in the training set. High-frequency labels are placed in the front. In addition, the bos and eos symbols are added to the head and tail of the label sequence, respectively.

The text sequence $\boldsymbol{x}$ is encoded to the the hidden states, which are aggregated to a context vector $\boldsymbol{c}_t$ by the attention mechanism at time-step t. The decoder takes the context vector $\boldsymbol{c}_t$, the last hidden state $\boldsymbol{s}_{t-1}$ of the decoder and the embedding vector $g(\boldsymbol{y}_{t-1})$ as the inputs to produce the hidden state $\boldsymbol{s}_t$ at time-step t. Here $\boldsymbol{y}_{t-1}$ is the predicted probability distribution over the label space $\mathcal{L}$ at time-step $t-1$. The function g takes $\boldsymbol{y}_{t-1}$ as input and produces the embedding vector which is then passed to the decoder. Finally, the masked softmax layer is used to output the probability distribution $\boldsymbol{y}_t$.

2.2 Sequence Generation

In this subsection, we introduce the details of our proposed model. The whole sequence generation model consists of an encoder and a decoder with the attention mechanism.

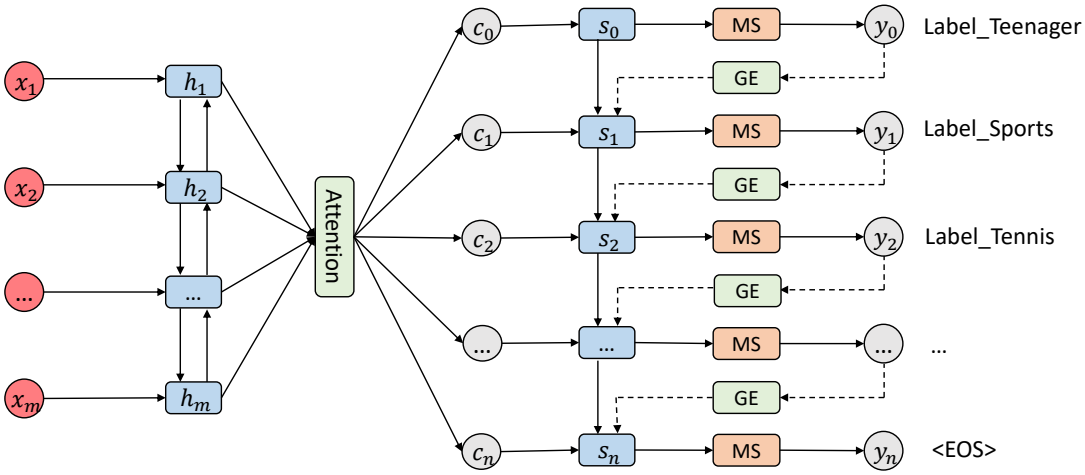

Figure 1: The overview of our proposed model. MS denotes the masked softmax layer. GE denotes the global embedding.

Encoder: Let $(\boldsymbol{w}_1, \boldsymbol{w}_2, \cdots, \boldsymbol{w}_m)$ be a sentence with m words and $\boldsymbol{w}_i$ is the one-hot representation of the i-th word. We first embed $\boldsymbol{w}_i$ to a dense embedding vector $\boldsymbol{x}_i$ by an embedding matrix $\boldsymbol{E} \in \mathbb{R}^{k \times |\mathcal{V}|}$. Here $|\mathcal{V}|$ is the size of the vocabulary, and k is the dimension of the embedding vector.

We use a bidirectional LSTM (Hochreiter and Schmidhuber, 1997) to read the text sequence $\boldsymbol{x}$ from both directions and compute the hidden states for each word,

$$\overrightarrow{\boldsymbol{h}}_i = \overrightarrow{\text{LSTM}}(\overrightarrow{\boldsymbol{h}}_{i-1}, \boldsymbol{x}_i) \tag{2}$$

$$\overleftarrow{\boldsymbol{h}}_i = \overleftarrow{\text{LSTM}}(\overleftarrow{\boldsymbol{h}}_{i+1}, \boldsymbol{x}_i) \tag{3}$$

We obtain the final hidden representation of the i-th word by concatenating the hidden states from both directions, $\boldsymbol{h}_i = [\overrightarrow{\boldsymbol{h}}_i; \overleftarrow{\boldsymbol{h}}_i]$, which embodies the information of the sequence centered around the i-th word.

Attention: When the model predicts different labels, not all text words make the same contribution. The attention mechanism produces a context vector by focusing on different portions of the text sequence and aggregating the hidden representations of those informative words. Specially, the attention mechanism assigns the weight α_{ti} to the i-th word at time-step t as follows:

$$e_{ti} = \boldsymbol{v}_a^T \tanh(\boldsymbol{W}_a \boldsymbol{s}_t + \boldsymbol{U}_a \boldsymbol{h}_i) \tag{4}$$

$$\alpha_{ti} = \frac{\exp(e_{ti})}{\sum_{j=1}^{m} \exp(e_{tj})} \tag{5}$$

where $\boldsymbol{W}_a$, $\boldsymbol{U}_a$, $\boldsymbol{v}_a$ are weight parameters and $\boldsymbol{s}_t$ is the current hidden state of the decoder at time-step t. For simplicity, all bias terms are omitted in this paper. The final context vector $\boldsymbol{c}_t$ which is passed to the decoder at time-step t is calculated as follows:

$$\boldsymbol{c}_t = \sum_{i=1}^{m} \alpha_{ti} \boldsymbol{h}_i \tag{6}$$

Decoder: The hidden state $\boldsymbol{s}_t$ of the decoder at time-step t is computed as follows:

$$\boldsymbol{s}_t = \text{LSTM}(\boldsymbol{s}_{t-1}, [g(\boldsymbol{y}_{t-1}); \boldsymbol{c}_{t-1}]) \tag{7}$$

where $[g(\boldsymbol{y}_{t-1}); \boldsymbol{c}_{t-1}]$ means the concatenation of the vectors $g(\boldsymbol{y}_{t-1})$ and $\boldsymbol{c}_{t-1}$. $g(\boldsymbol{y}_{t-1})$ is the embedding of the label which has the highest probability under the distribution $\boldsymbol{y}_{t-1}$. $\boldsymbol{y}_{t-1}$ is the probability

distribution over the label space $\mathcal{L}$ at time-step $t-1$ and is computed as follows:

$$\boldsymbol{o}_t = \boldsymbol{W}_o f(\boldsymbol{W}_d \boldsymbol{s}_t + \boldsymbol{V}_d \boldsymbol{c}_t) \tag{8}$$

$$\boldsymbol{y}_t = softmax(\boldsymbol{o}_t + \boldsymbol{I}_t) \tag{9}$$

where $\boldsymbol{W}_o$, $\boldsymbol{W}_d$, and $\boldsymbol{V}_d$ are weight parameters, $\boldsymbol{I}_t \in \mathbb{R}^L$ is the mask vector that is used to prevent the decoder from predicting repeated labels, and f is a nonlinear activation function.

$$(\boldsymbol{I}_t)_i = \begin{cases} -\infty & \text{if the label } l_i \text{ has been predicted at previous } t-1 \text{ time steps.} \\ 0 & \text{otherwise.} \end{cases} \tag{10}$$

At the training stage, the loss function is the cross-entropy loss function. We employ the beam search algorithm (Wiseman and Rush, 2016) to find the top-ranked prediction path at inference time. The prediction paths ending with the eos are added to the candidate path set.

2.3 Global Embedding

In the sequence generation model mentioned above, the embedding vector $g(\boldsymbol{y}_{t-1})$ in Equation (7) is the embedding of the label that has the highest probability under the distribution $\boldsymbol{y}_{t-1}$. However, this calculation only takes advantage of the maximum value of $\boldsymbol{y}_{t-1}$ greedily. The proposed sequence generation model generates labels sequentially and predicts the next label conditioned on its previously predicted labels. Therefore, it is likely that we would get a succession of wrong label predictions in the following time steps if the prediction is wrong at time-step t, which is also called *exposure bias*. To a certain extent, the beam search algorithm alleviates this problem. However, it can not fundamentally solve the problem because the *exposure bias* phenomenon is likely to occur for all candidate paths. $\boldsymbol{y}_{t-1}$ represents the predicted probability distribution at time-step $t-1$, so it is obvious that all information in $\boldsymbol{y}_{t-1}$ is helpful when we predict the current label at time-step t. The *exposure bias* problem ought to be relieved by considering all informative signals contained in $\boldsymbol{y}_{t-1}$.

Based on this motivation, we propose a new decoder structure, where the embedding vector $g(\boldsymbol{y}_{t-1})$ at time-step t is capable of representing the overall information at $(t-1)$-th time step. Inspired by the idea of the adaptive gate in highway network (Srivastava et al., 2015), here we introduce our global embedding. Let $\boldsymbol{e}$ denotes the embedding of the label which has the highest probability under the distribution $\boldsymbol{y}_{t-1}$. $\bar{\boldsymbol{e}}$ is the weighted average embedding at time t, which is calculated as follows:

$$\bar{\boldsymbol{e}} = \sum_{i=1}^{L} y_{t-1}^{(i)} \boldsymbol{e}_i \tag{11}$$

where $y_{t-1}^{(i)}$ is the i-th element of $\boldsymbol{y}_{t-1}$ and $\boldsymbol{e}_i$ is the embedding vector of the i-th label. Then the proposed global embedding $g(\boldsymbol{y}_{t-1})$ passed to the decoder at time-step t is as follows:

$$g(\boldsymbol{y}_{t-1}) = (\boldsymbol{1} - \boldsymbol{H}) \odot \boldsymbol{e} + \boldsymbol{H} \odot \bar{\boldsymbol{e}} \tag{12}$$

where $\boldsymbol{H}$ is the transform gate controlling the proportion of the weighted average embedding:

$$\boldsymbol{H} = \boldsymbol{W}_1 \boldsymbol{e} + \boldsymbol{W}_2 \bar{\boldsymbol{e}} \tag{13}$$

where $\boldsymbol{W}_1, \boldsymbol{W}_2 \in \mathbb{R}^{L \times L}$ are weight matrices. The global embedding $g(\boldsymbol{y}_{t-1})$ is the optimized combination of the original embedding and the weighted average embedding by using transform gate $\boldsymbol{H}$, which can automatically determine the combination factor in each dimension. $\boldsymbol{y}_{t-1}$ contains the information of all possible labels. By considering the probability of every label, the model is capable of reducing damage caused by mispredictions made in the previous time steps. This enables the model to predict label sequences more accurately.

Dataset	Total Samples	Label Sets	Words/Sample	Labels/Sample
RCV1-V2	804,414	103	123.94	3.24
AAPD	55,840	54	163.42	2.41

Table 1: Summary of datasets. **Total Samples**, **Label Sets** denote the total number of samples and labels, respectively. **Words/Sample** is the average number of words per sample and **Labels/Sample** is the average number of labels per sample.

3 Experiments

In this section, we evaluate our proposed methods on two datasets. We first introduce the datasets, evaluation metrics, experimental details, and all baselines. Then, we compare our methods with the baselines. Finally, we provide the analysis and discussions of experimental results.

3.1 Datasets

Reuters Corpus Volume I (RCV1-V2)[2]: This dataset is provided by Lewis et al. (2004). It consists of over 800,000 manually categorized newswire stories made available by Reuters Ltd for research purposes. Multiple topics can be assigned to each newswire story and there are 103 topics in total.

Arxiv Academic Paper Dataset (AAPD)[3]: We build a new large dataset for the multi-label text classification. We collect the abstract and the corresponding subjects of 55,840 papers in the computer science field from the website[4]. An academic paper may have multiple subjects and there are 54 subjects in total. The target is to predict corresponding subjects of an academic paper according to the content of the abstract.

We divide each dataset into training, validation and test sets. The statistics of the two datasets are shown in Table 1.

3.2 Evaluation Metrics

Following the previous work (Zhang and Zhou, 2007; Chen et al., 2017), we adopt hamming loss and micro-F_1 score as our main evaluation metrics. Micro-precision and micro-recall are also reported to assist the analysis.

- **Hamming-loss** (Schapire and Singer, 1999) evaluates the fraction of misclassified instance-label pairs, where a relevant label is missed or an irrelevant is predicted.
- **Micro-F_1** (Manning et al., 2008) can be interpreted as a weighted average of the precision and recall. It is calculated globally by counting the total true positives, false negatives, and false positives.

3.3 Details

We extract the vocabularies from the training sets. For the RCV1-V2 dataset, the size of the vocabulary is 50,000 and out-of-vocabulary (OOV) words are replaced with unk. Each document is truncated at the length of 500 and the beam size is 5 at the inference stage. Besides, we set the word embedding size to 512. The hidden sizes of the encoder and the decoder are 256 and 512, respectively. The number of LSTM layers of encoder and decoder is 2.

For the AAPD dataset, the size of word embedding is 256. There are two LSTM layers in the encoder and its size is 256. For the decoder, there is one LSTM layer of size 512. The size of the vocabulary is 30,000 and OOV words are also replaced with unk. Each document is truncated at the length of 500. The beam size is 9 at the inference stage.

We use the Adam (Kingma and Ba, 2014) optimization method to minimize the cross-entropy loss over the training data. For the hyper-parameters of the Adam optimizer, we set the learning rate $\alpha = 0.001$, two momentum parameters $\beta_1 = 0.9$ and $\beta_2 = 0.999$ respectively, and $\epsilon = 1 \times 10^{-8}$. Additionally,

Table 2: Comparison between our methods and all baselines on two datasets. GE denotes the global embedding. HL, P, R, and F1 denote hamming loss, micro-precision, micro-recall, and micro-F_1, respectively. The symbol "+" indicates that the higher the value is, the better the model performs. The symbol "-" is the opposite.

we make use of the dropout regularization (Srivastava et al., 2014) to avoid overfitting and clip the gradients (Pascanu et al., 2013) to the maximum norm of 10.0. During training, we train the model for a fixed number of epochs and monitor its performance on the validation set. Once the training is finished, we select the model with the best micro-F_1 score on the validation set as our final model and evaluate its performance on the test set.

3.4 Baselines

We compare our proposed methods with the following baselines:

- **Binary Relevance (BR)** (Boutell et al., 2004) transforms the MLC task into multiple single-label classification problems by ignoring the correlations between labels.
- **Classifier Chains (CC)** (Read et al., 2011) transforms the MLC task into a chain of binary classification problems and takes high-order label correlations into consideration.
- **Label Powerset (LP)** (Tsoumakas and Katakis, 2006) transforms a multi-label problem to a multi-class problem with one multi-class classifier trained on all unique label combinations.
- **CNN** (Kim, 2014) uses multiple convolution kernels to extract text features, which are then inputted to the linear transformation layer followed by a sigmoid function to output the probability distribution over the label space. The multi-label soft margin loss is optimized.
- **CNN-RNN** (Chen et al., 2017) utilizes CNN and RNN to capture both the global and local textual semantics and model the label correlations.

Following the previous work (Chen et al., 2017), we adopt the linear SVM as the base classifier in BR, CC and LP. We implement BR, CC and LP by means of Scikit-Multilearn (Szymański, 2017), an open-source library for the MLC task. We tune hyper-parameters of all baseline algorithms on the validation set based on the micro-F_1 score. In addition, training strategies mentioned in Zhang and Wallace (2015) are used to tune hyper-parameters for the baselines CNN and CNN-RNN.

3.5 Results

For the purpose of simplicity, we denote the proposed sequence generation model as **SGM**. We report the evaluation results of our methods and all baselines on the test sets.

The experimental results of our methods and the baselines on dataset RCV1-V2 are shown in Table 2a. Results show that our proposed methods give the best performance in the main evaluation metrics. Our proposed SGM model using global embedding achieves a reduction of 12.79% hamming-loss and an improvement of 2.33% micro-F_1 score over the most commonly used baseline BR. Besides, our methods outperform other traditional deep-learning models by a large margin. For instance, the proposed SGM model with global embedding achieves a reduction of 15.73% hamming-loss and an improvement

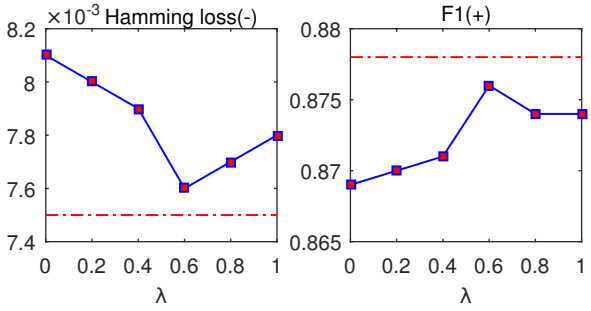

Figure 2: The performance of the SGM model when using different λ. The red dotted line represents the results of using the adaptive gate. The symbol "+" indicates that the higher the value is, the better the model performs. The symbol "-" is the opposite.

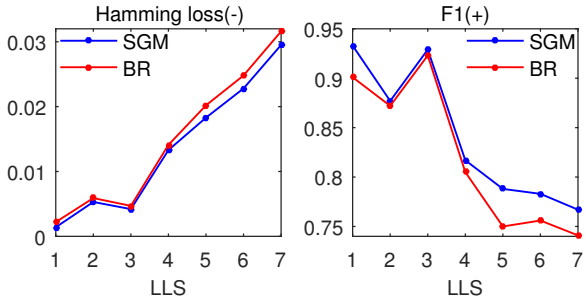

Figure 3: The performance of the SGM model on different subsets of the RCV1-V2 test set. LLS represents the length of label sequence of each sample in the subset. The explanations of symbol "+" and "-" can be found in Figure 2.

of 2.69% micro-F_1 score over the traditional CNN model. Even without the global embedding, our proposed SGM model is still able to outperform all baselines.

In addition, the SGM model is significantly improved by using global embedding. The SGM model with global embedding achieves a reduction of 7.41% hamming loss and an improvement of 1.04% micro-F_1 score on the test set compared with the model without global embedding.

Table 2b presents the results of the proposed methods and the baselines on the AAPD test set. Similar to the experimental results on the RCV1-V2 test set, our proposed methods still outperform all baselines by a large margin in main evaluation metrics. This further confirms that our methods have significant advantages over previous work on large datasets. Besides, the proposed SGM achieves a reduction of 2.39% hamming loss and an improvement of 1.57% micro-F_1 score on the test set by using global embedding. This further testifies that the global embedding is capable of helping the model to predict label sequences more accurately.

3.6 Analysis and Discussion

Here we perform further analysis on the model and experimental results. We report the evaluation results in terms of hamming loss and micro-F_1 score.

3.6.1 Exploration of Global Embedding

As is shown in Table 2, global embedding can significantly improve the performance of the model. The global embedding $g(\boldsymbol{y}_{t-1})$ at time-step t takes advantage of all information of possible labels contained in $\boldsymbol{y}_{t-1}$, so it is able to enrich the source information when the model predicts the current label, which leads to the performance of the model significantly improved. The global embedding is the combination of original embedding $\boldsymbol{e}$ and the weighted average embedding $\bar{\boldsymbol{e}}$ by using the transform gate $\boldsymbol{H}$. Here we conduct experiments on the RCV1-V2 dataset to explore how the performance of our model is affected by the proportion between two kinds of embeddings. In the exploratory experiment, the final embedding vector at time-step t is calculated as follows:

$$g(\boldsymbol{y}_{t-1}) = (1-\lambda) * \boldsymbol{e} + \lambda * \bar{\boldsymbol{e}} \tag{14}$$

The proportion between two kinds of embeddings is controlled by coefficient λ. $\lambda = 0$ denotes the proposed SGM model without global embedding. The proportion of weighted average embedding increases when we increase λ. The experimental results using different λ values in the decoder are shown in Figure 2.

As is shown in Figure 2, the performance of the model varies when different λ is used. Overall, the model using the adaptive gate performs the best, which achieves the best results in both hamming loss and micro-F_1. The models with $\lambda \neq 0$ outperform the model with $\lambda = 0$, which shows that the weighted average embedding contains richer information, leading to the improvement in the performance

Models	HL(-)	F1(+)
SGM	0.0081	0.869
w/o mask	0.0083(↓ 2.47%)	0.866(↓ 0.35%)
w/o sorting	0.0084(↓ 3.70%)	0.858(↓ 1.27%)

(a) Ablation study for the SGM model.

Models	HL(-)	F1(+)
SGM + GE	0.0075	0.878
w/o mask	0.0078(↓ 4.00%)	0.873(↓ 0.57%)
w/o sorting	0.0083(↓ 10.67%)	0.859(↓ 2.16%)

(b) Ablation study for SGM model with global embedding.

Table 3: Ablation study on the RCV1-V2 test set. GE denotes the global embedding. HL and F1 denote hamming loss and micro-F_1, respectively. The symbol "+" indicates that the higher the value is, the better the model performs. The symbol "-" is the opposite. ↑ means that the performance of the model improves and ↓ is the opposite.

of the model. Without using the adaptive gate, the performance of the model improves at first and then deteriorates as λ increases. It reveals the reason why the model with the adaptive gate performs the best: the adaptive gate can automatically determine the most appropriate λ value according to the actual condition.

3.6.2 The Impact of Mask and Sorting

Our proposed methods are developed based on traditional Seq2Seq models. However, the mask module is added to the proposed methods, which is used to prevent the models from predicting repeated labels. In addition, we sort the label sequence of each sample according to the frequency of appearance of labels in the training set. In order to explore the impact of the mask module and sorting, we conduct ablation experiments on the RCV1-V2 dataset. The experimental results are shown in Table 3. "*w/o mask*" means that we do not perform mask operation and "*w/o sorting*" means that we randomly shuffle the label sequence in order to perturb its original order.

As is shown in Table 3, the performance decline of the SGM model with global embedding is more significant compared with that of the SGM model without global embedding. In addition, the decline in the performance of the two models is more significant when we randomly shuffle the label sequence of the sample compared with removing mask module. The label cardinality of the RCV1-V2 dataset is small, so our proposed methods are less prone to predicting repeated labels. This explains the reason why experimental results indicate that the mask module has little impact on the models' performance. In addition, the proposed models are trained using the maximum likelihood estimation method and the cross-entropy loss function, which requires humans to predefine the order of the output labels. Therefore, the sorting of labels is very important for the models' performance. Besides, the performance of both models declines when we do not use the mask module. This shows that the performance of the model can be improved by using the mask operation.

3.6.3 Error Analysis

In the experiment, we find that the performance of all methods deteriorates when the length of the label sequence increases (for simplicity, we denote the length of the label sequence as *LLS*). In order to explore the influence of the value of the *LLS*, we divide the test set into different subsets based on different *LLS*. Figure 3 shows the performance of the SGM model and the most commonly used baseline BR on different subsets of the RCV1-V2 test set. As is shown in Figure 3, generally, the performance of both models deteriorates as the *LLS* increases. This shows that when the label sequence of the sample is particularly long, it is difficult to accurately predict all labels. Because more information is needed when the model predicts more labels. It is easy to ignore some true labels whose feature information is insufficient.

However, as is shown in Figure 3, the proposed SGM model outperforms BR with any value of *LLS*, and the advantages of our model are more significant when *LLS* is large. The traditional BR method predicts all labels at once only based on the sample input. Therefore, it tends to ignore some true labels whose feature information contained in the sample is insufficient. The SGM model generates labels sequentially, and predicts the next label based on its previously predicted labels. Therefore, even if the sample contains less information of some true labels, the SGM model is capable of generating these true labels by considering relevant labels that have been predicted.

• Generating descriptions for videos has many applications including human robot interaction.
• Many methods for image captioning rely on pre-trained object classifier CNN and Long Short Term Memory recurrent networks.
• How to learn robust visual classifiers from the weak annotations of the sentence descriptions.

Table 5: Several examples of the generated label sequences on the RCV1-V2 dataset. The red bold labels in each example indicate that they are highly correlated.

3.6.4 Visualization of Attention

When the model predicts different labels, there exist differences in the contributions of different words. The SGM model is able to select the most informative words by utilizing the attention mechanism. The visualization of the attention layer is shown in Table 4. According to Table 4, when the SGM model predicts the label "*CV*", it can automatically assign larger weights to more informative words, like `image`, `visual`, `captioning`, and so on. For the label "*CL*", the selected informative words are `sentence`, `memory`, `recurrent`, etc. This shows that our proposed models are able to consider the differences in the contributions of textual content when predicting different labels and select the most informative words automatically.

3.6.5 Case Study

We give several examples of the generated label sequences on the RCV1-V2 dataset in Table 5, where we compare the proposed methods with the most commonly used baseline BR. The red bold labels in each example indicate that they are highly correlated. For instance, the correlation coefficient between E51 and E512 is 0.7664. Therefore, these highly correlated labels are likely to appear together in the predicted label sequence. The BR algorithm fails to capture this label correlation, leaving many true labels unpredicted. However, our proposed methods accurately predict almost all highly correlated true labels. The proposed SGM captures the correlations between labels by utilizing LSTM to generate labels sequentially. Therefore, for some true labels whose feature information is insufficient, the proposed SGM is still able to generate them by considering relevant labels that have been predicted. In addition, label sequences that are more accurate are predicted by using global embedding. The SGM model with global embedding predicts more true labels compared with the SGM model without global embedding. The reason is that the source information is further enriched by incorporating overall informative signals in the probability distribution $\boldsymbol{y}_{t-1}$ when the model predicts the label at time-step t. Enriched information makes global embedding more smooth, which enables the model to reduce damage caused by mispredictions made in the previous time steps.

4 Related Work

The MLC task studies the problem where multiple labels are assigned to each sample. There are four main types of methods for the MLC task: problem transformation methods, algorithm adaptation methods, ensemble methods, and neural network models.

Problem transformation methods map the MLC task into multiple single-label learning tasks. Binary relevance (BR) (Boutell et al., 2004) decomposes the MLC task into independent binary classification problems by ignoring the correlations between labels. In order to model label correlations, label power-set (LP) (Tsoumakas and Katakis, 2006) transforms a multi-label problem to a multi-class problem with a classifier trained on all unique label combinations. Classifier chains (CC) (Read et al., 2011) transforms the MLC task into a chain of binary classification problems, where subsequent binary classifiers in the chain are built upon the predictions of preceding ones. However, the computational efficiency and performance of these methods are challenged by applications with a large number of labels and samples.

Algorithm adaptation methods extend specific learning algorithms to handle multi-label data directly. Clare and King (2001) construct decision tree based on multi-label entropy to perform classification. Elisseeff and Weston (2002) optimize the empirical ranking loss by using maximum margin strategy and kernel tricks. Collective multi-label classifier (CML) (Ghamrawi and McCallum, 2005) adopts maximum entropy principle to deal with multi-label data by encoding label correlations as constraint conditions. Zhang and Zhou (2007) adopt k-nearest neighbor techniques to deal with multi-label data. Fürnkranz et al. (2008) make ranking among labels by utilizing pairwise comparison. Li et al. (2015) propose a novel joint learning algorithm that allows the feedbacks to be propagated from the classifiers for latter labels to the classifier for the current label. Most methods, however, can only be used to capture the first or second order label correlations or are computationally intractable in considering high-order label correlations.

Among ensemble methods, Tsoumakas et al. (2011) break the initial set of labels into a number of small random subsets and employ the LP algorithm to train a corresponding classifier. Szymański et al. (2016) propose to construct a label co-occurrence graph and perform community detection to partition the label set.

In recent years, some neural network models have also been used for the MLC task. Zhang and Zhou (2006) propose the BP-MLL that utilizes a fully-connected neural network and a pairwise ranking loss function. Nam et al. (2013) propose a neural network using cross-entropy loss instead of ranking loss. Benites and Sapozhnikova (2015) increase classification speed by adding an extra ART layer for clustering. Kurata et al. (2016) utilize word embeddings based on CNN to capture label correlations. Chen et al. (2017) propose to represent semantic information of text and model high-order label correlations by combining CNN with RNN. Baker and Korhonen (2017) initialize the final hidden layer with rows that map to co-occurrence of labels based on the CNN architecture to improve the performance of the model. Ma et al. (2018) propose to use the multi-label classification algorithm for machine translation to handle the situation where a sentence can be translated into more than one correct sentences.

5 Conclusions and Future Work

In this paper, we propose to view the multi-label classification task as a sequence generation problem to model the correlations between labels. A sequence generation model with a novel decoder structure is proposed to improve the performance of classification. Extensive experimental results show that the proposed methods outperform the baselines by a substantial margin. Further analysis of experimental results demonstrates that our proposed methods not only capture the correlations between labels, but also select the most informative words automatically when predicting different labels.

As analyzed in Section 3.6.3, when a large number of labels are assigned to a sample, how to predict all these true labels accurately is an intractable problem. Our proposed methods alleviate this problem to some extent, but more effective solutions need to be further explored in the future.
