Abstract

We propose a sketch-based two-step neural model for generating structured queries (SQL) based on a user's request in natural language. The sketch is obtained by using placeholders for specific entities in the SQL query, such as column names, table names, aliases and variables, in a process similar to semantic parsing. The first step is to apply a sequence-to-sequence (SEQ2SEQ) model to determine the most probable SQL sketch based on the request in natural language. Then, a second network designed as a dual-encoder SEQ2SEQ model using both the text query and the previously obtained sketch is employed to generate the final SQL query. Our approach shows improvements over previous approaches on two recent large datasets (WikiSQL and SENLIDB) suitable for data-driven solutions for natural language interfaces for databases.

1 Introduction

The quest for a simpler, more intuitive interface to query databases and other sources of structured information is one of the main practical applications of natural language processing. Developing a natural language interface for databases (NLIDB), able to process text queries directly, would be the optimal solution with regards to ease of use, requiring no additional knowledge and allowing non-technical persons to interact with the data directly. Nevertheless, even after half of decade of research, this is merely a desideratum, as no current solution is able to perform efficiently for complex databases.

From a computational linguistics perspective, natural language interfaces for databases could be treated as a special case of machine translation. Given a text in natural language to query a data source, a NLIDB system needs to output a statement in an artificial language, designed especially by computer scientists to query the database. Several such query languages exist, the most widely used being SQL (Structured Query Language) for structured databases and SPARQL for knowledge bases and ontologies.

Traditional NLIDB solutions have been using mainly a combination of rules and heuristics built upon syntactic dependencies and semantic parsing, with machine learning playing only a marginal role. The lack of large datasets suitable for training data-driven solutions is probably the main reason for the lack of complex machine learning approaches. However, a couple of large datasets (Brad et al., 2017; Zhong et al., 2017) have been recently proposed. These corpora allowed deep learning solutions to be deployed.

An additional obstacle that needs to be overcome by natural language interfaces for databases, especially by data-driven approaches, is the strong dependence of the corpora on the schema of a given database. Thus, even if one model is trained on a large dataset for a given database schema, it will not have good performance on different schemas. As it is impossible to develop a new dataset with pairs of text queries and corresponding SQL statements for each new database, the solution must be looked for in the underlying model. To this extent, we propose using a two-step approach which employs two different SEQ2SEQ models. The first one is schema agnostic and learns to output an SQL sketch (defined in Section 3) without any elements specific to a given database schema. The second model uses both the generated sketch and additional information about the database schema (information encoded

Proceedings of the 27th International Conference on Computational Linguistics, pages 514–524
Santa Fe, New Mexico, USA, August 20-26, 2018.

by the model in its vocabulary) to generate the final SQL statement. We show that this model offers a significant improvement compared to a baseline SEQ2SEQ network with attention.

From a different standpoint, it is important to note that one of the biggest obstacles in generating code, including SQL, is that the output needs to be both syntactically and semantically valid. In previous research on code generation from natural language using neural models, this issue has been tackled by incorporating the syntax into a tree-based decoder (Yin and Neubig, 2017). To this end, our proposed two-step approach aims to learn separately the syntactic and semantic aspects of SQL generation without incorporating any human-defined grammar. The first step involves a SEQ2SEQ network trained on (text query, SQL sketch) pairs. The second step consists of a dual-encoder SEQ2SEQ architecture that generates SQL code based both on the user's request and the previously decoded sketch. Conditioning on the sketch can be seen as injecting syntactic information which helps the second network to focus more on the semantic aspects and on improving the syntax, given additional semantic elements. We show that this model offers a significant improvement compared to a baseline SEQ2SEQ model on two large datasets suitable for data-driven approaches for NLIDB.

The paper continues with an overview of existing solutions for NLIDBs, covering both incipient deep learning approaches and multi-stage conventional ones using a mix of rule-based and machine learning. In Section 3 we briefly present SENLIDB and WikiSQL, two large datasets of text queries and corresponding SQL statements which have already been used to train deep learning models for NLIDB. Section 4 presents the main contribution of our paper, introducing a two-step approach for generating SQL statements from textual input and query sketch using a novel dual-encoder neural model. Section 5 highlights the performance of the proposed two-step architecture compared to previous work. The paper ends with conclusions and future work.

2 Related Work

The first NLIDB solutions used dictionaries, grammars and dialogue to allow users to iteratively refine their query in natural language (Codd, 1974; Hendrix et al., 1978). For decades, complex multi-stage systems were designed for interacting in natural language with a database. They consisted of a mix of hand-crafted rules and heuristics, pattern matching, syntactic parsing, semantic grammar systems, and intermediate representation languages before generating the final statement in the query language (Androutsopoulos et al., 1995).

More recent conventional approaches combine syntactic parsing and semantic alignment to change the order of nodes in the parse trees in order to be correctly interpreted by a semantic analyzer (Popescu et al., 2004). To align the text with the generated SQL candidate statements, they propose using bipartite matching and dictionaries for semantic alignment. NaLIR (Li and Jagadish, 2014) also uses dependency parse trees and several hand-made rules and heuristics to generate candidate SQL statements. Given the input's dependency tree, the database schema and some manual semantic mappings, the system builds candidate query trees, as an intermediate step to SQL generation. The best query tree is computed using a scoring mechanism taking into account the similarity between the dependency and query trees and between adjacent nodes in the query tree, and an additional interaction with the user which is asked to select the best choice from a list of reformulations in natural language of top ranking candidate query trees.

Sqlizer (Yaghmazadeh et al., 2017) uses a mix of traditional rule-based and heuristics approaches combined with machine learning. Similar to our solution, a semantic parser is employed to generate a query sketch, which is then iteratively refined and repaired using rules and heuristics until the score of the generated SQL query cannot be improved. Sqlizer uses machine learning and Word2Vec (Mikolov et al., 2013) to determine the query sketch - a general form of the query, including clauses, but which does not contain any specific database schema information (e.g. table and column names). The reported results are surpassing previous solutions for several standard NLIDB datasets. While the underlying idea of Sqlizer (Yaghmazadeh et al., 2017) is similar to ours (using an intermediate sketch), there are significant differences. First, they do not employ a purely data-driven approach, as they use several hand-written heuristics. Secondly, the query sketch proposed by them is structurally different (encoding

merely column and table names). Thirdly, the sketch is generated by a semantic parser instead of a neural model. However, the neural dual-encoder model employed in the second step of SQL generation is actually the most original part of our work, differentiating our paper from previous proposals employing SQL sketches. This model is novel and provides a substantial improvement over previous rule-based systems for filling the query sketch.

Deep learning approaches for code generation and semantic parsing have allowed the mapping from language to structured output to be learned directly, without the need for intermediate processing steps and hand-crafted rules and heuristics. Iyer et al. (2017) apply an interactive user-based feedback learning scheme to improve the results of a standard SEQ2SEQ model for generating SQL statements. Other approaches (Yin and Neubig, 2017; Rabinovich et al., 2017) incorporate the syntactic structure of the target structured language and decode the Abstract Syntax Tree (AST) corresponding to the surface code. Other recent solutions in semantic parsing avoid the need for ground truth logical forms inferring them automatically from (textual input, answer) pairs and also showing how this process can be generalized to multiple tables (Yin et al., 2015; Neelakantan et al., 2016).

Several large datasets have been recently introduced to facilitate training of deep learning approaches for NLIDB. Brad et al. (2017) propose the SENLIDB dataset together with a baseline SEQ2SEQ architecture for generating complex SQL statements. Zhong et al. (2017) introduce the WikiSQL dataset which contains simpler SQL-like queries involving a single table. They also suggest augmenting a standard SEQ2SEQ model with pointer networks (Vinyals et al., 2015) and highlight the fact that the order of specific clauses from the generated SQL statement affects the accuracy of a SEQ2SEQ model despite having no impact on the actual execution results. To mitigate this issue they apply reinforcement learning and reward queries that diverge from the ground truth but which return the correct results. More recently, Xu et al. (2017) report improved results on the same dataset without the use of reinforcement learning. Their solution, called SQLNet, employs a sketch-based approach designed to align well with the specific structure of SQL statements found in WikiSQL. Their SQL sketch conditions the prediction of a slot only on those particular values it may depend on, instead of all previous predictions. Our sketch-based approach is extended to support full SQL queries, while the two-step approach which uses both the sketch and the description in a dual-encoder to generate the SQL statement differentiates our model from SQLNet.

On another hand, dual-encoder SEQ2SEQ models have been successfully employed used both for machine translation and neural conversational models. In machine translation, dual-encoders have shown to improve the results when using multiple sources as input to generate the target translation (Zoph and Knight, 2016). In addition, dual-attentive decoders using features both from the source sentence and from an additional image related to it have been shown to improve multi-modal machine translation (Calixto et al., 2017). For neural conversational models, while Li et al. (2016) paved the road by introducing a persona-based decoder fed both from an encoder modelling the user input and from a persona specific embedding, only recently dual-encoders have been shown to produce better results than more complex hierarchical neural models (Lowe et al., 2017). Our approach uses a similar dual-encoder model, however we provide as its input two different representations for the desired SQL statement, the textual description supplied by the user and an automatically generated SQL sketch modelling the syntax of the final statement.

3 Two-Step Sketch-Based Model

We define a two-step solution for the problem of generating SQL statements from natural language queries[1]. First, we employ a network that learns to generate an SQL sketch given the user's request. Second, using both the aforementioned generated sketch and the corresponding natural language query, we propose a dual-encoder model to generate the final SQL statement. We consider that the SQL sketch generation is a simpler task, whose intermediate result provides important additional insights for determining the correct SQL statement.

Moreover, as the sketch preserves the SQL syntax of the final statement and only removes semantic

[1]Implementation available at `https://github.com/johnthebrave/nlidb-datasets`

information (e.g. names of tables, columns, constants and other), the proposed two-step model effectively splits the SQL generation problem into two distinct subproblems:

1. The problem of learning the syntax of the SQL query language and generating the most probable SQL sketch given a query in natural language. This refers to learning the surface structure of an SQL stamtement: the order of SQL reserved keywords in a (syntactically) correct query, the precedence of different clauses and subclauses in a the statement, the usage of different operators and so on.

2. The problem of generating semantically correct SQL statements for a given database schema, taking into account both the user's description and the most probable SQL sketch. This task mainly involves choosing the correct table and column names to fill in the sketch, generating the appropriate clauses (WHERE, GROUP BY etc.) given these names, but also correcting the sketch based on the additional semantic and schema information.

3.1 SQL Sketch Generation

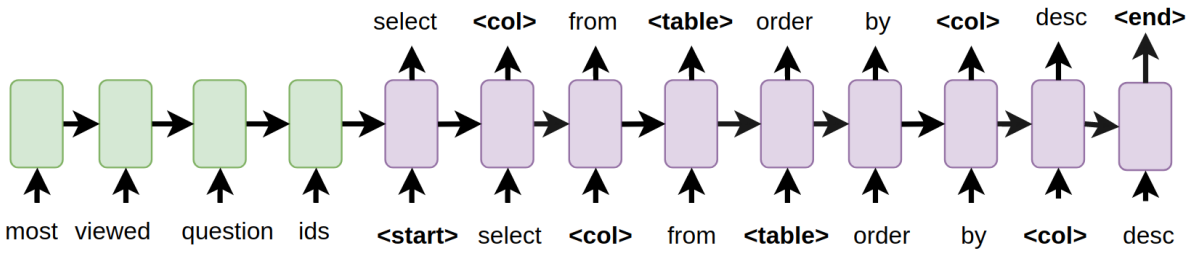

Figure 1: SQL sketch generation using a SEQ2SEQ network

In the first step, the model learns to generate an SQL sketch conditioned on the user's request. In order to obtain the sketches, we altered the dataset by replacing non-SQL keywords, reserved chars and operators within each SQL statement with placeholders (e.g. table names with <table>, similar notations for column names, aliases, variables, and constants). Thus, the SQL sketch only stores the surface form of an SQL statement and is syntactically correct, as we kept all mathematical and logical operators, SQL reserved keywords and special chars. All elements which are specific to the underlying database schema are removed from the sketch, therefore it is schema-agnostic.

To generate the SQL sketch, we have employed a standard SEQ2SEQ model with global-general attention (Luong et al., 2015) which we train on the (description, SQL sketch) pairs extracted from the dataset. An example of generating the SQL schema for a given user input is provided in Figure 1. Using placeholders for schema-related elements in the SQL sketch significantly reduces the output vocabulary for the decoder. This helps in two ways. First, it makes the model focus on the syntactic structure of the SQL statements. Second, it allows training the SEQ2SEQ network using less data - as the syntax is independent from the database schema, this data might even come from different datasets.

We used the open-source neural machine translation toolkit OpenNMT [2]. Both the encoder and the decoder are long short-term memory (LSTM) cells with two hidden layers and 500 neurons. The word embedding layer has 500 neurons. We used batches of maximum size 64. We trained the models with Stochastic Gradient Descent (SGD) for 25 epochs with a learning rate of 1.0 and a learning decay of 0.5 if perplexity did not decrease on the validation set. We generated the SQL sketch using a beam search of size 5.

3.2 Dual-Encoder for SQL Statement Generation

The second stage of the process consists of generating the full SQL statement using a dual-encoder SEQ2SEQ model, as shown in Figure 2. This model receives the natural language description of the query, as well as the SQL sketch obtained in the previous step, which are processed separately by each encoder. The last hidden states of each encoder are concatenated and fed to the decoder to generate the

[2] https://github.com/OpenNMT/OpenNMT-tf

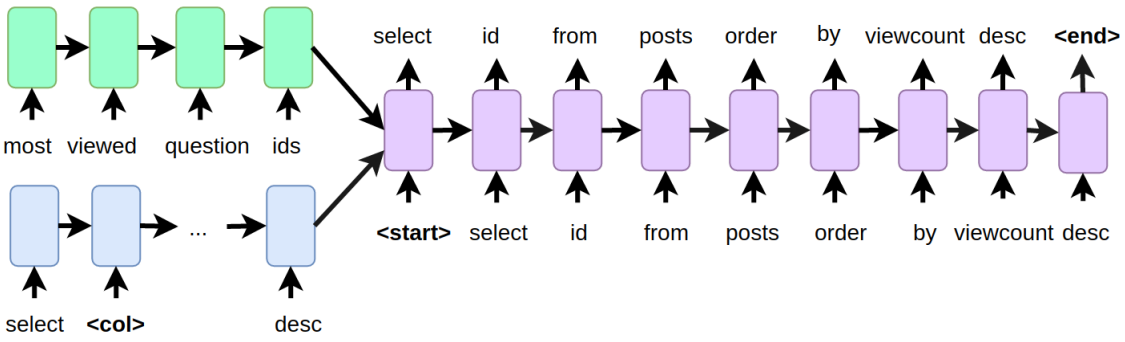

Figure 2: Query generation based on natural language and query sketch

final SQL statement. The decoder uses two attention mechanisms to attend both to the textual description and to the SQL sketch. By relying on the syntactical information provided by the sketch, the dual-decoder can focus more on schema specific entities (e.g. filling in the correct table and column names in the final statement) and on semantic aspects (e.g. generating the correct columns from a selected table). We also expect the dual-encoder model to be able to fix SQL sketches which contain some errors (when compared to the ground truth) after the first step as adding schema and semantic information might improve the syntax as well.

The encoders and the decoder share no weights with the first SEQ2SEQ network used for sketch generation. We used long short-term memory (LSTM) cells with two hidden layers and 500 neurons. The dual-encoder architecture was trained for 25 epochs using batches of 64 samples and a learning rate of 1.0 with learning decay of 0.5. We employed grid search for establishing the number of LSTM cells in the hidden layers and the size of the word embeddings (size 500). Additional hyperparameters that we used are dropout rate (0.3).

4 Results

We evaluated the proposed architecture on the SENLIDB and WikiSQL datasets. We compare our two-step dual-encoder model with a SEQ2SEQ baseline with global-general attention and unknown replacement (Luong et al., 2015). We also perform ablation tests by removing the attention mechanism, either on the textual description encoder or on the SQL sketch encoder, for the dual decoder that generates the final SQL statement.

Model	Dataset	BLEU	Accuracy
Dual-Encoder Seq2Seq (dual attention)	Dev	**83.89**	**39.50**
	Test	**83.2**	**38.99**
Dual-Encoder Seq2Seq (attention on description)	Dev	83.55	38.89
	Test	83.17	38.45
Dual-Encoder Seq2Seq (attention on SQL sketch)	Dev	83.86	38.54
	Test	83.21	38.47
Seq2Seq	Dev	78.90	32.60
	Test	78.50	32.00

Table 1: BLEU scores and accuracy for the generated SQL statements on the WikiSQL dataset

As it can be seen in Table 1 and Table 2, the proposed dual-encoder SEQ2SEQ model greatly outperforms the SEQ2SEQ baseline on both datasets. As expected, the BLEU and accuracy scores on the SENLIDB dataset are significantly smaller than on the WikiSQL dataset, due to the complexity of the SQL statements and database schema from the former dataset. In all experiments, accuracy is computed by checking whether the generated SQL statement matches the ground truth. This process does not take into account that different queries may actually provide the same results. This is especially true for the

Model	Dataset	BLEU	Accuracy
Dual-Encoder SEQ2SEQ	Validation	**21.70**	**3.52**
(dual attention)	Test-annotated	**22.92**	**3.97**
Dual-Encoder SEQ2SEQ	Validation	20.94	3.22
(attention on description)	Test-annotated	21.13	3.33
Dual-Encoder SEQ2SEQ	Validation	21.32	3.47
(attention on SQL sketch)	Test-annotated	21.80	3.60
SEQ2SEQ	Validation	16.90	2.80
	Test-annotated	18.20	2.44

Table 2: BLEU scores and accuracy for the generated SQL statements on SENLIDB dataset

more complex queries in the SENLIDB dataset (e.g. changing the order of the selected columns does not influence the results, but it influences the query match accuracy).

We also notice that removing any of the two attention mechanisms reduces the overall performance of the model on both datasets. This suggests that contextual information from both the SQL sketch and textual description is important to generate the final SQL statement.

Ultimately, all the dual-encoder models outperform the single encoder SEQ2SEQ model on the two datasets, which proves that the proposed two-step model benefits from the previously generated sketch. The added performance of our dual-encoder model comes from the initial task of SQL sketch generation. This demonstrates that even an incorrect, but approximate, syntactic surface form provides important additional information to the dual-encoder which corroborated with the textual description increases the performance of the model.

For the WikiSQL dataset, we also performed experiments with pretrained embeddings (GloVe) (Pennington et al., 2014) and a copying mechanism (See et al., 2017). Using these improvements, the proposed dual encoder model achieves an accuracy of 55.07%, outperforming most previous results.

4.1 Dataset Statistics

We have evaluated our proposed two-step neural architecture on two large datasets: WikiSQL (Zhong et al., 2017) and SENLIDB (Brad et al., 2017). Both datasets consist of several tens of thousand pairs of questions and corresponding SQL statements. However, they are different both with regard to the complexity of the database schemas and to the nature of the corresponding SQL statements. In this section, we briefly explain the characteristics of each dataset to highlight their different nature.

The content of the database tables used in WikiSQL (Zhong et al., 2017) was generated starting from $24,241$ Wikipedia tables. Schema-wise, the database is simplistic as all tables are independent from each other: there are no foreign keys or any other relationships between tables. The natural language queries and corresponding SQL statements were generated in several steps. First, SQL statements were randomly produced using a fixed template. Second, a corresponding interrogation in natural language was then generated automatically for each statement. Afterwards, human annotators from Amazon Mechanical Turk were employed to suggest several paraphrases for the automatically generated interrogations. Other human annotators were further employed to ensure the validity and quality of these paraphrases.

The fixed templates used to generate the SQL statements enforced them to have a specific, simple structure. Each statement contains a single $'select'$ clause requesting a unique column from only one table. An aggregation operator (e.g. $count()$) may be applied on the selected column. The only other component of the SQL statement is the $'where'$ clause, which also follows a very restricted form. Each corresponding subclause is actually a binary operation (e.g. equality operator, '=') applied on a column name and a substring which can always be found in the associated natural language query.

On the other hand, SENLIDB (Brad et al., 2017) consists of real-life SQL statements issued by users on the Data StackExchange Explorer website [3]. Unlike the ones from WikiSQL, these statements have no predefined syntactic limitations and are not generated automatically starting from a specific pattern.

[3] https://data.stackexchange.com/

Datasets / Sample Statistics	SENLIDB		WikiSQL		
	Train	**Test**	**Train**	**Dev**	**Test**
# Samples	24890	780	61297	9145	17284
# Tables	29	15	18471	2704	5200
# Columns	204	98	50207	10144	17642
Avg. Text Length	7.88	10.44	11.73	11.81	11.78
Avg. SQL Length	71.38	7.46	11.50	11.48	11.55
Avg. SQL AST Height	26.11	20.27	19.62	19.63	19.63

Table 3: Brief comparison between SENLIDB and WikiSQL datasets

Moreover, the statements are issued against the StackExchange database which has a complex schema with several relationships and constraints between the various tables. Each SQL statement has a corresponding textual description added by the user who created it. This process resembles a crowd-sourced dataset, with each pair of (textual description, SQL statement) created by a user. To ensure the quality of the dataset, Brad et al. (2017) have preprocessed the data to remove incorrect or uninformative queries. Moreover, a small subset of queries (SENLIDB Test) has been manually annotated by developers with corresponding queries in natural language.

Table 3 provides a brief comparison between the two datasets. Although the size of the training data is similar for both datasets, the test set for SENLIDB is significantly smaller than the corresponding one for WikiSQL. This can be explained by the fact that this data has been manually annotated by developers. Related to the number of tables, although WikiSQL references a significantly larger number of tables than SENLIDB, there is no relation between them and each SQL statement only queries one table. In contrast, the SQL statements in SENLIDB may require data from several tables (thus requiring several $'join'$ operations) or use subqueries or even data extracted from temporary tables created within the statement. Finally, the Abstract Syntax Tree (AST) for the statements in SENLIDB are more complex not only to the number and type of SQL subclauses, but also to the height of the AST.

4.2 Qualitative results

input: what is terrence ross ' nationality **generated sketch:** select <col>from table where <col> = <col> **ground truth sketch:** select <col> from table where <col> = <ct> **generated SQL:** select [nationality] from table where [player] = [terrence ross] **ground truth SQL:** select [nationality] from table where [player] = [terrence ross]
input: which podiums did the williams team have with a margin of defeat of 2 **generated sketch:** select <col> from table where <col> = <ct> **ground truth sketch:** select <col> from table where <col> = <ct> and <col> = <ct> **generated SQL:** select [podiums] from table where [margin of error] = [2] and [team] = [williams] **ground truth SQL:** select [podiums] from table where [team] = [williams] and [margin of defeat] = [2]

Table 4: Examples of SQL sketches and statements generated for the WikiSQL dataset

We list some decoded examples in Table 4 and Table 5. In the first example in Table 4, both the sketch and the final SQL statement are generated correctly by the dual-encoder model. The generated sketch in the second example is incorrect, but the final SQL statement is correct, which means the dual-encoder model actually rectified the surface syntactic form provided by the sketch. This shows that the dual-encoder not only adds specific schema elements and semantic information, but actually is able to modify some incorrect SQL sketches generated in the first step. This result is important as it means that additional semantic information is successfully used by the model to correct the proposed syntax.

In Table 5, we notice that for both examples, the generated sketch is very different from the ground

input: show top 50000 posts which have more than 10000 views **generated sketch:** select top <ct> <alias> . <col> as <alias> , <alias> . <table> , <alias> . <col> , <alias> . <col> from <table> as <alias> inner join <table> as <alias> on <alias> . <col> = <alias> . <col> where <alias> . <col> = <ct> and <alias> . <col> > = <ct> order by <alias> . <col> desc **ground truth sketch:** select top <ct> * from <table> where <table> . <col> > <ct> order by <table> . <col> desc **generated SQL:** select top 10000 posts . id , posts . body from posts where posts . viewcount > 10000 **ground truth SQL:** select top 50000 * from posts where posts . viewcount > 10000 order by posts . viewcount desc
input: list id , body of posts that have the same postid as the id of posttags and tagid of posttags = 17 and id of posts < 1000 **generated sketch:** select <table> . <col> , <col> (*) as <alias> from <table> inner join <table> on <table> . <col> = <table> . <col> inner join <table> on <table> . <col> = <table> . <col> inner join <table> on <table> . <col> = <table> . <col> and <col> = <ct> group by <table> . <col> order by <col> desc **ground truth sketch:** select <alias> . <col> , <alias> . <col> from <table> <alias> inner join <table> <alias> on <alias> . <col> = <alias> . <col> where <alias> . <col> = <ct> and <alias> . <col> < <ct> **generated SQL:** select count (*) from posts inner join posttags on posttags . postid = posts . id **ground truth SQL:** select p . id , p . body from posts p inner join posttags pt on p . id = pt . postid where pt . tagid = 17 and p . id < 1000

Table 5: Examples of SQL sketches and statements generated for the SENLIDB dataset

truth sketch. However, in the first example the generated SQL statement resembles the target SQL ($'top'$ clause, $'viewcount'$ column and $'posts'$ table are correctly identified). In the second example, the network correctly generates a more complex SQL query that contains a join operation between tables $'posts'$ and $'posttags'$. Again, the dissimilarity between sketches and similarity between final SQL statements suggests that the dual-encoder can recover from a incorrect generated sketch.

One of the reasons for which the SQL sketches on the SENLIDB dataset are more complex is related to the fact that the training data contains slightly more complex queries than the test set. This leads the sketch network to have a bias for more complex sketches.

4.3 Sketch accuracy

Dataset	BLEU	Accuracy
WikiSQL test	94.06	82.38
SENLIDB test	28.36	5.12

Table 6: BLEU scores and accuracy of the predicted SQL sketches

We have also investigated the performance of each of the two steps in our proposed model. In this subsection we measure the performance of the first step, the generation of the SQL sketch. In Table 6 we measure how many sketches are correctly predicted by the first SEQ2SEQ model. The BLEU score and accuracy of the generated sketches for the WikiSQL dataset are very high, as expected due to the much simpler nature of the SQL queries featured in this dataset. The accuracy of the final SQL statements is very low compared to the sketch accuracy, which means that the main difficulty with the WikiSQL dataset is correctly instantiating the SQL sketch with the appropriate columns names and constants thus resembling a slot filling task.

On the other hand, the sketch accuracy for SENLIDB is significantly lower compared to WikiSQL.

This is unsurprising, as the SQL queries are more complex. However, the difference between the sketch accuracy and the SQL accuracy for SENLIDB is small, which suggests that getting the right sketch is crucial for these queries and this step is actually more difficult than instantiating them.

4.4 Sketch feeding

We also evaluated the performance of our model when the correct sketch is being provided along with the textual description. To this extent, the dual-encoder in the second step receives the ground truth sketch at test time instead of the decoded sketch from the previous network.

Model	Dataset	BLEU	Accuracy
Dual-Encoder Seq2Seq	WikiSQL test	92.77	39.04
	SENLIDB test	68.20	25.89

Table 7: BLEU scores and accuracy of the generated SQL statements using the ground truth SQL sketch

We observe in Table 7 that the accuracy improves significantly on the SENLIDB corpus (21.92% improvement), which shows again the importance of generating the correct sketch for these difficult SQL statements. The accuracy boost on WikiSQL is small (1.15% improvement), reconfirming our earlier observation that WikiSQL is more challenging as a slot filling task.

4.5 Tables and Column Identification

Model	Task	Precision	Recall	F1 score
Dual-Encoder SEQ2SEQ	Table prediction	0.85	0.74	0.78
	Column prediction	0.59	0.53	0.55
SEQ2SEQ (Brad et al., 2017)	Table prediction	0.82	0.72	0.76
	Column prediction	0.55	0.47	0.50

Table 8: Results (using macro-averaging) for table and column prediction on the SENLIDB dataset

A simpler, but important subtask for the generation of SQL statements is the correct instantiation of table and column names in a query. In Table 8, we present different metrics for this task treated as a classification problem. As it can be observed, the dual-encoder model consistently outperforms the SEQ2SEQ baseline by merely using the SQL query sketch as input.

5 Conclusions

In this paper, we presented a two-step architecture for generating SQL statements starting from a user request expressed in natural language. The novelty resides in generating the underlying SQL sketch first, followed by the generation of the full SQL statement using a dual-encoder model conditioned by both the sketch and the query in natural language. The two-step approach actually separates the problem of generating an SQL statement into first constructing the correct syntactic surface form, which is later used to embed semantic and schema specific elements in the second step.

We demonstrated the validity of this approach by comparing the two-step model with a SEQ2SEQ baseline on two large datasets. The results show that the model significantly improves the results of the baseline. In addition, the best results are obtained when the dual-encoder model uses a dual attention mechanism on both textual description and SQL sketch. Future research should consider improving the two attention mechanisms and how they are combined. Other improvements can be obtained by training the sketch generation network on several datasets, considering that the sketch is schema-agnostic and might benefit from transfer learning between datasets.

A last insight of the paper relates to an important difference between the two datasets. As WikiSQL contains data from a simplistic database schema with artificial constraints for the SQL statements, it resembles a slot filling task. On the other hand, the main challenge for solving the more complex queries in SENLIDB is the generation of the correct SQL sketch corresponding to a query.

Abstract

The task of nuclearity recognition in Chinese discourse remains challenging due to the demand for more deep semantic information. In this paper, we propose a novel text matching network (TMN) that encodes the discourse units and the paragraphs by combining Bi-LSTM and CNN to capture both global dependency information and local n-gram information. Moreover, it introduces three components of text matching, the Cosine, Bilinear and Single Layer Network, to incorporate various similarities and interactions among the discourse units. Experimental results on the Chinese Discourse TreeBank show that our proposed TMN model significantly outperforms various strong baselines in both micro-F1 and macro-F1.

1 Introduction

During the past few years, the focus of Natural Language Understanding (NLU) has shifted from the word/sentence level to the discourse level. A challenging task in NLU is discourse parsing, which involves analysing the relations between discourse units and building the document structure. As one of the most influential discourse theories, Rhetorical Structure Theory (RST) (Mann and Thompson, 1988) defines a document as a collection of Elementary Discourse Units (EDUs) with semantic connections and combines adjacent EDUs with rhetorical relations in a hierarchical way to represent an entire document as a discourse tree.

As a critical subtask in discourse parsing, nuclearity recognition involves identifying the nuclearity between the discourse units and thus being able to extract the main information in a document. According to RST, a discourse relation can be divided into mononuclear and multinuclear. A mononuclear relation holds a nucleus and a satellite, where the nucleus expresses the main textual information and the satellite offers additional information about the nucleus (Stede, 2008), while a multinuclear relation holds two or more discourse units, which are all nuclei. Therefore, three types of nuclearity exist: Nucleus-Satellite if the left subtree is the nucleus and the right subtree is the satellite, Satellite-Nucleus if the order of the satellite and nucleus is inverted, and Nucleus-Nucleus for multinuclear relations.

Nuclearity recognition is helpful in detecting discourse relations (Iruskieta et al., 2014) and extracting the main content of a document, and it is widely used in various NLP tasks, including automatic summarisation (Louis et al., 2010; Marcu, 2000), question answering (Verberne et al., 2007) and information extraction (Zou et al., 2014). Consider the following document as an example:

Example 1: 中国机电产品进出口贸易继续增加 $_{a}$，占总进出口的比重继续上升 $_{b}$。其中，出口五十七点九亿美元 $_{c}$，占总出口的百分之三十二点五 $_{d}$；进口八十五点二亿美元 $_{e}$，占总进口的百分之四十六点四 $_{f}$，均比去年同期有所上升 $_{g}$。 *The import and export trade of China's mechanical and electronic products continues to increase* $_{a}$, *and its proportion of the total imports and exports also continues to rise* $_{b}$. *Among them, the exports amounted to 5.79 billion dollars* $_{c}$, *accounting for 32.5 percent of the total exports* $_{d}$; *and the imports of 8.52 billion dollars* $_{e}$, *accounting for 46.4 percent of the total imports* $_{f}$; *all of them were higher than those in the same period last year* $_{g}$.

Example 1 shows a paragraph that includes seven EDUs (*a*-*g*), and its corresponding nuclearity discourse tree is illustrated in Figure 1, where the leaf nodes (*a*-*g*) in Figure 1 are EDUs and the internal

Proceedings of the 27th International Conference on Computational Linguistics, pages 525–535
Santa Fe, New Mexico, USA, August 20-26, 2018.

nodes refer to relational nodes, which represent the combination of the relevant children. When connecting the parent and child nodes, the directed edge indicates that the child is a nucleus in the relationship and the undirected edge indicates that the child is a satellite.

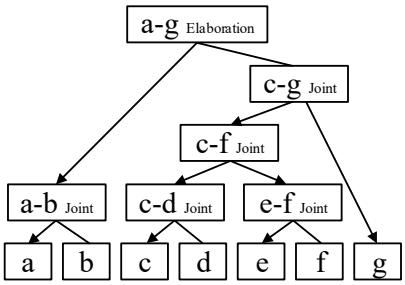

Figure 1: Discourse tree of Example 1.

Starting from the root node, i.e., *a-g* in Figure 1, we can continually select all of the branches labelled as nucleus until the leaf node, i.e., *a* in Figure 1 (中国机电产品进出口贸易继续增加 *The import and export trade of China's mechanical and electronic products continues to increase*), which can be used to represent a summary of this paragraph.

Although there are many studies on discourse parsing due to its vital role in NLP, only a few address nuclearity recognition. Among them only three studies (Li et al., 2015; Chu et al., 2015; Kong and Zhou, 2017) explore nuclearity recognition in Chinese due to the lack of annotated corpus and the abstract nature of Chinese itself. In addition, those studies heavily relied on manual feature engineering (Feng and Hirst, 2014; Heilman and Sagae, 2015; Wang et al., 2017). Only a few studies (Li et al., 2014; Li et al., 2016) used deep neural networks to explore automatic representation learning. One of the disadvantages of previous studies is that they lack deep semantic information extracted from discourse units due to the ineffectiveness of classifier-based models and simple neural network models. Even worse, different from those hypotactic languages such as English, Chinese is a paratactic (discourse-driven and pro-drop) language with a wide spread of ellipsis and open flexible sentence structures. Therefore, the shallow semantic features (syntactic features), which are widely used in English, might not be effective in Chinese. This property makes discourse parsing in Chinese more challenging.

In this paper, we propose a novel text matching network (TMN) for nuclearity recognition. The TMN model encodes the discourse units and paragraphs by combining Bi-LSTM and CNN to capture both the global dependency information and the local n-gram information. Moreover, it introduces three components of text matching, i.e., Cosine, Bilinear and Single Layer Network, to incorporate various similarities and interactions between discourse units and thus provide more useful information to recognise nuclearity. Experimental results on the Chinese Discourse TreeBank (CDTB) (Li et al., 2014) show that our proposed TMN model significantly outperforms various strong baselines in both micro-average and macro-average F1. We summarise the contributions of our work as follows:

- We combine Bi-LSTM and CNN to jointly learn proper representation of the discourse units, which can capture both global dependency information and local n-gram information.
- We introduce three text matching components, i.e., Cosine, Bilinear and Single Layer Network to capture various semantic similarities and interactions among the discourse units.
- We consider the semantic relations between the discourse units and paragraphs. These relations provide an effective supplement to recognise the nuclearity types.

The remainder of this paper is organised as follows: Section 2 introduces the related work, Section 3 gives the details of our model TMN, Section 4 reports the experimental results and Section 5 gives the conclusions.

2 Related Work

Previous studies on nuclearity recognition mainly focused on English, with RST Discourse Treebank (RST-DT) (Carlson et al., 2003) being the most popular corpus. However, most of them only regard

nuclearity recognition as a trivial component of overall discourse parsing, and they ignore its specific characteristics and critical importance.

The algorithms of nuclearity recognition published on RST-DT can mainly be categorised as shift-reduce algorithms (Ji and Eisenstein, 2014; Heilman and Sagae, 2015; Wang et al., 2017), probabilistic CKY-like algorithms (Joty et al., 2013; Li et al., 2014; Li et al., 2016) and greedy bottom-up algorithms (Feng and Hirst, 2014). Li et al. (2016) applied different classifiers to three discourse parsing subtasks separately, but they share the high level representation of discourse units by the same network structures. Wang et al. (2017) used a transition-based system to build discourse trees with nuclearity labels and then used Support Vector Machines (SVMs) to determine the discourse relations at different text levels.

Most of the previous studies used SVMs and variants of Conditional Random Fields (CRFs); only Li et al. (2014) and Li et al. (2016) introduced neural networks into nuclearity recognition. Li et al. (2014) used a two-layer feedforward neural network to determine the relation between text spans and computed the representation for each text span based on the representations of its subtrees by recursive neural models. Li et al. (2016), which is used as one of our baselines, proposed an attention-based hierarchical Bi-LSTM network to learn the representations of the text spans and used a tensor-based transformation function to capture interactions among the features of the text spans.

For recognising nuclearity between Chinese discourse units, there are only three studies. Li et al. (2015), Chu et al. (2015) and Kong and Zhou (2017) have done some preliminary work on Chinese Discourse TreeBank (CDTB) (Li et al., 2014). Li et al. (2015) used contextual features, lexical features and dependency tree features to recognise nuclearity by a Maximum Entropy (ME) classifier. Chu et al. (2015) used similar features to recognise three types of nuclearity by three different ME classifiers and used sampling techniques to obtain a balanced training set and testing set. Kong and Zhou (2017) integrated some previous research and proposed a CDT-styled End-to-End discourse parser, which can automatically detect discourse units and perform all three discourse parsing subtasks in sequence. They used the same model of nuclearity recognition as Li et al. (2015) and reported the same results.

3 Text Matching Network on Nuclearity Recognition

In this section, we propose a novel text matching network (TMN) for nuclearity recognition, and its high-level illustration is shown in Figure 2, which includes three modules: 1) Text Encoding, 2) Text Matching, and 3) Nuclearity Classification.

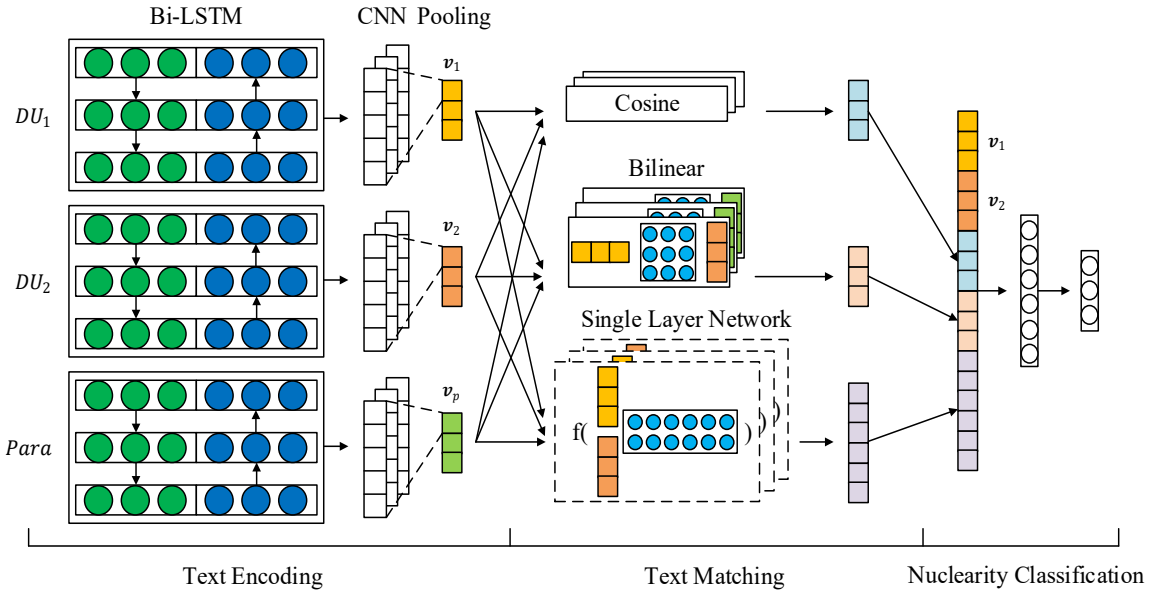

Figure 2: The basic framework of our model, including 1) Text Encoding, 2) Text Matching, and 3) Nuclearity Classification.

To recognise the nuclearity of two discourse units DU_1 and DU_2, their word sequences and the paragraph $Para$ that contains the above two units are the inputs of our model. Taking Example 1 as an instance, DU_1/DU_2 could be one of the EDUs *a*-*g* or their combinations, and $Para$ is the whole paragraph. The Text Encoding module first encodes these word sequences into the semantic vectors $\boldsymbol{v}_1, \boldsymbol{v}_2$ and $\boldsymbol{v}_p$ by Bi-LSTM and CNN. Then, these semantic representations are fed into the Text Matching module, which uses Cosine to calculate the similarity of different semantic vectors and applies Bilinear and Single Layer Network to incorporate the strong linear and nonlinear interactions between different semantic vectors. Finally, the combined feature vector, which is composed of two semantic vectors of two discourse units and one feature vector of all of the interactive information, is sent to the output layer, i.e., the Nuclearity Classification module, through a nonlinear transformation.

Our TMN model is based on two hypotheses. The first hypothesis is that there are strong correlations between the nuclearity and the semantic similarity or interactions of two discourse units. Commonly, the discourse units with similar semantics are multinuclear, and the discourse units with semantic interactions have a mononuclear relation.

The second hypothesis is that the nuclearity of two discourse units is relevant to the topic of the paragraph or document. For example, in the case of a mononuclear relation, the nucleus unit is usually semantically closer to the topic of the paragraph. Therefore, our TMN model makes the semantic match between not only the different discourse units but also the discourse unit and paragraph, by three similarity metrics, namely, the Cosine, Bilinear and Single Layer Network, which can capture the features that are related to nuclearity recognition adequately.

3.1 Text Encoding

Our Text Encoding module combines Bi-LSTM and CNN to encode the discourse unit DU_i and the paragraph $Para$, which is the modification of the Convolutional-pooling LSTM (Tan et al., 2016) in question answering.

Its input is a sequence of words $(t_1, t_2, \dots, t_T)$ in a discourse unit DU_i or a paragraph $Para$ where T is the number of words in the discourse unit or paragraph. Each word t_i in the sequence is represented as the combination of its word embedding $\boldsymbol{e}_i$ and POS (Part-Of-Speech) tag embedding $\boldsymbol{p}_i$ as follows:

$$\boldsymbol{w}_i = [\boldsymbol{e}_i, \boldsymbol{p}_i]. \tag{1}$$

LSTM models successfully keep the useful information from long-range dependency, but they focus more on the words that are behind. Due to the need for our model to treat each word equally, Bi-LSTM is introduced to the Text Encoding module. At each position t, we concatenate the output $\overrightarrow{\boldsymbol{h}_t}, \overleftarrow{\boldsymbol{h}_t} \in \mathbb{R}^l$ of the two inverted LSTMs as the output of the current word as follows:

$$\boldsymbol{h}_t = [\overrightarrow{\boldsymbol{h}_t}, \overleftarrow{\boldsymbol{h}_t}]. \tag{2}$$

Therefore, each output contains not only the current word information but also the contextual information. Consequently, we choose it as the input of a 1D CNN to capture richer local n-gram information. The 1D CNN is similar to the traditional n-gram model. It can effectively capture the local interaction information between the words in the word window, and thus, it can make up for the lack of LSTM. Finally, all of the features captured by the convolution kernels are collected by the global max pooling operation to obtain the textual representation $\boldsymbol{v}_i \in \mathbb{R}^c$. In addition, the number l of LSTM neurons, the size k and the number c of the CNN convolution kernels are all hyperparameters of our model.

3.2 Text Matching

After obtaining the representations $\boldsymbol{v}_1, \boldsymbol{v}_2, \boldsymbol{v}_P$ of the discourse units DU_1, DU_2 and the paragraph $Para$ by Bi-LSTM and CNN in the Text Encoding module, we apply the Cosine, Bilinear (Sutskever et al., 2009; Jenatton et al., 2012) and Single Layer Network (Collobert and Weston, 2008) to capture the interactions between different discourse units and between the discourse unit and the paragraph.

The cosine distance calculates the angle between two vectors, which is usually used to measure the degree of similarity. **Cosine** is defined as follows:

$$cos(\boldsymbol{v}_1, \boldsymbol{v}_2) = \frac{\boldsymbol{v}_1^{\mathrm{T}} \boldsymbol{v}_2}{\|\boldsymbol{v}_1\| \cdot \|\boldsymbol{v}_2\|}. \tag{3}$$

Because the discourse units with multinuclear relations are usually similar in content, the cosine similarity $cos(\boldsymbol{v}_1, \boldsymbol{v}_2)$ between the semantic representations of two discourse units can be used as an effective feature to determine their nuclearity. We also calculated the cosine similarities $cos(\boldsymbol{v}_1, \boldsymbol{v}_P)$ and $cos(\boldsymbol{v}_2, \boldsymbol{v}_P)$ between the discourse unit and the paragraph to measure the similarity between the discourse unit and the topic of the paragraph. These two similarities are helpful for identifying the mononuclear relations.

Bilinear is a simple way to incorporate the linear interactions between two vectors and is defined as follows:

$$s(\boldsymbol{v}_1, \boldsymbol{v}_2) = \boldsymbol{v}_1^{\top} \boldsymbol{W} \boldsymbol{v}_2, \tag{4}$$

where $\boldsymbol{W} \in \mathbb{R}^{c \times c}$ is the parameter matrix. Usually, when using the Bilinear model (Chen et al., 2016; Wan et al., 2016; Wu et al., 2017), the Bilinear value $s(\boldsymbol{h}_{x_i}, \boldsymbol{h}_{y_j}) = \boldsymbol{h}_{x_i}^{T} \boldsymbol{W} \boldsymbol{h}_{y_j}$ is calculated for any two words in the two word sequences $\{x_1, x_2, \ldots, x_m\}$ and $\{y_1, y_2, \ldots, y_n\}$ to obtain a matching matrix, where $\boldsymbol{h}_{x_i}, \boldsymbol{h}_{y_i}$ are semantic vectors that correspond to word x_i and y_j.

A discourse unit or a paragraph could contain a larger number of words, and it will lead to generating an enormous matching matrix. However, the number of training samples that can be used in our model is relatively small, which results in great difficulty with training the parameter $\boldsymbol{W}$. Therefore, we simplified this process to calculate the Bilinear values $\boldsymbol{v}_1^{\top} \boldsymbol{W} \boldsymbol{v}_2, \boldsymbol{v}_1^{\top} \boldsymbol{W} \boldsymbol{v}_P$ and $\boldsymbol{v}_2^{\top} \boldsymbol{W} \boldsymbol{v}_P$ directly on the encoded discourse units and encoded paragraphs. Since $\boldsymbol{v}_1, \boldsymbol{v}_2$ and $\boldsymbol{v}_P$ contain the semantic information of the discourse units and the paragraph, Bilinear is equivalent to capturing the linear interaction between DU_1, DU_2 and $Para$ at the textual level.

Single Layer Network is defined as follows:

$$\begin{aligned} s(\boldsymbol{v}_1, \boldsymbol{v}_2) &= f(\boldsymbol{V}_1[\boldsymbol{v}_1, \boldsymbol{v}_2] + \boldsymbol{b}_1) \\ s(\boldsymbol{v}_1, \boldsymbol{v}_P) &= f(\boldsymbol{V}_2[\boldsymbol{v}_1, \boldsymbol{v}_P] + \boldsymbol{b}_2), \end{aligned} \tag{5}$$

where $\boldsymbol{V}_1 \in \mathbb{R}^{w \times 2c}, \boldsymbol{b}_1 \in \mathbb{R}^{w}$ and $\boldsymbol{V}_2 \in \mathbb{R}^{w \times 2c}, \boldsymbol{b}_2 \in \mathbb{R}^{w}$ are parameters to incorporate nonlinear interactions between the discourse units and between the unit and the paragraph, and we choose $tanh$ as the activation function f. The number w of neurons is the hyperparameter of our model. Because of the existence of nonlinear activation functions, the Single Layer Network can capture nonlinear interactions between different discourse units and between the discourse unit and the paragraph. Bilinear focuses on capturing linear interactions, while Single Layer Network focuses on capturing non-linear interactions, and thus, Single Layer Network can make up for the lack of Bilinear to some extent. We can obtain nonlinear feature vectors $\boldsymbol{v}_{S_{12}}, \boldsymbol{v}_{S_{1P}}$ and $\boldsymbol{v}_{S_{2P}} \in \mathbb{R}^{w}$ by Single Layer Network as follows:

$$\begin{aligned} \boldsymbol{v}_{S_{12}} &= f(\boldsymbol{V}_1[\boldsymbol{v}_1, \boldsymbol{v}_2] + \boldsymbol{b}_1) \\ \boldsymbol{v}_{S_{1P}} &= f(\boldsymbol{V}_2[\boldsymbol{v}_1, \boldsymbol{v}_P] + \boldsymbol{b}_2) \\ \boldsymbol{v}_{S_{2P}} &= f(\boldsymbol{V}_2[\boldsymbol{v}_2, \boldsymbol{v}_P] + \boldsymbol{b}_2) \end{aligned} \tag{6}$$

With Cosine, Bilinear, and Single Layer Network, we measure the similarity and capture the linear and non-linear interactions among the discourse units and between the unit and the paragraph, and by training the parameter matrices $\boldsymbol{W}, \boldsymbol{V}_1, \boldsymbol{V}_2$ and the parameter vectors $\boldsymbol{b}_1, \boldsymbol{b}_2$, the matching features that play an important role in recognising nuclearity are extracted. This process is how our Text Matching module identifies important information in the discourse unit and performs text matching methods under supervised learning.

3.3 Nuclearity Classification

Based on the discourse unit DU_1, DU_2 and the paragraph $Para$, we obtain the semantic representation vectors $\boldsymbol{v}_1, \boldsymbol{v}_2$ from the Text Encoding module and the Cosine values, the Bilinear values and the nonlinear feature vectors from the Text Matching module. We concatenate all of these values and the vectors above as the input feature vector $\tilde{\boldsymbol{v}}$ of the Nuclearity Classification module as follows:

$$\begin{aligned} \boldsymbol{v}_{cos} &= [\cos(\boldsymbol{v}_1, \boldsymbol{v}_2), \cos(\boldsymbol{v}_1, \boldsymbol{v}_P), \cos(\boldsymbol{v}_2, \boldsymbol{v}_P)]^{\top} \\ \boldsymbol{v}_{bl} &= [\boldsymbol{v}_1^{\top} \boldsymbol{W} \boldsymbol{v}_2, \boldsymbol{v}_1^{\top} \boldsymbol{W} \boldsymbol{v}_P, \boldsymbol{v}_2^{\top} \boldsymbol{W} \boldsymbol{v}_P]^{\top} \\ \boldsymbol{v}_{sln} &= [\boldsymbol{v}_{S_{12}}, \boldsymbol{v}_{S_{1P}}, \boldsymbol{v}_{S_{2P}}] \\ \tilde{\boldsymbol{v}} &= [\boldsymbol{v}_1, \boldsymbol{v}_2, \boldsymbol{v}_{cos}, \boldsymbol{v}_{bl}, \boldsymbol{v}_{sln}] \end{aligned} \tag{7}$$

We implement the Nuclearity Classification module using a two-layer feedforward neural network. The input vector is first sent to a nonlinear transformation and then fed into a standard softmax layer, where the nonlinear transformation uses the $Relu$ function (Nair and Hinton, 2010) as follows:

$$\boldsymbol{t} = Relu(\boldsymbol{W}_t\,\tilde{\boldsymbol{v}} + \boldsymbol{b}_t) \tag{8}$$

$$\tilde{y} = softmax(\boldsymbol{W}_s\boldsymbol{t} + \boldsymbol{b}_s), \tag{9}$$

where $\boldsymbol{W}_t \in \mathbb{R}^{w_t \times (2c+6+3w)}$, $\boldsymbol{b}_t \in \mathbb{R}^{w_t}$ and $\boldsymbol{W}_s \in \mathbb{R}^{3 \times w_t}$, $\boldsymbol{b}_s \in \mathbb{R}^3$ are the parameters in the nonlinear transformation and in the softmax layer, respectively. Additionally, the number w_t of neurons in the nonlinear transformation layer is the hyperparameter of our model. During the training, we use the Adam optimiser (Kingma and Ba, 2014) to optimise the network parameters by maximising the log-likelihood loss function between the predicted label $\tilde{y}$ and the real label y.

4 Experimentation

In this section, we first introduce the CDTB corpus in the Chinese and experimental setting, and then we report and analyse the experimental results.

4.1 CDTB Corpus

Following the tree structure, the representation of nuclearity in RST and the representation of connectives in the Penn Discourse Treebank (PDTB) (Prasad et al., 2008), Li et al. (2014) built the Chinese Discourse TreeBank (CDTB) corpus based on the Chinese Treebank (CTB) (Xue et al., 2005) with a connective-driven dependency tree scheme. In CDTB, each paragraph is marked as a connective-driven dependency tree (CDT), where its leaf nodes are EDUs, its intermediate nodes represent connectives, and EDUs connected by connectives can be combined into higher level discourse units.

Similar to RST-DT, there are three types of nuclearity in CDTB: Nucleus-Satellite, Satellite-Nucleus and Nucleus-Nucleus. However, CDTB labels relations that link two discourse units on their parent node, and thus, a binary tree with *n* EDUs has only *n-1* relations. Moreover, CDTB marks paragraphs instead of documents as discourse trees, which will also lead to fewer annotated relations.

Currently, the CDTB corpus consists of 500 newswire articles, which are further divided into 2342 paragraphs with a CDT representation for one paragraph. CDTB contains 10650 EDUs, and each EDU has 22 Chinese characters on average. There are 7310 annotated relations in CDTB in which 3555 (48.6%) relations are mononuclear relations, with 2110 Nucleus-Satellite and 1445 Satellite-Nucleus, while the remaining 3755 (51.4%) relations are Nucleus-Nucleus. The reason is that COORDINATION (mononuclear/multinuclear: 468/3683) is the largest category (56.8%) in CDTB, which leads to a large number of multinuclear instances.

4.2 Experimental Setup

We evaluate our model on the corpus CDTB. Following the previous work (Kong and Zhou, 2017), we also choose the same 450 documents as the training set and 50 documents as the testing set. The specific division and labelling situation is shown in Table 1. In our evaluation, all of the non-binary trees are transformed into left binary trees, and the numbers of multinuclear relations in the converted training set and testing set are 4257 and 485, respectively. Moreover, we report the Precision (P), Recall (R) and F1 on each nuclearity type and also give the micro-average and macro-average F1.

	Training set	Testing set
Document	0001-0090, 0101-0190, 0201-0290, 0301-0325, 0400-0454, 0500-0509, 0520-0554, 0590-0596, 0600-0647	0091-0100, 0191-0200, 0291-0300, 0510-0519, 0648-0657
Nuclearity	#Nucleus-Satellite/#Satellite-Nucleus: 1901/1343 # Nucleus-Nucleus: 3371	#Nucleus-Satellite/#Satellite-Nucleus: 207/104 # Nucleus-Nucleus: 384

Table 1: Division of dataset. There are 3244 mononuclear relations and 3371 multinuclear relations in the training set, and these figures are 311 and 384 in the testing set, respectively.

The dimension of the word embeddings is set to 300, and the dimension of the POS embeddings is set to 50. We pre-trained the word embeddings with Word2Vec (Mikolov et al., 2013) on the Wikipedia Chinese corpus[1]. We used HanLP[2] to preprocess the texts, including the word segmentation and POS tagging, and we used the Keras[3] library to implement our model. All of the parameters are randomly initialised except for the word embeddings. We adopted the dropout strategy (Hinton et al., 2012) to avoid overfitting and set the dropout rate to 0.5.

We selected one-ninth of the samples from the training set as a development set to tune the hyperparameters by a grid search, and for a fair comparison, all of the models in our experiment use the same parameters. In the Text Encoding module, the number l of LSTM neurons is set to 50, and the size k and the number c of the CNN convolution kernels are set to 5 and 400, respectively, according to the empirical results in Table 2. In the Text Matching module, the number of neurons w in the Single Layer Network is set to 50. In the Nuclearity Classification module, the number w_t of neurons in the nonlinear transformation layer is set to 128.

Filter size	#Feature map				
	100	200	300	400	500
3	55.06	57.73	58.34	58.18	59.38
4	56.47	57.23	58.42	59.21	59.66
5	56.84	57.71	59.17	**59.70**	58.44
6	56.65	58.85	58.22	58.53	57.05

Table 2: Macro-average F1 with different CNN parameter settings on the development set.

4.3 Experimental Results

To exhibit the effectiveness of our TMN model, the experiment results consist of two parts: the baselines and TMN.

Baselines: We collect five baselines for our experiment: ME (Kong and Zhou, 2017), Bi-LSTM, Bi-LSTM(A), Bi-LSTM+CNN and Bi-LSTM(A)+T (Li et al., 2016). The ME model proposed by (Kong and Zhou, 2017) used contextual features, lexical features and dependency tree features to recognise nuclearity by an ME classifier. We obtained their source codes and found a data partition error in their system: some instances appeared in both the training set and the testing set. For a fair comparison, we corrected the data partition following their paper and report the revised results of their system in this paper. Considering that the attention-based hierarchical Bi-LSTM network proposed by (Li et al., 2016) performs better than the recursive neural model (Li et al., 2014), we implemented four neural network-based systems. The first is a Bi-LSTM network model (Bi-LSTM), and the second is a Bi-LSTM network model with the attention mechanisms (Bi-LSTM(A)). The third is a Bi-LSTM network model with the attention mechanisms and the tensor-based transformation function (Bi-LSTM(A)+T) (Li et al., 2016). The fourth is a Bi-LSTM+CNN model that combines Bi-LSTM and CNN.

Model	Nucleus-Satellite P / R / F1	Satellite-Nucleus P / R / F1	Nucleus-Nucleus P / R / F1	Macro-F1	Micro-F1
ME	32.2 / 15.1 / 20.5	40.0 / 15.0 / 21.8	65.6 / **87.8** / 75.0	42.3	60.5
Bi-LSTM	53.6 / 50.2 / 51.9	30.4 / 33.7 / 32.0	74.3 / 74.6 / 74.5	52.8	62.9
Bi-LSTM(A)	55.7 / 44.9 / 49.7	34.9 / 36.5 / 35.7	74.6 / 80.0 / 77.2	54.4	65.2
Bi-LSTM+CNN	59.6 / 46.4 / 52.1	**40.2** / 31.7 / 35.5	73.2 / 83.5 / 78.0	55.7	67.1
Bi-LSTM(A)+T	56.8 / **50.7** / 53.6	37.5 / 43.4 / 40.2	**77.0** / 77.9 / 77.5	57.2	66.3
TMN	**69.1** / 45.4 / **54.8**	39.2 / **49.0** / **43.6**	76.2 / 83.3 / **79.6**	**60.4**	**69.0**

Table 3: The experimental results of five baselines and TMN.

The experimental results of the above models are shown in Table 3, and these results show that our

[1] https://dumps.wikimedia.org/zhwiki/
[2] https://github.com/hankcs/HanLP
[3] https://keras.io/

TMN model outperforms the other five baselines in both the micro-average and macro-average F1. Compared with the traditional method ME, the other five neural network models improve the micro-average and macro-average F1 significantly, especially the macro-average F1, with large gains from 10.5 up to 18.1. These results justify the effectiveness of the neural network models on the nuclearity recognition to capture the deeper semantic information that is hiding in the discourse units.

Compared with Bi-LSTM, Bi-LSTM(A) improves the macro-average and micro-average F1 by 1.6 and 2.3, respectively, because Bi-LSTM(A) can pick up prominent semantic information on the output of Bi-LSTM using the attention mechanism. Furthermore, the performance of Bi-LSTM(A)+T is better than Bi-LSTM(A), and this result ensures that tensor-based transforms are also helpful to Bi-LSTM. Moreover, due to the Bi-LSTM+CNN model combining the ability of capturing the global information by Bi-LSTM and the local information by CNN, it performs better than both Bi-LSTM and Bi-LSTM(A).

Our TMN model outperforms all of the other five models, with large gains from 3.2 up to 18.1 in the macro-average F1 and a significant gain from 1.9 up to 8.5 in the micro-average F1. Compared with the Bi-LSTM, Bi-LSTM(A) and Bi-LSTM+CNN, which focus on obtaining the representations of text, our TMN model can capture the semantic features and incorporates interactions between the representations of the discourse units and the paragraphs. Moreover, compared with the Bi-LSTM(A)+T model, our TMN combines both Bi-LSTM and CNN in the Text Encoding module and uses many simple but efficient methods to incorporate richer interactions in the Text Matching module.

4.4 Analysis

We also compare the performances of the different nuclearity types, and Table 3 shows that the performance of multinuclear (Nucleus-Nucleus) is much higher (>24 in F1) than that of the mononuclear relations (Nucleus-Satellite and Satellite-Nucleus). This result derives from two aspects. The first is that the majority of the training set is Nucleus-Nucleus, which occupies 56.8% of all annotated nuclearity, while the percentages of the Nucleus-Satellite and Satellite-Nucleus are 25.3% and 17.9%, respectively. The second is that our Text Matching module is helpful for identifying similar discourse units via the matching mechanisms of Cosine, Bilinear and Single Layer Network, and then assigns Nucleus-Nucleus to them.

The Bi-LSTM+CNN model is a simplified version of TMN that does not use the Text Matching module. Compared with the Bi-LSTM+CNN model, TMN combines the semantic similarity and the interaction information simultaneously to improve the macro-average and micro-average F1 by 4.7 and 1.9, respectively. These figures justify our first hypothesis that there are strong correlations between the nuclearity and the semantic similarity or the interactions of two different discourse units.

To analyse the contribution of each mechanism in the Text Matching module, we conduct experiments on some variants of TMN, and the results are shown in Table 4. In Table 4, the basic model (TMN-CBS) is equal to Bi-LSTM+CNN, which does not have the Text Matching module. The TMN-BS model refers to the TMN model whose Text Matching module only uses Cosine, while TMN-C refers to the TMN model whose Text Matching module only uses Bilinear and Single Layer Networks.

Model	Nucleus-Satellite P / R / F1	Satellite-Nucleus P / R / F1	Nucleus-Nucleus P / R / F1	Macro-F1	Micro-F1
TMN-CBS	59.6 / 46.4 / 52.1	40.2 / 31.7 / 35.5	73.2 / 83.5 / 78.0	55.7	67.1
TMN-BS	56.5 / 50.7 / 53.4	**47.6** / 28.9 / 35.9	74.2 / **83.7** / 78.7	56.8	68.0
TMN-C	61.5 / **54.1** / **57.6**	39.6 / 34.6 / 36.9	75.7 / 81.7 / 78.6	57.8	68.3
TMN-P	60.9 / 51.2 / 55.6	34.7 / 41.4 / 37.7	**76.9** / 79.0 / 77.9	57.3	66.8
TMN	**69.1** / 45.4 / 54.8	39.2 / **49.0** / **43.6**	76.2 / 83.3 / **79.6**	**60.4**	**69.0**

Table 4: Experimental results of variants of the TMN Model.

Compared with TMN-CBS, the TMN-BS model and the TMN-C model improve the macro-average and micro-average F1, and these improvements show that the semantic similarity or interaction information captured by the Cosine, Bilinear, and Single Layer Network are helpful for nuclearity recognition. Especially after adding the interaction information using the Bilinear and Single Layer Network, the F1 of the relation Nucleus-Satellite achieves a 5.5% improvement.

The TMN-P model is a simplification of the TMN model, which removes the input of the paragraph *Para* in Figure 2. TMN-P captures only the similarity and interaction information between the different discourse units, without the similarity and interaction information between the discourse unit and the paragraph. Compared with TMN-P, TMN significantly improves the macro-average and micro-average F1 by 3.1 and 2.2, respectively, which justifies our second hypothesis that nuclearity recognition is relevant to the topic of the paragraph.

Nuclearity	Nucleus-Satellite	Satellite-Nucleus	Nucleus-Nucleus
Nucleus-Satellite	-	14.5%	40.1%
Satellite-Nucleus	9.6%	-	41.4%
Nucleus-Nucleus	6.6%	10.1%	-

Table 5: The percentages of misclassified samples.

Table 5 shows the error statistics of our TMN model in nuclearity recognition. It shows that 40.1% of the Nucleus-Satellite instances and 41.4% of the Satellite-Nucleus instances are frequently identified as Nucleus-Nucleus by our TMN model. These results show that the errors mainly arise from the judgment of whether an instance is mononuclear or multinuclear. This finding is mainly due to two reasons: 1) the number of Nucleus-Nucleus instances accounts for more than half of the training set; and 2) many discourse units differ in nuclearity but are semantically similar. We consider the following two discourse units as examples.

Example 2: 农业获得较好收成 $_{a}$，全年粮食总产量达七十六点六亿公斤 $_{b}$。 *Farming received good harvests* $_{a}$, *the total grain output in the year amounted to 7.66 billion kg* $_{b}$.

The nuclearity type between the two EDUs *a* and *b* in Example 2 is Nucleus-Satellite due to the content in EDU *a* being more generalised and being able to semantically contain the content described in EDU *b*. However, there is a strong correlation between "农业 *farming*" and "粮食 *grain*" and between "收成 *harvest*" and "产量 *output*", at a semantic level. Therefore, the Text Matching module will misjudge their relation as Nucleus-Nucleus via the similarity and interaction information between the two EDUs *a* and *b*.

5 Conclusions

In this paper, we propose a novel TMN model for nuclearity recognition in Chinese discourse. First, we employ a Text Encoding module to capture both the global dependency information and the local n-gram information via Bi-LSTM and CNN. In this way, the overall discourse semantics can be much better represented. Then, we employ a Text Matching module to capture various similarities and interactions between different discourse units and between the encoded unit and the paragraph by the Cosine, Bilinear and Single Layer Network. Here, while Cosine calculates the semantic similarity, Bilinear and Single Layer Network incorporate the strong linear and nonlinear interactions between the semantic vectors. Experimental results on the CDTB corpus show that our TMN model significantly outperforms various strong baselines both in micro-average and macro-average F1. Our future work will focus on how to better tune the input of our neural network model and apply this model to other languages.

Abstract

Discourse parsing is a challenging task and plays a critical role in discourse analysis. This paper focus on the macro level discourse structure analysis, which has been less studied in the previous researches. We explore a macro discourse structure presentation schema to present the macro level discourse structure, and propose a corresponding corpus, named Macro Chinese Discourse Treebank. On these bases, we concentrate on two tasks of macro discourse structure analysis, including structure identification and nuclearity recognition. In order to reduce the error transmission between the associated tasks, we adopt a joint model of the two tasks, and an Integer Linear Programming approach is proposed to achieve global optimization with various kinds of constraints.

1 Introduction

A typical document is usually organized in a coherent way that each discourse unit is relevant to its context and plays a role in the entire semantics. Discourse structure analysis not only helps to understand the discourse structure and semantics, but also can benefit variety of downstream applications including question answering (Sadek and Meziane, 2016), machine translation (Guzmán et al., 2014), text summarization (Ferreira et al., 2014; Cohan and Goharian, 2017), and so forth.

There exist two hierarchical levels of discourse structures: micro level and macro level. The micro level structure refers to the structure and relation among the discourse units in a sentence, or consecutive sentences, or sentences groups. The macro level structure refers to the structure and relation among paragraphs, or chapters, or discourses. Corresponding to related research based on Rhetorical Structure Theory Discourse Treebank (RST-DT), the micro level is similar to the sentence-level discourse parsing, and the macro level is similar to the document-level discourse parsing.

To make a clearer explanation of the macro discourse structure, take the chtb_0019 as an example, which is a typical news article from Chinese Treebank 8.0 (Xue et al., 2013). The macro discourse structure of this article is shown as Figure 1. There are five paragraphs (P1, P2, P3, P4 and P5) in the news "Significant achievements in the construction of Ningbo Bonded Area". The paragraphs are connected by discourse relations (*Elaboration*, *Background*, *Joint*). In this article, paragraph P1 points out the theme of the overall article. Depending on the direction of arrows from the root node to the leaf node in the discourse structure tree, the most important part can be quickly located.

Limited to the length of this paper, the full discourse text of this example is not included, please refer to the corpus. The main contents of the five paragraphs respectively are: P1) Ningbo Bonded Area achieved fruitful results after three years of construction; P2) the basic situation of the Ningbo Bonded Area; P3) the situation of import and export trade, warehouses, storage area, etc. P4) the situation of industrial processing projects and enterprises; P5) the situation of administrative services and information construction.

† The corresponding author is Qiaoming Zhu.

Proceedings of the 27th International Conference on Computational Linguistics, pages 536–546
Santa Fe, New Mexico, USA, August 20-26, 2018.

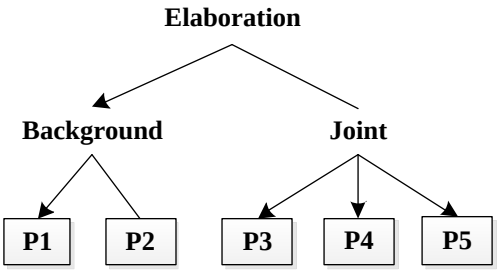

Figure 1: Macro structures tree of chtb_0019.

From the discourse structure tree of this example, we can see that the analysis of discourse structure is beneficial for the understanding of the content and the theme of the discourse. Based on the macro discourse structure analysis, we can further enhance the performance of natural language processing applications. For example, we can use the information of discourse structure to summarize the content and purpose of an article, use the information of discourse relation to assist the construction of question answering system, and improve the performance of automatic summarization by using the nuclearity information.

The existing research on discourse structure is mainly focused on the micro level, and the performance has not yet achieve the level for application. However, the macro level research still stays in the theoretical research, and there is no available corpus resource, nor a corresponding computational model. For the two reasons mentioned above, in this paper, we take the macro discourse structure as the main research object, that is different from the previous research. We explore a macro discourse structure presentation schema to present the macro level discourse structure, and propose a Macro Chinese Discourse Treebank (MCDTB) on the top of existing Chinese Discourse Treebank (CDTB) (Li et al., 2014). On the basis of the presentation schema and annotated corpus, we divide the macro level discourse structure analysis into four tasks, including structure identification, nuclearity recognition, relation classification and discourse tree building.

There are certain differences from the analysis of the micro level discourse structure. For example, macro discourse structure analysis takes paragraphs as the elementary discourse units, and the relations between the units are fairly loose, so it brings difficulties to the task of structure identification. Furthermore, there are virtually no connectives between the discourse units, and the texts of each discourse unit are relatively long, making discourse relation classification lack of effective cue phrase and lexical information.

The task of discourse structure identification is the first and the most crucial step in the macro discourse analysis and also the basis step of further tasks. Nuclearity recognition is only part of the discourse relation classification task in the existing research, and has not been given sufficient attention. However, in our study, we find that the performance improvement of nuclearity recognition contributes to the improvement of the overall performance. Therefore, in this paper, we concentrate on these two tasks of macro discourse structure, structure identification and nuclearity recognition, and take structure identification as the main task.

Our contribution is three-fold. First, we explore a macro discourse structure presentation schema to present the macro level discourse structure, and propose a macro discourse structure corpus, named Macro Chinese Discourse Treebank (MCDTB). The presentation schema and corpus resource can lay the foundation for macro discourse structure analysis. Second, we propose discourse structure identification and nuclearity recognition models on macro level discourse structure analysis. By using CRF models to label sequences of discourse units, we can incorporate contextual information in a more natural way, and achieve a satisfactory performance. Third, we propose a joint model of structure identification and nuclearity recognition to reduce the error transmission between the associated tasks, and achieve global optimization via Inter Linear Programming.

The rest of this paper is organized as follows. Section 2 overviews related work on discourse parsing.

Section 3 introduces our macro discourse structure presentation schema and corpus resources. Section 4 introduce the framework of our joint model of structure identification and nuclearity recognition. Section 5 describes the local models, and the joint approach we used with ILP is introduced in Section 6. Section 7 presents the experimental results. Section 8 gives the conclusion and future work.

2 Related Work

Discourse parsing is the task of discovering the presence and type of the discourse relations between discourse units. The existing discourse parsing researches are mainly based on Rhetorical Structure Theory Discourse Treebank (RST-DT). The RST-DT (Carlson et al., 2003) is built in the framework of Rhetorical Structure Theory, consisting of 385 Wall Street Journal articles from the Penn Treebank (Marcus et al., 1993) and representing over 176,000 words of text.

While recent advances in sentence-level discourse parsing have attained accuracies close to human performance (Joty et al., 2012), discourse parsing at the document-level still poses challenges.

The HILDA discourse parser (Hernault et al., 2010) is the first attempt at document-level discourse parsing on RST-DT. It adopts a pipeline framework, and greedily builds the discourse tree from the bottom-up. In particular, at each step of the tree-building, a binary Support Vector Machine (SVM) classifier is applied to determine which pair of adjacent discourse constituents should be merged to form a larger span, and then another multi-class SVM classifier is applied to assign the type of discourse relation between the chosen pair of constituents.

Joty et al. (2013) approach the document-level discourse parsing using a model trained by Conditional Random Fields (CRF). They decomposed the problem of document-level discourse parsing into two stage: intra-sentential and multi-sentential parsing. Specifically, they employed two separate models for intra- and multi-sentential parsing. They jointly modeled the structure and the relation for a given pair of discourse units, such that information from each aspect can interact with the other.

Feng and Hirst (2014) develop a much faster model whose time complexity is linear in the number of sentences. Their model adopts a greedy bottom-up approach, with two linear-chain CRFs applied as local classifiers. An approach of post-editing is performed, which modified a fully-built tree by considering information from upper-levels, to improve the accuracy.

There is no relevant research on document-level discourse parsing in Chinese so far. For micro level discourse structure analysis, Li (2015) proposes a Connective-driven Dependency Tree (CDT) schema to represent the discourse rhetorical structure in Chinese language, with elementary discourse units as leaf nodes and connectives as non-leaf nodes, largely motivated by the Penn Discourse Treebank and the Rhetorical Structure Theory. On this basis, a Chinese Discourse Treebank (CDTB) consisting of 500 discourses is annotated, and a Chinese discourse structure analysis platform is realized.

3 Macro Chinese Discourse Treebank

3.1 Macro Discourse Structure Representation Schema

Rhetorical Structure Theory (RST) (Mann and Thompson, 1987), one of the most influential theories of discourse, represents a discourse by a hierarchical structure, called discourse tree. The leaves of a discourse tree correspond to Elementary Discourse Units (EDUs). Adjacent EDUs are connected by rhetorical relations, forming larger discourse units. RST defines two different types of discourse units, in which the nucleus is considered as the central part, and the satellite is considered as the peripheral part.

A concept of "macrostructures" is put forward by Van Dijk (1980) in Macrostructure Theory. The point of "macrostructures" is that texts not only have local or micro structural relations between subsequent sentences, but also have overall structures that define their global coherence and organization. But even today, the crucial global structures (including macrostructures, superstructures) that define the overall meaning and form of texts are almost ignored.

Inspired by Van Dijk's Macrostructure Theory and Rhetorical Structure Theory, we explore a macro discourse structure representation schema. In this representation schema, each discourse is represented as a hierarchical discourse tree (as shown in Figure 1). In the macro discourse structure tree, leaf nodes

represent paragraphs, and non-leaf nodes represent discourse relations. The edges connect the discourse units, with the arrows pointing to the "Nucleus" units.

Detailed definitions of macro discourse structure are described as follows.

Leaf nodes: Unlike the definition on the micro level (the elementary units are treated as leaf nodes), we directly treat the paragraphs which are naturally segmented in the discourses as leaf nodes on the macro level.

Non-leaf nodes: Discourse relations connect discourse units, which are treated as non-leaf nodes in our macro discourse structure. We classify the discourse relations into three categories and fifteen subcategories, including **Coordination** (Joint, Sequence, Progression, Contrast, Supplement), **Causality** (Cause-Result, Result-Cause, Background, Behavior-Purpose, Purpose-Behavior), and **Elaboration** (Elaboration, Summary, Evaluation, Statement-Illustration, Illustration-Statement).

Arrow pointing: A discourse unit linked by a discourse relation can be either a "Nucleus" or a "Satellite" depending on how central the message is. In the macro discourse structure, we use the arrows pointing to represent the "Nucleus-Satellite" relations. Specifically, the edges with arrows point to the "Nucleus" units, and the edges without arrows point to the "Satellite" units.

3.2 Corpus Annotating

Guided by the macro discourse structure framework defined in Section 3.1, we have carried out annotating work of macro Chinese discourse structure, which we call Macro Chinese Discourse Treebank (MCDTB)[1]. In the process of annotating, the structure definition and annotating criteria are modified iteratively. After nearly a year of annotation, 720 news wire articles are annotated, the source of which is Chinese Treebank 8.0 (CTB 8.0). (Xue et al., 2002; Xue et al., 2013)

Because the discourse units are not isolated from the overall discourse, it's difficult to judge whether the discourse units are important or not and what relations are between the discourse units simply from the units themselves. It is necessary to have a comprehensive understanding of the overall article before the annotating.

We divide the annotating work into three main stages. **The first stage** lasted four months, with three annotators participating. We selected the first 50 news articles from CTB 8.0, and annotated them together. After a lot of discussions, a preliminary annotating specification was formed. **The second stage** lasted for three months. Three annotators annotated articles independently and discussed the annotating result in groups. At the same time, the imperfect parts of the representation schema and annotating specification were discussed and amended. **The third stage**, which lasted four months, we added three new annotators to improve the efficiency of the annotating. Six annotators were divided into three groups, and each group was composed of a new staff and an old staff. The annotators of each group annotated independently and discussed in groups.

To ensure the quality of our corpus, we adopt the annotating consistency using agreement and kappa. Table 1 illustrates the annotating consistency in detail. We measure the agreement and kappa of discourse structures, nuclearity and discourse relations in the second and the third stage respectively. The method of consistency calculation used in this paper refers to the work of the corpus of RST (Marcu et al., 1999), and the appropriate adjustment is made according to the contents of our annotation.

Annotating Consistency of the Stage 2			**Annotating Consistency of Stage 3**		
Categories	**Agreement**	**Kappa**	**Categories**	**Agreement**	**Kappa**
Structure	88.54%	0.771	Structure	86.07%	0.671
Nuclearity	80.67%	0.694	Nuclearity	83.35%	0.647
Relation	83.05%	0.556	Relation	80.20%	0.597

Table 1: Annotating consistency

After the annotating work finished, the corpus consists of 720 newswire articles with a total of 398,829

[1]The Macro Chinese Discourse TreeBank is available at https://figshare.com/s/250474dba44e4161b040.

Chinese characters. 3,981 paragraphs with 8,391 sentences are annotated. There are 5.53 paragraphs and 554 Chinese characters in each article on average. 2,870 discourse relations are annotated.

4 Overview of Framework

Figure 2 demonstrates the framework of our joint model of structure identification and nuclearity recognition. The test dataset is processed first, and it becomes groups of discourse units' sequences to be labeled. Then we perform two CRF models to identify the structure and recognize the nuclearity using different feature sets respectively. In order to reduce the error transmission between the associated tasks, we adopt a joint model of the two tasks, and an Integer Linear Programming (ILP) approach is proposed to achieve global optimization with various kinds of constraints. In this way, a joint model of two layers is formed.

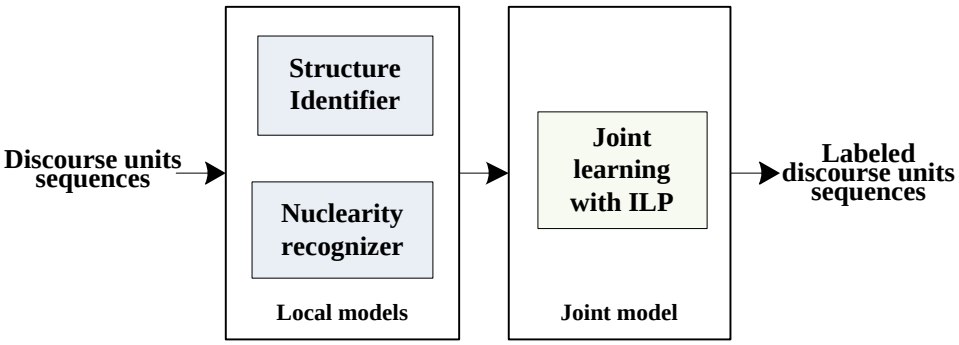

Figure 2: Joint model framework.

5 Local Models

We convert the macro discourse structure and the nuclearity prediction tasks into the sequence labeling problems. It has the following advantages of these conversions. 1) Context information can be fused conveniently. We use a window to capture the features of the previous and next discourse units. 2) Make the prediction process more naturally. In previous studies, in order to classify the structure and relations, methods of left join and right join were used to convert multiple relations to binary relations. There are two shortcomings of these approach, on the one hand, the number of non-original samples is added, and on the other hand, it is difficult to automatically build a complete real structure tree.

We build the local models of structure identification and nuclearity recognition respectively. Our local models are implemented using CRFs. In this way, we are able to take into account the sequential information from contextual discourse units, which cannot be naturally represented with Support Vector Machine (SVM) or Maximum Entropy (ME) as local classifiers.

As shown by Feng and Hirst (2012; 2014), for a pair of discourse units of interest, the sequential information from contextual units is crucial for determining structures. Therefore, it is well motivated to use CRF, which is a discriminative probabilistic graphical model, to make predictions for a sequence of units surrounding the pair of interest.

Figure 3 shows our structure identification model M_{struct} implemented with conditional random field algorithm. The first layer of the chain is composed of discourse units U_j's, and the second layer is composed of nodes of S_j's to indicate the probability of merging adjacent discourse units. When there is a relation between the discourse unit U_j and the previous one U_{j-1}, the structure of S_j is labeled as "1", and on the other hand, when there is no relation between the two consecutive discourse units, the structure of S_j is labeled as "0". To improve the accuracy of the structure identification, we enforce additional commonsense constraints in its Viterbi decoding. In particular, we disallow the existence of all-zero sequences (at least one pair must be merged).

The nuclearity recognition model $M_{nuclear}$ works in a similar way to M_{struct}, in which the first layer of the chain is composed of discourse units U_j's, and the second layer is composed of nodes of N_j's to

indicate the probability of nuclearity between the adjacent discourse units. When the current discourse unit U_j is more important than the previous discourse unit U_{j-1}, N_j is labeled as "1". When the current discourse U_j is less important than U_{j-1}, N_j is labeled as "2". When the two discourse units are equally important, the N_j is labeled as "3".

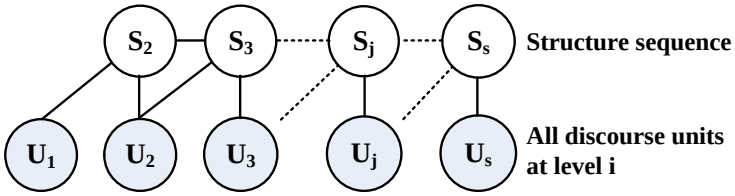

Figure 3: Local structure identification model.

In our local models, to encode two adjacent units, U_j and U_{j+1}, within a CRF chain, we use the following features listed in Table 2, some of which are modified from (Joty et al., 2013)'s and (Feng and Hirst, 2014)'s models.

Some of the helpful features of the RST discourse parsing cannot be used in macro discourse analysis or in Chinese discourse analysis. For example: 1) For macro level discourse analysis, the particles of the N-gram model are too small to represent the information of a paragraph, so the lexical features are not used in our tasks. 2) Syntactic information and dominance set features are very useful for micro level discourse analysis. However, the elementary units of the macro level are paragraphs, and these features are not applicable. 3) Since there is no tense in Chinese, we cannot use temporal features in macro level structure analysis.

Due to the appearance of word vector representation (Mikolov et al., 2013), the methods of co-occurrence (Sporleder and Lascarides, 2004) and word pairs (Feng and Hirst, 2012) are not necessary when the semantic similarity is calculated. We use the word2vec model to train word vector representation on the CTB 8.0, and use the method proposed by Jiang et al. (2018) to calculate the semantic similarity (including the semantic similarity between adjacent discourse units and the similarity between the discourse unit and the topic). In particular, in order to prevent the sparsity of the features, we discretize the semantic similarity into 10 levels.

Features	Used in SI	Used in NR
Organization features		
The beginning and end location of U_j.	Y	Y
Distances of U_j to the beginning and to the end.	Y	Y
Number of sentences (or paragraphs) in U_j.	Y	N
Whether U_j contains more sentences (or paragraphs) than U_{j+1}.	N	Y
Tree structure features		
Whether U_j is a bottom-level constituent.	Y	Y
Whether U_j is a combined unit in the previous step.	Y	Y
Similarity features		
The similarity between U_j and U_{j+1}.	Y	Y
The similarity between U_j and the topic of the discourse.	Y	Y
The similarity between U_{j+1} and the topic of the discourse.	Y	Y
Whether the similarity between U_j and the topic is greater than the similarity between U_{j+1} and the topic.	N	Y

Table 2: Features used in local models.

6 Joint Learning with Integer Linear Programing

While a pipeline model may suffer from the errors propagated from upstream tasks, a joint model can benefit from the close interaction between two or more tasks. Recently, joint modeling has been widely attempted in various NLP tasks, such as joint syntactic parsing and semantic role labeling (Li et al., 2010), joint argument identification and role determination (Li et al., 2013), joint structure identification and relation recognition (Joty et al., 2012), etc.

In our joint model, an ILP (Integer Logic Programming) -based inference framework is introduced to integrate two CRF-based local models, the structure identifier and the nuclearity recognizer. In this section, we propose a joint model of structure identification and nuclearity recognition with some intra-instance and contextual constraints.

We assume $p_{SI}(s_{<i,j>}|seq_i)$ the probability of M_{struct} identifying $s_{<i,j>}$ as a structure of an sequence seq_i, where $s_{<i,j>}$ is the jth structure to be identified in the ith sequence seq_i. We define following assignment costs with $-log$:

$$c^{SI}_{<i,j>} = -log(p_{SI}(s_{<i,j>}|seq_i)) \tag{1}$$

$$c^{-SI}_{<i,j>} = -log(1 - p_{SI}(s_{<i,j>}|seq_i)) \tag{2}$$

where $c^{SI}_{<i,j>}$ and $c^{-SI}_{<i,j>}$ are the cost of $s_{<i,j>}$ whether or not a structure in sequence seq_i respectively.

There are three types of nuclearity labels between discourse units, including "NS", "SN", and "NN". In addition, when there is no structure between the two successive units, we add a "NO-STR" label to distinguish it. The label of nuclearity could be represented as a 4-dimension vector and the value of each element in the vector is either 1 or 0 denoting whether the corresponding label is assigned or not. For instance, $n_{<i,j>}$=[1,0,0,0] denotes the assigned label is "NO-STR" and $n_{<i,j>}$=[0,1,0,0] denotes the assigned label is "NS", where $n_{<i,j>[k]}$ denotes the kth label in the vector and $p_{NR}(n_k|s_{<i,j>})$ denotes the probability belonging the kth label. The cost of nuclearity recognition can be defined as follow:

$$c^{NR}_{<i,j>[k]} = -log(p_{NR}(n_k|s_{<i,j>})) \tag{3}$$

where $c^{NR}_{<i,j>[k]}$ is the cost of assigning or not assigning nuclearity n_k to $s_{<i,j>}$.

Besides, we use indication variable $x_{<i,j>}$ which is set to 1 if $s_{<i,j>}$ is a structure of seq_i, and 0 otherwise. Similar to $x_{<i,j>}$, we use another indicator variable $y_{<i,j,k>}$ which is set to 1 if the $s_{<i,j>}$ has the kth nuclearity label, and 0 otherwise. The objective function for the overall sample set can be represented as follows, where D denotes the overall sample set.

$$min \sum_{seq_i \in D} (\sum_{s_{<i,j>} \in seq_i} (c^{SI}_{<i,j>} x_{<i,j>} + c^{-SI}_{<i,j>}(1 - x_{<i,j>}) + \sum_{k=0}^{3} c^{NR}_{<i,j>[k]} y_{<i,j,k>})) \tag{4}$$

Subject to

$$x_{<i,j>} \in \{0, 1\} \tag{5}$$

$$y_{<i,j,k>} \in \{0, 1\} \tag{6}$$

Constraints (5) and (6) are used to make sure that $x_{<i,j>}$ and $y_{<i,j,k>}$ are binary values.

Furthermore, we enforce following constraints (C1 and C2) on the consistency between SI and NR.

(C1) **Nuclearity type constraints:** the task of nuclearity recognition is a single-label classification problem. That is, the label of an instance could be only one option.

$$\sum_{k=0}^{3} y_{<i,j,k>} = 1 \tag{7}$$

(C2) **Correlation constraints:** if $s_{<i,j>}$ is a structure, it must have a nuclearity label, otherwise, if $s_{<i,j>}$ is not a structure, it must not have a nuclearity label.

$$\sum_{k=1}^{3} y_{<i,j,k>} = x_{<i,j>} \tag{8}$$

Similar to local models, we disallow the existence of all-zero sequences, so we add the constraint C3 to the joint model. This constraint also lays the foundation for subsequent task of discourse tree building.

(C3) **Contextual constraints:** a sequence must have at least one structure. In order to avoid the ILP model optimizing the sequences into all-zero sequences, which has been already constrained by the Viterbi algorithm in the local models, this constraint is added.

$$\sum_{s_{<i,j>} \in seq_i} x_{<i,j>} \geq 1 \tag{9}$$

7 Experiments

In this section, we first describe the experimental setting and then evaluate our joint model of structure identification and nuclearity recognition on MCDTB.

7.1 Experimental Setting

Data: We use the the corpus annotated by ourselves for experiment, and the detailed corpus data is described in the Table 3.

Statistics Items	Value	Statistics Items	Value
Count of documents	720	Amount of sentences	8,391
Count of paragraphs	3,981	Average paragraphs (paragraphs/document)	5.53
Maximal of paragraphs	22	Average sentences (sentences/paragraph)	2.1
Minimal of paragraphs	2	Average characters (characters /paragraph)	554

Table 3: Corpus statistic data

There are 8,863 instances in MCDTB, and we use fivefold cross-validation to ensure the objectivity of the experiment. In particular, we divide the articles into 5 datasets and assign articles of the different lengths (length means the number of paragraphs of a discourse) into the 5 datasets relatively equally, so that the size of each data set is nearly the same. The number of discourses of different lengths is shown in Table 4.

Length	**2**	**3**	**4**	**5**	**6**	**7**	**8**	**9**	**10**	**11**	**12**	**>13**
Number	29	112	159	144	91	58	37	33	15	13	14	15

Table 4: Discourses of different lengths

Classification Algorithm: The CRF tool (*CRF++*)[2] is employed to train individual component classifiers and *lp_solver*[3] is used to construct the joint model.

Evaluation Measurement: The performance is evaluated using the standard accuracy measurement.

7.2 Experimental Results

Table 5 compares the performance of local models when different feature sets are leveraged. The features used in local models are mentioned in Section 5. This table indicates the structure features make the greatest contribution to the local models. Although the performances of tree structure and similarity features is not good when used alone, combining with the organization features improves the performance of the model. Especially, when both these two kinds of features are used, the performance reaches the best

Features	Structure		Nuclearity	
	Accuracy	Macro-F1	Accuracy	Macro-F1
Organization	76.13	74.46	74.46	49.17
Tree Structure	74.48	73.38	70.21	36.86
Similarity	74.57	73.32	66.68	39.70
Organization + Tree Structure	76.31	74.64	74.70	47.25
Organization + Tree Structure + Similarity	77.52	75.98	75.50	49.83

Table 5: Comparison of experimental results of different feature sets

accuracy of 77.52% and 75.50% in SI and NR tasks respectively. The Macro-F1 values reach 75.98% and 49.83% in SI and NR tasks respectively. In the following experiments of joint model, we use the best performance for comparison.

Constraint	Accuracy	Macro-F1
Local model	77.52	75.98
ILP(C1)	77.95	77.68
ILP(C1+C2)	78.51	77.81
ILP(C1+C2+C3)	78.54	77.68

Table 6: Performance of structure identification with joint model

Table 6 shows the performance of the ILP approach when different constraints are used. From this table, we can see that the constraints C1,C2 and C3 are capable of improving the performance of structure identification. When all these constraints are utilized, the inference performance reaches the best of 78.54% in accuracy and 77.68% in Macro-F1, 1.02% in accuracy and 1.70% in Macro-F1 better than the best performance of local model. This indicates the beneficiary of label correlations intra- and multi-instance to the task of structure identification.

It is worthwhile to note that our ILP approach could also benefit the task of nuclearity recognition when the constraints are employed. Table 7 shows our ILP approach improve the performance of nuclearity recognition by 0.51% in accuracy and 1.86% in Macro-F1.

	Accuracy	Macro-F1
Local model	75.50	49.83
ILP approach	76.01	51.69

Table 7: Performance of nuclearity recognition with joint model

There are some discoveries in our experiment: 1) The lexical features of connective, such as "therefore", "as a result" etc. are very useful on the micro level discourse analysis. But when used on macro level, the connective may confuse the model. That is because connectives usually occur between successive clauses or consecutive sentences, and are seldom used to express the relationship between paragraphs, especially in Chinese. 2) We have already tried some linguistic features, including lexical and syntactic, but the features are not outstanding in the experiment. There are several sentences in a paragraph, so syntactic information is not easy to use. We will explore other linguistic features and effective expression on macro level discourse structure analysis in the future.

8 Conclusion

In this paper, we present an efficient joint model of structure identification and nuclearity recognition on macro level discourse structure analysis. In particular, various kinds of feature sets are introduced to improve the performance of local models, and various constraints are introduced to improve the performance of joint model.

In future work, we will explore better joint modeling and effective linguistic features in discourse structure analysis. Furthermore, we wish to explore the other two tasks of macro discourse structure analysis, and build an End-to-End analysis platform.

Abstract

Implicit discourse relation recognition aims to understand and annotate the latent relations between two discourse arguments, such as temporal, comparison, etc. Most previous methods encode two discourse arguments separately, the ones considering pair specific clues ignore the bidirectional interactions between two arguments and the sparsity of pair patterns. In this paper, we propose a novel Neural **T**ensor Network framework with **I**nteractive **A**ttention and **S**parse **L**earning (TIASL) for implicit discourse relation recognition. (1) We mine the most correlated word pairs from two discourse arguments to model pair specific clues, and integrate them as interactive attention into argument representations produced by the bidirectional long short-term memory network. Meanwhile, (2) the neural tensor network with sparse constraint is proposed to explore the deeper and the more important pair patterns so as to fully recognize discourse relations. The experimental results on PDTB show that our proposed TIASL framework is effective.

1 Introduction

Discourse relation describes how two adjacent text units (e.g. clauses, sentences, and larger sentence groups), called arguments, named *Arg*1 and *Arg*2, are connected semantically, such as temporally, causally, etc. Yet implicit discourse relation recognition without explicit connectives (Pitler et al., 2008), which needs to infer the relation from specific context, is still a challenging problem. It can be used in text summarization(Gerani et al., 2014), conversation system (Higashinaka et al., 2014) and so on.

Previous researches mainly include (1) traditional feature-based models and (2) neural network based models. Most feature-based models adopt various linguistic features (such as polarity, word pairs, and position information, etc.) and design complicated rules to recognize implicit discourse relations (Pitler et al., 2009; Zhou et al., 2010; Braud and Denis, 2015). They can not fully use the local and the global context, and the human cost is huge. Neural network based models get the better argument representations and more precisely capture discourse relations (Braud and Denis, 2015; Zhang et al., 2015; Liu et al., 2016). However, they encode two discourse arguments separately, and ignore pair specific clues. The further researches adopt the different hybrid neural models (Chen et al., 2016; Lei et al., 2017) and attention mechanism (Cai and Zhao, 2017) to mine the semantic interactions of argument pairs. Yet, they ignore the bidirectional interactions between two arguments during the representation stage since there is asymmetry from the perspective of human-like reading strategy. And the sparsity of word pair patterns indicating discourse relation is neither considered.

Therefore, a novel neural **T**ensor network model with **I**nteractive **A**ttention and **S**parse **L**earning is proposed for implicit discourse relation recognition, namely TIASL. We imitate the human-like reading strategy, and model the relatedness between two discourse arguments as a kind of interactive attention from bidirectional aspects. It is added into the argument representations with a bidirectional Long Short-Term Memory network (Bi-LSTM), and then plugged in neural tensor network (NTN) with l_1 reg-

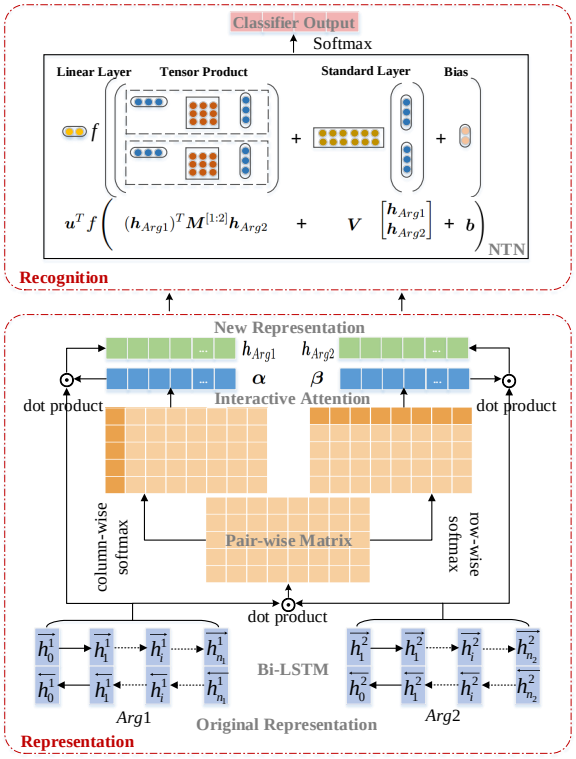

Figure 1: The TIASL framework.

ularization. This helps to mine the different aspects of semantic interactions between two arguments and select the important and the informative word pair patterns.

Our main contributions are as follows:

- Propose a novel TIASL framework from the perspectives of the human-like bidirectional reading strategy and the sparsity of word pair patterns;
- Encode the discourse arguments by the Bi-LSTM with interactive attention for implicit discourse relation recognition;
- Use neural tensor network with sparse constraint to capture the deeper and the more indicative pair patterns;
- Experimental results on PDTB show that our TIASL model is effective.

2 The Proposed Method

We formalize implicit discourse relation recognition as a classification problem. The proposed TIASL framework is shown in Figure 1. The main steps include (1) discourse argument representations with interactive attention based on Bi-LSTM and (2) sparse pair pattern selection and implicit discourse relation recognition.

2.1 Discourse Argument Representations with Interactive Attention

Attention mechanism has achieved great success in image recognition, which is based on the visual attention principle found in humans. Recently, it is widely adopted in many NLP tasks. Inspired by (Herzog et al., 2016), we imitate the human-like bidirectional reading strategy, and propose an interactive attention mechanism to enhance discourse argument representations.

For the original representations of discourse arguments shown in Figure 1, we first associate each word w in the vocabulary with a vector representation $\boldsymbol{x}_w \in \mathbb{R}^d$, where d is the dimension of the embeddings.

Since each argument is viewed as a sequence of word vectors, let $\boldsymbol{x}_i^1(\boldsymbol{x}_i^2)$ be the i-th word vector in *Arg*1 (*Arg*2), thus the arguments in a discourse relation are expressed as,

$$Arg1 : [\boldsymbol{x}_1^1, \boldsymbol{x}_2^1, ..., \boldsymbol{x}_{n_1}^1], \qquad Arg2 : [\boldsymbol{x}_1^2, \boldsymbol{x}_2^2, ..., \boldsymbol{x}_{n_2}^2].$$

where *Arg*1 (*Arg*2) has n_1 (n_2) words.

2.1.1 The Basic Bi-LSTM

Long Short-Term Memory network (LSTM) (Hochreiter and Schmidhuber, 1997) is a variant of recurrent neural network. Considering that it can model long-term dependencies and encode context information, we use it in the basic argument representation. Given the word representations of two arguments as we just described, the LSTM computes the state sequence for each position t using the following equations:

$$\boldsymbol{i}_t = \sigma(\boldsymbol{W}_i[\boldsymbol{x}_t, \boldsymbol{h}_{t-1}] + \boldsymbol{b}_i), \tag{1}$$
$$\boldsymbol{f}_t = \sigma(\boldsymbol{W}_f[\boldsymbol{x}_t, \boldsymbol{h}_{t-1}] + \boldsymbol{b}_f), \tag{2}$$
$$\boldsymbol{o}_t = \sigma(\boldsymbol{W}_o[\boldsymbol{x}_t, \boldsymbol{h}_{t-1}] + \boldsymbol{b}_o), \tag{3}$$
$$\tilde{\boldsymbol{c}}_t = \tanh(\boldsymbol{W}_c[\boldsymbol{x}_t, \boldsymbol{h}_{t-1}] + \boldsymbol{b}_c), \tag{4}$$
$$\boldsymbol{c}_t = \boldsymbol{i}_t \odot \tilde{\boldsymbol{c}}_t + \boldsymbol{f}_t \odot \boldsymbol{c}_{t-1}, \tag{5}$$
$$\boldsymbol{h}_t = \boldsymbol{o}_t \odot \tanh(\boldsymbol{c}_t). \tag{6}$$

where $\boldsymbol{i}_t$, $\boldsymbol{f}_t$, $\boldsymbol{o}_t$, $\boldsymbol{c}_t$, $\boldsymbol{h}_t$ denote the input gate, forget gate, output gate, memory cell and hidden state at position t respectively. $\boldsymbol{W}_i$, $\boldsymbol{W}_f$, $\boldsymbol{W}_o$, $\boldsymbol{W}_c$, $\boldsymbol{b}_i$, $\boldsymbol{b}_f$, $\boldsymbol{b}_o$, $\boldsymbol{b}_c$ are the neural network parameters. [ ] means the concatenation operation of $\boldsymbol{x}_t$, $\boldsymbol{h}_{t-1}$. σ denotes the logistic sigmoid function and $\odot$ denotes the element-wise multiplication.

Since LSTM only considers the context from the previous, we utilize a bidirectional LSTM (Bi-LSTM) preserving both history and future information. Therefore, at each position t of the sequence, we can obtain two representations $\overrightarrow{\boldsymbol{h}_t}$ and $\overleftarrow{\boldsymbol{h}_t}$. Then we concatenate them to get the intermediate state $\boldsymbol{h}_t = [\overrightarrow{\boldsymbol{h}_t}, \overleftarrow{\boldsymbol{h}_t}]$. For *Arg*1 and *Arg*2, we encode them into the contextual representations by Bi-LSTM. That is, $\boldsymbol{h}_i^1 = [\overrightarrow{\boldsymbol{h}_i^1}, \overleftarrow{\boldsymbol{h}_i^1}]$ and $\boldsymbol{h}_j^2 = [\overrightarrow{\boldsymbol{h}_j^2}, \overleftarrow{\boldsymbol{h}_j^2}]$ are the intermediate states of i-th word in *Arg*1 and j-th word in *Arg*2 respectively, where $\overrightarrow{\boldsymbol{h}_i^1}, \overleftarrow{\boldsymbol{h}_i^1}, \overrightarrow{\boldsymbol{h}_j^2}, \overleftarrow{\boldsymbol{h}_j^2} \in \mathbb{R}^d$.

Separately encoding arguments with Bi-LSTM could not reflect the semantic between two discourse arguments in a discourse relation. In order to fully use their semantic connections, we explore a novel argument representation.

2.1.2 Model the Asymmetry of Reciprocal Attention on Discourse Arguments

Herzog et al. (2016) proposed the two stage model of visual perception which indicated that people's image recognition includes two stages: collecting information and understanding information. In daily life, we have a similar feeling intuitively during reading: a more reasonable strategy is that people may read two discourse arguments back and forth, and find some relevant and informative clues helpful to judge the discourse relation. Due to the different reading order of two arguments, people may get the different focused information and thus have the different decisions. Therefore, we model the reciprocal attention on discourse arguments from two directions.

Firstly, we calculate semantic connections between word pairs in two arguments as a pair-wise matrix shown in Eq.(7), which indicates the relevant score of i-th *Arg*1 word and j-th *Arg*2 word by dot product of their hidden representations.

$$\boldsymbol{S}(i, j) = (\boldsymbol{h}_i^1)^T \cdot \boldsymbol{h}_j^2. \tag{7}$$

where $\boldsymbol{S} \in \mathbb{R}^{n_1 \times n_2}$, n_1 and n_2 are the lengths of *Arg*1 and *Arg*2, respectively.

Secondly, as the concerns of the forward and the reverse reading order are asymmetric when judging the relation of two discourse arguments. For each word in *Arg*2, we apply a column-wise softmax function on the pair-wise matrix $\boldsymbol{S}$ to get a probability distribution $\boldsymbol{\alpha}_t$ over *Arg*1, shown in Eq.(8). Similarly, we conduct a row-wise softmax function to get $\boldsymbol{\beta}_t$ over *Arg*2 when considering one *Arg*1

word, shown in Eq.(9). We denote $\boldsymbol{\alpha}_t \in \mathbb{R}^{n_1}$ as *Arg*2-to-*Arg*1 attention, and $\boldsymbol{\beta}_t \in \mathbb{R}^{n_2}$ as *Arg*1-to-*Arg*2 attention at position t, which are named **interactive attention**.

$$\boldsymbol{\alpha}_t = softmax(\boldsymbol{S}(1,t), ..., \boldsymbol{S}(n_1,t)), \tag{8}$$

$$\boldsymbol{\beta}_t = softmax(\boldsymbol{S}(t,1), ..., \boldsymbol{S}(t,n_2)). \tag{9}$$

where $\boldsymbol{\alpha}_t = [\boldsymbol{\alpha}_t^1, \boldsymbol{\alpha}_t^2, ..., \boldsymbol{\alpha}_t^{n_1}]$, $\boldsymbol{\alpha}_t^i$ means the attention value of i-th word in *Arg*1 at position t. Likewise, $\boldsymbol{\beta}_t = [\boldsymbol{\beta}_t^1, \boldsymbol{\beta}_t^2, ..., \boldsymbol{\beta}_t^{n_2}]$, $\boldsymbol{\beta}_t^j$ is the attention value of j-th word in *Arg*2 at position t.

In order to exploit the overall influence information to represent semantic connection of two discourse arguments, we average all the $\boldsymbol{\alpha}_t$, $\boldsymbol{\beta}_t$ to get the final attention of *Arg*1 and *Arg*2.

$$\boldsymbol{\alpha} = \frac{1}{n_2}\sum_{t=1}^{n_2}\boldsymbol{\alpha}_t, \qquad \boldsymbol{\beta} = \frac{1}{n_1}\sum_{t=1}^{n_1}\boldsymbol{\beta}_t. \tag{10}$$

The new argument representations integrating argument context and interactive attention are shown as Eq.(11), which reflect the human-like bidirectional reading strategy to some extent.

$$\boldsymbol{h}_{Arg1} = \boldsymbol{h}^1\boldsymbol{\alpha}, \qquad \boldsymbol{h}_{Arg2} = \boldsymbol{h}^2\boldsymbol{\beta}. \tag{11}$$

2.2 Sparse Pair Pattern Selection and Discourse Relation Recognition

Observations show that there are some pair patterns in a discourse relation. Once we detect these interactions expressing pair patterns, discriminating discourse relation is obvious. However, how to represent and select this kind of interaction is a problem.

2.2.1 Neural Tensor Network

Conventional methods to measure the relevance between two arguments includes bilinear model (Jenatton et al., 2012), and single layer neural networks (Collobert and Weston, 2008), etc. These methods could hardly model the complex and informative interactions. Success in knowledge graph (Socher et al., 2013a) shows that tensor can model multiple interactions in data. Therefore, we further employ a tensor layer to mine the deeper semantic interactions based on the new argument representations so as to recognize implicit discourse relations.

Tensor is a geometric object that describes relations between vectors, scalars, and others. It can be represented as a multi-dimensional array of numerical values. Following the NTN (Socher et al., 2013a; Pei et al., 2014), we utilize a 3-way tensor $\boldsymbol{M}^{[1:k]} \in \mathbb{R}^{d_h \times d_h \times k}$ to model the interactions shown in Eq.(12).

$$g(\boldsymbol{h}_{Arg1}, \boldsymbol{h}_{Arg2}) = \boldsymbol{u}^T f\left((\boldsymbol{h}_{Arg1})^T \boldsymbol{M}^{[1:k]} \boldsymbol{h}_{Arg2} + \boldsymbol{V}\begin{bmatrix}\boldsymbol{h}_{Arg1}\\ \boldsymbol{h}_{Arg2}\end{bmatrix} + \boldsymbol{b}\right). \tag{12}$$

where f is a standard nonlinearity applied element-wise, $\boldsymbol{M}^{[1:k]} \in \mathbb{R}^{d_h \times d_h \times k}$ is a tensor and the bilinear tensor product $(\boldsymbol{h}_{Arg1})^T \boldsymbol{M}^{[1:k]} \boldsymbol{h}_{Arg2}$ results in a vector $\boldsymbol{m} \in \mathbb{R}^k$, where each entry is computed by one slice $i = 1, 2, ..., k$ of the tensor: $\boldsymbol{m}_i = (\boldsymbol{h}_{Arg1})^T \boldsymbol{M}^{[i]} \boldsymbol{h}_{Arg2}$. The other parameters $\boldsymbol{V} \in \mathbb{R}^{k \times 2d_h}$, $\boldsymbol{u} \in \mathbb{R}^k$, $\boldsymbol{b} \in \mathbb{R}^k$ are the standard form of a neural network. Here, each tensor slice can be seen as a "feature extractor", which extracts the features expressing the *Arg*1-*Arg*2 interactions.

Through the tensor layer, we can obtain the semantic interactions between two arguments as features, which are further reshaped to a vector and fed to a full connection hidden layer. Then we apply a softmax function in the output layer to compute the probabilities of different relations and recognize them.

2.2.2 Model Training with Sparse Constraint

Given a training corpus which contains n instances $\{(\boldsymbol{x}, \boldsymbol{y})\}_{r=1}^n$, $(\boldsymbol{x}, \boldsymbol{y})$ denotes an argument pair and its label. We employ the cross-entropy error to assess how well the predicted relation represents the real relation, defined as:

$$L(\hat{\boldsymbol{y}}, \boldsymbol{y}) = -\sum_{j=1}^{C} \boldsymbol{y}_j \log(Pr(\hat{\boldsymbol{y}}_j)). \tag{13}$$

where $Pr(\hat{\boldsymbol{y}}_j)$ is the predicted probabilities of labels, C is the class number.

Based on argument representations with interactive attention, tensor embodies the different aspects of semantic interactions between two arguments. However, not all the interactions are useful. There could exist some redundant and noisy interactions influencing the system performance. In order to remove the irrelevant interactions and select the indicative pair patterns, the large portion of $\boldsymbol{M}^{[i]}$ should be zero. Therefore, we introduce the 1-norm regularizer to promote the feature sparsity. This element-wise sparsity can be helpful when most of the features are irrelevant to the learning objective. Furthermore, we also add l_2 regularization to avoid over-fitting issue. And the training objective function is transformed as:

$$J(\boldsymbol{\theta}) = \frac{1}{n}\sum_{r=1}^{n} L(\hat{\boldsymbol{y}}^{(r)}, \boldsymbol{y}^{(r)}) + R(\boldsymbol{\theta}), \tag{14}$$

$$R(\boldsymbol{\theta}) = \lambda_M \|\boldsymbol{\theta}_M\|_1 + \frac{\lambda_O}{2}\|\boldsymbol{\theta}_O\|_2. \tag{15}$$

where $R(\boldsymbol{\theta})$ is the regularization term with respect to $\boldsymbol{\theta}$. We divide $\boldsymbol{\theta}$ into two parts: $\boldsymbol{\theta}_M$ is the tensor term weights, and $\boldsymbol{\theta}_O$ is the other parameters of our model. Especially, $\|\boldsymbol{\theta}_M\|_1$ in Eq.(15) is l_1 regularization for the tensor slices, which is used to filter the important values.

To minimize the objective, we employ the proximal gradient descent method (Parikh and Boyd, 2014) since l_1 regularization is non-differentiable at zero. It is used for optimizing the objective as a combination of both smooth and non-smooth terms. The update formulas is as follows:

$$\boldsymbol{\theta}_i^{(t')} = \boldsymbol{\theta}_i^{(t)} - \gamma(\frac{\partial L}{\partial \boldsymbol{\theta}_i} + \lambda\frac{\partial R}{\partial \boldsymbol{\theta}_i})|_{\boldsymbol{\theta}_i=\boldsymbol{\theta}_i^{(t)}}, \tag{16}$$

$$\frac{\partial R}{\partial \boldsymbol{\theta}_i} = \begin{cases} 2\boldsymbol{\theta}_i^{(t)}, & \text{if } \|\boldsymbol{\theta}\|_2; \\ sign(\boldsymbol{\theta}_i^{(t)}), & \text{if } \|\boldsymbol{\theta}\|_1, \text{ and } \boldsymbol{\theta}_i^{(t)} \neq 0. \end{cases} \tag{17}$$

$$\boldsymbol{\theta}_i^{(t+1)} = prox_\lambda(\boldsymbol{\theta}_i^{t'}) = \tau(\boldsymbol{\theta}_i^{t'}, \gamma\lambda), \tag{18}$$

$$\tau(a, z) = \begin{cases} a - z, & \text{if } a > z; \\ a + z, & \text{if } a < -z; \\ 0, & \text{otherwise.} \end{cases} \tag{19}$$

where $prox_\lambda$ is a proximal operator, τ is a soft-thresholding operator, and γ is the learning rate.

3 Experiments

3.1 Data Preparation

Corpus. We use the Penn Discourse TreeBank (PDTB) (Prasad et al., 2008), which is the largest hand-annotated discourse relation corpus annotated on 2312 Wall Street Journal (WSJ) articles. Experiments are conducted on the four top-level classes as in previous work (Rutherford and Xue, 2014; Chen et al., 2016). Following the conventional data splitting, we use Section 2-20 as training set, Section 21-22 as testing set, and Section 0-1 as development set. The relevant statistics is shown in Table 1.

Relation	Train	Dev.	Test
Comparison	1842	393	144
Contingency	3139	610	266
Expansion	6658	1231	537
Temporal	579	83	55

Table 1: Statistics of implicit discourse relations.

Hyper-parameters	Value
Initial learning rate	0.01
Minibatch size	30
Dropout rate	0.1
Number of tensor slice	3

Table 2: Hyper-parameters for our TIASL model.

Experimental Settings. The 50-dimensional pre-trained word embeddings are provided by GloVe (Pennington et al., 2014), which are fixed during our model training. All the discourse arguments are padded

to the same length of 50. And the length of intermediate representation for our network is also 50. The other parameters are initialized by random sampling from uniform distribution in [-0.1,0.1]. We do not present the details of tuning the hyper-parameters and only give their final settings as shown in Table 2.

To evaluate our model, we adopt two kinds of experiment settings, including a four-way classification and four separate one-vs-other binary classification. The former is to observe the overall performance. And the latter is to solve the problem of unbalance data, where each top level class is against the other three discourse relation classes. We use an equal number of positive and negative instances in the training set in each class. The testing set and development set keep the natural state.

3.2 Comparison Methods

We choose the following models as our baselines, which are the state-of-the-art models in argument representation, interaction and attention aspects during implicit discourse relation recognition.

- **Ji2015**: Ji and Eisenstein (2014) utilized two recursive neural networks on the syntactic parse tree to induce argument representation and entity spans.
- **Qin2016**: Qin et al. (2016b) integrated a CNN and a Collaborative Gated Neural Network (CGNN) into argument representation.
- **Chen2016**: Chen et al. (2016) used a Gated Relevance Network (GRN) and incorporated both the linear and non-linear interactions between word pairs.
- **Liu2016**: Liu and Li (2016) designed Neural Networks with Multi-level Attention (NNMA) and selected the important words for recognizing discourse relation. Here, we select the models with two and three levels attention as baselines.

Besides, we also use the following variants of RNN and the proposed TIASL model for comparisons.

- **LSTM**: encode two discourse arguments by LSTM respectively, and concatenate the two representations, feeding them to the full connection hidden layer as the input of softmax classifier.
- **Bi-LSTM**: based on **LSTM**, we consider the bidirectional context information, and use Bi-LSTM to encode two discourse arguments.
- **Bi-LSTM+Interactive Attention**: further integrate the interactive attention to obtain the new argument representations shown in Eq.(11).
- **Bi-LSTM+Tensor Layer**: based on **Bi-LSTM**, adopt the neural tensor network to capture the semantic interaction between two arguments.
- **TIA with k-Max Pooling**: use k-max pooling operation instead of our sparse strategy to select features after tensor layer in neural Tensor network with Interactive Attention model (TIA).
- **Our TIASL**: based on **Bi-LSTM** with **Interactive Attention** and **Tensor Layer**, we add l_1 regularization for tensor parameters in order to capture the most important interactions.

3.3 The Overall Performance

Table 3 shows the overall performance, using F_1 score and accuracy for four-wary classification and F_1 score for binary classification. With respect to four-way classification, we have the following observations:

- Ji2015 gains the lowest performance on both F_1 score and accuracy, which separately computes discourse argument representations by integrating syntactic parse tree into RNN. It indicates a simple neural network, which ignores the interactive context of two discourse arguments, is not sufficient for implicit discourse relation recognition.

Model	Binary Classification				Four-way Classification	
	Comp.	Cont.	Expa.	Temp.	F1	Acc.
Ji2015	35.93%	52.78%	-	27.63%	38.52%	43.56%
Qin2016	41.55%	57.32%	71.50%	35.43%	-	-
Chen2016	40.17%	54.76%	-	31.32%	44.61%	57.84%
Liu2016 (two levels)	36.70%	54.48%	70.43%	38.84%	46.29%	57.17%
Liu2016 (three levels)	39.86%	53.69%	69.71%	37.61%	44.95%	57.57%
Our TIASL	40.35%	56.81%	72.11%	38.65%	47.59%	59.06%

Table 3: Comparisons with the state-of-the-art models.

- The accuracy of Chen2016 model is better than that of other baselines. It verifies the effectiveness word pair information, which uses gate mechanism to control the combination of linear and non-linear interactions between argument pairs. However, there unavoidably exits some noises, and this model has not considered the sparsity of pair patterns. F_1 score of Liu2016 (two levels) model is higher than that of other baselines, which achieves 1.34% than that of three levels attention's. It indicates that attention mechanism is useful, and yet paying more attention may bring the over-fitting problem due to more parameters.

- Our TIASL gains an improvement 1.30% on F_1 score than that of Liu2016 (two levels), and an improvement 1.22% on accuracy than that of Chen2016. The results imply that our model with interactive attention for the bidirectional asymmetry of two arguments and sparse pair pattern selection is useful for recognizing implicit discourse relation.

For binary classification, the observations are as follows:

- F_1 scores of Temporal relation are the lowest in all models. This is reasonable since it accounts for the smallest number of instances (only 5%) in the corpus. With the increase of instance number in different relations, F_1 scores also rise. It proves that the corpus is also crucial to implicit discourse relation recognition.

- Qin2016 gains the best performance on Contingency, and our TIASL model obtains the comparable score with it. Notably, Chen2016 and Liu2016 (two levels) are quite relevant work to ours. Different from them, our model integrates the attention-based interactive information between arguments at representation stage. This may be the main reason why our TIASL model is better than the two models (the improvements of 2.05% and 2.33%, respectively). Similar results are in Comparison relation.

- Our TIASL model achieves state-of-the-art performance in recognition of the Expansion relation. The reasons are two-fold: (1) some argument pairs may have confusable word pairs, which can be effectively mined by asymmetric attention; (2) some complex argument pairs need to be further understood their semantic representation and explore the indicative and interactive patterns. Our TIASL model integrates these two aspects and performs well.

3.4 The Effectiveness of Each Component

In order to verify the effectiveness of attention mechanism, neural tensor layer and l_1 regularization, we design five experiments to compare with our TIASL model. Seen from Table 4, we have the following observations:

- The performance of LSTM is the worst on each relation. Although Bi-LSTM captures more information than LSTM, the results are not very good. The reason is that separately encoding discourse argument by LSTM or Bi-LSTM ignores the local focused words since it equally treats every word.

Model	Binary Classification				Four-way Classification	
	Comp.	Cont.	Expa.	Temp.	F1	Acc.
LSTM	32.95%	43.38%	68.10%	30.80%	36.40%	54.50%
Bi-LSTM	34.01%	44.68%	68.53%	31.27%	36.54%	55.31%
Bi-LSTM + Interactive Attention	35.43%	45.92%	68.57%	32.50%	43.27%	55.68%
Bi-LSTM + Tensor Layer	37.36%	46.73%	69.81%	33.89%	43.61%	55.97%
TIA with k-max pooling	39.78%	55.13%	70.96%	37.65%	46.77%	57.83%
Our TIASL	40.35%	56.81%	72.11%	38.65%	47.59%	59.06%

Table 4: The effects of different components.

- Bi-LSTM with Interactive Attention performs better than the above two simple models. In detail, the F_1 score of this model gains 2.48%, 2.54%, 1.70% improvement on Comparison, Contingency and Temporal than that of LSTM, respectively. We perform significance test for these improvements, and they are both significant under one-tailed t-test ($p < 0.05$). It indicates that the model could find pair specific clues in two arguments by constructing the relevance of word pairs to some extent. And the effectiveness of our attention mechanism for capturing the interactive information between the arguments is crucial at representation stage.
- Bi-LSTM with Tensor Layer slightly achieves better performance. This indicates the effectiveness of tensor layer for capturing complex interactive features. The TIA model, which combines attention mechanism and tensor layer, also performs better, but lower than our TIASL model. It is because that k-max pooling strategy could not guarantee getting the important interaction pairs from the global perspective. How to represent and explain these interactive features mined in our model will be our next research focus.
- Our TIASL model achieves the best performance. It not only encodes discourse arguments with important word pairs by interactive attention, but also captures the more deeper and the more important semantic interactions by NTN with l_1 regularization. The integration of all components is useful for recognizing implicit discourse relations.

The observations of each component's four-way classification are consistent with the binary classification.

3.5 Interactive Attention Analysis

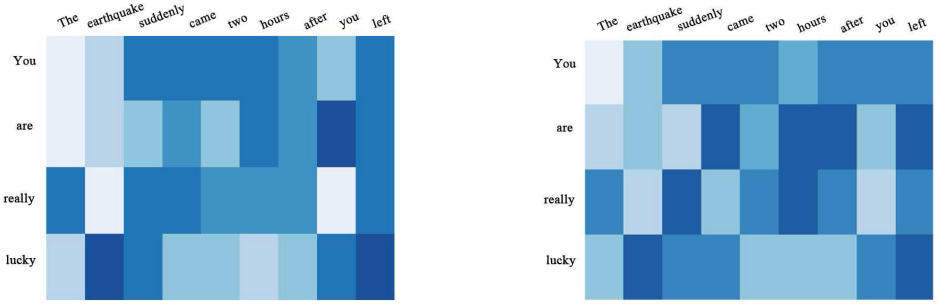
To demonstrate the validity of our interactive attention, we visualize the heat maps of argument pairs shown in Figure 2, which shows the interaction matrices of only using Bi-LSTM and our interactive attention on an example. Every word accompanies with the various background colors. The darker patches denote the correlations of word pairs are higher. The example of *Contingency* relation is listed below:

***Arg*1:** *You are really lucky.*

***Arg*2:** *The earthquake suddenly came two hours after you left.*

However, it might be classified as a *Comparison* relation if we only focus on the informative word pair (lucky, earthquake) with contrasting sentiment polarity. Therefore, we need to consider the context of the whole argument pair to infer the correct relation from two back and forth reading directions.

Seen from Figure 2(a), the word pairs (are, you), (lucky, earthquake), (lucky, left) get the higher scores, the scores on the other pairs are arbitrary. It demonstrates the Bi-LSTM model may be influenced by the word pair frequency in corpus. Meanwhile, it encodes two arguments separately, which ignores the relevant and informative interactions between two arguments. Figure 2(b) as a comparison, we observe that there are the more word pairs obtaining the higher scores, which are ignored in Figure 2(a). This proves that the effectiveness of generating interactive argument representation by our interactive attention, which imitates human-like reading strategy.



(a) Bi-LSTM (only word embedding) (b) Bi-LSTM + Interactive attention

Figure 2: The relatedness between two arguments.

4 Related Work

Traditional methods for implicit discourse relation recognition rely on artificial and shallow features, such as POS, polarity, word position, etc. Recent neural network based methods acquire the better performance, and mainly focus on two aspects:

4.1 Argument Representation

The prerequisite of recognizing discourse relation is to have a good argument representation. Most previous researches use various neural networks, such as CNN, RNN, and hybrid models (Zhang et al., 2015; Qin et al., 2016a; Rutherford et al., 2016) to encode discourse arguments as low-dimensional, dense and continuous representations. Ji and Eisenstein (2014) integrate the linguistic features, including syntactic parsing and coreferent entity mentions into compositional distributed representations.

Though argument representation contains the high-level semantic, it does not embody emphasis during reading comprehension. Some used neural architectures with attention mechanism pick up the important information from discourse arguments (Mnih et al., 2014; Zhang et al., 2016). Li et al. (2016) exploit the hierarchical attention to capture the focus of different granularity. Liu and Li (2016) imitate the repeated reading strategy, and proposes neural networks with multi-level attention to recognize discourse relations. However, these researches have not considered the human-like reading strategy from two directions. The imagination by first reading one argument is different from the other, which has the reciprocal effects on implicit discourse relation recognition.

4.2 Pair Interactions

The emphasis of discourse arguments is partly obtained by attention mechanism. Most studies tend to discover more semantic interactions between two arguments by complex neural networks (Chen et al., 2016; Qin et al., 2016b; Lan et al., 2017). Cai and Zhao (2017) generate discourse argument representations via pair-specified feature extraction. Lei et al. (2017) conduct word interaction score to capture both linear and quadratic relation for argument representation.

Neural tensor network is good at capturing multiple interactions in data, and gets the good performance on entity relation (Socher et al., 2013a), Chinese word segmentation(Pei et al., 2014) and sentiment analysis (Socher et al., 2013b) tasks. And some NTN-like methods learn the semantic interaction between discourse arguments (Chen et al., 2016). Yet they do not discriminate the noises and the redundant information existed in interactions, and ignore the sparsity of pair patterns.

Inspired by sparse learning in deep neural networks (Collins and Kohli, 2014; Yoon and Hwang, 2017; Wen et al., 2017), they use sparse regularization to obtain compact deep networks by removing unnecessary weighs. In our paper, we introduce sparse learning into neural tensor network to select some indicative and informative word pair patterns. To our knowledge, our study is the first to employ the idea of sparse learning in implicit discourse relation recognition.

5 Conclusion

A novel neural tensor network framework with interactive attention and sparse learning (TIASL) is proposed for implicit discourse relation recognition. We imitate human-like bidirectional reading strategy, and encode the semantic representation with reciprocal influence of discourse arguments through interactive attention. And we further adopt neural tensor network with l_1 regularization to capture the indicative and informative interactions between discourse arguments. Our experimental results on PDTB show that the proposed TIASL model is effective.

However, we just take the surface word pairs to express the correlation by calculating the pair-wise matrix in this paper. We will automatically mine the deeper interaction between two arguments and explain the specific patterns of the different relations.

Abstract

Syntax has been a useful source of information for statistical RST discourse parsing. Under the neural setting, a common approach integrates syntax by a recursive neural network (RNN), requiring discrete output trees produced by a supervised syntax parser. In this paper, we propose an implicit syntax feature extraction approach, using hidden-layer vectors extracted from a neural syntax parser. In addition, we propose a simple transition-based model as the baseline, further enhancing it with dynamic oracle. Experiments on the standard dataset show that our baseline model with dynamic oracle is highly competitive. When implicit syntax features are integrated, we are able to obtain further improvements, better than using explicit Tree-RNN.

1 Introduction

Discourse parsing is an important task in natural language processing (NLP), which aims to identify the relations between text units in documents. It has received great attention (Sagae, 2009; Hernault et al., 2010; Feng and Hirst, 2012; Joty et al., 2013; Feng and Hirst, 2014; Ji and Eisenstein, 2014; Heilman and Sagae, 2015; Li et al., 2016; Wang et al., 2017; Braud et al., 2017; Liu and Lapata, 2017), especially by performing the task based on rhetorical structure theory (RST) (Mann and Thompson, 1988). The RST-based parsing represents a document by a hierarchical tree, where leaf nodes are basic text units referred as elementary discourse unit (EDU), and non-terminal nodes define the discourse relations between adjacent tree nodes. Figure 1 shows an example, where each discourse relation has two parts, specifying its label and indicating its nuclearity, respectively.

Early studies adopt traditional statistical models for this task, using sophisticated manually-designed discrete features (Soricut and Marcu, 2003; Sagae, 2009; Hernault et al., 2010; Feng and Hirst, 2012; Joty et al., 2013; Feng and Hirst, 2014; Heilman and Sagae, 2015; Wang et al., 2017). Recently, inspired by the success of neural network models in NLP (Collobert et al., 2011; Devlin et al., 2014), several neural models for RST discourse parsing have been proposed as well (Li et al., 2014; Li et al., 2015b; Li et al., 2016; Braud et al., 2016; Braud et al., 2017; Liu and Lapata, 2017). Compared with statistical models, neural models exploit low-dimensional dense features, being able to avoid the feature sparsity problem, and on the other hand well-designed neural network structures such as long short term memory (LSTM) (Schmidhuber and Hochreiter, 1997) are capable of capturing high-order compositional features as well as global features automatically. In addition, we can use pre-trained neural word embeddings (Mikolov et al., 2013) on large scale corpus for neural network initialization. These characteristics show that neural models are promising for RST discourse parsing.

Intuitively, syntax is a potential avenue for the task, as it offers long-distance syntax relations between sentential words as well as key components of sentences. Syntax features have been demonstrated helpful in statistical models with human designed features (Soricut and Marcu, 2003; Sagae, 2009; Hernault et al., 2010; Feng and Hirst, 2012; Joty et al., 2013; Feng and Hirst, 2014; Heilman and Sagae, 2015). For neural network models, recursive neural network is a natural choice to represent tree-structural syntax trees globally. Only Li et al. (2015b) apply such a neural structure to incorporate syntax trees for

RST discourse parsing. Other studies still adopt discrete syntax features proposed by statistical models, feeding them into neural network models (Braud et al., 2016; Braud et al., 2017).

The above approaches model syntax trees in an explicit way, requiring discrete syntax parsing outputs as inputs for RST parsing. These approaches may suffer from the error propagation problem. Syntax trees produced by a supervised syntax parsing model could have errors, which may propagate into discourse parsing models. The problem could be extremely serious when inputs of discourse parsing have different distributions with the training data of the supervised syntax parser. Recently, Zhang et al. (2017) suggest an alternative method, which extracts syntax features from a Bi-Affine dependency parser (Dozat and Manning, 2016), and the method gives competitive performances on relation extraction. It actually represents syntax trees implicitly, thus it can reduce the error propagation problem.

In this work, we investigate the implicit syntax feature extraction approach for RST parsing. In addition, we propose a transition-based neural model for this task, which is able to incorporate various features flexibly. We exploit hierarchical bi-directional LSTMs (Bi-LSTMs) to encode texts, and further enhance the transition-based model with dynamic oracle. Based on the proposed model, we study the effectiveness of our proposed implicit syntax features. We conduct experiments on a standard RST discourse TreeBank (Carlson et al., 2003). First, we evaluate the performance of our proposed transition-based baseline, finding that the model is able to achieve strong performances after applying dynamic oracle. Then we evaluate the effectiveness of implicit syntax features extracted from a Bi-Affine dependency parser. Results show that the implicit syntax features are effective, giving better performances than explicit Tree-LSTM (Li et al., 2015b). Our codes will be released for public under the Apache License 2.0 at `https://github.com/yunan4nlp/NNDisParser`.

In summary, we mainly make the following two contributions in this work: (1) we propose a transition-based neural RST discourse parsing model with dynamic oracle, (2) we compare three different syntactic integration approaches proposed by us. The rest of the paper is organized as follows. Section 2 describes our proposed models including the transition-based neural model, the dynamic oracle strategy and the implicit syntax feature extraction approach. Section 3 presents the experiments to evaluate our models. Section 4 shows the related work. Finally, section 5 draws conclusions.

2 Transition-based Discourse Parsing

We follow Ji and Eisenstein (2014), exploiting a transition-based framework for RST discourse parsing. The framework is conceptually simple and flexible to support arbitrary features, which has been widely used in a number of NLP tasks (Zhu et al., 2013; Dyer et al., 2015; Zhang et al., 2016). In addition, a transition-based model formalizes a certain task into predicting a sequence of actions, which is essential similar to sequence-to-sequence models proposed recently (Bahdanau et al., 2014). In the following, we first describe the transition system for RST discourse parsing, and then introduce our neural network model by its encoder and decoder parts, respectively. Thirdly, we present our proposed dynamic oracle strategy aiming to enhance the transition-based model. Then we introduce the integration method of implicit syntax features. Finally we describe the training method of our neural network models.

2.1 The Transition-based System

The transition-based framework converts a structural learning problem into a sequence of action predictions, whose key point is a transition system. A transition system consists of two parts: states and actions. The states are used to store partially-parsed results and the actions are used to control state transitions.

Step	Stack	Queue	Action	Relation
1	$\varnothing$	e_1, e_2, e_3, e_4	SH	$\varnothing$
2	e_1	e_2, e_3, e_4	SH	$\varnothing$
3	e_1, e_2	e_3, e_4	RD (attr, SN)	$\varnothing$
4	$e_{1:2}$	e_3, e_4	SH	$\widehat{e_1\mathbf{e_2}}$
5	$e_{1:2}, e_3$	e_4	SH	$\widehat{e_1\mathbf{e_2}}$
6	$e_{1:2}, e_3, e_4$	$\varnothing$	RD (elab, NS)	$\widehat{e_1\mathbf{e_2}}$
7	$e_{1:2}, e_{3:4}$	$\varnothing$	RD (elab, SN)	$\widehat{e_1\mathbf{e_2}}, \widehat{\mathbf{e_3}e_4}$
8	$e_{1:4}$	$\varnothing$	PR	$\widehat{e_1\mathbf{e_2}}, \widehat{\mathbf{e_3}e_4}, \widehat{e_{1:2}\mathbf{e_{3:4}}}$

Table 1: An example of the transition-based system for RST discourse parsing.

The initial state is an empty state, and the final state represents a full result. There are three kinds of actions in our transition system:

- **Shift** (SH), which removes the first EDU in the queue onto the stack, forming a single-node subtree.
- **Reduce** (RD) (l,d), which merges the top two subtrees on the stack, where l is a discourse relation label, and $d \in \{\texttt{NN}, \texttt{NS}, \texttt{SN}\}$ indicates the relation nuclearity (nuclear (N) or satellite (S)).
- **Pop Root** (PR), which pops out the top tree on the stack, marking the decoding being completed, when the stack holds only one subtree and the queue is empty.

Given the RST tree as shown in Figure 1, it can be generated by the following action sequence: {SH, SH, RD (attr, SN), SH, SH, RD (elab, NS), RD (elab, SN), PR}. Table 1 shows the decoding process in detail. By this way, we naturally convert RST discourse parsing into predicting a sequence of transition actions, where each line includes a state and next step action referring to the tree.

2.2 Encoder-Decoder

Previous transition-based RST discourse parsing studies exploit statistical models, using manually-designed discrete features (Sagae, 2009; Heilman and Sagae, 2015; Wang et al., 2017). In this work, we propose a transition-based neural model for RST discourse parsing, which follows an encoder-decoder framework. Given an input sequence of EDUs $\{e_1, e_2, ..., e_n\}$, the encoder computes the input representations $\{\mathbf{h}_1^e, \mathbf{h}_2^e, ..., \mathbf{h}_n^e\}$, and the decoder predicts next step actions conditioned on the encoder outputs.

2.2.1 Encoder

We follow Li et al. (2016), using hierarchical Bi-LSTMs to encode the source EDU inputs, where the first-layer is used to represent sequencial words inside of EDUs, and the second layer is used to represent sequencial EDUs. Given an input sentence $\{w_1, w_2, ..., w_m\}$, first we represent each word by its form (e.g., w_i) and POS tag (e.g. t_i), concatenating their neural embeddings. By this way, the input vectors of the first-layer Bi-LSTM are $\{\mathbf{x}_1^w, \mathbf{x}_2^w, ..., \mathbf{x}_m^w\}$, where $\mathbf{x}_i^w = emb(w_i) \oplus emb(t_i)$, and then we apply Bi-LSTM directly, obtaining:

$$\{\mathbf{h}_1^w, \mathbf{h}_2^w, ..., \mathbf{h}_m^w\} = \text{Bi-LSTM}(\{\mathbf{x}_1^w, \mathbf{x}_2^w, ..., \mathbf{x}_m^w\}) \quad (1)$$

The second-layer Bi-LSTM is built over sequential EDUs. We should first obtain a suitable representation for each EDU, which is composed by a span of words inside a certain sentence. Assuming an EDU with its words by $\{w_s, w_{s+1}, ..., w_t\}$, after applying the first-layer Bi-LSTM, we obtain their representations by $\{\mathbf{h}_s^w, \mathbf{h}_{s+1}^w ..., \mathbf{h}_t^w\}$, then we calculate the EDU representation by average pooling:

$$\mathbf{x}^e = \frac{1}{t-s+1} \sum_{s}^{t} \mathbf{h}_k^w \quad (2)$$

When the EDU representations are ready, we apply the second-layer Bi-LSTM directly, resulting:

$$\{\mathbf{h}_1^e, \mathbf{h}_2^e, ..., \mathbf{h}_n^e\} = \text{Bi-LSTM}(\{\mathbf{x}_1^e, \mathbf{x}_2^e, ..., \mathbf{x}_n^e\}) \quad (3)$$

Algorithm 1 Dynamic Oracle.

$S \leftarrow empty$;
$a_g \leftarrow Oracle(S, T)$;
$a_p \leftarrow Predict(S)$;
while S is not $terminal$ **do**
    $Train(S, a_g)$;
    if $pick\_gold > \alpha$ **then**
        $S \leftarrow Apply(S, a_g)$;
    else
        $S \leftarrow Apply(S, a_p)$;

2.2.2 Decoder

The decoder part is to predict the next-step action based on a given state. As mentioned before, each transition state has a sequence of subtrees on the stack and a sequence of unprocessed EDUs in the queue. We simply choose the top three stack subtrees (s_0, s_1, s_2) and the first EDU (q_0) in the queue as major clues for prediction, applying a feed-forward neural layer to calculate next-step action scores:

$$\mathbf{o} = \mathbf{W}(\mathbf{h}^{sbt}_{s_0} \oplus \mathbf{h}^{sbt}_{s_1} \oplus \mathbf{h}^{sbt}_{s_2} \oplus \mathbf{h}^{e}_{q_0}) \tag{4}$$

where $\mathbf{o}$ is the output scores and $\mathbf{W}$ is a model parameter.

The hidden vector $\mathbf{h}^{e}_{q_0}$ is obtained directly from the encoder outputs. The hidden vectors $\mathbf{h}^{sbt}_{s_0}$, $\mathbf{h}^{sbt}_{s_1}$ and $\mathbf{h}^{sbt}_{s_2}$ are representations of partially-parsed subtrees. For efficiency, we exploit average pooling over the covering EDUs $\{e_i, e_{i+1}, ..., e_j\}$ of a subtree s to derive its representation:

$$\mathbf{h}^{sbt}_{s} = \frac{1}{j-i+1} \sum_{i}^{j} \mathbf{h}^{e}_{k} \tag{5}$$

2.3 Dynamic Oracle

The transition-based model converts discourse parsing into an incremental action prediction problem. For a given state, we require its answer for training. When the state follows the traces of gold-standard actions, its answer is exactly the next gold-standard action. Majority work trains a classifier based on gold-standard state-answer pairs (Ji and Eisenstein, 2014; Heilman and Sagae, 2015; Braud et al., 2017; Wang et al., 2017). However, we usually have error states during the test stage, which are resulted by historical error actions. These error states have never been seen during training, which makes prediction difficult for them. The phenomenon brings inconsistency between training and testing.

Here we adopt dynamic oracle to alleviate the above problem, which has been firstly exploited by Goldberg and Nivre (2012) for dependency parsing. The main idea is to add error states and their oracle actions into the training corpus randomly. On the one hand, by exploring a percentage of error states, the transition-based model is able to handle these states more confidently. On the other hand, by defining oracle actions over error states, the model is able to make best choices even when errors occur.

In this work, we suggest a similar dynamic oracle strategy for our transition-based neural model. Algorithm 1 shows the pseudo codes. During training, we explore into predicted states randomly by a probability α. At each step, we generate a random number $pick\_gold$ between [0,1]. If the value is less than α, we use the predicted state as the next-step input, making the training process consistent with the testing. The oracle function is defined by minimizing the future decoding loss referring to gold-standard RST trees, which is defined as follows:

$$a_g = \begin{cases} \text{RD},\ s.t.\ \widehat{s_0 s_1} \text{ is a subtree in G (relation labels and nuclearities are neglected)} \\ \text{SH},\ \text{otherwise,} \end{cases} \tag{6}$$

where s_0, s_1 are top two stack subtrees, and G is the set of gold-standard subtrees. Simply speaking, if s_0 and s_1 can be composed as a subtree according to the gold-standard RST-tree, we apply RD, and otherwise we apply SH.

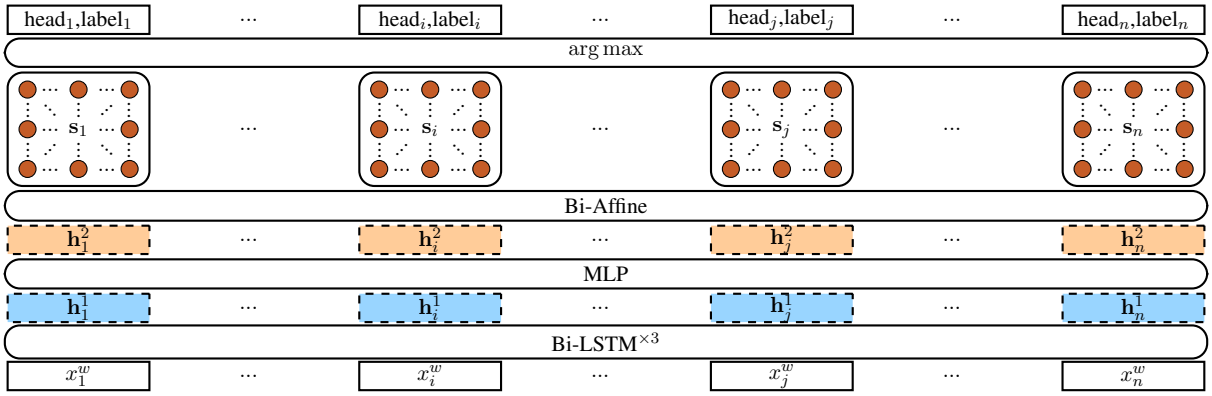

Figure 2: The framework of Bi-Affine neural parser.

2.4 Syntax Features

Intuitively, syntax information could be a valuable source for RST parsing (Soricut and Marcu, 2003; Sagae, 2009; Hernault et al., 2010; Feng and Hirst, 2012; Joty et al., 2013; Feng and Hirst, 2014; Heilman and Sagae, 2015). Previously, the information is integrated into RST discourse parsing by manually-designed discrete features, except the work of Li et al. (2015b), which exploits a bi-directional Tree-LSTM to model syntax trees.

In addition, all previous studies use deterministic parsing outputs as inputs for RST discourse parsing, which may suffer from error propagation problem since syntax parsing outputs can have errors. To alleviate this problem, Zhang et al. (2017) suggest an alternative method, which extracts intermediate hidden outputs of a neural parsing model as inputs for relation-extraction. The method exploits an implicit way to incorporate syntax features without the the need of parsing outputs. Inspired by their work, we investigate the same method for RST discourse parsing.

We follow Zhang et al. (2017) to use the Bi-Affine dependency neural parser of Dozat and Manning (2016) for syntax feature extraction. Zhang et al. (2017) formalize the Bi-Affine parser as an encoder-decoder architecture, and exploit the encoder outputs as inputs for relation extraction. Here we study the Bi-Affine parser in deep, examining other hidden layers as well. Next we will introduce the Bi-Affine parser briefly, and then describe our implicit syntax feature extraction method.

2.4.1 The Bi-Affine Parser

The Bi-Affine neural dependency parser has achieved the top performances (Dozat and Manning, 2016). As shown by Figure 2, the model has four components: (1) a three-layer Bi-LSTM (Bi-LSTM$^{\times 3}$) over the input sentential words; (2) a multi-layer perceptron (MLP) layer; (3) a Bi-Affine layer; (4) an $\arg\max$ decoder. Their outputs are $\{\mathbf{h}_1^1, \mathbf{h}_2^1 ..., \mathbf{h}_n^1\}$, $\{\mathbf{h}_1^2, \mathbf{h}_2^2, ..., \mathbf{h}_n^2\}$, $\{\mathbf{s}_{ij}^l, i \in [1,n], j \in [1,n], l \in L$ (The set of dependency labels.)$\}$, and $\{(\text{head}_1, \text{label}_1), ..., (\text{head}_n, \text{label}_n)\}$, respectively, which are computed by follow formulas:

$$
\begin{aligned}
&\{\mathbf{h}_1^1, \mathbf{h}_2^1, ..., \mathbf{h}_n^1\} = \text{Bi-LSTM}^{\times 3}(\{\mathbf{x}_1^w, \mathbf{x}_2^w, ..., \mathbf{x}_n^w\}) \\
&\{\mathbf{h}_1^2, \mathbf{h}_2^2, ..., \mathbf{h}_n^2\} = \text{MLP}(\{\mathbf{h}_1^1, \mathbf{h}_2^1, ..., \mathbf{h}_n^1\}) \\
&\mathbf{s}_{i,j}^l = \text{Bi-Affine}(\mathbf{h}_i^2, \mathbf{h}_j^2, l) \\
&\text{head}_i, \text{label}_i = argmax_{\{h,l\}}(\mathbf{s}_{i,h}^l)
\end{aligned}
\tag{7}
$$

Noticeably, the above formulas are only an approximate description of the Bi-Affine parser. For more details, one can refer to their paper.

2.4.2 Implicit Syntax Feature Extraction

Zhang et al. (2017) formalize the Bi-Affine parser as an encoder-decoder model, where the encoder part includes the neural structures ending by the Bi-LSTM$^{\times 3}$, and they use the encoder outputs for implicit syntax feature extraction. Additionally, by carefully examining, we find that the MLP outputs have

similar attributes to the Bi-LSTM$^{\times 3}$ outputs, both of which are aligned with the input sentential words perfectly, being closely related to the words at the aligned positions. In addition, the MLP outputs are closer to the final syntax parsing outputs, thus are able to encode syntax information more sufficiently.

Concretely, for a given sentence $\{w_1, w_2, ..., w_n\}$, we feed it into the Bi-Affine parser, extracting the encoder outputs $\{\mathbf{h}_1^1, \mathbf{h}_2^1, ..., \mathbf{h}_n^1\}$ or the MLP outputs $\{\mathbf{h}_1^2, \mathbf{h}_2^2, ..., \mathbf{h}_n^2\}$, respectively. Then we concatenate them with the encoder outputs of our transition-based neural RST parsing model. The resulting vectors are used as inputs for the decoder part. The overall syntax incorporation process can be formalized as follows:

$$\{\mathbf{h}'_1, \mathbf{h}'_2, ..., \mathbf{h}'_n\} = \{\mathbf{h}_1^w \oplus \mathbf{h}_1^*, \mathbf{h}_2^w \oplus \mathbf{h}_2^*, ..., \mathbf{h}_n^w \oplus \mathbf{h}_n^*\} \tag{8}$$

where $*$ could be either 1 or 2, denoting the Bi-LSTM$^{\times 3}$ or the MLP outputs.

2.5 Training

We follow the majority work of transition-based deterministic neural models, using a cross-entropy loss plus with an l_2 regularization as our training objective. Given a state S and its oracle action a, we calculate the decode outputs by using equation (4), and then apply a softmax operation to obtain the oracle action probalility: $p_{a_g} = \frac{exp(\mathbf{o}_{a_g})}{\sum_{a' \in A} exp(\mathbf{o}_{a'})}$, which is then fed into the cross-entropy function:

$$L(\Theta) = -log(p_{a_g}) + \frac{\lambda}{2}||\Theta||^2 \tag{9}$$

where Θ is the set of model parameter and λ is an l_2 regularization factor. We train our model by online learning with mini-batch, updating model parameters by using Adam algorithm (Kingma and Ba, 2014).

3 Experiments

3.1 Settings

3.1.1 Data

We follow previous studies (Ji and Eisenstein, 2014; Li et al., 2014; Feng and Hirst, 2014; Heilman and Sagae, 2015; Li et al., 2016; Wang et al., 2017; Braud et al., 2017), conducting experiments by using the RST discourse Treebank (Carlson et al., 2003). It has annotated 385 documents, where 347 for training and the remaining 38 for testing. All the documents are collected from Wall Street Journal (WSJ), belonging to newswire gene. We use 18 coarse-grained relations in our experiments. For preprocessing, we exploit the StanFord CoreNLP toolkit[1](Manning et al., 2014) to lemmatize words and get their POS tags. To facilitate parameter tuning, we select 35 documents from the training corpus randomly as the development corpus. All experiments are conducted on manually segmented EDUs.

3.1.2 Evaluation

We adopt standard evaluation methods (Marcu, 2000) to test model performances, including three metrics `Span`, `Nuclearity` and `Relation`. The `Span` evaluates the capability of predicting tree skeletons, the `Nuclearity` evaluates tree skeletons and nuclearity indications, and the `Relation` evaluates tree skeletons together with discourse relations, while ignoring nuclearities. The `Full` evaluates the tree skeletons together with both nuclearity indications and discourse relations. We follow (Morey et al., 2017) to report the micro-averaged F scores.

3.1.3 Hyper-Parameters

There are several hyper-parameters in our proposed models. We set the values according to their development performances. We set sizes of all hidden vectors (e.g. the dimension of word embeddings, the Bi-LSTM outputs and etc.) by 200. The word embeddings are initialized by pre-trained GloVe embeddings[2](Pennington et al., 2014). For training, the l_2 regularization factor, the mini-batch size, the initial learning rate, the dropout probability and the max norm of gradient clipping are set by 10^{-6}, 8, 0.001,

(a) Span (b) Nuclearity (c) Relation

Figure 3: The influence of the dynamic oracle strategy in different α.

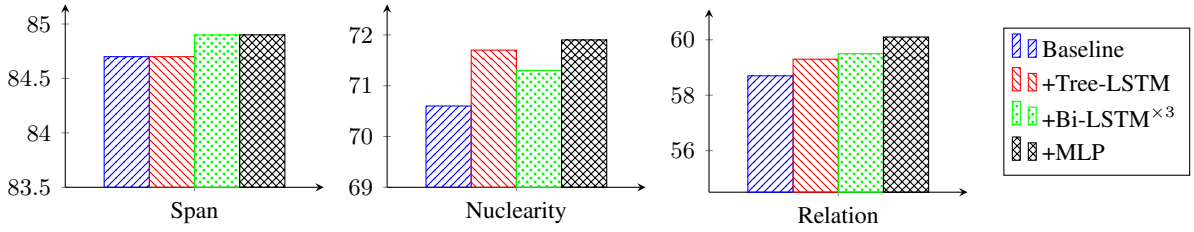

Figure 4: The influence of different syntax feature integration methods.

0.5 and 10, respectively. We train models iteratively on the entire training corpus by 60 rounds, and use the best-performance iteration on the development corpus as the final model.

3.2 Development Results

We conduct two sets of development experiments to show important factors of our proposed model, which are related to dynamic oracle and syntax features, respectively.

3.2.1 Dynamic Orcale

First, we examine the strategy of dynamic oracle. As shown in Algorithm 1, there is a hyper-parameter α to control the exploration, which is used to produce extra training instances. Here we study how α influences the model performances. Figure 3 shows the development performances with respect to α. The performances are relatively stable surrounding 0.7, where all metrics under both settings are close to their peak values. Thus we exploit $\alpha = 0.7$ as the final setting.

3.2.2 Syntax Features

There are two choices of our implicit syntax feature extraction approach. We can use either the encoder Bi-LSTM$^{\times 3}$ outputs or the MLP outputs as described in section 2.4. In addition, we implement a bi-directional dependency based Tree-LSTM (Teng and Zhang, 2017) as well for comparisons. Figure 4 shows the results. First, we find that syntax features[3] are very useful for RST discourse parsing, which is consistent with previous observations (Soricut and Marcu, 2003; Sagae, 2009; Braud et al., 2016). Second, the implicit syntax feature extraction method is slightly better than explicit Tree-LSTM. In particular, the model can achieve the best performances by using the MLP outputs. Thus we exploit the MLP outputs as the final implicit syntax features in our RST discourse parsing model.

[3] We use the English PTB corpus to train the Bi-Affine parser, which achieves 95.88% UAS and 94.16% LAS.

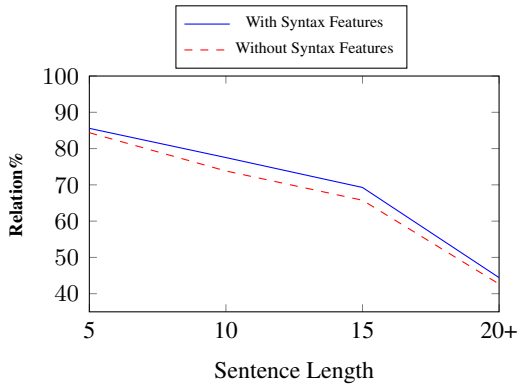

Figure 6: The span-level F-measures with respect to the span length.

3.3 Final Results

Table 2 shows the final results of our proposed neural models on the test corpus. Our baseline model achieves a `Span` F-measure of 85.0 and a `Nuclearity` F-measure of 71.0, which are exceed most models. When dynamic oracle and implicit syntax features are exploited, our final model achieves 60.2 on the `Relation` F-measure, resulting overall improvements 60.2 - 57.6 = 2.6. The `Span`, `Nucleartiy` and `Full` metrics have similar tendencies as well.

We compare the proposed neural model with other state-of-the-art systems as well. (Hayashi et al., 2016) is a greedy bottom-up parser with a linear SVM classification. (Surdeanu et al., 2015) is also a greedy bottom-up parser, which uses the perceptron for tree skeleton building and nuclearity indication, the logistic regression for relation labelling. (Joty et al., 2015) is a two-stage (intra-sentential then multi-sentential parsing) parser with dynamic conditional random field models, and (Feng and Hirst, 2014) is a two-stage parser with linear-chain conditional random field models. (Braud et al., 2016) is a sequence-to-sequence hierarchical neural parser, and (Li et al., 2016) is an attention-based hierarchical neural parser. (Ji and Eisenstein, 2014) is a transition-based statisitical model with the representation learning. (Braud et al., 2017) is a transition-based neural model by embedding and composing a number of manually-designed sophisticated atomic features. As shown by Table 2, we can see that transition-based models are able to achieve state-of-the-art performances under both discrete and neural settings, demonstrating the robustness of this framework. Our final model is able to achieve competitive results compared with these systems.

3.4 Analysis

In this subsection, we perform several analysis experiments on the test corpus to illustrate the benefits from dynamic oracle and syntax features, respectively.

First, in order to understand the influence of dynamic oracle, we evaluate the `Relation` performances with respect to the EDU number. In our transition-based model, a subtree with more EDUs requires more transition actions to be produced. As introduced in section 2.3, our neural model with dynamic oracle is robust to error input states. Figure 5 shows the comparison results. We can find that the model with dynamic oracle performs better on spans of the EDU number between [2,4], which is consistent with our intuitions. However, when the EDU number increases to 5+, both settings perform very poorly.

Second, we investigate the benefits by using our proposed syntax features. Intuitively, the dependency parsing outputs exploit tree structures to re-organize sentential words, thus a number of long-distance word pairs are connected directly. We would expect that spans covering a long range of words could be better handled with syntax features. We verify this assumption by comparing performances with respect to the word number in span. As shown by Figure 6, we can see that syntax features do improve the performances of spans containing more words. The observation is consistent with our assumption.

4 Related Work

RST discourse parsing has been studied intensively since early (Marcu, 1997; Marcu, 1999; Soricut and Marcu, 2003). Initial work focuses on statistical models by using manually-designed feature (Soricut and Marcu, 2003; Sagae, 2009; Hernault et al., 2010; Feng and Hirst, 2012; Joty et al., 2013; Feng and Hirst, 2014; Heilman and Sagae, 2015; Wang et al., 2017). Among these studies, transition-based models have achieved state-of-the-art performances (Sagae, 2009; Ji and Eisenstein, 2014; Heilman and Sagae, 2015; Wang et al., 2017). Recently, neural network models have been investigated. Braud et al. (2017) have proposed a transtion-based neural model by using several well-designed atomic features, embedding them directly and then feeding them into feed-forward neural networks. In this work, we suggest hierarchical Bi-LSTMs, following Li et al. (2016) to encode documents, which are more popular in document modeling (Li et al., 2015a; Chen et al., 2016).

Syntax features have been demonstrated useful for RST discourse parsing by a number of studies (Soricut and Marcu, 2003; Sagae, 2009; Hernault et al., 2010; Feng and Hirst, 2012; Joty et al., 2013; Feng and Hirst, 2014; Heilman and Sagae, 2015). The majority work exploits manually-designed features to achieve this goal. The work of Li et al. (2015b) have compared a Tree-LSTM structrue over syntax trees with a sequential LSTM over input sentences, finding that the syntax tree does not show better performances. In this work, we propose a different implicit feature extraction to represent syntax information, using them as a supplementary for RST discourse parsing.

The exploration of dynamic oracle has been proposed for transition-based dependency parsing (Goldberg and Nivre, 2012), bringing significantly better performances for dependency parsing. Our dynamic oracle is mainly inspired by this work, and we apply it on RST discourse parsing. To our knowledge, it is the first work of transition-based RST parsing by using dynamic oracle.

Zhang et al. (2017) suggest a new method of integrating syntax features implicitly. First they extract a sequence of hidden vectors from a supervised neural dependency parsing model, and then feed these implicit syntax features into a neural relation extraction model. The method has been also applied to targeted sentiment analysis (Gao et al., 2017). We follow their work to investigate the implicit syntax feature extraction for RST discourse parsing, and improve this method accordingly for our task.

5 Conclusion

In this work, we investigated an implicit syntax feature extraction method for neural RST discourse parsing. First, we proposed a transition-based neural baseline, and further enhanced it with a dynamic oracle mechanism. Second, we examined the implicit syntax feature extraction method proposed by Zhang et al. (2017) and suggested use outputs of a different neural layer of a Bi-Affine dependency parsing model (Dozat and Manning, 2016). We conducted experiments on standard RST discourse TreeBank (Carlson et al., 2003) to evaluate our proposed models. Results show that our transition-based parser is very competitive after applying dynamic oracle. Further, we find that the proposed implicit syntax features are highly effective, better than explicit Tree-LSTMs.

Abstract

Implicit discourse relation recognition is a challenging task as the relation prediction without explicit connectives in discourse parsing needs understanding of text spans and cannot be easily derived from surface features from the input sentence pairs. Thus, properly representing the text is very crucial to this task. In this paper, we propose a model augmented with different grained text representations, including character, subword, word, sentence, and sentence pair levels. The proposed deeper model is evaluated on the benchmark treebank and achieves state-of-the-art accuracy with greater than 48% in 11-way and F_1 score greater than 50% in 4-way classifications for the first time according to our best knowledge.

1 Introduction

Discourse parsing is a fundamental task in natural language processing (NLP) which determines the structure of the whole discourse and identifies the relations between discourse spans such as clauses and sentences. Improving this task can be helpful to many downstream tasks such as machine translation (Li et al., 2014), question answering (Jansen et al., 2014), and so on. As one of the important parts of discourse parsing, implicit discourse relation recognition task is to find the relation between two spans without explicit connectives (e.g., *but, so*, etc.), and needs recovering the relation from semantic understanding of texts.

The Penn Discourse Treebank 2.0 (PDTB 2.0) (Prasad et al., 2008) is a benchmark corpus for discourse relations. In PDTB style, the connectives can be explicit or implicit, and one entry of the data is separated into *Arg1* and *Arg2*, accompanied with a relation sense. Since the release of PDTB 2.0 dataset, many methods have been proposed, ranging from traditional feature-based methods (Lin et al., 2009; Pitler et al., 2009) to latest neural-based methods (Qin et al., 2017; Lan et al., 2017). Especially through many neural network methods used for this task such as convolutional neural network (CNN) (Qin et al., 2016b), recursive neural network (Ji and Eisenstein, 2015), embedding improvement (Wu et al., 2017), attention mechanism (Liu and Li, 2016), gate mechanism (Chen et al., 2016), multi-task method (Lan et al., 2017), the performance of this task has improved a lot since it was first introduced. However, this task is still very challenging with the highest reported accuracy still lower than 50% due to the hardness for the machines to understand the text meaning and the relatively small task corpus.

In this work, we focus on improving the learned representations of sentence pairs to address the implicit discourse relation recognition. It is well known that text representation is the core part of state-of-the-art deep learning methods for NLP tasks, and improving the representation from all perspective will benefit the concerned task.

The representation is improved by two ways in our model through three-level hierarchy. The first way is embedding augmentation. Only with informative embeddings, can the final representations be better. This is implemented in our word-level module. We augment word embeddings with subword-level

Proceedings of the 27th International Conference on Computational Linguistics, pages 571–583
Santa Fe, New Mexico, USA, August 20-26, 2018.

embeddings and pre-trained ELMo embeddings. Subwords coming from unsupervised segmentation demonstrate a better consequent performance than characters for being a better minimal representation unit. The pre-trained contextualized word embeddings (ELMo) can make the embeddings contain more contextual information which is also involved with character-level inputs. The second way is a deep residual bi-attention encoder. Since this task is about classifying sentence pairs, the encoder is implemented in sentence and sentence-pair levels. A deeper model can support richer representations but is hard to train, especially with a small dataset. So we apply residual connections (He et al., 2016) to each module for facilitating signal propagation and alleviating gradient degradation. The stacked encoder blocks make the single sentence representation richer and bi-attention module mixes two sentence representations focusingly. With introducing richer and deeper representation enhancement, we report the deepest model so far for the task.

Our representation enhanced model will be evaluated on the benchmark PDTB 2.0 and demonstrate state-of-the-art performance to verify its effectiveness.

This paper is organized as follows. Section 2 reviews related work. Section 3 introduces our model. Section 4 shows our experiments and analyses the results. Section 5 concludes this work.

2 Related Work

After the release of Penn Discourse Treebank 2.0, many works have been made to solve this concerned task. Lin et al. (2009) is the first work who considered the second-level classification of the task by empirically evaluating the impact of surface features. Feature based methods (Pitler et al., 2009; Zhou et al., 2010; Chen et al., 2015; Li et al., 2016) mainly focused on using linguistic, or semantic features from the discourse units, or the relations between unit pairs and word pairs. Zhang et al. (2015) is the first one who modeled this task using end-to-end neural network and gained great performance improvement. Neural network methods also used by lots of works (Zhang et al., 2016; Cai and Zhao, 2016) for better performance. Since then, a lot of methods have been proposed. Braud and Denis (2015) found that word embeddings trained by neural networks is very useful to this task. Qin et al. (2016a) augmented their system with character-level and contextualized embeddings. Recurrent networks and convolutional networks have been used as basic blocks in many works (Ji et al., 2016; Rönnqvist et al., 2017; Qin et al., 2016b). Ji and Eisenstein (2015) used recursive neural networks. Attention mechanism was used by Liu and Li (2016), Cai and Zhao (2017) and others. Wu et al. (2016) and Lan et al. (2017) applied multi-task component. Qin et al. (2017) utilized adversarial nets to migrate the connective-based features to implicit ones.

Sentence representation is a key component in many NLP tasks. Usually, better representation means better performance. Plenty of work on language modeling has been done, as language modeling can supply better sentence representations. Since the pioneering work of Bengio et al. (2006), neural language models have been well developed (Mikolov and Zweig, 2012; Williams et al., 2015; Kim et al., 2016). Sentence representation is directly handled in a series of work. Lin et al. (2017) used self attention mechanism and used matrix to represent sentence, and Conneau et al. (2017) used encoders pre-trained on SNLI (Bowman et al., 2015) and MultiNLI (Williams et al., 2017).

Different from all the existing work, for the first time to our best knowledge, this work is devoted to an empirical study on different levels of representation enhancement for implicit discourse relation classification task.

3 Model

3.1 Overview

Figure 1 illustrates an overview of our model, which is mainly consisted of three parts: word-level module, sentence-level module, and pair-level module. Token sequences of sentence pairs (*Arg1* and *Arg2*) are encoded by word-level module first and every token becomes a word embedding augmented by subword and ELMo. Then these embeddings are fed to sentence-level module and processed by stacked encoder blocks (CNN or RNN encoder block). Every block layer outputs representation for each token. Furthermore, the output of each layer is processed by bi-attention module in the pair-level

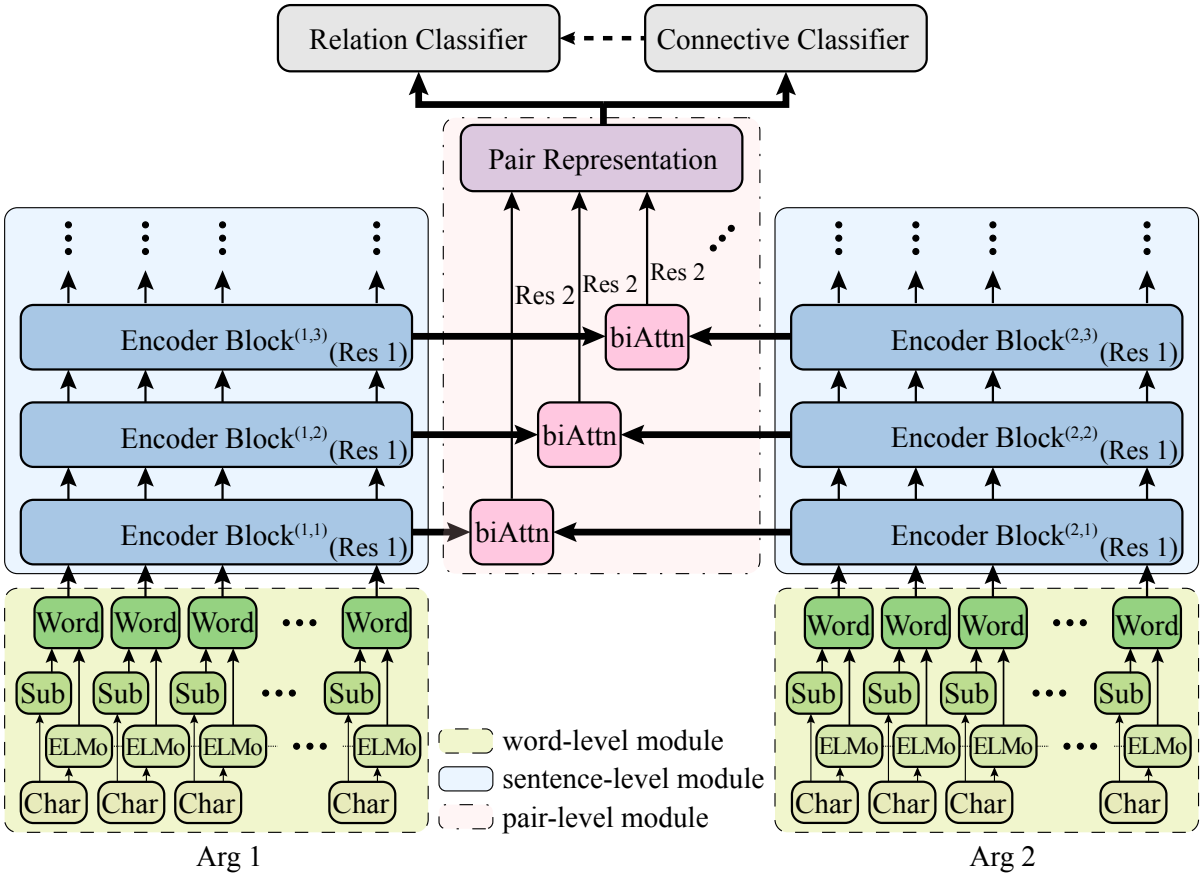

Figure 1: Model overview.

module, and concatenated to pair representation, which is finally sent to classifiers which are multiple layer perceptrons (MLP) with softmax. The model details are given in the rest of this section.

3.2 Word-Level Module

An inputed token sequence of length N is encoded by the word-level module into an embedding sequence $(\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3, \cdots, \mathbf{e}_N)$. For each embedded token $\mathbf{e}_i$, it is concatenated from three parts,

$$\mathbf{e}_i = [\mathbf{e}_i^w;\ \mathbf{e}_i^s;\ \mathbf{e}_i^c] \in \mathbb{R}^{d_e} \tag{1}$$

$\mathbf{e}_i^w \in \mathbb{R}^{d_w}$ is pre-trained word embedding for this token, and is fixed during the training procedure. Our experiments show that fine-tuning the embeddings slowed down the training without better performance. $\mathbf{e}_i^s \in \mathbb{R}^{d_s}$ is subword-level embedding encoded by subword encoder. $\mathbf{e}_i^c \in \mathbb{R}^{d_c}$ is contextualized word embedding encoded by pre-trained ELMo encoders, whose parameters are also fixed during training. Subword is merged from single-character segmentation and the input of ELMo encoder is also character.

Subword Encoder

Character-level embeddings have been used widely in lots of works and its effectiveness is verified for out-of-vocabulary (OOV) or rare word representation. However, character is not a natural minimal unit for there exists word internal structure, we thus introduce a subword-level embedding instead.

Subword units can be computationally discovered by unsupervised segmentation over words that are regarded as character sequences. We adopt byte pair encoding (BPE) algorithm introduced by Sennrich et al. (2016) for this segmentation. BPE segmentation actually relies on a series of iterative merging operation over bigrams with the highest frequency. The number of merging operation times is roughly equal to the result subword vocabulary size.

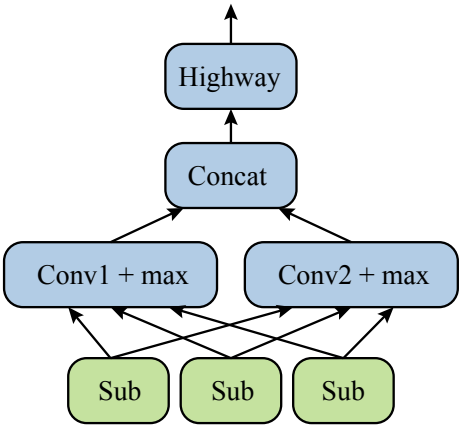

Figure 2: Subword encoder.

For each word, the subword-level embedding is encoded by a subword encoder as in Figure 2. Firstly, the subword sequence (of length n) of the word is mapped to subword embedding sequence $(\mathbf{se}_1, \mathbf{se}_2, \mathbf{se}_3, \cdots, \mathbf{se}_n)$ (after padding), which is randomly initialized. Then K (we empirically set K=2) convolutional operations $Conv_1, Conv_2, \cdots, Conv_K$ followed by max pooling operation are applied to the embedding sequence, and the sequence is padded before the convolutional operation. For the i-th convolution kernel $Conv_i$, suppose the kernel size is k_i, then the output of $Conv_i$ on embeddings $\mathbf{se}_j$ to $\mathbf{se}_{j+k_i-1}$ is

$$\mathbf{C}_j = \tanh\left(Conv_i[\mathbf{se}_j : \mathbf{se}_{j+k_i-1}]\right)$$

The final output of $Conv_i$ after max pooling is

$$\mathbf{u}_i = maxpool\left(\mathbf{C}_1,\ \cdots,\ \mathbf{C}_j,\ \cdots,\ \mathbf{C}_n\right)$$

Finally, the K outputs are concatenated,

$$\mathbf{u} = [\mathbf{u}_1;\ \mathbf{u}_2;\ \cdots;\ \mathbf{u}_K] \in \mathbb{R}^{d_s}$$

to feed a highway network (Srivastava et al., 2015),

$$\begin{aligned} \mathbf{g} &= \sigma(\mathbf{W}_g\mathbf{u}^T + \mathbf{b}_g) \in \mathbb{R}^{d_s} \\ \mathbf{e}_i^s &= \mathbf{g} \odot ReLU(\mathbf{W}_h\mathbf{u}^T + \mathbf{b}_h) + (\mathbf{1} - \mathbf{g}) \odot \mathbf{u} \\ &\in \mathbb{R}^{d_s} \end{aligned} \tag{2}$$

where $\mathbf{g}$ denotes the gate, and $\mathbf{W}_g \in \mathbb{R}^{d_s \times d_s}, \mathbf{b}_g \in \mathbb{R}^{d_s}, \mathbf{W}_h \in \mathbb{R}^{d_s \times d_s}, \mathbf{b}_h \in \mathbb{R}^{d_s}$ are parameters. $\odot$ is element-wise multiplication. The above Eq. 2 gives the subword-level embedding for the i-th word.

ELMo

ELMo (Embeddings from Language Models) (Peters et al., 2018) is a pre-trained contextualized word embeddings involving character-level representation. It is shown useful in some works (He et al., 2018; Lee et al., 2018). This embedding is trained by bidirectional language models on large corpus using character sequence for each word token as input. The ELMo encoder employs CNN and highway networks over characters, whose output is given to a multiple-layer biLSTM with residual connections. Then the output is contextualized embeddings for each word. It is also can be seen as a hybrid encoder for character, word, and sentence. This encoder can add lots of contextual information to each word, and can ease the semantics learning of the model.

For the pre-trained ELMo encoder, the output is the result of the last two biLSTM layers. Suppose $\mathbf{c}_i$ is the character sequence of i-th word in a sentence, then the encoder output is

$$[\cdots, \mathbf{h}_i^0, \cdots; \ \cdots, \mathbf{h}_i^1, \cdots] = ELMo(\cdots, \mathbf{c}_i, \cdots)$$

where $\mathbf{h}_i^0$ and $\mathbf{h}_i^1$ denote the outputs of first and second layers of ELMo encoder for i-th word.

Following Peters et al. (2018), we use a self-adjusted weighted average of $\mathbf{h}_i^0, \mathbf{h}_i^1$,

$$\mathbf{s} = softmax(\mathbf{w}) \in \mathbb{R}^2$$
$$\mathbf{h} = \gamma \sum_{j=0}^{1} s_j \mathbf{h}_i^j \in \mathbb{R}^{d_c'}$$

where $\gamma \in \mathbb{R}$ and $\mathbf{w} \in \mathbb{R}^2$ are parameters tuned during training and d_c' is the dimension of the ELMo encoder's outputs. Then the result is fed to a feed forward network to reduce its dimension,

$$\mathbf{e}_i^c = \mathbf{W}_c \mathbf{h}^T + \mathbf{b}_c \in \mathbb{R}^{d_c} \tag{3}$$

$\mathbf{W}_c \in \mathbb{R}^{d_c' \times d_c}$ and $\mathbf{b}_c \in \mathbb{R}^{d_c}$ are parameters. The above Eq. 3 gives ELMo embedding for the i-th word.

3.3 Sentence-Level Module

The resulting word embeddings $\mathbf{e}_i$ (Eq. 1) are sent to sentence-level module. The sentence-level module is composed of stacked encoder blocks. The block in each layer receives output of the previous layer as input and sends output to next layer. It also sends its output to the pair-level module. Parameters in different layers are not the same.

We consider two encoder types, convolutional type and recurrent type. We only use one encoder type in one experiment.

For the sentence-level module for different arguments (*Arg1* and *Arg2*), many previous works used same parameters to encode different arguments, that is, one encoder for two type arguments. But as indicated by Prasad et al. (2008), *Arg1* and *Arg2* may have different semantic perspective, we thus introduce argument-aware parameter settings for different arguments.

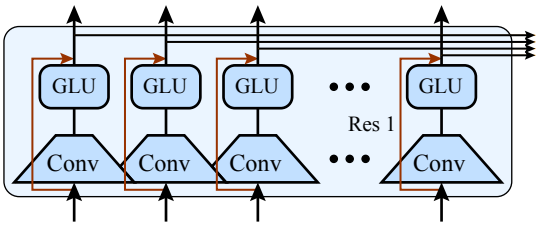

Figure 3: Convolutional encoder block.

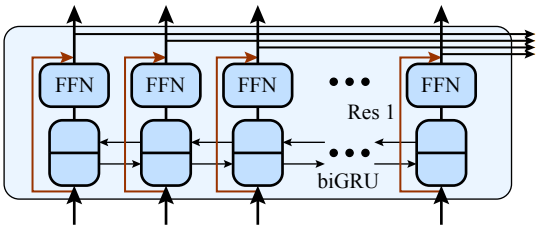

Figure 4: Recurrent encoder block.

Convolutional Encoder Block

Figure 3 is the convolutional encoder block. Suppose the input for the encoder block is $\mathbf{x}_i$ $(i = 1, \cdots, N)$, then $\mathbf{x}_i \in \mathbb{R}^{d_e}$. The input is sent to a convolutional layer and mapped to output $\mathbf{y}_i = [\mathbf{A}_i \ \mathbf{B}_i] \in \mathbb{R}^{2d_e}$. After the convolutional operation, gated linear units (GLU) (Dauphin et al., 2016) is applied, i.e.,

$$\mathbf{z}_i = \mathbf{A}_i \odot \sigma(\mathbf{B}_i) \in \mathbb{R}^{d_e}$$

There is also a residual connection (Res 1) in the block, which means adding the output of GLU and the input of the block as final output, so $\mathbf{z}_i + \mathbf{x}_i$ is the output of the block corresponding to the input $\mathbf{x}_i$. The output $\mathbf{z}_i + \mathbf{x}_i$ for all $i = 1, \cdots, N$ is sent to both the next layer and the pair-level module as input.

Recurrent Encoder Block

Similar to the convolutional one, recurrent encoder block is shown in Figure 4. The input $\mathbf{x}_i$ is encoded by a biGRU (Cho et al., 2014) layer first,

$$\mathbf{y}_i = biGRU(\mathbf{x}_i) \in \mathbb{R}^{2d_e}$$

then this is sent to a feed forword network,

$$\mathbf{z}_i = \mathbf{W}_r \mathbf{y}_i^T + \mathbf{b}_r \in \mathbb{R}^{d_e} \tag{4}$$

$\mathbf{W}_r \in \mathbb{R}^{2d_e \times d_e}$ and $\mathbf{b}_r \in \mathbb{R}^{d_e}$ are parameters. There is also a similar residual connection (Res 1) in the block, so $\mathbf{z}_i + \mathbf{x}_i$ for all $i = 1, \cdots, N$ is the final output of the recurrent encoder block.

3.4 Pair-Level Module

Through the sentence-level module, the word representations are contextualized, and these contextualized representations of each layer are sent to pair-level module.

Suppose the encoder block layer number is l, and the outputs of j-th block layer for *Arg1* and *Arg2* are $\mathbf{v}_1^j, \mathbf{v}_2^j \in \mathbb{R}^{N \times d_e}$, each row of which is the embedding for the corresponding word. N is the length of word sequence (sentence). Each sentence is padded or truncated to let all sentences have the same length. They are sent to a bi-attention module, the attention matrix is

$$\mathbf{M}_j = (FFN(\mathbf{v}_1^j))\mathbf{v}_2^{jT} \in \mathbb{R}^{N \times N}$$

FFN is a feed froward network (similar to Eq. 4) applied to the last dimension corresponding to the word. Then the projected representations are

$$\mathbf{w}_2^j = softmax(\mathbf{M}_j)\mathbf{v}_2^j \in \mathbb{R}^{N \times d_e}$$
$$\mathbf{w}_1^j = softmax(\mathbf{M}_j^T)\mathbf{v}_1^j \in \mathbb{R}^{N \times d_e}$$

where the $softmax$ is applied to each row of the matrix. We apply 2-max pooling on each projected representation and concatenate them as output of the j-th bi-attention module

$$\mathbf{o}_j = [top2(\mathbf{w}_1^j);\ \ top2(\mathbf{w}_2^j)] \in \mathbb{R}^{4d_e}$$

The number of max pooling operation (top-2) is selected from experiments and it is a balance of more salient features and less noise. The final pair representation is

$$\mathbf{o} = [\mathbf{o}_1, \mathbf{o}_2, \cdots, \mathbf{o}_l] \in \mathbb{R}^{4ld_e} \tag{5}$$

Since the output is concatenated from different layers and the outputs of lower layers are sent directly to the final representation, this also can be seen as residual connections (Res 2). Then the output as Eq. 5 is fed to an MLP classifier with softmax. The parameters for bi-attention modules in different levels are shared.

3.5 Classifier

We use two classifiers in our model. One is for relation classification, and another one is for connective classification. The classifier is only a multiple layer perceptron (MLP) with softmax layer. Qin et al. (2017) used adversarial method to utilize the connectives, but this method is not suitable for our adopted attention module since the attended part of a sentence will be distinctly different when the argument is with and without connectives. They also proposed a multi-task method that augments the model with an additional classifier for connective prediction, and the input of it is also the pair representation. It is straightforward and simple enough, and can help the model learn better representations, so we include this module in our model. The implicit connectives are provided by PDTB 2.0 dataset, and the connective classifier is only used during training. The loss function for both classifiers is cross entropy loss, and the total loss is the sum of the two losses, i.e., $Loss = Loss_{relation} + Loss_{connective}$.

4 Experiments[1]

Our model is evaluated on the benchmark PDTB 2.0 for two types of classification tasks.

PDTB 2.0 has three levels of senses: Level-1 *Class*, Level-2 *Type*, and Level-3 *Subtypes*. The first level consists of four major relation Classes: COMPARISON, CONTINGENCY, EXPANSION, and TEMPORAL. The second level contains 16 Types.

All our experiments are implemented by PyTorch[2]. The pre-trained ELMo encoder is from AllenNLP toolkit (Gardner et al., 2017) [3].

4.1 11-way Classification

Dataset Setup

Following the settings of Qin et al. (2017), we use two splitting methods of PDTB dataset for comprehensive comparison. The first is PDTB-Lin (Lin et al., 2009), which uses section 2-21, 22 and 23 as training, dev and test sets respectively. The second is PDTB-Ji (Ji and Eisenstein, 2015), which uses section 2-20, 0-1, and 21-22 as training, dev and test sets respectively. According to Ji and Eisenstein (2015), five relation types have few training instances and no dev and test instance. Removing the five types, there remain 11 second level types. During training, instances with more than one annotated relation types are considered as multiple instances, each of which has one of the annotations. At test time, a prediction that matches one of the gold types is considered as correct. All sentences in the dataset are padded or truncated to keep the same 100-word length.

Model Details

For the results of both splitting methods, we share some hyperparameters. Table 1 is some of the shared hyperparameter settings. The pre-trained word embeddings are 300-dim *word2vec* (Mikolov et al., 2013) pre-trained from Google News[4]. So $d_w = 300, d_s = 100, d_c = 300$, then for the final embedding ($\mathbf{e}_i$), $d_e = 700$. For the encoder block in sentence-level module, kernel size is same for every layer. We use AdaGrad optimization (Duchi et al., 2011).

The encoder block layer number is different for the two splitting methods. The layer number for PDTB-Ji splitting method is 4, and the layer number for PDTB-Lin splitting method is 5.

Hyperparameter	Value	Hyperparameter	Value
BPE merge operation num.	$1k$	classifier layer num.	1
subword embedding dim. (d_s)	50	embedding dropout	0.4
subword CNN kernel num.	2	encoder block dropout	0.4
subword CNN kernel size	[2, 3]	classifier dropout	0.3
reduced ELMo embedding dim.	300	learning rate	0.001
encoder block type	Conv.	batch size	64
encoder block kernel size	5		

Table 1: Shared hyperparameter settings. Before dimension reducing, the dimension of pre-trained ELMo embedding is 1024.

Results

Compared to other recent state-of-the-art systems in Table 2, our model achieves new state-of-the-art performance in two splitting methods with great improvements. As to our best knowledge, our model is the first one that exceeds the 48% accuracy in 11-way classification.

Analysis

Ablation Study

To illustrate the effectiveness of our model and the contribution of each module, we use the PTDB-Ji splitting method to do a group of experiments. For the baseline model, we use 4 layer stacked convolutional encoder blocks without the residual connection in the block with only pre-trained word embeddings. We only use the output of the last layer and the output is processed by 2-max pooling without attention and sent to the relation classifier and connective classifier. Without the two residual connections, using 4 layers may be not the best for baseline model but is more convenient to comparison.

Firstly, we add modules from high level to low level accumulatively to observe the performance improvement. Table 3 is the results, which demonstrate that every module has considerable effect on the performance.

Then we test the effects of the two residual connections on the performance. The results are in Table 4. The baseline$^+$ means baseline + bi-attention, i.e., the second row of Table 3. We find that Res 1 (residual connection in the block) is much more useful than Res 2 (residual connection for pair representation), and they work together can bring even better performance.

Level	Model	Performance
-	baseline	41.48
pair	+ bi-attention	42.25
sentence	+ Res	46.29
word	+ subword	47.03
word	+ ELMo	48.22

Table 3: Accumulatively performance test result.

Model	Performance
baseline$^+$	42.25
baseline$^+$ + Res 1	45.33
baseline$^+$ + Res 2	43.57
baseline$^+$ + Res 1 + Res 2	46.29

Table 4: The effects of residual connections.

Without ELMo (the same setting as 4-th row in Table 3), our data settings is the same as Qin et al. (2017) whose performance was state-of-the-art and will be compared directly. We see that even without the pre-trained ELMo encoder, our performance is better, which is mostly attributed to our better sentence pair representations.

Subword-Level Embedding For the usefulness of subword-level embedding, we compare its performance to a model with character-level embedding, which was ever used in Qin et al. (2016a). We use the same model setting as the 4-th row of Table 3, and then replace subword with character sequence. The subword embedding augmented result is **47.03%**, while the character embedding result is **46.37%**, which verifies that the former is a better input representation for the task.

Parameters for Sentence-Level Module As previously discussed, argument specific parameter settings may result in better sentence-level encoders. We use the model which is the same as the third row in Table 3. If shared parameters are used, the result is **45.97%**, which is lower than argument specific parameter settings (**46.29%**). The comparison shows argument specific parameter settings indeed capture the difference of argument representations and facilitate the sentence pair representation.

Encoder Block Type and Layer Number In section 3.3, we consider two encoder types, here we compare their effects on the model performance. Like the previous part, The model setting is also the same as the third row in Table 3 except for the block type and layer number. The results are shown in

Figure 5.

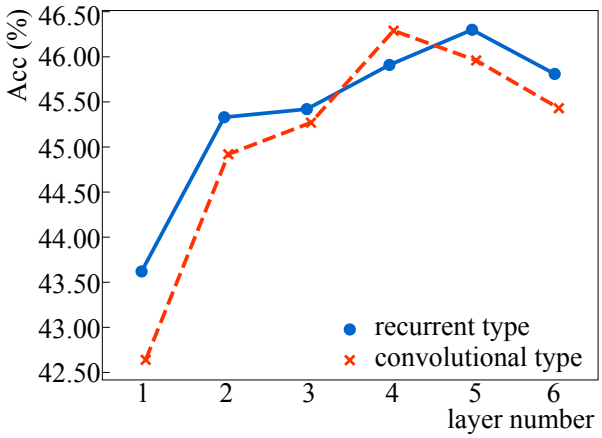

Figure 5: Effects of block type and layer number.

The results in the figure show that both types may reach similar level of top accuracies, as the order of word is not important to the task. We also try to add position information to the convolutional type encoder, and receive a dropped accuracy. This further verifies the order information does not matter too much for the task. For most of the other numbers of layers, the recurrent type shows better, as the number of layers has an impact on the window size of convolutional encoders. When convolutional type is used, the training procedure is much faster, but choosing the suitable kernel size needs extra efforts.

Bi-Attention

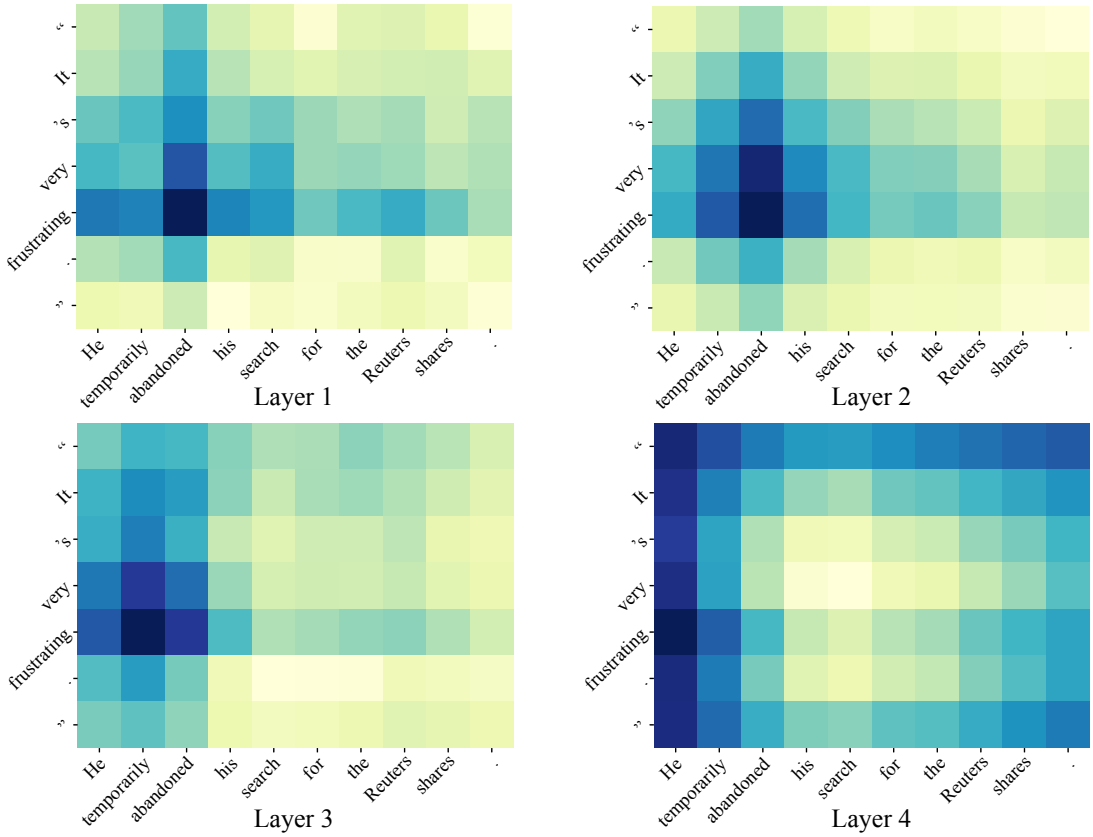

Figure 6: Attention visualization.

We visualize the attention weight of one instance in Figure 6. For lower layers, the attended part is more concentrated. For higher layers, the weights are more average and the attended part moves to the

sentence border. This is because the window size is bigger for higher layers, and the convolutional kernel may have higher weights on words at the window edge.

4.2 Binary and 4-way Classification

Settings For the first level classification, we perform both 4-way classification and one-vs-others binary classification. Following the settings of previous works, the dataset splitting method is the same as PDTB-Ji without removing instances. The model uses 5 block layers with kernel size 3, other details are the same as that for 11-way classification on PDTB-Ji.

Results Table 5 is the result comparison on first level classification. For binary classification, the result is computed by F_1 score (%), and for 4-way classification, the result is computed by macro average F_1 score (%). Our model gives the state-of-the-art performance for 4-way classification by providing an F_1 score greater than 50% for the first time according to our best knowledge.

Model	Comp.	Cont.	Exp.	Temp.	4-way
Zhang et al. (2015)	33.22	52.04	69.59	30.54	-
Ji and Eisenstein (2015)	35.93	52.78	-	27.63	-
Chen et al. (2016)	40.17	54.76	-	31.32	-
Qin et al. (2016c)	41.55	57.32	71.50	35.43	-
Liu and Li (2016)	39.86	54.48	70.43	**38.84**	46.29
Qin et al. (2017)	40.87	54.56	72.38	36.20	-
Lan et al. (2017)	40.73	**58.96**	72.47	38.50	47.80
Lei et al. (2018)	43.24	57.82	**72.88**	29.10	47.15
Ours	**47.85**	54.47	70.60	36.87	**51.06**

Table 5: F_1 score (%) comparison on binary and 4-way classification.

5 Conclusion

In this paper, we propose a deeper neural model augmented by different grained text representations for implicit discourse relation recognition. These different module levels work together and produce task-related representations of the sentence pair. Our experiments show that the model is effective and achieve the state-of-the-art performance. As to our best knowledge, this is the first time that an implicit discourse relation classifier gives an accuracy higher than 48% for 11-way and an F_1 score higher than 50% for 4-way classification tasks.

Abstract

Identifying discourse relations that are not overtly marked with discourse connectives remains a challenging problem. The absence of explicit clues indicates a need for the combination of world knowledge and weak contextual clues, which can hardly be learned from a small amount of manually annotated data. In this paper, we address this problem by augmenting the input text with external knowledge and context and by adopting a neural network model that can effectively handle the augmented text. Experiments show that external knowledge did improve the classification accuracy. On the other hand, contextual information provided no significant gain for implicit discourse relations while it worked for explicit ones.

1 Introduction

Discourse relation recognition has a wide variety of potential applications including summarization (Louis et al., 2010), sentiment analysis (Somasundaran et al., 2009) and machine translation (Meyer et al., 2015). In one of the two most prevalent discourse treebanks, the Penn Discourse TreeBank (PDTB) (Prasad et al., 2008), discourse relations are conventionally divided into two types: explicit and implicit. Explicit relations are overtly marked with discourse connectives such as "because" and "however." Because of these strong cues, explicit relations are relatively easy to classify (Pitler et al., 2008; Xue et al., 2016). By contrast, implicit relations lack discourse connectives and classifying such relations remains a challenging problem.

Recent studies on implicit discourse relation classification have shown success in applying various neural network models including feedforward networks (Zhang et al., 2015; Schenk et al., 2016), convolutional neural networks (Mihaylov and Frank, 2016; Wang and Lan, 2016) and bidirectional LSTM (bi-LSTM) (Chen et al., 2016; Liu and Li, 2016; Dai and Huang, 2018). Although these studies on network engineering report performance improvement, Rutherford et al. (2017) demonstrated that a simple feed-forward neural network was astonishingly competitive, outperforming LSTM- and Tree LSTM-based models. He claimed that training data for implicit discourse relation classification were too small to train powerful neural networks like LSTM. This motivates us to view this task from a different perspective.

We argue that the neural network models need to be provided with world knowledge, which can hardly be learned from a small amount of manually annotated data. To see this, suppose that we want to classify the discourse relation of the following pair of text spans (referred to as `Arg1` (in *italic*) and `Arg2` (in **bold**) throughout this paper):

> `Arg1`: *Not counting the extraordinary charge it would have had a net loss of $3.1 million, or seven cents a share*
> `Arg2`: **A year earlier, it had profit of $7.5 million, or 18 cents a share**
> (Comparison.Contrast)

We can easily recognize that the discourse relation between this pair is Comparison.Contrast partly because we know that "loss" in `Arg1` and "profit" in `Arg2` are antonyms. However, it is difficult for a

Proceedings of the 27th International Conference on Computational Linguistics, pages 584–595
Santa Fe, New Mexico, USA, August 20-26, 2018.

neural network model trained on small training data to recognize the antonymy. Although many recent studies make use of word2vec word embeddings (Mikolov et al., 2013), which are typically trained with a large amount of unannotated data, it is well known that synonyms and antonyms are distributionally similar and thus are hardly distinguishable (Ono et al., 2015). For this reason, we need to look for different knowledge sources as well as an efficient way to integrate them into neural network models.

In this paper, we use MAGE-GRU (Dhingra et al., 2017) to encode external knowledge. It is a straightforward extension to the Gated Recurrent Unit (GRU) (Cho et al., 2014). The input to MAGE-GRU is no longer a sequence of words but a directed acyclic graph in which the word sequence is augmented with edges between arbitrarily distant words for which external knowledge suggests some explicit signals such as antonymy. Thus "loss" and "profit" in the example above are directly connected, making a downstream network layer more easily classify the discourse relation.

In the experiments, we augmented the inputs with ConceptNet (Speer and Havasi, 2012) and coreference resolution. We found that MAGE-GRU significantly outperformed others when ConceptNet was used.

While recurrent neural networks have considerable difficulty in capturing long-range dependencies, MAGE-GRU is expected to mitigate this problem because it creates shortcuts within word sequences. This leads us to explore another question: Do `Arg1` and `Arg2` provide sufficient information to determine discourse relations?

Let us consider the following example:

> Good service programs require recruitment, screening, training and supervision – all of high quality. They involve stipends to participants. Full-time residential programs also require housing and full-time supervision; *they are particularly expensive – more per participant than a year at Stanford or Yale*. **Non-residential programs are cheaper, but good ones still come to some $10,000 a year** (Comparison.Contrast)

In this example, "Non-residential programs" in `Arg2` is contrasted with "they" in `Arg1`. To recognize the fact, we need to resolve the pronoun "they" by looking back at the text preceding `Arg1` to find the antecedent "Full-time residential programs." Although other clues such as the pair of "expensive" and "cheaper" are present, contextual information makes it easier to classify this argument pair as Comparison.Contrast. Although the current standard approach to this task is to use the pair of `Arg1` and `Arg2` out of context, the computer might also benefit from the wider context, given the power of MAGE-GRU.

We compared the performance of MAGE-GRU with and without the text chunk that preceded a given argument pair in the paragraph. It turned out that contextual information provided no significant improvement for implicit discourse relations. However, we also found that contextual information yielded a significant gain for explicit discourse relations. The results appear to strengthen the observation that explicit and implicit discourse relations are dissimilar (Prasad et al., 2014).

2 Related Work

Before neural networks were introduced to the task of implicit discourse relation classification, Lin et al. (2009) proposed a linear classifier that was based on various lexical and syntactic features and was combined with extensive feature selection. Rutherford et al. (2017) built a simple feedforward neural network model where only one pooling layer and one hidden layer were stacked on top of word embeddings. They reported that the simple model outperformed LSTM- and Tree LSTM-based models but lost to Lin et al. (2009).

LSTM has demonstrated success in a wide range of NLP tasks including implicit discourse relation classification. Chen et al. (2016) proposed a combination of a bi-LSTM and a gated relevance network while Liu and Li (2016) combined a bi-LSTM with multi-level attentions. Dai and Huang (2018) proposed a combination of a word-level bi-LSTM and a paragraph-level neural networks. Rutherford et al. (2017) argued that the annotated corpus was too small to train LSTM-based models, however. Note that the present work is complementary to these studies. Since our model is a straightforward extension to

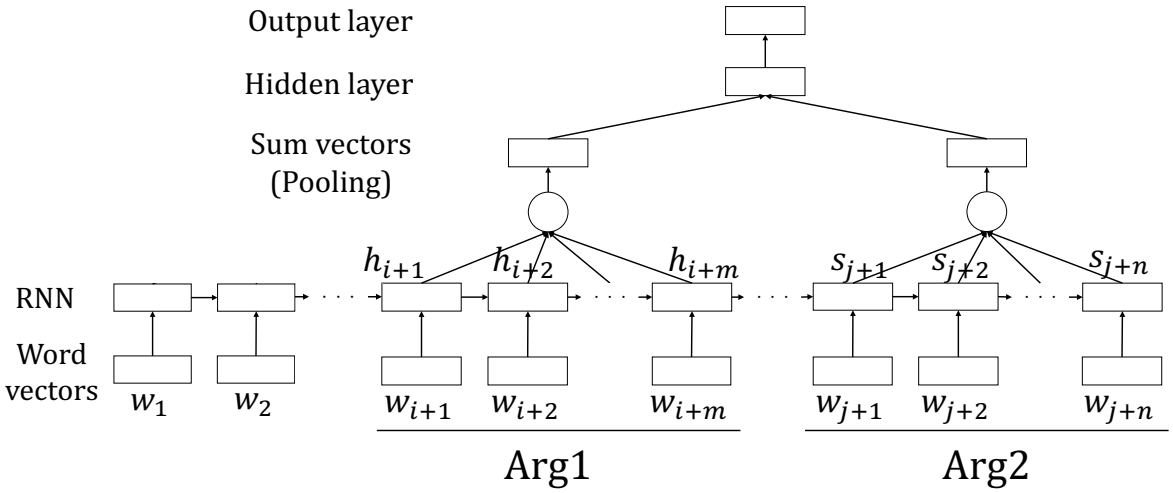

Figure 1: System architecture.

the recurrent neural network, it can easily be combined with other neural network models that are built on top of LSTMs.

Another popular choice of network is convolutional neural networks (CNN). Wang and Lan (2016) proposed an end-to-end shallow discourse parser. In their pipeline system, a CNN is used for non-explicit relation classification.[1] It ranked second on the blind datasets in the CoNLL 2016 Shared Task. Qin et al. (2016) proposed a combination of a bi-LSTM and CNNs. They constructed character-based word representations by transforming character embeddings with CNN and bi-LSTM layers. Another CNN layer was used to extract an argument representation from a sequence of words.

Some recent studies exploited external knowledge sources and some of them were reported to improve the performance of implicit discourse relation classification (Rutherford and Xue, 2014). In the closed track of the CoNLL 2016 Shared Task (Xue et al., 2016), the organizers allowed participants to use a limited set of linguistic resources: Brown Clusters, VerbNet, a sentiment lexicon and an off-the-shelf word2vec model. In addition to these, Inquirer Tags, Levin classes and Modality were tested by Shi and Demberg (2017). They extracted features from these resources and added them to a neural network layer just before the output. Dhingra et al. (2017), who proposed MAGE-GRU, tested a more direct approach as a baseline, in which they appended to word embeddings a sequence of features which are fired by external knowledge. They found that MAGE-GRU consistently outperformed the baseline in various tasks when coreference resolution is used as external knowledge.

A huge performance gap between explicit and implicit relations leads some to transform explicit relations in unannotated corpora to generate pseudo-training data of implicit relations. Sporleder and Lascarides (2008) reported negative results, suggesting that explicit and implicit discourse relations were linguistically dissimilar. Rutherford and Xue (2015) worked on selecting discourse connectives that can be safely dropped. Qin et al. (2017) generated a different kind of pseudo-training data. They inserted to implicit relations *implicit connectives* PDTB annotators assigned to them. They used domain adversarial training to transfer knowledge from the recognition model supplied with implicit connectives to the model without connectives. These methods can be combined with our approach.

3 Proposed Method

The overall system architecture is shown in Figure 1. It is based on the RNN architecture of Rutherford et al. (2017) although we made two major modifications to it, which will be described in Sections 3.1 and 3.3. For each of `Arg1` and `Arg2`, a sequence of words are transformed into a sequence of hidden

[1]Non-explicit relation classification is closely related to implicit discourse relation classification but differs in the treatment of another type of relation, AltLex.

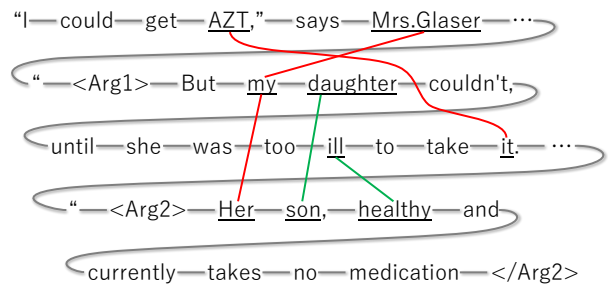

Figure 2: Sequence augmented with extra edges. Words in the sequence are connected by gray edges. In addition, pairs of words are connected by red edges if they are coreferential. Similarly, green edges denote antonymy.

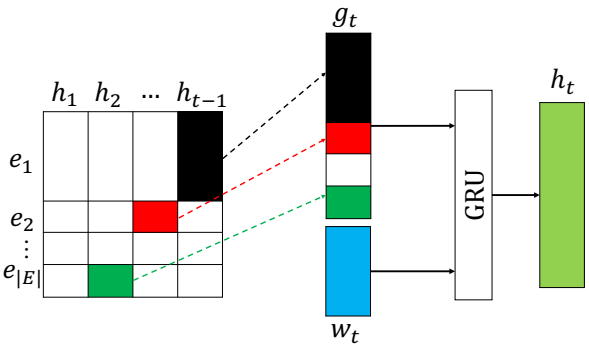

Figure 3: One step of MAGE-GRU.

vectors by an RNN. It is followed by a pooling operation, the concatenation of the two arguments, a linear transformation with non-linear activation, and a softmax classification to predict the relation. The linear transformation is designed to capture the interaction between the arguments.

3.1 MAGE-GRU

One major difference from the architecture of Rutherford et al. (2017) is that whereas Rutherford et al. (2017) used LSTM as the RNN component, we adopt MAGE-GRU (Dhingra et al., 2017). It extends the Gated Recurrent Unit (GRU) (Cho et al., 2014) such that it can incorporate external linguistic knowledge as explicit signals.

The input to MAGE-GRU is no longer a sequence of words but a directed acyclic graph as shown in Figure 2. The graph is constructed by augmenting the word sequence with edges between arbitrarily distant words. Sequential transitions are now treated as a special type of edges. An edge is added if external knowledge suggests an explicit signal for the given word pair. We represent a signal as a triplet (*word A*, *relation type*, *word B*). For example, green edges in Figure 2 denote antonymy: (daughter, `Antonym`, son) and (ill, `Antonym`, healthy). Edges are directed and we assume that *word A* always comes before *word B*. If relation types in external knowledge are asymmetric (e.g., (thinking, `Causes`, acting)), we create reverse relation types to keep the directionality. If external knowledge deals with a phrase, we use the last word for the triplet. We also constrain every node to have at most one incoming edge per relation type because this drastically simplifies computation. If *word B* has two or more candidates for *word A*, the nearest one is chosen.

Given a directed acyclic graph, MAGE-GRU outputs a hidden vector h_t at each time step t. One step of MAGE-GRU is illustrated in Figure 3. The peculiarity of MAGE-GRU is that whereas vanilla GRU receives word vector w_t and hidden vector h_{t-1} as the inputs, MAGE-GRU substitutes h_{t-1} with a special vector g_t. g_t is created by partially and selectively combining the history of hidden vectors, $h_1, \cdots, h_{t-1}$:

$$g_t = [g_t^{e_1}; g_t^{e_2}; \cdots; g_t^{e_{|E|}}]$$
$$g_t^{e_i} = \begin{cases} h_{t'}^{e_i} & \text{if } (x_{t'}, e_i, x_t) \text{ exists} \\ \mathbf{0} & \text{otherwise} \end{cases}$$

where ; denotes vector concatenation. $h_{t'}$ is decomposed into $[h_{t'}^{e_1}; h_{t'}^{e_2}; \cdots; h_{t'}^{e_{|E|}}]$, where e_i $(1 \leq i \leq |E|)$ is a relation type. Thus $h_{t'}^{e_i}$ is a subvector of $h_{t'}$ corresponding to relation type e_i. In Figure 2, for example, when w_t is "healthy", g_t consists of $h_{\text{son}}^{\text{sequence}}$ due to the gray edge and $h_{\text{ill}}^{\text{antonym}}$ due to the green edge and zero vectors for the rest. Note that e_1 is reserved for ordinary sequential transitions.

3.2 External Knowledge

We use ConceptNet (Speer and Havasi, 2012) and coreference resolution as external knowledge. ConceptNet is an open-source project for building in a large linguistic knowledge base. It was constructed through various means including handcrafting (Open Mind Common Sense), automatic extraction from web pages such as Wikipedia, and gamification. ConceptNet covers not only lexical definitions but also common sense. Some relations in ConceptNet appear to be particularly useful for implicit discourse relation classification. For example, the relation `Causes` is closely related to the discourse relation Contingency.Cause. We expect the system to classify such discourse relations more easily when the input is augmented with ConceptNet.

We also use coreference resolution as external knowledge. As we discussed in Section 1, coreference resolution is a straightforward approach to connecting arguments to contextual information. Coreference resolution was also used by Dhingra et al. (2017) in their experiments.

3.3 Input Formats

Another major modification we make to the architecture of Rutherford et al. (2017) is about the formats of input sequences. While Rutherford et al. (2017) among others treated `Arg1` and `Arg2` separately, we combine them into a single sequence. Additionally, we append to the sequence a text chunk that precedes the arguments in the paragraph.[2]

We insert special tags, <Arg1>, </Arg1>, <Arg2>, and </Arg2>, into a given sequence to indicate where the arguments start and end. A similar technique is used in neural machine translation (Johnson et al., 2016). Although the PDTB annotates implicit relations on adjacent sentences, an argument pair does not necessarily form a complete span mainly because sub-sentential spans are sometimes selected as arguments (The PDTB Research Group, 2007). In addition, arguments sometimes contain non-argument text spans as in the following example (underlined):

> *At Quantum*, which is based in New York, *the trouble is magnified by the company's heavy dependence on plastics*. Once known as National Distillers & Chemical Corp., **the company exited the wine and spirits business and plowed more of its resources into plastics after Mr. Stookey took the chief executive's job in 1986**.
> (Contingency.Cause)

To cope with this problem, we enclose a non-argument span with <Skip> and </Skip>.

4 Experiments

4.1 Setup

4.1.1 Penn Discourse TreeBank

We evaluated our model's performance on the Penn Discourse TreeBank (PDTB) (Prasad et al., 2008). It is the most popular and largest corpus of discourse relations in English. The annotation is done as another layer on Wall Street Journal sections of the Penn Treebank. Each discourse relation consists of two text spans (arguments) and a relation label. Arguments are annotated such that they are minimally required to infer the discourse relation.

Relation labels are organized as a 3-level hierarchy in the PDTB. However, it is too difficult for current systems to perform classification in its original form, and previous studies have used more coarse-grained relation labels. Popular settings include top-level one-versus-all binary classification (Pitler et al., 2009), top-level 4-way classification (Pitler et al., 2009; Ji and Eisenstein, 2015), second-level 11-way classification (Lin et al., 2009; Rutherford et al., 2017), and modified second-level classification for the CoNLL 2015 Shared Task (Xue et al., 2015). We used second-level 11-way classification in the experiments.

Following Shi and Demberg (2017), we conducted 10-fold cross validation using the whole corpus of sections 0–24 (referred to as Cross Validation). The standard approach (referred to as Most-used Split)

[2] Rönnqvist et al. (2017) also concatenated `Arg1` and `Arg2` in the task of Chinese implicit discourse relation classification. They did not incorporate contextual information, however.

is to use sections 2–21 for the training set, section 22 for the development set and section 23 for the test set (Lin et al., 2009; Rutherford et al., 2017). However, Shi and Demberg (2017) argued that the standard test set was too small for a reliable evaluation especially when second-level classification was employed.

Table 1 shows the distribution of relation labels in the Cross Validation dataset. Note that although we tried to replicate the procedures described by Shi and Demberg (2017) as closely as possible, there remained slight differences in the discourse relation distribution. For comparison, we also trained the model on the Most-used Split dataset. Table 2 shows the relation label distribution in this dataset. We can confirm that the test set distribution diverged from the development set distribution.

4.1.2 Model Configurations

As word embeddings, we used an off-the-shelf word2vec model specified by the CoNLL 2016 Shared Task organizers. Word embeddings were fixed during training except for some words such as special tags <Arg1> and </Skip>.

As we described in Section 3.2, we used `ConceptNet` and coreference resolution (`Coref`) as external knowledge. Note that if none of the external knowledge is used, MAGE-GRU is reduced to vanilla GRU. For ConceptNet, we removed some triplets that contained stop words. We selected all relation types that appeared in the PDTB except `RelatedTo`. The number of relation types is 35. We added reverse relation types for 30 asymmetric relation types (e.g. `AtLocation` and `Causes`). As a result, the number of ConceptNet relation types used in the experiments was increased to 65.

Although ConceptNet was a relatively high-quality and high-coverage knowledge base, it nevertheless (1) contained questionable triplets (e.g., (time, `Antonym`, year)) and (2) failed to cover some important relations (stock, `AtLocation`, market). We mitigated the first problem by checking weights ConceptNet assigned to triplets. We removed triplets whose weight was smaller than 1.0. The second problem might potentially be addressed graph embedding techniques (Xie et al., 2017), but in the experiments, we used a simpler method. For each word in the input, we prepared the top-10 nearest neighbors in terms of cosine similarity of word2vec vectors with the threshold value of 0.6. We searched ConceptNet for all combinations of the original words and neighbors. As a result, the average number of edges given to an argument pair increased from 4.0 to 17.6.

As for a coreference resolution system, we used Stanford CoreNLP[3] (ver.3.7.0). CoreNLP had three different coreference systems. We chose a neural model since it performed the best among the three.

We tested two input formats: `Args` and `Paragraph`. In `Args`, an input sequence started with <Arg1> and ended with </Arg2>. In the longer `Paragraph` format, it started at the beginning of the paragraph that contained `Arg1` and `Arg2`.

Table 4 summarizes the model configurations. We found that mini-batch did not work for our model. Given that training set accuracy was as low as development set accuracy, we conjecture that training

signals in a mini-batch might have canceled out each other.

4.1.3 Models for Comparison

For comparison, we collected model scores from the literature. As for the Cross Validation dataset, we compared the proposed model with that of Shi and Demberg (2017) and a feedforward network (Rutherford et al., 2017). Shi and Demberg (2017) used an LSTM-based model, optionally with surface features derived from Brown Clusters, Modality, etc. The best score was achieved by LSTM+Modality. We reimplemented the feedforward model of Rutherford et al. (2017) because their evaluation was not based on the Cross Validation dataset.

For the Most-used Split dataset, the models for comparison were a feedforward network (Rutherford et al., 2017), a maximum entropy classifier (Lin et al., 2009) and a CNN-based model (Qin et al., 2017).

4.2 Results

Table 5 shows the results for the Cross Validation dataset. In all configurations, our model outperformed Shi and Demberg (2017)'s models. The best score was achieved by `Paragraph+ConseptNet`. The performance gain of `Paragraph+ConceptNet` over `Paragraph` was statistically significant ($p = 2.63 \times 10^{-7}, p < 0.01$) while `Paragraph+Coref` was no different from `Paragraph` ($p = 0.463$). The `Paragraph` models consistently outperformed the corresponding `Args` models when the input was augmented with external knowledge. However, the impact of contextual information was not statistically significant ($p = 0.081$ for `+Coref+ConceptNet`).

A breakdown of the performance by discourse relation is shown in `Paragraph+ConceptNet` are

Qin et al. (2017)	-	**0.4465**

Table 7: Accuracy in the Most-used Split dataset.

shown in Table 6. Comparing Table 6 with Table 1, we can see that the model ended up ignoring very-low-frequency relations such as Comparison.Concession and Expansion.Alternative, which appeared less than 300 times in training set. This problem could possibly be mitigated by leveraging an unlabeled corpus to increase the size of training instances (Jiang et al., 2016).

The results for the Most-used Split dataset are shown in Table 7. In this dataset, the proposed method was outperformed by models in the literature. Although the F-measure of `Args+Coref+ConceptNet` was about 2 points higher than that `Args`, the performance varied too inconsistently to draw meaningful conclusions. For this reason, we support Shi and Demberg (2017)'s argument for the need of cross validation for implicit discourse relation classification.

4.3 Discussion

As we have seen in Table 5, ConceptNet brought performance gain. However, it appears to leave much room for improvement. Consider the following examples:

`Ex1`:
Another, "Jeux Sans Frontieres ," where villagers from assorted European countries make fools of themselves performing pointless tasks, *is a hit in France*. **A U.S.-made imitation under the title "Almost Anything Goes" flopped fast**.
(Comparison.Contrast)

`Ex2`:
HOMESTEAD FINANCIAL CORP., Millbrae, financial services concern, annual revenue of $562 million, OTC, said *three of its 17 Bay-area branches were closed yesterday*. **The company expects all branches to reopen today**.
(Comparison.Contrast)

In `Ex1`, a baseline model wrongly chose Expansion.Conjunction but our model seems to have suppressed the discourse relation presumably because it found the antonym pair "hit" (`Arg1`) and "flopped" (`Arg2`) in ConceptNet. However, our model misclassified `Ex2` as Expansion.Conjunction even though "yesterday" and "today" were correctly identified as antonyms. This indicates that our model might not have given due weight to ConceptNet, possibly because of some noise in the knowledge base.

In our experiments, coreference resolution did not help implicit discourse relation classification. What we relied on was standard pronominal and nominal coreference resolution, but the following example suggests the need for resolving event coreference (Lu et al., 2016):

	Test
Args+Coref+ConceptNet	0.7723 ($\pm$0.008)
Paragraph+Coref+ConceptNet	0.7921 ($\pm$0.006)

Table 8: Accuracy of explicit discourse relation classification. Result indicates the mean accuracy across folds and the standard deviation.

Is an American Secretary of State seriously suggesting that the Khmer Rouge should help govern Cambodia? *Apparently so*. **There are no easy choices in Cambodia, but we can't imagine that it benefits the U.S. to become the catalyst for an all-too-familiar process that could end in another round of horror in Cambodia**.
(Comparison.Contrast)

In this example, `Arg1` is surprisingly uninformative. In order to classify the discourse relation between `Arg1` and `Arg2`, the system would need to identify what "so" in `Arg1` refers to.

To explore the effect of contextual information in detail, we compared the two input formats, `Args` and `Paragraph`, in the task of *explicit* discourse relation classification. The experimental settings are basically the same as in Section 4.1.2, but the Cross Validation dataset now contained explicit relations. The result is shown in Table 8. Contextual information did help in explicit discourse relation classification, with statistical significance at $p < 0.01$.

It is hard to see exactly why we obtained different results for implicit and explicit relations, but a hint is given by the PDTB annotation itself. The PDTB limits arguments to the minimal text needed to interpret a given relation, and provides *supplementary information* to each of `Arg1` and `Arg2` (named `Sup1` and `Sup2`) (The PDTB Research Group, 2007). Consider the following examples:

That pattern hasn't always held, *but recent strong growth in dividends makes some market watchers anxious*. Payouts on the S&P 500 stocks rose 10% in 1988, according to Standard & Poor's Corp., and Wall Street estimates for 1989 growth are generally between 9% and 14%. Many people believe the growth in dividends will slow next year, although a minority see double-digit gains continuing. **Meanwhile, many market watchers say recent dividend trends raise another warning flag: While dividends have risen smartly, their expansion hasn't kept pace with even stronger advances in stock prices**
(Expansion.Conjunction)

The underlined text span is annotated with `Sup1`. This tag is assigned to a text span supplementary to `Arg1` if it appears relevant but not necessary for interpretation. According to Prasad et al. (2014), only 126 implicit relations were annotated with supplementary information while 1,571 explicit relations were. They amounted to about 0.8% and 8% of the whole implicit and explicit relations, respectively. This great gap indicates that explicit relation classification may benefit more from the text chunks outside of the arguments than implicit relation classification. In fact, a baseline model wrongly chose Comparison.Contrast in this example, but our model chose a correct discourse relation. It should be noted that according to Prasad et al. (2014), consistency control over supplementary information annotation was rather weak. They warned that the gap could be an accidental feature of the PDTB annotation. However, our results lend support to the hypothesis that the gap reflects an intrinsic feature of the discourse relations, or at least that of the PDTB's task specifications.

5 Conclusion

In this paper, we adopted MAGE-GRU to efficiently incorporate external knowledge into the task of implicit discourse relation classification. The experiments show that external knowledge improved accuracy in this task. In addition to a pair of arguments, the text chunk that preceded the pair in the paragraph was given to the model with the hope that it could help classifying its relation. The contextual information

yielded a significant improvement not for implicit discourse relations but for explicit discourse relations. Additionally, we reconfirmed the need for cross validation in this task, as argued by Shi and Demberg (2017).

In the future, we would like to work on extending the neural network architecture. The high composability of MAGE-GRU means that it can easily be combined with other neural network models that are built on top of RNNs. A bidirectional extension to MAGE-GRU may be worth trying. Another future direction is to look for different sources of external knowledge. The candidates include other knowledge bases (e.g. Freebase (Bollacker et al., 2008)) and results of high-level NLP analyses (e.g. event coreference).

Abstract

Sentences in a well-formed text are connected to each other via various links to form the cohesive structure of the text. Current neural machine translation (NMT) systems translate a text in a conventional sentence-by-sentence fashion, ignoring such cross-sentence links and dependencies. This may lead to generate an incoherent target text for a coherent source text. In order to handle this issue, we propose a cache-based approach to modeling coherence for neural machine translation by capturing contextual information either from recently translated sentences or the entire document. Particularly, we explore two types of caches: a dynamic cache, which stores words from the best translation hypotheses of preceding sentences, and a topic cache, which maintains a set of target-side topical words that are semantically related to the document to be translated. On this basis, we build a new layer to score target words in these two caches with a cache-based neural model. Here the estimated probabilities from the cache-based neural model are combined with NMT probabilities into the final word prediction probabilities via a gating mechanism. Finally, the proposed cache-based neural model is trained jointly with NMT system in an end-to-end manner. Experiments and analysis presented in this paper demonstrate that the proposed cache-based model achieves substantial improvements over several state-of-the-art SMT and NMT baselines.

1 Introduction

Neural machine translation (Sutskever et al., 2014; Bahdanau et al., 2015) as an emerging machine translation approach, quickly achieves the state-of-the-art translation performance on many language pairs, e.g., English-French (Jean et al., 2015; Luong et al., 2015b), English-German (Shen et al., 2015; Luong et al., 2015a) and so on. In principle, NMT is established on an encoder-decoder framework, where the encoder reads a source sentence and encodes it into a fixed-length semantic vector, and the decoder generates a translation according to this vector.

In spite of its current success, NMT translates sentences of a text independently, ignoring document-level information during translation. This largely limits its success since document-level information imposes constraints on the translations of individual sentences of a text. And such document-level constraints, at least, can be categorized into three aspects: consistency, disambiguation and coherence. First, the same phrases or terms should be translated consistently across the entire text as much as possible, no matter in which sentence they occur. If sentences of a text are translated independent of each other, it will be difficult to maintain the translation consistency across different sentences. Second, document-level information provides a global context that can help disambiguate words with multiple senses if sentence-level local context is not sufficient for disambiguation. Third, the topic of a document is able to keep individual sentences translated in a coherent way.

In the literature, such informative constraints have been occasionally investigated in statistical machine translation and achieved certain success via a variety of document-level models, such as cache-based

language and translation models (Tiedemann, 2010; Gong et al., 2011; Nepveu et al., 2004) for the consistency constraint, topic-based coherence model (Xiong and Zhang, 2013; Tam et al., 2007) for the coherence constraint. By contrast, in neural machine translation, to the best of our knowledge, such constraints have not been explored so far.

Partially inspired by the success of cache models in SMT, we propose a cache-based approach to capturing coherence for neural machine translation. Particularly, we incorporate two types of caches into NMT: a static topic cache and a dynamic cache being updated on the fly. For the topic cache, we first use a projection-based bilingual topic learning approach to infer the topic distribution for each document to be translated and obtain the corresponding topical words on the target side. These topical words are then integrated into the topic cache. For the dynamic cache, words are retrieved from the best translation hypotheses of recently translated sentences. While the topic cache builds a global profile for a document, which helps impose the coherence constraint on document translation, the dynamic cache follows an intuition that words occurred previously should have higher probabilities of recurrence even if they are rare words in the training data.

In order to integrate these two caches into neural machine translation, we further propose a cache-based neural model, which adds a new neural network layer on the cache component to score each word in the cache. During decoding, we estimate the probability of a word from the cache according to its score and combine this cache probability with the original probability computed by the decoder via a gating mechanism to obtain the final word prediction probability.

On the NIST Chinese-English translation tasks, our experiment results show that the proposed cache-based neural approach can achieve significant improvements of up to 1.60 BLEU points on average (up to 2.53 BLEU points on NIST04) over the state-of-the-art attention-based NMT baseline.

2 Related Work

In the literature, several cache-based translation models have been proposed for conventional statistical machine translation, besides traditional n-gram language models and neural language models. In this section, we will first introduce related work in cache-based language models and then in translation models.

For traditional n-gram language models, Kuhn and De Mori (1990) propose a cache-based language model, which mixes a large global language model with a small local model estimated from recent items in the history of the input stream for speech recongnition. Della Pietra et al. (1992) introduce a MaxEnt-based cache model by integrating a cache into a smoothed trigram language model, reporting reduction in both perplexity and word error rates. Chueh and Chien (2010) present a new topic cache model for speech recongnition based on latent Dirichlet language model by incorporating a large-span topic cache into the generation of topic mixtures.

For neural language models, Huang et al. (2014) propose a cache-based RNN inference scheme, which avoids repeated computation of identical LM calls and caches previously computed scores and useful intermediate results and thus reduce the computational expense of RNNLM. Grave et al. (2016) extend the neural network language model with a neural cache model, which stores recent hidden activations to be used as contextual representations. Our caches significantly differ from these two caches in that we store linguistic items in the cache rather than scores or activations.

For neural machine translation, Wang et al. (2017) propose a cross-sentence context-aware approach and employ a hierarchy of Recurrent Neural Networks (RNNs) to summarize the cross-sentence context from source-side previous sentences. Jean et al. (2017) propose a novel larger-context neural machine translation model based on the recent works on larger-context language modelling (Wang and Cho, 2016) and employ the method to model the surrounding text in addition to the source sentence.

For cache-based translation models, Nepveu et al. (2004) propose a dynamic adaptive translation model using cache-based implementation for interactive machine translation, and develop a monolingual dynamic adaptive model and a bilingual dynamic adaptive model. Tiedemann (2010) propose a cache-based translation model, filling the cache with bilingual phrase pairs from the best translation hypotheses of previous sentences in a document. Gong et al. (2011) further propose a cache-based approach

to document-level translation, which includes three caches, a dynamic cache, a static cache and a topic cache, to capture various document-level information. Bertoldi et al. (2013) describe a cache mechanism to implement online learning in phrase-based SMT and use a repetition rate measure to predict the utility of cached items expected to be useful for the current translation.

Our caches are similar to those used by Gong et al. (2011) who incorporate these caches into statistical machine translation. We adapt them to neural machine translation with a neural cache model. It is worthwhile to emphasize that such adaptation is nontrivial as shown below because the two translation philosophies and frameworks are significantly different.

3 Attention-based NMT

In this section, we briefly describe the NMT model taken as a baseline. Without loss of generality, we adopt the NMT architecture proposed by Bahdanau et al. (2015), with an encoder-decoder neural network.

3.1 Encoder

The encoder uses bidirectional recurrent neural networks (Bi-RNN) to encode a source sentence with a forward and a backward RNN. The forward RNN takes as input a source sentence $x = (x_1, x_2, ..., x_T)$ from left to right and outputs a hidden state sequence $(\overrightarrow{h_1}, \overrightarrow{h_2}, ..., \overrightarrow{h_T})$ while the backward RNN reads the sentence in an inverse direction and outputs a backward hidden state sequence $(\overleftarrow{h_1}, \overleftarrow{h_2}, ..., \overleftarrow{h_T})$. The context-dependent word representations of the source sentence h_j (also known as word annotation vectors) are the concatenation of hidden states $\overrightarrow{h_j}$ and $\overleftarrow{h_j}$ in the two directions.

3.2 Decoder

The decoder is an RNN that predicts target words y_t via a multi-layer perceptron (MLP) neural network. The prediction is based on the decoder RNN hidden state s_t, the previous predicted word y_{t-1} and a source-side context vector c_t. The hidden state s_t of the decoder at time t and the conditional probability of the next word y_t are computed as follows:

$$s_t = f(s_{t-1}, y_{t-1}, c_t) \tag{1}$$

$$p(y_t|y_{<t}; x) = g(y_{t-1}, s_t, c_t) \tag{2}$$

3.3 Attention Model

In the attention model, the context vector c_t is calculated as a weighted sum over source annotation vectors $(h_1, h_2, ..., h_T)$:

$$c_t = \sum_{j=1}^{T_x} \alpha_{tj} h_j \tag{3}$$

$$\alpha_{tj} = \frac{exp(e_{tj})}{\sum_{k=1}^{T} exp(e_{tk})} \tag{4}$$

$$e_{tj} = a(s_{t-1}, h_j) \tag{5}$$

where α_{tj} is the attention weight of each hidden state h_j computed by the attention model, and a is a feed forward neural network with a single hidden layer.

The dl4mt tutorial[1] presents an improved implementation of the attention-based NMT system, which feeds the previous word y_{t-1} to the attention model. We use the dl4mt tutorial implementation as our baseline, which we will refer to as RNNSearch*.

The proposed cache-based neural approach is implemented on the top of RNNSearch* system, where the encoder-decoder NMT framework is trained to optimize the sum of the conditional log probabilities of correct translations of all source sentences on a parallel corpus as normal.

[1] https://github.com/nyu-dl/dl4mt-tutorial/tree/master/session2

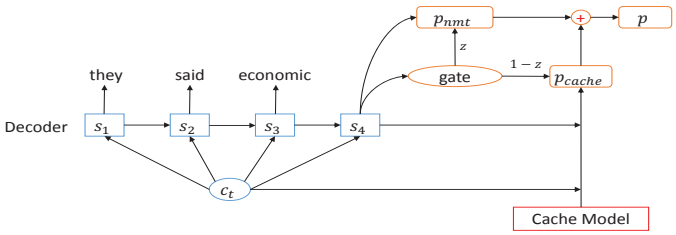

Figure 1: Architecture of NMT with the neural cache model. P_{cache} is the probability for a next target word estimated by the cache-based neural model.

4 The Cache-based Neural Model

In this section, we elaborate on the proposed cache-based neural model and how we integrate it into neural machine translation, Figure 1 shows the entire architecture of our NMT with the cache-based neural model.

4.1 Dynamic Cache and Topic Cache

The aim of cache is to incorporate document-level constraints and therefore to improve the consistency and coherence of document translations. In this section, we introduce our proposed dynamic cache and topic cache in detail.

4.1.1 Dynamic Cache

In order to build the dynamic cache, we dynamically extract words from recently translated sentences and the partial translation of current sentence being translated as words of dynamic cache. We apply the following rules to build the dynamic cache.

a) The max size of the dynamic cache is set to $|c_d|$.

b) According to the first-in-first-out rule, when the dynamic cache is full and a new word is inserted into the cache, the oldest word in the cache will be removed.

c) Duplicate entries into the dynamic cache are not allowed when a word has been already in the cache.

It is worth noting that we also maintain a stop word list, and we added English punctuations and "UNK" into our stop word list. Words in the stop word list would not be inserted into the dynamic cache. So the common words like "a" and "the" cannot appear in the cache. All words in the dynamic cache can be found in the target-side vocabulary of RNNSearch*.

4.1.2 Topic Cache

In order to build the topic cache, we first use an off-the-shelf LDA topic tool[2] to learn topic distributions of source- and target-side documents separately. Then we estimate a topic projection distribution over all target-side topics $p(z_t|z_s)$ for each source topic z_s by collecting events and accumulating counts of (z_s, z_t) from aligned document pairs. Notice that z_s/z_t is the topic with the highest topic probability $p(z_\cdot|d)$ on the source/target side. Then we can use the topic cache as follows:

1) During the training process of NMT, the learned target-side topic model is used to infer the topic distribution for each target document. For a target document d in the training data, we select the topic z with the highest probability $p(z|d)$ as the topic for the document. The $|c_t|$ most probable topical words in topic z are extracted to fill the topic cache for the document d.

2) In the NMT testing process, we first infer the topic distribution for a source document in question with the learned source-side topic model. From the topic distribution, we choose the topic with the highest probability as the topic for the source document. Then we use the learned topic projection function to

[2]http://www.arbylon.net/projects/

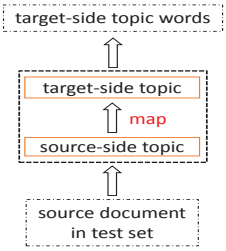

Figure 2: Schematic diagram of the topic projection during the testing process.

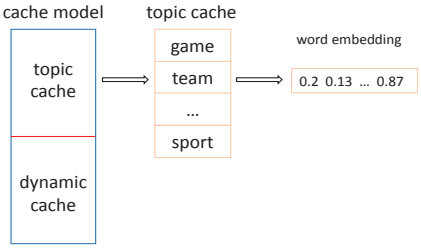

Figure 3: Architecture of the cache model.

map the source topic onto a target topic with the highest projection probability, as illustrated in Figure 2. After that, we use the $|c_t|$ most probable topical words in the projected target topic to fill the topic cache.

The words of topic cache and dynamic cache together form the final cache model. In practice, the cache stores word embeddings, as shown in Figure 3. As we do not want to introduce extra embedding parameters, we let the cache share the same target word embedding matrix with the NMT model. In this case, if a word is not in the target-side vocabulary of NMT, we discard the word from the cache.

4.2 The Model

The cache-based neural model is to evaluate the probabilities of words occurring in the cache and to provide the evaluation results for the decoder via a gating mechanism.

4.2.1 Evaluating Word Entries in the Cache

When the decoder generates the next target word y_t, we hope that the cache can provide helpful information to judge whether y_t is appropriate from the perspective of the document-level cache if y_t occurs in the cache.To achieve this goal, we should appropriately evaluate the word entries in the cache.

In this paper, we build a new neural network layer as the scorer for the cache. At each decoding step t, we use the scorer to score y_t if y_t is in the cache. The inputs to the scorer are the current hidden state s_t of the decoder, previous word y_{t-1}, context vector c_t, and the word y_t from the cache. The score of y_t is calculated as follows:

$$score(y_t|y_{<t}, x) = g_{cache}(s_t, c_t, y_{t-1}, y_t) \tag{6}$$

where g_{cache} is a non-linear function.

This score is further used to estimate the cache probability of y_t as follows:

$$p_{cache}(y_t|y_{<t}, x) = softmax(score(y_t|y_{<t}, x)) \tag{7}$$

4.2.2 Integrating the Cache-based Neural Model into NMT

Since we have two prediction probabilities for the next target word y_t, one from the cache-based neural model p_{cache}, the other originally estimated by the NMT decoder p_{nmt}, how do we integrate these two probabilities? Here, we introduce a gating mechanism to combine them, and word prediction probabilities on the vocabulary of NMT are updated by combining the two probabilities through linear interpolation between the NMT probability and cache-based neural model probability. The final word prediction probability for y_t is calculated as follows:

$$p(y_t|y_{<t}, x) = (1 - \alpha_t)p_{cache}(y_t|y_{<t}, x) + \alpha_t p_{nmt}(y_t|y_{<t}, x) \tag{8}$$

Notice that if y_t is not in the cache, we set $p_{cache}(y_t|y_{<t}, x) = 0$, where α_t is the gate and computed as follows:

$$\alpha_t = g_{gate}(f_{gate}(s_t, c_t, y_{t-1})) \tag{9}$$

where f_{gate} is a non-linear function and g_{gate} is sigmoid function.

We use the contextual elements of s_t, c_t, y_{t-1} to score the current target word occurring in the cache (Eq. (6)) and to estimate the gate (Eq. (9)). If the target word is consistent with the context and in the cache at the same time, the probability of the target word will be high.

Finally, we train the proposed cache model jointly with the NMT model towards minimizing the negative log-likelihood on the training corpus. The cost function is computed as follows:

$$L(\theta) = -\sum_{i=1}^{N}\sum_{t=1}^{T} logp(y_t|y_{<t}, x) \tag{10}$$

where θ are all parameters in the cache-based NMT model.

4.3 Decoding Process

Our cache-based NMT system works as follows:

(1) When the decoder shifts to a new test document, clear the topic and dynamic cache.

(2) Obtain target topical words for the new test document as described in Section 4.1 and fill them in the topic cache.

(3) Clear the dynamic cache when translating the first sentence of the test document.

(4) For each sentence in the new test document, translate it with the proposed cache-based NMT and continuously expands the dynamic cache with newly generated target words and target words obtained from the best translation hypothesis of previous sentences.

In this way, the topic cache can provide useful global information at the beginning of the translation process while the dynamic cache is growing with the progress of translation.

5 Experimentation

We evaluated the effectiveness of the proposed cache-based neural model for neural machine translation on NIST Chinese-English translation tasks.

5.1 Experimental Setting

We selected corpora LDC2003E14, LDC2004T07, LDC2005T06, LDC2005T10 and a portion of data from the corpus LDC2004T08 (Hong Kong Hansards/Laws/News) as our bilingual training data, where document boundaries are explicitly kept. In total, our training data contain 103,236 documents and 2.80M sentences. On average, each document consists of 28.4 sentences. We chose NIST05 dataset (1082 sentence pairs) as our development set, and NIST02, NIST04, NIST06 (878, 1788, 1664 sentence pairs. respectively) as our test sets. We compared our proposed model against the following two systems:

- **Moses** (Koehn et al., 2007): an off-the-shelf phrase-based translation system with its default setting.
- **RNNSearch***: our in-house attention-based NMT system which adopts the feedback attention as described in Section 3 .

For Moses, we used the full training data to train the model. We ran GIZA++ (Och and Ney, 2000) on the training data in both directions, and merged alignments in two directions with "grow-diag-final" refinement rule (Koehn et al., 2005) to obtain final word alignments. We trained a 5-gram language model on the Xinhua portion of GIGA-WORD corpus using SRILM Toolkit with a modified Kneser-Ney smoothing.

For RNNSearch, we used the parallel corpus to train the attention-based NMT model. The encoder of RNNSearch consists of a forward and backward recurrent neural network. The word embedding dimension is 620 and the size of a hidden layer is 1000. The maximum length of sentences that we used to train RNNSearch in our experiments was set to 50 on both Chinese and English side. We used the most

Moses	31.52	32.73	29.52	29.57	30.69
RNNSearch*	36.18	36.36	32.56	30.57	33.92
+ Cd	36.86	37.16	33.10	32.60	34.93
+ Cd, Ct	38.04	38.89	33.31	31.85	35.52

Table 1: Experiment results on the NIST Chinese-English translation tasks. [+Cd] is the proposed model with the dynamic cache. [+Cd, Ct] is the proposed model with both the dynamic and topic cache. Avg means the average BLEU score on all test sets.

frequent 30K words for both Chinese and English. We replaced rare words with a special token "UNK". Dropout was applied only on the output layer and the dropout rate was set to 0.5. All the other settings were the same as those in (Bahdanau et al., 2015). Once the NMT model was trained, we adopted a beam search to find possible translations with high probabilities. We set the beam width to 10.

For the proposed cache-based NMT model, we implemented it on the top of RNNSearch*. We set the size of the dynamic and topic cache $|c_d|$ and $|c_t|$ to 100, 200, respectively. For the dynamic cache, we only kept those most recently-visited items. For the LDA tool, we set the number of topics considered in the model to 100 and set the number of topic words that are used to fill the topic cache to 200. The parameter α and β of LDA were set to 0.5 and 0.1, respectively. We used a feedforward neural network with two hidden layers to define g_{cache} (Equation (6)) and f_{gate} (Equation (9)). For f_{gate}, the number of units in the two hidden layers were set to 500 and 200 respectively. For g_{cache}, the number of units in the two hidden layers were set to 1000 and 500 respectively. We used a pre-training strategy that has been widely used in the literature to train our proposed model: training the regular attention-based NMT model using our implementation of RNNSearch*, and then using its parameters to initialize the parameters of the proposed model, except for those related to the operations of the proposed cache model.

We used the stochastic gradient descent algorithm with mini-batch and Adadelta to train the NMT models. The mini-batch was set to 80 sentences and decay rates ρ and ϵ of Adadelta were set to 0.95 and 10^{-6}.

5.2 Experimental Results

Table 1 shows the results of different models measured in terms of BLEU score[3]. From the table, we can find that our implementation RNNSearch* using the feedback attention and dropout outperforms Moses by 3.23 BLEU points. The proposed model $RNNSearch*_{+Cd}$ achieves an average gain of 1.01 BLEU points over RNNSearch* on all test sets. Further, the model $RNNSearch*_{+Cd,Ct}$ achieves an average gain of 1.60 BLEU points over RNNSearch*, and it outperforms Moses by 4.83 BLEU points. These results strongly suggest that the dynamic and topic cache are very helpful and able to improve translation quality in document translation.

Effect of the Gating Mechanism

In order to validate the effectiveness of the gating mechanism used in the cache-based neural model, we set a fixed gate value for $RNNSearch*_{+Cd,Ct}$, in other words, we use a mixture of probabilities with fixed proportions to replace the gating mechanism that automatically learns weights for probability mixture.

Table 2 displays the result. When we set the gate α to a fixed value 0.3, the performance has an obvious decline comparing with that of $RNNSearch*_{+Cd,Ct}$ in terms of BLEU score. The performance is even worse than RNNSearch* by 10.11 BLEU points. Therefore without a good mechanism, the cache-based neural model cannot be appropriately integrated into NMT. This shows that the gating mechanism plays a important role in $RNNSearch*_{+Cd,Ct}$.

[3]As our model requires document boundaries so as to gurantee that cache words are from the same document, we use all LDC corpora that provide document boundaries. Most training sentences are from Hong Kong Hansards/Laws Parallel Text (accounting for 57.82% of our training data) which are in the law domain rather than the news domain of our test/dev sets. This is the reason that our baseline is lower than other published results obtained using more news-domain training data without document boundaries.

Reference	2.39	2.51	2.20	1.28	2.09

Table 3: The average number of words in translations of beginning sentences of documents that are also in the topic cache. Reference represents the average number of words in four human translations that are also in the topic cache.

Effect of the Topic Cache

When the NMT decoder translates the first sentence of a document, the dynamic cache is empty. In this case, we hope that the topic cache will provide document-level information for translating the first sentence. We therefore further investigate how the topic cache influence the translation of the first sentence in a document. We count and calculate the average number of words that appear in both the translations of the beginning sentences of documents and the topic cache.

The statistical results are shown in Table 3. Without using the cache model, RNNSearch* generates translations that contain words from the topic cache as these topic words are tightly related to documents being translated. With the topic cache, our neural cache model enables the translations of the first sentences to be more relevant to the global topics of documents being translated as these translations contain more words from the topic cache that describes these documents. As the dynamic cache is empty when the decoder translates the beginning sentences, the topic cache is complementary to such a cold cache at the start. Comparing the numbers of translations generated by our model and human translations (Reference in Table 3), we can find that with the help of the topic cache, translations of the first sentences of documents are becoming closer to human translations.

Analysis on the Cache-based Neural Model

As shown above, the topic cache is able to influence both the translations of beginning sentences and those of subsequent sentences while the dynamic cache built from translations of preceding sentences has an impact on the translations of subsequent sentences. We further study what roles the dynamic and topic cache play in the translation process. For this aim, we calculate the average number of words in translations generated by $RNNSearch*_{+Cd,Ct}$ that are also in the caches. During the counting process, stop words and "UNK" are removed from sentence and document translations.

Table 4 shows the results. If only the topic cache is used ([$document \in [Ct]$,$sentence \in (Ct)$] in Table 4), the cache still can provide useful information to help NMT translate sentences and documents. 28.3 words per document and 2.39 words per sentence are from the topic cache. When both the dynamic and topic cache are used ([$document \in [Ct, Cd]$,$sentence \in (Ct, Cd)$] in Table 4), the numbers of words that both occur in sentence/document translations and the two caches sharply increase from 2.61/30.27 to 6.73/81.16. The reason for this is that words appear in preceding sentences will have a large probability of appearing in subsequent sentences. This shows that the dynamic cache plays a important role in keeping document translations consistent by reusing words from preceding sentences.

We also provide two translation examples in Table 5. We can find that RNNSearch* generates different translations "operations" and "actions" for the same chinese word "行动(xingdong)", while our proposed model produces the same translation "actions".

Model	NIST02	NIST04	NIST05	NIST06	Avg
$document \in (Ct)$	25.70	27.48	26.89	41.00	30.27

$RNNSearch*_{+Cd,Ct}$	0.4274
Human Reference	0.4347

Table 6: The average cosine similarity of adjacent sentences (coherence) on all test sets.

5.3 Analysis on Translation Coherence

We want to further study how the proposed cache-based neural model influence coherence in document translation. For this, we follow Lapata and Barzilay (2005) to measure coherence as sentence similarity. First, each sentence is represented by the mean of the distributed vectors of its words. Second, the similarity between two sentences is determined by the cosine of their means.

$$sim(S_1, S_2) = cos(\mu(\vec{S_1}), \mu(\vec{S_2})) \tag{11}$$

where $\mu(\vec{S_i}) = \frac{1}{|S_i|} \sum_{\vec{w} \in S_i} \vec{w}$, and $\vec{w}$ is the vector for word w.

We use Word2Vec[4] to get the distributed vectors of words and English Gigaword fourth Edition[5] as training data to train Word2Vec. We consider that embeddings from word2vec trained on large monolingual corpus can well encode semantic information of words. We set the dimensionality of word embeddings to 200. Table 6 shows the average cosine similarity of adjacent sentences on all test sets. From the table, we can find that the $RNNSearch*_{+Cd,Ct}$ model produces better coherence in document translation than RNNSearch* in term of cosine similarity.

6 Conclusion

In this paper, we have presented a novel cache-based neural model for NMT to capture the global topic information and inter-sentence cohesion dependencies. We use a gating mechanism to integrate both the topic and dynamic cache into the proposed neural cache model. Experiment results show that the cache-based neural model achieves consistent and significant improvements in translation quality over several state-of-the-art NMT and SMT baselines. Further analysis reveals that the topic cache and dynamic cache are complementary to each other and that both are able to guide the NMT decoder to use topical words and to reuse words from recently translated sentences as next word predictions.

Fusing Recency into Neural Machine Translation with an Inter-Sentence Gate Model

Shaohui Kuang **Deyi Xiong***

shaohuikuang@foxmail.com, dyxiong@suda.edu.cn

Abstract

Neural machine translation (NMT) systems are usually trained on a large amount of bilingual sentence pairs and translate one sentence at a time, ignoring inter-sentence information. This may make the translation of a sentence ambiguous or even inconsistent with the translations of neighboring sentences. In order to handle this issue, we propose an inter-sentence gate model that uses the same encoder to encode two adjacent sentences and controls the amount of information flowing from the preceding sentence to the translation of the current sentence with an inter-sentence gate. In this way, our proposed model can capture the connection between sentences and fuse recency from neighboring sentences into neural machine translation. On several NIST Chinese-English translation tasks, our experiments demonstrate that the proposed inter-sentence gate model achieves substantial improvements over the baseline.

1 Introduction

In NMT systems (Bahdanau et al., 2015; Cho et al., 2014; Sutskever et al., 2014), an encoder first reads variable-length source sentences and encodes them into a sequence of vectors, then a decoder generates a target translation from the sequence of source vectors. Although NMT is an emerging machine translation approach, the translation process of a document in NMT is similar to conventional statistical machine translation (SMT), treating the document as a bag of sentences and ignoring cross-sentence dependencies.

Sentences are the constituent elements of paragraphs. Harper (1965) argues that sentences possess two attributes: continuity that maintains consistency with other sentences and development that introduces new information. For any adjacent sentences of a well-formed text, they tend to have considerable degree of continuity, which is usually described and measured at two levels: cohesion at the surface level and coherence at the underlying level. These two continuity metrics are two well-known means to estalish such inter-sentence links within a text. Harper (1965) finds that word recurrence, as the most common device of cohesion, occurs in 70% of adjacent sentence pairs. Xiong et al. (2015) show that about 60% of sentences have the same topics (coherence) as those of the documents where these sentences occur.

Such inter-sentence dependencies can and should be used to help document-level machine translation. In the literature, a variety of models have been proposed to capture these dependencies in the context of SMT, such as cache-based language and translation models (Tiedemann, 2010; Gong et al., 2011), topic-based coherence model (Xiong and Zhang, 2013) and lexical cohesion model (Xiong et al., 2013). However, integrating inter-sentence information into an NMT system is still an open problem.

In this paper, we propose a simple yet effective approach to model the inter-sentence information for NMT. In order to capture the connection between two adjacent sentences, i.e. the preceding sentence and current sentence, we first use the same encoder to encode the two adjacent sentences at the same time to form a context vector a for the preceding sentence and a context vector b for current sentence. Then, we introduce a gate mechanism to combine a and b into the final context vector, which is further

Santa Fe, New Mexico, USA, August 20-26, 2018.

used to update the hidden states of the decoder. In this way, we can model the links and dependencies between adjacent sentences. To some extent, our approach models the inter-sentence relationship from the underlying semantic coherence perspective.

On the NIST Chinese-English translation tasks, our experimental results show that the proposed approach can achieve significant improvements of up to 2.0 BLEU points over the NMT baseline.

2 Related Work

In the literature, a series of document-level translation models have been proposed for conventional SMT. Just to name a few, Gong et al. (2011) propose a cache-based approach to document-level translation, which includes three caches, a dynamic cache, a static cache and a topic cache to capture various kind of document-level information. Hardmeier et al. (2012) present a beam search decoding procedure for phrase-based SMT with features modeling cross-sentence dependencies. Xiong and Zhang (2013) propose a topic-based coherence model to produce discourse coherence for document translation. Xiong et al. (2013) present a lexical cohesion model to capture lexical cohesion for document-level translation.

In neural language models, inter-sentence connections can be captured in a contextual model. For example, Lin et al. (2015) propose a hierarchical recurrent neural network (HRNN) language model for document modeling, consisting of a sentence-level and word-level language model, and use the proposed model to model sentence-level coherence. In speech recognition, as input speech signals can contain thousands of frames, Chan et al. (2016) employ Bidirectional Long Short Term Memory with a pyramidal structure to capture the context of a large number of input time steps. Wang and Cho (2016) introduce a late fusion method to incorporate corpus-level discourse information into recurrent language modeling.

In neural conversation systems, links between multi-turn conversations are usually modeled with hierarchical neural networks. Serban et al. (2015) use a hierarchical recurrent encoder-decoder(HRED) to model the dialogue into two-level hierarchy: a sequence of utterances and a sequence of words. The proposed model can track states over many utterances to generate context-aware multiple rounds of dialogue. Serban et al. (2016) further propose a HRED model with an additional component: a high-dimensional stochastic latent variable at every dialogue turn to sample a vaussian variable as input to the decoder.

It is natural to adapt the HRED model to document-level NMT. However, document boundaries are usually missing in bilingual training corpora, indicating that we do not have sufficient data to train the sentence-level hierarchy. In our proposed gate model, we do not need entire documents to train the NMT model. We only use pairs of two adjacent sentences to train the gate. Furthermore, each sentence in a sentence pair can be used twice: one as a preceding sentence and the other as a current sentence. Additionally, in order to reduce the number of extra parameters, we use the same encoder to encode the adjacent sentences, which can also keep the semantic consistency for the same source sentence.

3 Neural Machine Translation

In this section, we briefly describle the atttention-based NMT model proposed in (Bahdanau et al., 2015).

In their framework, the encoder encodes a source sentence as a sequence of vectors with bi-directional RNNs. The forward RNN reads the source sentence $x = (x_1, x_2, ..., x_T)$ from left to right and the backward RNN reads the source sentence in an inverse direction. The hidden states $\overrightarrow{h} = (\overrightarrow{h_1}, \overrightarrow{h_2}, ..., \overrightarrow{h_T})$ in the forward RNN can be computed as follows:

$$\overrightarrow{h_j} = f(\overrightarrow{h_{j-1}}, x_j), \tag{1}$$

where f is a non-linear function, here defined as a gated recurrent unit (GRU) (Chung et al., 2014). Similarly, Hidden states of the backward RNN can be calculated. The forward and backward hidden states are concatenated into the final annotation vectors $h = (h_1, h_2, ..., h_T)$. The decoder is also an RNN that predicts the next word y_t given the context vector c_t , the hidden state s_{t-1} and the previously generated word sequence $y_{<t} = [y_1, y_2, ..., y_{t-1}]$. The probability of the next word y_t is calculated as follows:

$$p(y_t|y_{<t}; x) = g(c_t, y_{t-1}, s_t), \tag{2}$$

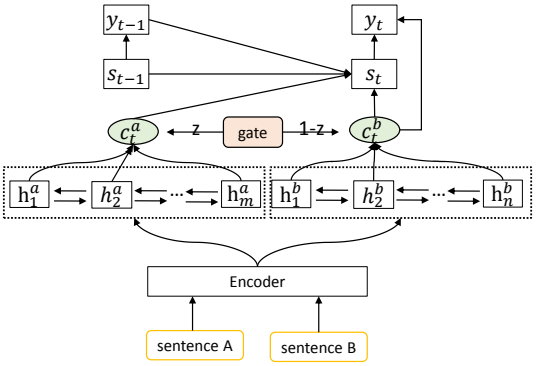

Figure 1: Architecture of NMT with the inter-sentence gate.

where g is a softmax layer, s_t is the state of decoder RNN at time step t computed as

$$s_t = f(s_{t-1}, y_{t-1}, c_t). \tag{3}$$

where f is a function, the same as function used in the encoder. The context vector c_t is calculated as a weighted sum of all hidden states of the encoder as follows:

$$c_t = \sum_{i=1}^{T_x} \alpha_{tj} h_j, \tag{4}$$

$$\alpha_{tj} = \frac{exp(e_{tj})}{\sum_{k=1}^{T_x} exp(e_{tk})}, \tag{5}$$

$$e_{tj} = a(s_{t-1}, h_j). \tag{6}$$

where α_{tj} is the weight of each hidden state h_j computed by the attention model, a is a feedforward neural network with a single hidden layer.

We also implement an NMT system which adopts feedback attention (Wang et al., 2016b; Wang et al., 2016a), which will be referred to as RNNSearch in this paper. In the feedback attention, e_{tj} is computed as follows:

$$e_{tj} = a(\widetilde{s}_{t-1}, h_j), \tag{7}$$

where $\widetilde{s}_{t-1} = GRU(s_{t-1}, y_{t-1})$. The hidden state of the decoder is updated as follows:

$$s_t = GRU(\widetilde{s}_{t-1}, c_t) \tag{8}$$

In this paper, our proposed model is implemented on the top of RNNSearch system.

4 The Inter-Sentence Gate Model

In this section, we will elaborate the proposed inter-sentence gate model, which we refer to as NMT_{ISG}. Figure 1 shows the entire architecture of our NMT with the inter-sentence gate. For notational convenience, we denote two adjacent sentences as A and B: A for the preceding sentence and B for the current sentence.

4.1 Encoder

We employ the same encoder to encode the adjacent sentence A and B into hidden vector representations $[h_1^a, h_2^a, ..., h_m^a]$ and $[h_1^b, h_2^b, ..., h_n^b]$ respectively. We then use the attention network described in Equation (4) of Section 3 to compute their context representations c_t^a and c_t^b.

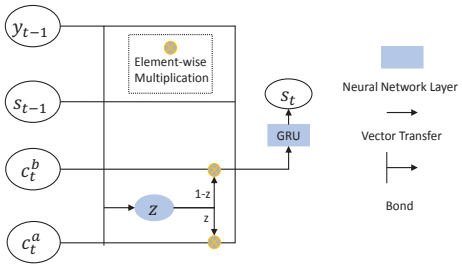

Figure 2: The framework of updating the decoding state using the proposed gate model.

4.2 Inter-Sentence Gate Model

When we translate the current sentence B, we have to make sure that the decoder is provided with sufficient information from sentence B, and at the same time, with helpful imformation from the preceding sentence A. In other words, we need a mechanism to control the scale of information flowing from the sentence A and sentence B to the decoder. Inspired by the success of gated units in RNN (Chung et al., 2014), we propose an inter-sentence gate to control the amount of information flowing from A and B. Formally, we employ a sigmoid neural network layer and an element-wise multiplication operation, as illustrated in Figure 2. Similarly, Tu et al. (2016) also propose a gating mechanism to combine source and target contexts. The gate framework assigns element-wise weights z to the input signals, calculated by

$$z_t = \sigma(U_z s_{t-1} + W_z y_{t-1} + C_b c_t^b + C_a c_t^a) \tag{9}$$

here σ is a logistic sigmoid function, and U_z, W_z, C_b, C_a are the parameter matrix.

4.3 Decoder

Next, we integrate the inter-sentence gate into the decoder to decide the amount of context information used in producing the decoder hidden state at each time step. In this way, we want the hidden states of the decoder to store the inter-sentence context information. The framework of updating the hidden state of the decoder at time step t is illustrated in Figure 2. The decoder hidden state s_t is computed as follows:

$$s_t = GRU(U s_{t-1} + W y_{t-1} + C_1 c_t^a * z_t + C_2 c_t^b * (1 - z_t)) \tag{10}$$

where $*$ is an element-wise multiplication, U, W, C_1, C_2 is the parameter matrix, and z_t is the inter-sentence gate computed by Equation (10).

The conditional probability of the next word y_t is calculated as follows:

$$p(y_t|y_{<t}, x) = g(f(s_t, y_{t-1}, c_t^b)) \tag{11}$$

where c_t^b is the context vector of the current sentence B.

Our aim is to translate the current sentence B with the additional information from the preceding sentence A. We do not want to have the excessive impact of the preceding sentence on the translation output of the current sentence. Therefore, in the stage of generating the next word, we just use the context c_t^b.

5 Experiments

We carried out a series of Chinese-to-English translation experiments to evaluate the effectiveness of the proposed inter-sentence gate model on document-level NMT and conducted in-depth analyses on experiment results and translations.

5.1 Experimental Settings

We selected corpora LDC2003E14, LDC2004T07, LDC2005T06, and LDC2005T10 as our bilingual training data, where document boundaries are kept. We also used all data from the corpus LDC2004T08

Table 1: Experiment results on the NIST Chinese-English translation task. We adopted the RNNSearch, an in-house NMT system, as our baselines. NMT_{ISG} is the proposed model without replacing UNK words. The BLEU scores are case-insensitive. Avg means the average BLEU score on all the test sets. "‡" : statistically better than RNNSearch ($p < 0.01$).

(Hong Kong Hansards/Laws/News). In total, our training data contain 103,236 documents and 2.80M sentences. Averagely, each document consists of 28.4 sentences. We chose NIST05 dataset as our development set, and NIST02, NIST03, NSIT04, NIST06, NIST08 as our test sets. We used case-insensitive BLEU-4 as our evaluation metric. We compared our NMT_{ISG} with the following two systems:

- **Moses** (Koehn et al., 2007): an open phrase-based translation system with its default setting.
- **RNNSearch**: our new implementation of NMT system with the feedback attention as described in Section 3.

For Moses, we used the full training data (parallel corpus) to train the model. Word alignments were produced by GIZA++ (Och and Ney, 2000). We ran GIZA++ on the corpus in both directions, and merged alignments in two directions with "grow-diag-final" refinement rule (Koehn et al., 2005). We trained a 5-gram language model on the Xinhua portion of the Gigaword corpus using SRILM Toolkit with a modified Kneser-Ney smoothing.

For RNNSearch, we used the parallel corpus to train the attention-based NMT model. The encoder of RNNSearch consists of a forward (1000 hidden unit) and backward (1000 hidden unit) recurrent neural network. The maximum length of sentences that we used to train NMT in our experiments was set to 50 for both the Chinese and English sides. We used the most frequent 30K words for both Chinese and English, covering approximately 99.0% and 99.2% of the data in the two languages respectively. We replaced rare words with a special token "UNK". We also adopted the dropout technique. Dropout is applied only on the output layer and the dropout rate was set to 0.5. All the other settings are the same as the setting up described by Bahdanau et al. (2015). Once the NMT model was trained, we employed a beam search algorithm to find possible translations with high probabilities. We set the beam width to 10.

For the proposed NMT_{ISG} model, we implemented it on the top of RNNSearch. We used tuples (x, before-x, y) as input of NMT_{ISG}, where x and y are a parallel sentence pair, before-x is the previous sentence of source sentence x in the same document[1]. As the first sentence of a document does not have before-x, we used the stop symbol to form the sentence s = (eos, eos, eos) as the before-x. We used a simple pre-training strategy to train our NMT_{ISG} model: training the regular attention-based NMT model using our implementation of RNNSearch, and then using its parameters to initialize the parameters of the proposed model, except for those related to the operations of the inter-sentence gate.

We used the stochastic gradient descent algorithm with mini-batch and Adadelta (Zeiler, 2012) to train the NMT model. The mini-batch was set to 80 sentences and decay rates ρ and ϵ of Adadelta were set to 0.95 and 10^{-6}, respectively.

5.2 Experimental Results

Table 1 shows the results of different NMT systems measured in terms of BLEU score. From the table, we can find that our implementation RNNSearch using the feedback attention and dropout outperforms

[1]We obtain tuples (x, before-x, y) from the training corpus. During the acquisition of these tuples, we follow two constraints. First, we discard the tuple (x,before-x,y) if there is a big difference in the length of the sentence x and before-x. For example, sentence x or before-x is a date expression at the end of a document or an organization name at the beginning of a document. Second, the length of any element in a tuple (x, before-x, y) is not longer than 50.

Model	NIST02	NIST03	NIST04	NIST05	NIST06	NIST08
RNNSearch	32.56	36.18	34.85	36.36	30.57	23.69
RNNSearch + concat	21.81	18.72	19.44	16.11	16.60	9.81

Table 2: The BLEU scores of RNNSearch + concat model which uses the concatenation of two neighboring sentence as input of RNNSearch.

Model	NIST05	NIST02	NIST03	NIST04	NIST06	NIST08	Avg
RNNSearch	32.56	36.18	34.85	36.36	30.57	23.69	32.37
NMT_{ISG}	34.58	36.68	36.29	38.15	31.83	24.67	33.7
+NULL	33.22	36.46	35.27	37.11	30.77	23.80	32.77
+z=**0**	30.49	31.71	31.05	35.10	29.89	22.10	30.06
+RV	31.88	36.21	34.51	35.93	29.96	22.99	31.91

Table 3: Effect of the inter-sentence gate and information of before-x. BLEU scores in the table are case-insensitive. [+NULL] is set the before-x to a NULL sentence. [+z=0] is set the gate vector to all-zero vector. And [+RV] is set the context vector of before-x to a random vector which value of vector is between -1 and 1. Avg meaning the average BLEU score on all the test sets.

Moses by 2.65 BLEU points. The proposed model NMT_{ISG} achieves an average gain of 1.33 BLEU points over RNNSearch on all test sets. And it outperforms Moses by 3.98 BLEU points.

One might use the concatenation of two neighboring source sentences as input of RNNSearch to explore the information of the preceding sentence. However, this will degenerate translation quality as shown in Table 2. The main reason is that the conventional NMT has difficulties in translating long sentences (Pougetabadie et al., 2014). Thus, we conclude that the information of preceding sentences cannot be directly explored via concatenation.

5.3 Effect of the Inter-Sentence Gate

In order to examine the effectiveness of the proposed inter-sentence gate and inter-sentence information from before-x, we also conducted three additional validation experiments in the test sets: (1) we set all before-x to NULL (the before-x sentence consists of only stop symbols). (2) we set z_t to the fixed vector value **0** for NMT_{ISG} to block the inter-sentence gate mechanism. (3) we set the context vector c_t^a of before-x to a random vector, the purpose of which is to test whether the information of the preceding sentence has bad influence on the translation of the current sentence when the preceding sentence is not quite related with the current sentence, for example, a topic change happens between x and before-x. The results are shown in Table 3, from which can find that:

- When we set before-x as NULL (+NULL in Table 3), the performance has an obvious decline comparing with that of NMT_{ISG}, but is still better than RNNSearch in term of BLEU score. We conjecture that the reasons for this are twofold. First, in the training process, when before-x dose not exist for the first sentence of a document, we set before-x to a NULL sentence, which makes NMT_{ISG} model learn the relevant capabilities. That is to say, NMT_{ISG} treats all sentences in the test sets as the first sentences of documents, where some sentences are correctly handled while others not. Second, the gate mechanism assigns a pretty low rate for NULL before-x during context combination.

- When we set the gate weight vector z to a fixed all-zero vector (+z=**0** in Table 3), NMT_{ISG} blocks the inter-sentence information from before-x. From the Table 3, we find a huge loss in performance. The NMT_{ISG} (+z=**0**) is even worse than RNNSearch by 2.31 BLEU points. Although the preceding sentence information is not used, this NMT_{ISG} (+z=**0**) is not exactly the baseline RNNSearch. There are two groups of parameters in NMT_{ISG}: one group of parameters (new parameters) are related with the inter-sentence gate and the other group of parameters (old parameters) are from

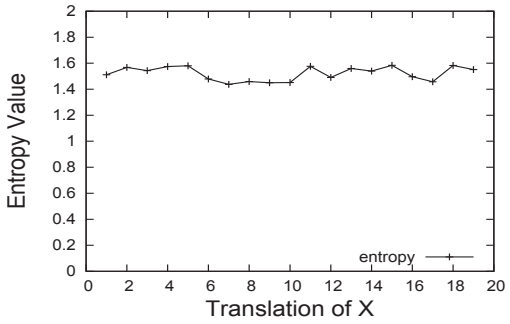

Figure 3: The entropy curve for a NULL preceding sentence. This is a sample generated by NMT_{ISG} in one test set. The horizontal axis represents the translation of a current sentence x. The vertical axis represents the entropy of the preceding sentence before-x obtained from the inter-sentence gate model when translating x.

RNNSearch but have been optimized towards the maximum usage of inter-sentence information. When the inter-sentence gate is closed, old parameters are not able to guide the decoder to generate translations that best use the current sentence information. That is the reason why this result is even worse than RNNSearch.

- When we set the context vector c_t^a of before-x to a random vector (+RV in Table 3), sampled from a uniform distribution between -1 and 1, the performance is worse than the baseline RNNSearch by 0.46 BLEU points. Setting the c_t^a to a random vector, the information from the pseudo preceding sentence becomes meaningless, and even has a bad or uncorrelated impact on the translation of the current sentence. However, the drop of the performance is not as big as that of NMT_{ISG} (+z=**0**). This suggests that the gate mechanism is able to effectively shield these useless and counteractive information from a pseudo and random preceding sentence.

The three experiments further demonstrate that the proposed inter-sentence gate is able to detect useful information for translation and block unrelated information and reconfirm that inter-sentence information is useful for translation.

5.4 Analysis on Inter-Sentence Attention

Many studies (Bahdanau et al., 2015; Luong et al., 2015) on attention-based NMT have proved that attention networks are able to detect alignments between parallel sentence pairs. In our NMT_{ISG} model, we use two attention networks: the first is built for the correspondences between the current source sentence and its target translation and the second for the correspondences between the preceding sentence and the target translation of the current sentence. We are interested in what correspondences the second attention network detect.

We use the entropy as the evaluation criterion to measure how attention weights distribute over words in the preceding sentence before-x for a target word in the translation of the current sentence x. If the attention distribution is even, the entropy will be large. Otherwise, the entropy is small, it suggests that the attention distribution is uneven and that the decoder pays attention to one or several particular words in the preceding sentence when generating a target word for the current sentence. The entropy is computed as follows:

$$H = -\sum_{j=1}^{n} \alpha_j log \alpha_j \tag{12}$$

We calculated entropy values in two cases:

- The before-x is a NULL sentence, being composed of stop symbols.
- The before-x is an ordinary sentence.

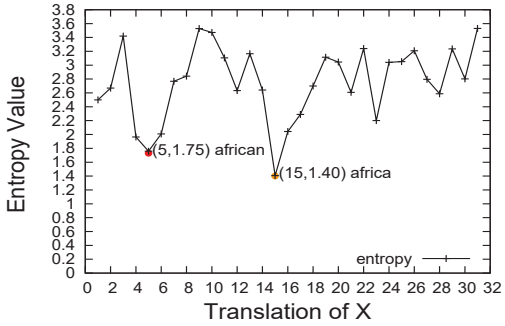

Figure 4: The entropy curve for a normal preceding sentence.

Before-x	进入 新 世纪 后 ， 经济 全球化 成为 非洲 国家面临 的 一个 重大 而 严峻 的 挑战 。
X	非洲 国家领导人 越来越 清楚 地 认识 到,非洲再也 不 能 坐失良机 , 应 奋起 寻求 应对 之 策 。
NMT_{ISG}	the leaders of the african countries have become more and more clearly aware that africa can no longer be able to UNK and take the initiative to pursue countermeasures.

Table 4: Example translation genereted by NMT_{ISG}, before-x is the preceding sentence of x.

If before-x is NULL, it cannot provide useful information except for the indicator of being the first sentence of a document. The attention weight distribution over stop symbols in before-x when generating a target word is supposed to be uniform. Figure 3 exactly visualizes such a case when translating the first sentence in a document. The entropy value in Figure 3 ranges from 1.44 to 1.58 while the entire curve is quite smooth.

Figure 4 demonstrates the second case with an example (in Table 4) where some words in the preceding sentence reoccur in the current sentence. When the NMT_{ISG} model generates the target translation for "非洲国家(feizhou guojia)" and "非洲(feizhou)", the entropy significantly drops as these words have occurred both in the preceding and current sentence. This indicates that the attention network in NMT_{ISG} successfully captures this word repetition (the most common lexical cohesion device) and convey such an inter-sentence relation collectively with the proposed inter-sentence gate to the prediction of target words via hidden states of the decoder.

5.5 Analysis on Translation Coherence

We want to further study how the proposed inter-sentence gate model influence coherence in document translation. For this, we follow Lapata and Barzilay (2005) to measure coherence as sentence similarity. First, each sentence is represented by the mean of the distributed vectors of its words. Second, the similarity between two sentences is determined by the cosine of their means.

$$sim(S_1, S_2) = cos(\mu(\vec{S_1}), \mu(\vec{S_2})) \tag{13}$$

where $\mu(\vec{S_i}) = \frac{1}{|S_i|} \sum_{\vec{w} \in S_i} \vec{w}$, and $\vec{w}$ is the vector for word w.

We use Word2Vec[2] to obtain the distributed vectors of words and English Gigaword fourth Edition as training data to train Word2Vec. We consider that embeddings from word2vec trained on large monolingual corpus can well encode semantic information of words. We set the vectors of words to 400.

Table 5 shows the average cosine similarity of adjacent sentences in test sets. From the table, we can find that the NMT_{ISG} model produces better coherence in document translation than RNNSearch in term of cosine similarity.

NMT_{ISG}	according to the UNK treaty signed between south korea and the united states, the number of us troops stationed in south korea is about UNK. the us troops stationed in south korea have been maintaining vigilance since last december last year when north korea's nuclear plan was exposed.

Table 6: Example translations genereted by NMT_{ISG}.

In order to better reflect the performance of the model about coherence, we also provide two examples displayed in Table 6 to verify the impact of inter-sentence information on document-level NMT. In the first example, source x does not have enough context information to correctly translate word "动作(dongzuo)". Fortunately, the before-x provides extra information: the background is about politices, which guide the decoder to select a better translation "action" for "动作(dongzuo)". In the second example, RNNSearch generates different translations for "驻韩(zhuhan)" and "驻南韩(zhunanhan)". NMT_{ISG} generates consistent translations for these two different words but with the same meaning.

6 Conclusion and Future Work

In this paper, we have presented a novel inter-sentence gate model for NMT to deal with document-level translation. Experimental results show that the NMT_{ISG} model achieves consistent and significant improvements in translation quality over strong NMT baselines. In-depth analyses further demonstrate that the proposed model inter-sentence gate is able to capture cross-sentence dependencies and lexical cohesion devices.

The proposed inter-sentence gate model only uses source-side information to capture document-level information for translation. In the future, we would like to integrate target-side information into document-level NMT.

Abstract

This paper focuses on subword-based Neural Machine Translation (NMT). We hypothesize that in the NMT model, the appropriate subword units for the following three modules (layers) can differ: (1) the encoder embedding layer, (2) the decoder embedding layer, and (3) the decoder output layer. We find the subword based on Sennrich et al. (2016) has a feature that a large vocabulary is a superset of a small vocabulary and modify the NMT model enables the incorporation of several different subword units in a single embedding layer. We refer these small subword features as hierarchical subword features. To empirically investigate our assumption, we compare the performance of several different subword units and hierarchical subword features for both the encoder and decoder embedding layers. We confirmed that incorporating hierarchical subword features in the encoder consistently improves BLEU scores on the IWSLT evaluation datasets.

Title and Abstract in Japanese

階層的部分単語特徴を用いたニューラル機械翻訳

本稿では、部分単語 (subword) を用いたニューラル機械翻訳 (Neural Machine Translation, NMT) に着目する。NMT モデルでは、エンコーダの埋め込み層、デコーダの埋め込み層およびデコーダの出力層の 3 箇所で部分単語が用いられるが、それぞれの層で適切な部分単語単位は異なるという仮説を立てた。我々は、Sennrich et al. (2016) に基づく部分単語は、大きな語彙集合が小さい語彙集合を必ず包含するという特徴を利用して、複数の異なる部分単語列を同時に一つの埋め込み層として扱えるよう NMT モデルを改良する。以降、この小さな語彙集合特徴を階層的部分単語特徴と呼ぶ。本仮説を検証するために、様々な部分単語単位や階層的部分単語特徴をエンコーダ・デコーダの埋め込み層に適用して、その精度の変化を確認する。IWSLT 評価セットを用いた実験により、エンコーダ側で階層的な部分単語を用いたモデルは BLEU スコアが一貫して向上することが確認できた。

1 Introduction

The approach of end-to-end Neural Machine Translation (NMT) continues to make rapid progress. A simple encoder-decoder model was proposed by Sutskever et al. (2014), and an attentional mechanism was added to better exploit the encoder-side information (Luong et al., 2015; Bahdanau et al., 2015). Compared to traditional Statistical Machine Translation (SMT), NMT has relatively simple architecture, which only uses a large single neural network, but its accuracy surpasses SMT (Junczys-Dowmunt et al., 2016).

A conventional NMT uses a limited vocabulary and a decoder generates a "word" in the vocabulary at each time step, but a problem occurs when it encounters an out-of-vocabulary word. Since NMT cannot correctly encode and generate such out-of-vocabulary words, the task performance is degraded. To solve this problem, Sennrich et al. (2016) proposed a method that expresses a word by combining "subwords."

Proceedings of the 27th International Conference on Computational Linguistics, pages 618–629
Santa Fe, New Mexico, USA, August 20-26, 2018.

A subword is a fraction of a word, determined by Byte Pair Encoding (BPE) operations. By the BPE operation, a word that appears frequently can be one unit, and rare or uncommon words can be expressed by the combination of several subword units. Thus we can express any words by the combination of small subword vocabularies to alleviate the out-of-vocabulary problem. Several similar works exist to make subword units (e.g., (Schuster and Nakajima, 2012; Kudo, 2018)), but in the following, we denote the units segmented by BPE as subword units unless otherwise noted.

The primary reason why we use subword units is to generate rare or unknown words on the decoder side. In other words, our purpose is to change the vocabulary at the decoder output layer into subwords. Once we decide the vocabulary in the decoder output layer, it is natural to use the same vocabulary in the decoder embedding layer. We also use subword units in the encoder side to maintain consistency with the decoder. As described, NMT has three layers that are related to subwords: the encoder embedding layer, the decoder embedding layer, and the decoder output layer. However, we generally use the same operations to make subword units.

We hypothesize that the optimal subword units can be different among these three layers. Since these layers play different roles in the model, the subword units should be determined based on each role. To validate this hypothesis, we modify the model to simultaneously deal with several different subword units.

We focus on the property that the large subword vocabulary is always a superset of the small subword vocabulary. By taking advantage of this, we propose the model uses these small subword vocabularies as additional features of an embedding layer. We name these small subword vocabulary features as hierarchical subword features. We simply use the sum of the embeddings of each hierarchical subword features to represent each embedding. This simple approach is GPU friendly and does not increase the computational time.

We empirically investigate our assumption and find that incorporating several different subword units for encoder embedding layers consistently improves the BLEU scores on the IWSLT 2012, 2013, and 2014 evaluation datasets.

2 Neural Machine Translation with Subword Units

Among many options for a model architecture of NMT models, our baseline's model architecture was introduced in Luong et al. (2015) with a global attention mechanism and a bi-directional encoder (Bahdanau et al., 2015).

2.1 Formulation

In general, the NMT model receives an input sentence and returns a corresponding (translated) output sentence. Here, to concisely explain the NMT model, its input and output are both sequences of one-hot vectors $\boldsymbol{X}$ and $\boldsymbol{Y}$ that respectively correspond to input and output sentences. This conversion can be performed straightforwardly without loss of generality since each token (word) has a one-to-one correspondence to a one-hot vector.

Let $\mathcal{V}_s$ and $\mathcal{V}_t$ respectively represent the vocabulary sizes of the input and the output. Let $\boldsymbol{x}_i \in \{0,1\}^{V_s}$ represent the one-hot vector of the i-th token in $\boldsymbol{X}$. Similarly, let $\boldsymbol{y}_j \in \{0,1\}^{V_t}$ represent the one-hot vector of the j-th token in $\boldsymbol{Y}$. We introduce notation $\boldsymbol{x}_{1:I}$ to represent a list of one-hot vectors, i.e., $(\boldsymbol{x}_1, \ldots, \boldsymbol{x}_I)$, as a short notation where I represents the length (the number of instances) of the list. Then the NMT model approximates the following conditional probability:

$$p(\boldsymbol{Y}|\boldsymbol{X}) = \prod_{j=1}^{J+1} p(\boldsymbol{y}_j|\boldsymbol{y}_{0:j-1}, \boldsymbol{X}), \tag{1}$$

where $\boldsymbol{y}_0$ is a one-hot vector of a special begin-of-sentence (BOS) token and $\boldsymbol{y}_{J+1}$ is a one-hot vector of a special end-of-sentence (EOS) token. Moreover, $\boldsymbol{X} = \boldsymbol{x}_{1:I}$ and $\boldsymbol{Y} = \boldsymbol{y}_{0:J+1}$.

Our baseline NMT model consists of three primary components (modules): encoder, attention, and decoder. The following briefly explains these three components. Hereafter, we assume that the number

of tokens in the input sentence is I, the number of tokens in the output sentence is J, the dimensions of the embedding vectors are D, and the dimensions of the hidden vectors are H.

Encoder: The encoder generates a list of hidden vectors $\boldsymbol{h}_{1:I}$ given an input sequence of one-hot vectors $\boldsymbol{x}_{1:I}$. Let $\boldsymbol{E} \in \mathbb{R}^{D \times |\mathcal{V}_s|}$ represent an (encoder) embedding matrix. Then $\texttt{Enc}(\cdot)$, which denotes a function that returns a list of encoded vectors $\boldsymbol{h}_{1:I}$, is calculated:

$$\boldsymbol{h}_{1:I} = \texttt{Enc}(\boldsymbol{e}_{1:I}), \quad \text{where} \quad \boldsymbol{e}_i = \boldsymbol{E}\boldsymbol{x}_i \quad \text{for all } i. \tag{2}$$

Finally, the encoder outputs $\boldsymbol{h}_{1:I}$.

Decoder and attention mechanism: The decoder estimates the probability of the output sentence given the encoded information generated by the encoder: $\boldsymbol{h}_{1:I}$. The attention mechanism allows the decoder to directly incorporate $\boldsymbol{h}_{1:I}$ at each decoder time step j.

Let $\boldsymbol{F} \in \mathbb{R}^{D \times |\mathcal{V}_t|}$ represent an (decoder) embedding matrix. Let $\texttt{Dec\_Attn}(\cdot)$ be a function that returns the final hidden vector at decoder time step j, namely, $\boldsymbol{z}_j$, which is calculated based on $\boldsymbol{f}_j$, $\boldsymbol{z}_{j-1}$, and $\boldsymbol{h}_{1:I}$ for all j:

$$\boldsymbol{z}_j = \texttt{Dec\_Attn}\big(\boldsymbol{z}_{j-1}, \boldsymbol{f}_j, \boldsymbol{h}_{1:I}\big), \quad \text{where} \quad \boldsymbol{f}_j = \boldsymbol{F}\boldsymbol{y}_{j-1}. \tag{3}$$

Here we assume that both $\boldsymbol{y}_j$ and $\boldsymbol{z}_j$ are zero-vectors if $j = 0$.

Then let $\boldsymbol{W} \in \mathbb{R}^{|\mathcal{V}_t| \times H}$ and $\boldsymbol{b} \in \mathbb{R}^{|\mathcal{V}_t|}$ be a weight matrix and a bias term in the decoder's output layer. Finally, the decoder calculates the probability of $\boldsymbol{y}_j$ at each time step j, which is $p(\boldsymbol{y}_j | \boldsymbol{y}_{0:j-1}, \boldsymbol{X})$ from Eq. 1:

$$p(\boldsymbol{y}_j | \boldsymbol{y}_{0:j-1}, \boldsymbol{X}) = \frac{\exp(\boldsymbol{o}_j) \cdot \boldsymbol{y}_j}{\exp(\boldsymbol{o}_j) \cdot \boldsymbol{1}}, \quad \text{where} \quad \boldsymbol{o}_j = \boldsymbol{W}\boldsymbol{z}_j + \boldsymbol{b}, \tag{4}$$

where $\boldsymbol{1}$ is a vector whose elements are all 1.

In the generation (test) phase, we generally use a K-best beam search to generate output sentences with the (approximated) K-highest probability given input sequence $\boldsymbol{X}$.

2.2 Subword Units Based on Byte-Pair Encoding

Several approaches have been proposed to obtain a set of subword units based on statistics, e.g., (Schuster and Nakajima, 2012; Sennrich et al., 2016). The scheme based on Byte-Pair Encoding (BPE) (Sennrich et al., 2016) is one of the most frequently used methods in current NMT researches. Following this trend, this paper focuses only on a method based on BPE to obtain a set of subword units and refers to Sennrich et al. (2016)'s method as SubW_{BPE} to distinguish it from others for clarity.

The following briefly describes the SubW_{BPE} procedure for building a set of subword units given a set of training data. SubW_{BPE} first splits the input sentences into character units and then combines the two frequently appearing consecutive (character or subword) units into one subword unit. SubW_{BPE} repeats this merge operation predefined m times. For splitting sentences into obtained subword units, we straightforwardly apply merge operations in the obtained order of the above procedure.

Here we revisit several interesting properties of SubW_{BPE}. For example, generated subword units become identical to the character units if and only if we set the number of merge operations m to zero ($m = 0$). All the subword units always recover and match the original word units if we set m to ∞ ($m = \infty$). These two properties imply that SubW_{BPE} naturally involves the methods using either character or word units in a single unified framework in terms of using subword units. Therefore, using SubW_{BPE}, we are not required to distinguish the methods of using character or word units since they are respectively just a special case of SubW_{BPE} with certain hyperparameters $m = 0$ and $m = \infty$. From this perspective, this paper does not explicitly distinguish among character, subword, and word units and treats all of them as subword units.

Another interesting property of SubW_{BPE} is that every subword unit obtained by $m = m'$ can be represented as a series of subword units obtained by $m = m''$ if $m' > m''$. This property is easily provable. SubW_{BPE} consists only of a *merge operation* of two consecutive subwords during the subword

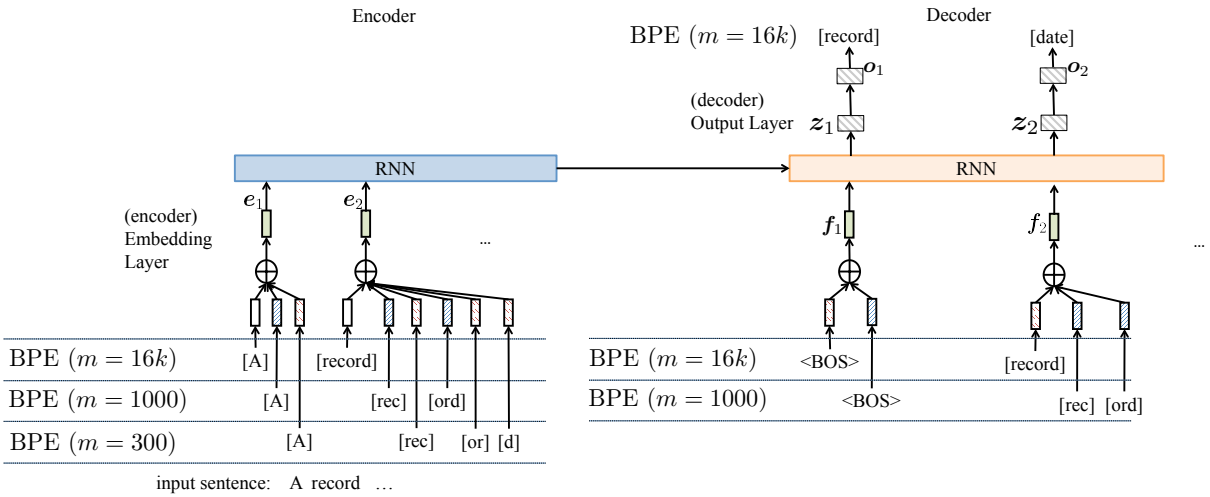

Figure 1: Overview of hierarchical subword features

unit construction, and thus, subword units with m are always identical to a subword with $m-1$ except the merged subwords as the m-th merge operation. Therefore, there is a relation where a subword unit obtained by a larger m is always a concatenation of (several) subword units obtained by a smaller m. This relation is always satisfied by any m' and m'' pairs, indicating a hierarchical *subword in subword* structure for all m from 1 to ∞.

Generally, the number of merge operations (m) is a hyperparameter that is empirically derived. Recent NMT researches usually set this m within a range from 1,000 to 100,000: apparently never less than 1,000 or over 100,000. This is because a set of subword units obtained with few merge operations resembles character units, and therefore the sentence becomes too long to process[1] On the other hand, since a set of subword units obtained with relatively large merge operations becomes nearly identical to the original word units, it lacks the advantage of using subword units. Hence, it is intuitively reasonable to set m in a range from 1,000 to 100,000.

3 Hierarchical Subword Features

Fig. 1 shows an overview of our proposed method. In it, we extend the encoder's and the decoder's embedding layers by modifying our model to work with several subwords units at once.

To formally explain our modification, we first introduce distinct Q encoder embedding matrices and R decoder embedding matrices. Let $\boldsymbol{E}_q$ represent the q-th encoder embedding matrix, where $q \in \{1, \ldots, Q\}$. Similarly, let $\boldsymbol{F}_r$ represent the r-th decoder embedding matrix, where $r \in \{1, \ldots, R\}$. Then we modify the operations to obtain encoder and decoder embedding vectors, which are shown respectively in Eqs. 2 and 3. For the encoder embedding vectors, we introduce the following operator:

$$\boldsymbol{e}_i = \sum_q \boldsymbol{E}_q \phi_q(\boldsymbol{x}_i), \tag{5}$$

where $\phi_q(\boldsymbol{x}_i)$ is a mapping function that returns a binary vector that corresponds to $\boldsymbol{x}_i$. For the decoder embedding vectors, we obtain $\boldsymbol{f}_j$ by the following equation:

$$\boldsymbol{f}_j = \sum_r \boldsymbol{F}_r \psi_r(\boldsymbol{y}_{j-1}), \tag{6}$$

where $\psi_r(\boldsymbol{y}_{j-1})$ is a mapping function that returns a binary vector that corresponds to previously estimated result $\boldsymbol{y}_{j-1}$. For example, if we get `record` as an estimation result of BPE(m =16k), mapping

[1] NMT lacks the ability to translate longer sentences (Koehn and Knowles, 2017).

Table 2: Model and optimization configurations

function $\psi_r(\boldsymbol{y}_{j-1})$ returns a binary vector that corresponds to the subwords with smaller merge operations (e.g., `rec` and `ord`). As we described in Section 2.2, every subword unit obtained with $m = m'$ can be represented as a series of subword units obtained with $m = m''$ if $m'' < m'$, and the series of subword units are uniquely determined. Thus, our modification can be interpreted as adding features of smaller subword units, which were derived from previously estimated output $\boldsymbol{y}_{j-1}$. We refer to our method that incorporates smaller subword features as *hierarchical subword features*.

Note that we use different embeddings for each hierarchical subword feature[2]. This means that NMT can learn different features for each hierarchical subword.

The hierarchical subword features slightly increased the number of model parameters (see Section 4.2.1 for more detail). However, increasing the memory requirement and runtime is limited, which allows us to run almost the same speed and memory requirement as the baseline system[3].

We can simultaneously use several subword features. In Fig. 1, we use both BPE (m =1k) and BPE (m=300) for the encoder side. By adding several subword features, the model can use more information with which we expect to improve the task performance.

4 Experiments

4.1 Setup

In this paper, we focused on from/to English (EN) to/from French (FR), German (DE) translations. We carried out our experiments on the IWSLT evaluation campaign dataset (Cettolo et al., 2012), which is based on a TED talk that has been translated into several languages. We used the IWSLT 2016 training set for the training models, tst2012 as the development set, and tst2013 and tst2014 as the test sets. For preprocessing, we used the Moses tokenizer[4] and the truecaser[5]. For the training set, we removed sentences over 50 words to clean the corpus. Table 1 shows the cleaned corpora statistics on the IWSLT datasets. To split words into subwords, we used the scripts[6] provided by Sennrich et al. (2016).

As an NMT framework, we used almost the same structure as Luong et al. (2015), except for our proposed embedding layers. Detailed NMT configurations are shown in Table 2. We set the initial

[2]We also tested using the same embeddings. However, we found through preliminary experiments that it is more effective to use different embeddings.

[3]The number of model parameters and size of the memory requirement largely depend on the vocabulary size. However, we use a smaller m (e.g., 1k or 300) for the hierarchical subword features, and since these features only affect the embedding layer, its effect on computational cost is limited.

Table 3: Compared experimental settings

learning rate to 1.0, but after 30 epochs we multiplied it by 0.8 for every epoch and continued training until 40 epochs. For decoding, we performed a beam search with a beam size of 20. To prevent the model from outputting short sentences, we applied the length normalization technique by dividing the negative log-likelihood by the sentence length (Cromieres et al., 2016; Morishita et al., 2017). As evaluation metrics, we used case-sensitive[7] BLEU scores (Papineni et al., 2002) using `multi-bleu.perl`[8].

To fix the experimental settings, we carried out a preliminary analysis to find the relation between the sentence length and the vocabulary size ($\simeq$ the number of BPE merge operations). Fig. 2 shows the results on the English sentences of the IWSLT 2016 German-English training set. When we reduce the vocabulary size, the average sentence length rapidly increases. Unfortunately, longer sentences require more computational cost and are time-consuming. Thus in our experiments, we set the baseline system's vocabulary size to 16,000, which balances the sentence length without affecting the advantage of the subwords.

The experimental settings are compared in Table 3. Our experiments answer the following questions:

- Does the hierarchical subword feature improve the model?
- Which part of the model should we use it? The encoder side, decoder side or both?
- How does it affect the translation results?

4.2 Results

Tables 4 and 5 show the experimental results with various word units and hierarchical subword features. All the scores are averages of four independently trained models. We used different parameter initialization and random seeds to train them. The score differences between the baseline system (a) and the proposed system are shown in the brackets.

(b) and (c) show some improvements using smaller subword units. However, as mentioned in Section 4.1 and shown in Fig. 2, these units are too small and lengthen the sentences. Thus computational time is also extended (see Table 6).

Then we added hierarchical subword features to the encoder side. From (d), (e), and (f), we confirmed that these features improved the model. System (f) uses both BPE (m =1k) and (m = 300)

[7] For a reference, we used a true-cased test set.

as hierarchical subword features and shows more improvement than using a single feature. Since these models use BPE(m =16k) as a unit, the computational cost is almost the same as the baseline system (a).

In (d), (e), and (f), we used BPE (m =16k) as a unit, but it is more natural to use "word" (BPE ($m = \infty$)) as a unit. For the comparison, we did experiments from word to BPE translation without hierarchical subword features (g). As we expected, that step degraded the accuracy more than the baseline with BPE. This is because its vocabulary contains many rare words, and thus it is difficult to train these word embeddings well. However, by adding hierarchical subword features ((h) to (k)), the accuracy improved at the same level as the system with BPE units. Hierarchical subword features helped the model correctly encode the rare words and improved the accuracy.

For system (h), we saw no improvement, perhaps because large subword units (e.g., BPE (m =16k)) seem too similar to the word units, so it did not help the model very much. Fig. 3 shows the relation

between the (sub-)word frequency and its rank on the English sentences of the German-English training set. The word's graph follows Zipf's law, and thus these word embeddings that appear a few times in the training set are relatively hard to train. The graph shows that BPE (m =16k) is almost the same as the word, because the frequently appearing subword pairs are connected until a subword to be a word. On the other hand, since each subword in BPE (m = 300) appears in the training set more frequently, its embedding layer is trained well. Perhaps the number of merge operations for the hierarchical subword features should be smaller than the one we commonly use. Our method can use both small and large subword features at once, thus we can cherry pick an advantage of small subword with maintaining the sentence length.

For systems (l), (m), and (n), we also added features to the decoder side, but we did not find as much improvement as the encoder side. A possible reason for this observation is that our method works

Table 7: BLEU scores on IWSLT German-to-English and English-to-German experiments. All scores are *ensembles* of four independently trained models.

as a regularizer of the model and might degrade the decoder's language modeling ability: in other words, its ability to predict the next token given previous tokens.

Even though (o) and (p) systems showed slight improvements from (f) and (k), such insignificant improvements suggest that the usefulness of (o) and (p) is limited.

Our results suggest the following conclusions: (1) add hierarchical subword features to the encoder side but not to the decoder side and (2) use fewer merge operations, e.g., $m=300$ and $m=1$k.

4.2.1 Number of Parameters and Required Training Time

Table 6 shows the number of parameters and required training times per epoch. The number of model parameters significantly increases if we add *word*-level features ((g), (h), (i), (j), (k), and (g)). In contrast, adding *subword*-level features does not significantly increase the number of parameters.

We also checked the required training times for each setting. The training time with hierarchical subword features is comparable to the baseline NMT. These results revealed that our methods do not require further computational costs and can be easily applied to any existing systems.

4.2.2 Model Ensembling Results

Tables 7 and 8 show the BLEU scores of ensembling four independently trained models. Hierarchical subword features consistently improved the BLEU scores even for ensembling. This means that our method can be applied to highly tuned systems such as the one submitted to WMT.

4.2.3 Example of Improved Translation

Table 9 shows an example of an improved translation from French to English. The input includes a rare combination of two words, "Britney Spears", which is a proper noun that is hard to translate. Table 10 shows an example of how the words "Britney Spears" were segmented into subwords. These words have been split into small bits of subwords. The subwords are slightly different based on the number of merge operations.

On the one hand, the baseline system with BPE 16k for both the encoder and decoder side cannot correctly translate the two words. On the other hand, our proposed system with hierarchical subword features did correctly translate them. One significant reason is that the embedding layer of subwords with large merge operations is not trained well, as described in Section 4.2. In contrast, our proposed model can make use of both large and small features for correct translations of such rare words.

5 Related Work

Sennrich and Haddow (2016) added linguistic features to NMT embedding layer and achieved significant improvement. They modified the embedding layer to exploit several features, such as part-of-speech tags and syntactic dependency labels. This method resembles our work in terms of providing more information to the embedding layer. However, to use these linguistic features, since we need to prepare a morphological analyzer and/or a dependency parser, applicable languages are limited. In our method, BPE features are language independent and applicable to all languages.

Our method can also be interpreted as a regularizer to the embedding layer. Recently, Kudo (2018) proposed a subword regularization method that uses different subword segmentation based on its segmentation probability. This method increases NMT's robustness to noise and segmentation errors. Their experiments showed that the subword regularization method is significantly effective when testing accuracy with a different dataset than the training set. This means that their method is effective with open-domain settings. Our method might have a similar tendency, but we will investigate in future work. It might be interesting to verify the effect of combining our method and the subword regularization method.

Several studies incorporated the Recurrent Neural Network (RNN) or the Convolutional Neural Network (CNN) into the embedding layer for encoding character-, subword-, or morpheme-level informa-

tion (Luong and Manning, 2016; Lee et al., 2017). Comparing with these approaches, our work has a significant advantage in terms of the fast computation since our method increases negligible computational cost as clarified in Section 4.2.1.

6 Conclusion

In this paper, we focused on neural machine translation with subword units and experimented with hierarchical subword features. Our experiments confirmed that adding hierarchical subword features to the encoder side consistently improved the BLEU scores. Our method, which is quite simple and easy to adapt to any models that use subwords as a unit (such as text summarization and language modeling), has the potential to be a de-facto standard in the future. Our codes and scripts are available for reproduction and further experiments[9].

In this paper, we just experimented with an RNN-based NMT, even though recently several new NMT architectures have been proposed, including an attentional-based (Vaswani et al., 2017) and a CNN-based NMT (Gehring et al., 2017). As future work, we want to try our method with these new NMT models and see whether it is effective. Future work will also apply hierarchical subword features to a larger dataset.

Abstract

We analyze some of the fundamental design challenges that impact the development of a multilingual state-of-the-art named entity transliteration system, including curating bilingual named entity datasets and evaluation of multiple transliteration methods. We empirically evaluate the transliteration task using the traditional weighted finite state transducer (WFST) approach against two neural approaches: the encoder-decoder recurrent neural network method and the recent, non-sequential Transformer method. In order to improve availability of bilingual named entity transliteration datasets, we release personal name bilingual dictionaries mined from Wikidata for English to Russian, Hebrew, Arabic, and Japanese Katakana. Our code and dictionaries are publicly available[1].

1 Introduction

Named entity transliteration is the process of converting a named entity from one language script to another, using the correct characters that represent the entity in the target language. It is an important component in many search and language understanding tasks, such as robust cross-language information retrieval (CLIR) and machine translation (MT), among others.

A possible simple transliteration approach is mapping every character (or sequence of characters) in the source language to its most common counterpart in the target language. However, spelling and pronunciation of many languages (e.g., English, Japanese) can be ambiguous and inconsistent (Fushimi et al., 1999). As a result, most transliteration systems are data driven and use context for disambiguation; *e.g.*, (Yan and Nivre, 2016; Haizhou et al., 2004; Ekbal et al., 2006).

While transliteration has been a long studied problem, some important aspects received little attention. There is not clear guidance that addresses a number of common design considerations faced when building a robust multilingual transliteration system, such as data representation and the huge gap in results depending on the language pairs and transliteration direction (Rosca and Breuel, 2016). Like many other NLP fields recently, *neural* transliteration systems have gained popularity. However, it is still unclear if neural systems consistently outperform traditional approaches and what architecture is ideal for this task. For example, in (Yan and Nivre, 2016) the authors applied a stack of convolutional layers and simple recurrent layer on top for English to Chinese transliteration, which achieved competitive results but still below a phrase-based statistical machine translation system. Other works show that bidirectional long short-term memory (LSTM) neural networks and the encoder-decoder architecture (Sutskever et al., 2014) achieve comparable results with WFST based n-gram models that are considered state-of-the-art (Rao et al., 2015; Yao and Zweig, 2015). However, these works only studied grapheme-to-phoneme (G2P) conversion from English to standard English pronunciation sets, such as the CMU pronunciation dictionary (Weide, 2014). Also, there is not empirical evidence comparing the neural encoder-decoder method with LSTM to the recently proposed Transformer (Vaswani et al., 2017) neural method on the

transliteration task. The Transformer method uses a simple neural network architecture based solely on attention mechanisms. That motivated us to learn if it can produce strong results on transliteration as it did on translation.

The contributions in this paper are summarized as follows:

- We enumerate and experimentally evaluate a number of design considerations important to building a named entity transliteration system such as: handling infrequent or unique name tokens in training and test data, building a bilingual training corpus from Wikidata[2], and top-1 versus top-k result performance.
- We present empirical results comparing design choices across four different language/script pairs mined from Wikidata: English to Hebrew, English to Russian, English to Arabic, and English to Katakana. We are releasing each of the bilingual datasets and the particular train, development, and test splits to encourage future experimentation and benchmarking.
- We empirically evaluate the traditional Weighted Finite State Transducer (WFST) approach against two neural network-based approaches: the sequence-to-sequence encoder-decoder architecture and the recent Transformer approach based of self-attention.

The rest of this paper is organized as follows: first, we briefly describe the traditional and neural approaches to transliteration present in the literature; second, we describe data collection considerations and our multilingual datasets; lastly, we describe our experimental setup, present a number of empirical results, and provide guidance based on our experience and analysis.

2 Transliteration Approaches

2.1 Traditional Approaches

Early transliteration works utilized dictionaries and phonetic resources to learn probabilistic mapping rules between languages (Knight and Graehl, 1998; Stalls and Knight, 1998). Later works introduced more robust methods that do not require an intermediate phonemic mapping and can learn direct orthographical mapping between two languages given a bilingual dictionary (Haizhou et al., 2004). Traditionally, such works are modeled based on the common Grapheme-to-Phoneme (G2P) joint-sequence modeling technique. Given word-to-pronunciation examples, an initial alignment between corresponding grapheme (word) and phoneme (pronunciation) sequences is learned. Then, a language model is learned on the aligned tokens (see (Bisani and Ney, 2008) for a detailed description of joint-sequence models for G2P). The open source Phonetisaurus (Novak et al., 2012) has shown to achieve state-of-the-art scores on different G2P tasks (Thu et al., 2016). Phonetisaurus implements the common EM-driven sequence alignment algorithm, with a few constraints such as allowing only m-to-one and one-to-m alignments. It trains an n-gram language model from the aligned pairs, which is converted into a Weighted Finite-State Transducer (WFST). Decoding can then be done by extracting the shortest path through the phoneme lattice created via composition with the input word.

2.2 Neural Approaches

Recent work in Neural Machine Translation (NMT) has proposed a number of approaches to use neural networks in variable-length sequence-to-sequence tasks such as transliteration. The encoder-decoder architecture (Sutskever et al., 2014) is a recurrent neural network setup with two parts. An *encoder* is fed input tokens one at a time and encodes them into a hidden state vector. At the end of the input sequence, an end-of-sentence token is fed to signify the end of the encoding phase. Next, the hidden state output of the encoder is fed into the *decoder*. The decoder emits tokens and updated hidden states, which are recursively fed into itself, until there are no more output tokens to produce. An additional mechanism, *attention* (Bahdanau et al., 2014), allows the decoder to focus on different parts of the input sequence and capture long-range dependencies. More recently, the Transformer (Vaswani et al., 2017)

[2] http://wikidata.org

model was proposed, which avoids the need for sequential processing, relying only on self-attention. A benefit of this approach is there is no information bottleneck in the encoded hidden state vector as in the Encoder-Decoder approach. Additionally, because there is no longer a sequential recurrent network, model training can be better parallelized, decreasing model training time.

Previous work applied variations of the encoder-decoder approach to the name transliteration task (Rosca and Breuel, 2016) and grapheme-to-phoneme transduction (Rao et al., 2015), suggesting strong results on both. (Rosca and Breuel, 2016) reports that on English to Japanese Katakana transliteration a unidirectional encoder-decoder with 2 hidden layers using gated recurrent unit (GRU) as the underlying neural cell type achieves the best result: a word error rate (WER) of 0.50.

3 Data

The transliteration shared task, as part of the named entities workshop (NEWS)[3], has been a continuous effort of benchmarking different transliteration approaches and systems across different languages. The workshop released multiple multilingual datasets over the years. However, datasets from previous years are not publicly available and their license is restrictive. That motivated us to create new multilingual datasets based on Wikidata that will be publicly available and free for all.

Wikipedia has been widely used in transliteration works (e.g., (Irvine et al., 2010; Rosca and Breuel, 2016; Pasternack and Roth, 2009)). Wikidata is a central knowledge base in all languages for Wikipedia and other Wikimedia projects. Most Wikidata pages contain labels[4] in one or multiple languages. We automatically collected all "en" (English) labels where they pair with one of the following labels: "ja" (Japanese), "he" (Hebrew), "ar" (Arabic), and "ru" (Russian). We filtered out labels containing characters not belonging to their main script (e.g., English labels containing non-Latin characters). For Japanese, we only included labels with Katakana characters. For English tokens, we did *not* strip out diacritics[5] as these may carry useful information in the context of named entity transliteration. We did convert all characters to lowercase and strip some punctuation such as underscores, braces, exclamation marks, etc.

The first version of our dataset contained many types of entities, such as song and book titles. A quick analysis of the data revealed that many label pairs are translations and not transliterations. Consequently, we used the Wikidata "instance-of" property to only include labels of type "human". There are significantly more pages of this type than any other type on Wikidata, and they are less noisy than other types for the transliteration task. Since no direction specific information was used in data gathering, we evaluate performance on both directions (*e.g.* English $\rightarrow$ Arabic and Arabic $\rightarrow$ English).

We also report performance on two publicly available datasets: (1) The CMU pronunciation dictionary (Weide, 2014); and (2) The Arabic to English dataset extracted from Wikipedia titles in (Rosca and Breuel, 2016). The former is used mainly for evaluating G2P systems and not named entity transliteration, but the two tasks are related and many papers use it solely for evaluation.

4 Experimental Setup

4.1 Data Representation

Pronunciation of English names usually does not carry context across tokens. In the majority of names, the pronunciation of a last name is independent of the previous tokens (middle or first names). Hence, it makes sense to train a transliteration system on name pairs that consist of a single token on each side. Our Wikidata datasets contain many multi-token names. Consequently, for constructing the train and test examples, we learn the word alignments of multi-token names, which is a simple task since the majority of name pairs contain the same word order, and we are not dealing with CJK languages with no token boundaries. The majority of our Katakana names contain a middledot to separate the tokens. We throw away English to Katakana name pairs if the English name contains more than one token and the Katakana

[3] http://workshop.colips.org/news2018/

[4] A Wikidata label is the most common name that the item would be known by. It does not need to be unique, in that multiple items can have the same label.

[5] We did not remove any Latin script characters

Table 1: Dataset statistics. Note that "EN" refers to English labels in Wikidata, but in our setup it actually means Latin script. That is why the source alphabet size exceeds 100 for all the four Wikidata datasets. As expected, the "EN-RU" dataset has the largest Latin alphabet size (source alphabet size).

Dataset	Total Size	Training Set Size	Avg. Source Length	Avg. Target Length	Source Alphabet Size	Target Alphabet Size
WD-EN-RU	164,640	105,371	7.0	6.6	188	62
WD-EN-KA	98,820	63,246	7.0	4.8	170	105
WD-EN-AR	74,973	41,584	6.7	5.9	145	67
WD-EN-HE	50,039	32,036	6.7	5.6	135	57
Rosca and B., 2016	15,898	12,877	6.0	6.8	48	39
CMUdict	126,191	113,438	7.5	6.3	27	39

name has no middledots or spaces. It is worth noting that the majority of Russian names in Wikidata are written as "last, first" and not "first last" as most other languages.

After alignment, we construct our cross-validation splits with only single, unique name tokens. Splitting names into single token examples produces many duplicates. For example, every name that starts with "John" would produce a "John" example. For train, development, and test splits, we only include a single instance for each unique name token. When we encounter multiple possible target script transliterations for the same English token, we only include the most frequent target transliteration[6]. We found that including multiple transliteration targets instead of only the single most-frequent one, only impacts performance in a small way, and thus, we opted for the simpler approach.

We used a typical 64/16/20 cross-validation split of the single token data. We used 64% of the data for training, 16% for a development evaluation set to pick hyperparameters, and a 20% held-out test set for metric reporting in Section 5. Our curated datasets are being released publicly in two forms. We are releasing the original name phrases where each line contains two tab-separated columns with the English name phrase in the first and the target script name phrase in the second column. Additionally, we are releasing the particular 64/16/20 splits of the aligned single token data in order that future researchers can replicate and benchmark against our results. Table 1 provides more information about the aligned, single token versions of each dataset.

For evaluating performance on the Arabic to English dataset from (Rosca and Breuel, 2016), we used the same train, dev, and test splits used in the paper. For evaluating CMUdict performance, we used the same 90% train, 10% split used in (Novak et al., 2012). We used these datasets without making any changes.

4.2 Libraries

We evaluate the previously discussed approaches using the following libraries:

- `Phonetisaurus` library[7] (Novak et al., 2012), the traditional WFST approach to sequence to sequence transduction.
- `seq2seq` library[8], the encoder-decoder recurrent neural network approach (Luong et al., 2017) as implemented in the TensorFlow (Abadi et al., 2015) machine learning platform.
- `tensor2tensor` library[9], the reference implementation of the Transformer approach to neural sequence to sequence transduction tasks (Vaswani et al., 2017), which is implemented on top of TensorFlow.

[6] We resolve ties by picking one of the targets arbitrarily

[7] `https://github.com/AdolfVonKleist/Phonetisaurus`

[8] `https://github.com/tensorflow/nmt`

[9] `https://github.com/tensorflow/tensor2tensor`

For the experiments using Phonetisaurus, we used the default configuration with an 8-order MITLM (Hsu and Glass, 2008) language model. For the many-to-many alignment, we disallowed ϵ-transitions on the source side and allowed them on the target side (with the `-seq2_del` option). For the encoder-decoder experiments, we simply adapted the Seq2Seq tutorial (Luong et al., 2017) to use the library for our character-level transliteration task. We used an LSTM cell-type, 2 hidden layers, 128 units per layer, a dropout probability of 0.2, and default 'luong' attention mechanism. Lastly, for the Tensor2Tensor experiments, we used the default configuration but tested with both 64 units per layer and 128 units per layer. Using 128 units per layer improved WER for every language by $\approx$ 2-3 points, and thus we only report results with 128 units. All of the scripts used in these experiments along with the mined Wikidata datasets are publicly available[10].

4.3 Evaluation Metric

Since many names may have multiple correct transliterations, in most experiments, we report the Word Error Rate (WER) metric, which is based on the proportion of name tokens that were transliterated and exactly match the expected target script from the test set (ground truth). The lower the WER score, the better. We report WER scores as 1-best, 2-best, and 3-best, which reflects when the correct transliteration occurs in the top spot, or in one of the top 2 spots, or in one of the top 3 spots. Since we do not penalize bad transliterations, 2-best is always at least as accurate as 1-best, and 3-best is always at least as accurate as 1-best and 2-best. We feel it is important to report in this way, because in many cases, such as information retrieval, it is feasible to generate multiple possible transliterations and use all of them at search time to improve recall. In other cases, such as text-to-speech, the top-1 result is the only result that matters, because the system only has a single opportunity to provide the correct transliteration.

5 Experimental Results

Table 2 summarizes the results of each method on different datasets. The recent Tensor2Tensor Transformer architecture outperforms the WFST approach and the Seq2Seq approach on every language. However, it is worth noting that the training time using Tensor2Tensor is between 5-8 hours using an AWS p3.2xlarge[11] instance type, which has a Tesla V100 GPU. The Phonetisaurus training time only takes a couple of minutes on a typical dual-core Intel Core-i7 personal laptop. We did not expect the WER difference between T2T and Phonetisaurus to be that significant. Our hypothesis was that given the small number of characters in every language and small average input size, the n-gram based models would be hard to beat. NMT approaches have a clear advantage in handling long term dependencies, but we expected that the small input size of our named entity tokens implied few important long term dependencies. The CMUdict dataset is the only case in which Phonetisaurus (slightly) outperforms the neural Transformer approach. One explanation is that the CMUdict dataset is not that challenging, as can be seen by the difference in WER compared to all other datasets.

Another observation is the WER gap between the languages. Among the English to X tasks, Katakana has the worse WER, followed by Arabic that is only slightly behind Hebrew. Given that Arabic and Hebrew belong to the same language family, it is not surprising that their WER is similar. Russian has the best WER by a large margin. It also has the largest training data and it is the closest language to English among the four evaluated. We were interested to learn the impact of training size on the error rate. Figure 2 shows learning curves for various datasets. We used Phonetisaurus since it was the fastest to train. One interesting observation is that training size is not a big factor. When the number of training examples is equal across all languages, Russian still has the best WER by a large margin and Katakana the worst by a large margin. Another interesting observation is that we reach close to optimal performance with about 50% of the training data. For example, WER on WD-EN-RU (English to Russian) is 0.40 and 0.38 after training on 50K and 100K examples, respectively. CMUdict has the steepest reduction in WER as the number of training examples increases, with WER of 0.33 and 0.28 after training on 50K and 100K examples, respectively.

Table 2: Word Error Rate (WER) using different methods for named entity transliteration. "WD" refers to our produced Wikidata datasets. "T2T" refers to the Tensor2Tensor system.

Task	Dataset	Method	1-best WER	2-best WER	3-best WER
English → Arabic	WD-EN-AR	T2T	**0.45**	**0.30**	**0.24**
		Seq2Seq	0.53	0.41	0.36
		Phonetisaurus	0.51	0.37	0.30
English → Hebrew	WD-EN-HE	T2T	**0.44**	**0.27**	**0.22**
		Seq2Seq	0.49	0.36	0.31
		Phonetisaurus	0.49	0.32	0.26
English → Katakana	WD-EN-KA	T2T	**0.51**	**0.35**	**0.29**
		Seq2Seq	0.60	0.48	0.43
		Phonetisaurus	0.57	0.43	0.36
English → Russian	WD-EN-RU	T2T	**0.35**	**0.22**	**0.17**
		Seq2Seq	0.40	0.29	0.25
		Phonetisaurus	0.38	0.24	0.19
Arabic → English	Rosca and B., 2016	T2T	**0.75**	**0.63**	**0.57**
		Seq2Seq	0.81	0.71	0.67
		Phonetisaurus	0.75	0.65	0.59
English → ARPAbet	CMUdict	T2T	0.29	0.16	0.11
		Seq2Seq	0.29	0.18	0.14
		Phonetisaurus	**0.27**	**0.14**	**0.10**

The seq2seq system consistently performed the worst. Based on design guidance in Neural Machine Translation literature (Sutskever et al., 2014), we experimented with feeding the source string in reverse order as this showed a significant improvement in encoder-decoder approaches. In our experiments, this did not meaningfully impact the WER. The resulting score was either identical or within one point for each of the language pairs that we tested.

5.1 Removing tokens that occur only once

One design question that we set out to answer is how to be handle unique name token pairs in dataset curation (e.g., the 'EN-KA' transliteration pair ["escalada", "エスカラーダ"] occurs only once in the data we collected from Wikidata). Name tokens, like other language tokens, follow a Zipfian distribution and thus there are likely to be many tokens that appear infrequently. On the one hand, tokens that occur only once may be erroneous, and it may be better to exclude them from the training and test sets. Taking the English to Hebrew dataset as an example, 77% of the name tokens only occur once. Our hypothesis was that given this distribution of token frequency, excluding them would likely remove more useful information than noise. Table 3 illustrates the impact of excluding single occurrence name tokens from both train and test against a baseline of training and testing on everything. All of these results use the Transformer neural approach with 128 units per layer and 2 hidden layers.

Comparing column 1 (baseline) and column 2 in Table 3 shows that excluding the infrequent tokens from test, results in a surprisingly high reduction in WER. If we also filter the tokens from train (as shown in column 4), we see an increase in WER. The worse WER is achieved when filtering the train set but testing on the full test set. In English to Hebrew (WD-EN-HE), filtering the train set but testing on the full set increases the WER by 7.0 points over the baseline. Industrial transliteration systems will contain dictionary look-ups for frequent named entity transliterations and employ automated methods, as evaluated here, to handle out-of-vocabulary cases. Thus, it stands to reason that a fair evaluation of automated methods should include infrequent names even in the presence of some noise. The results presented in other sections include unique tokens at both train and test time.

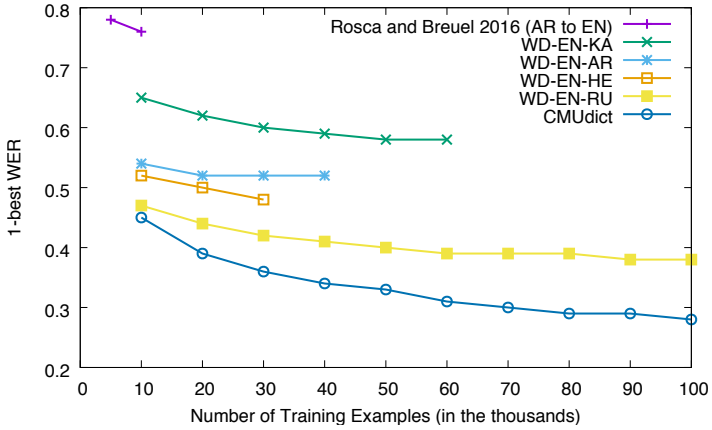

Figure 1: Phonetisaurus: Impact of the number of training examples on WER.

Table 3: T2T 1-Best Word Error Rate (WER) when filtering single occurrence name tokens from training and/or testing.

Dataset	**Full Train, Full Test (Baseline)**	**Full Train, Filtered Test**	**Filtered Train, Full Test**	**Filtered Train, Filtered Test**
WD-EN-AR	0.45	0.32	0.50	0.35
WD-EN-HE	0.43	0.31	0.50	0.35
WD-EN-RU	0.35	0.24	0.39	0.26
WD-EN-KA	0.50	0.36	0.56	0.41

An interesting question is why infrequent names in our data happen to be the hardest instances. One possible factor is that these names are less known to the public so there is no spelling convention to follow, leading to higher ambiguity. Wikidata labels are updated by many people from all over the world, hence name frequency can be thought as a proxy for annotator agreement. We also found that infrequent names in our data are longer on average, with a strong negative correlation between token frequency and token length. For example, the average length of all single occurrence English name tokens based on all of our test datasets is 7.1 characters, while the average length of all other English name tokens (at least two occurrences) is 6.4. Word-based evaluation metrics like we use here might be biased towards shorter names. Some prior works have used character-based metrics for transliteration, such as length-normalized edit distance (Irvine et al., 2010; Noeman and Madkour, 2010), which might be a good alternative (depending on the application).

5.2 English as source or target language

We performed experiments comparing the performance of modeling the transliteration problem as English $\rightarrow X$ versus $X \rightarrow$ English. Our hypothesis was that learning the transliteration with English as the source language was going to result in a lower word error rate due to the loss of information when going to languages like Hebrew or Arabic. Table 4 reports the differences in these two approaches. In every case using English as the source language results in much better word error rate, but the impact varies depending on the language. Hebrew and Arabic are impacted the most, and Russian is the least penalized. Previous works that focus on back-transliterating (recovering names of English origin) report similar findings (Irvine et al., 2010). In the error analysis section we provide some insights on why the reverse task is harder.

Table 4: T2T Word Error Rate (WER) when modeling as English to X versus X to English.

Dataset	Task	1-best WER	2-best WER	3-best WER
WD-EN-AR	English → Arabic	**0.45**	**0.30**	**0.24**
WD-EN-AR	Arabic → English	0.75	0.64	0.58
WD-EN-HE	English → Hebrew	**0.44**	**0.27**	**0.22**
WD-EN-HE	Hebrew → English	0.77	0.65	0.59
WD-EN-KA	English → Katakana	**0.51**	**0.35**	**0.29**
WD-EN-KA	Katakana → English	0.70	0.57	0.50
WD-EN-RU	English → Russian	**0.35**	**0.22**	**0.17**
WD-EN-RU	Russian → English	0.47	0.35	0.30

5.3 Error Analysis

Given the nature of Wikidata, our extracted datasets contain a diverse set of names from different origins, including many foreign names with different linguistic conventions. Names can be pronounced differently depending on origin and context can play a role as well. This explains why only outputting the top transliteration is usually not enough, as our results show. One example showing how hard the task can be is the Irish name "Domhnall", pronounced as DONAL, which none of the models transliterated correctly. The Hebrew, Arabic, and Russian models all included an 'm' in each of their 3-best outputs.

Figure 2 shows error examples in the various tasks. Vowel confusion is a common error. As expected, the Hebrew and Arabic models are affected by it the most. The problem becomes even worse when English is the target language. Hebrew and Arabic names in Wikidata, like in most of the web, do not include diacritical marks. This means that often English names with vowels are written in Arabic and Hebrew without the vowels. For example, "barak" is written as "brk" (in Hebrew letters) in modern Hebrew. When transliterating to English, the model often needs to recover the missing vowels. One of the figure examples is the name "Rashid"/"Rashed" that was transliterated incorrectly since the model failed to recover the letter 'i'/'e' that is not included in the original Arabic name. Vowel confusion is also a problem in Japanese, as the "ewan" example in the figure shows (the name Ewan MacGregor is quite known in Japan). The third best transliteration is "ユーアン", which differs from the correct transliteration only by the Katakana long vowel "ー". There seem to be different vowel variations in Katakana, such as long vs. short vowels. We found it often happens in the word final position. Having a special treatment to handle such cases could significantly boost accuracy. Some errors are more language specific. For example, in English to Russian the model often fails on the letter 'w' that can be ambiguous since the sound does not exist in Russian. The figure shows how the model made the same error in all three transliterations of the name "edwarda", replacing 'w' with the Russian letter 'В' ('v' sound), which is commonly used as a replacement.

Another interesting observation is that the models also fail on common names. This happens in all languages but more frequently occurs when English is the target language. For example, the Hebrew to English model transliterated "hillary" from Hebrew to English as "hilari", "hilarry", and "hillari". We believe this is a result of our problem setup. Since all our test names are unseen in training and every name only occurs once without making use of frequency info, the language model cannot learn that "hillary" is more common than "hilarry", for example, unless it is a sub-token of a longer name in training. Incorporating name frequency or large character-based n-gram language models learned from a large corpus (as in (Al-Onaizan and Knight, 2002; Irvine et al., 2010)) could possibly help such cases.

6 Future Directions

We will continue exploring best practices for multilingual transliteration. We are planning to evaluate design criteria for doing transliteration with CJK languages, where alignment is a more difficult problem. We are also interested to understand better the relationship between token frequency and transliteration

		Ground Truth	Prediction
Task	**Source**	**Target**	**3-best**
English → Russian	edwarda	эдуарда	эдварда эдворда эдварде
Russian → English	анатольевич	anatolyevich	anatolyevich anatolievitch anatoljević
English → Hebrew	hicham	הישאם	היצ'ם היחם היכהאם
Hebrew → English	הילרי	hillary	hilari hilarry hillari
English → Arabic	amos	عاموس	أموس اموس أمس
Arabic → English	راشد	rashid/rashed	rachd rašd -
English → Katakana	ewan	ユアン	エヴァン エワン ユーアン
Katakana → English	マツクイーン	mcqueen	mcquin mcquiin mcquine

Figure 2: Model errors across different languages

quality. Resources like Wikidata are extremely useful for curating large multilingual datasets, but some thought should be given to how we can reduce bias and noise with minimal effort, aiming to achieve quality that is comparable with manually annotated datasets. We believe that token frequency can be used as a proxy for annotator agreement and are planning to study this further. Finally, we are interested to study how well character-based NMT systems such as (Ling et al., 2015) perform on named entity transliteration.

7 Conclusions

We described a number of design considerations that one must address when building a robust, multilingual named entity transliteration system. We empirically demonstrated that the Tensor2Tensor neural Transformer method produces consistently strong results against the LSTM-based encoder-decoder neural method and WFST-based traditional method. We described a number of challenges and design choices when building bilingual dictionaries from mined knowledge bases, such as Wikidata. Our Wikidata curated datasets, including both the name phrase bilingual data and the aligned, single token datasets are being released for further experimentation and benchmarking.

Abstract

Recently, neural machine translation (NMT) has been extended to multilinguality, that is to handle more than one translation direction with a single system. Multilingual NMT showed competitive performance against pure bilingual systems. Notably, in low-resource settings, it proved to work effectively and efficiently, thanks to shared representation space that is forced across languages and induces a sort of transfer-learning. Furthermore, multilingual NMT enables so-called zero-shot inference across language pairs never seen at training time. Despite the increasing interest in this framework, an in-depth analysis of what a multilingual NMT model is capable of and what it is not is still missing. Motivated by this, our work (i) provides a quantitative and comparative analysis of the translations produced by bilingual, multilingual and zero-shot systems; (ii) investigates the translation quality of two of the currently dominant neural architectures in MT, which are the Recurrent and the Transformer ones; and (iii) quantitatively explores how the closeness between languages influences the zero-shot translation. Our analysis leverages multiple professional post-edits of automatic translations by several different systems and focuses both on automatic standard metrics (BLEU and TER) and on widely used error categories, which are lexical, morphology, and word order errors.

1 Introduction

As witnessed by recent machine translation evaluation campaigns (IWSLT (Cettolo et al., 2017), WMT (Bojar et al., 2017)), in the past few years several model variants and training procedures have been proposed and tested in neural machine translation (NMT). NMT models were mostly employed in conventional single language-pair settings, where the training process exploits a parallel corpus from a source language to a target language, and the inference involves only those two languages in the same direction. However, there have also been attempts to incorporate multiple languages in the source (Luong et al., 2015a; Zoph and Knight, 2016; Lee et al., 2016), in the target (Dong et al., 2015), or in both sides like Firat et al. (2016) which combines a shared attention mechanism and multiple encoder-decoder layers. Regardless, the simple approach proposed in Johnson et al. (2016) and Ha et al. (2016) remains outstandingly effective: it relies on single "universal" encoder, decoder and attention modules, and manages multilinguality by introducing an artificial token at the beginning of the input sentence to specify the requested target language.

The current NMT state-of-the-art includes the use of recurrent neural networks, initially introduced in Sutskever et al. (2014; Cho et al. (2014), convolutional neural networks, proposed by Gehring et al. (2017), and so-called transformer neural networks, recently proposed by Vaswani et al. (2017). All of them implement an encoder-decoder architecture, suitable for sequence-to-sequence tasks like machine translation, and an attention mechanism (Bahdanau et al., 2014).

Besides specific studies focusing on new architectures and modules, like Luong et al. (2015b) that empirically evaluates different implementations of the attention mechanism, the comprehension of what a model can learn and the errors it makes has been drawing much attention of the research community, as

Proceedings of the 27th International Conference on Computational Linguistics, pages 641–652
Santa Fe, New Mexico, USA, August 20-26, 2018.

evidenced by the number of recent publications aiming at comparing the behavior of neural vs. phrase-based systems (Bentivogli et al., 2016; Toral and Sánchez-Cartagena, 2017; Bentivogli et al., 2018). However, understanding the capability of multilingual NMT models in general and zero-shot translation, in particular, has not been thoroughly analyzed yet. By taking the bilingual model as the reference, this work quantitatively analyzes the translation outputs of multilingual and zero-shot models, aiming at answering the following research questions:

- How do bilingual, multilingual, and zero-shot systems compare in terms of general translation quality? Is there any translation aspect better modeled by each specific system?
- How do Recurrent and Transformer architectures compare in terms of general translation quality? Is there any translation aspect better modeled by each specific system?
- What is the impact of using related languages data in training a zero-shot translation system for a given language pair?

To address these questions, we exploit the data collected in the IWSLT 2017 MT evaluation campaign (Cettolo et al., 2017) and made publicly available by the organizers. The campaign was the first featuring a multilingual shared MT task, spanning five languages (English, Dutch, German, Italian, and Romanian) and all their twenty possible translation directions. In addition to the official external single reference of the test sets, we can also rely on professional post-edits of the outputs of nine Romanian→Italian and of nine Dutch→German participants' systems. Hence, we exploit the availability of multiple Italian and German references to perform a thorough analysis for identifying, comparing and understanding the errors made by different neural system/architectures we are interested in; in particular, we consider pairs of both related languages (Romanian→Italian, Dutch→German) and unrelated languages (Romanian→German and Dutch→Italian). Furthermore, to explore the impact of using data from other related languages, French and Spanish are considered for training purposes as well, in particular for analyzing the behavior of zero-shot x→Italian systems, x representing any source language distant from Italian.

In the following sections, we begin with a brief review of related work on quantitative analysis of MT tasks (§2). Then, we give an overview of NMT (§3) with a contrast between the Recurrent (§3.1) and Transformer (§3.2) approaches, and a summary on multilingual and zero-shot translation (§3.3). Section (§4), describes the dataset and preprocessing pipeline (§4.1), qualitative evaluation data (§4.2), experimental setting (§4.3), models (§4.4) and the evaluation methods (§4.5). In Section (§5), we analyze the overall translation quality for related and unrelated language directions. Before the summary and conclusion, we will focus on lexical, morphological and word-order error types for the fine-grained analysis (§6).

2 Related Work

Recent trends in NMT evaluation show that post-editing helps to identify and address the weakness of systems (Bentivogli et al., 2018). Furthermore, the use of multiple post-edits in addition to the manual reference is gaining more and more ground (Bentivogli et al., 2016; Koehn and Knowles, 2017; Toral and Sánchez-Cartagena, 2017; Bentivogli et al., 2018). For our investigation, we follow the error analysis approach defined in Bentivogli et al. (2018), where multiple post-edits are exploited in order to quantify morphological, lexical, and word order errors, a simplified error classification with respect to that proposed in Vilar et al. (2006), which settles two additional classes, namely missing and extra words.

The first work that compares bilingual, multilingual, and zero-shot systems comes from the IWSLT 2017 evaluation campaign (Cettolo et al., 2017). The authors analyze the outputs of several systems through two human evaluation methods: direct assessment which focuses on the generic assessment of overall translation quality, and post-editing which directly measures the utility of a given MT output to translators. Post-edits are also exploited to run a fine-grained analysis of errors made by the systems. The main findings are that (i) a single multilingual system is an effective alternative to a bunch of bilingual systems, and that (ii) zero-shot translation is a viable solution even in low-resource settings. Motivated by

those outcomes, in this work we explore in more detail the practical feasibility of multilingual and zero-shot approaches. In particular, we explore the benefit of adding training data involving related languages in a zero-shot setting and, in that framework, we compare the behavior of state-of-the-art Transformer and Recurrent NMT models.

3 Neural Machine Translation

A standard state-of-the-art NMT system comprises of an encoder, a decoder and an attention mechanism, which are all trained with maximum likelihood in an end-to-end fashion (Bahdanau et al., 2014). Although there are different variants of the encoder-attention-decoder based approach, this work focuses on the Recurrent LSTM-based variant (Sutskever et al., 2014) and the Transformer model (Vaswani et al., 2017).

In both the Recurrent and Transformer approaches, the encoder is purposed to cipher a source sentence into hidden state vectors, whereas the decoder uses the last representation of the encoder to predict symbols in the target language. In a broad sense, the attention mechanism improves the prediction process by deciding which portion of the source sentence to emphasize at a time (Luong et al., 2015b). In the following two subsections, we briefly summarize the two architecture types.

3.1 Recurrent NMT

In this case, the source words are first mapped to vectors with which the encoder recurrent network is fed. When the <eos> (i.e. end of sentence) symbol is seen, the final time step initializes the decoder recurrent network. At each time step of the decoding, the attention mechanism is applied over the encoder hidden states and combined with the current hidden state of the decoder to predict the next target word. Then, the prediction is fed back to the decoder (i.e. input feeding), to predict the next word, until the <eos> symbol is generated (Sutskever et al., 2014; Cho et al., 2014).

3.2 Transformer NMT

The Transformer architecture works by relying on a self-attention (*intra-attention*) mechanism, removing all the recurrent operations that are found in the previous approach.In other words, the attention mechanism is repurposed to compute the latent space representation of both the encoder and the decoder sides. However, with the absence of recurrence, *positional-encoding* is added to the input and output embeddings. Similarly, as the time-step in a recurrent network, the positional information provides the Transformer network with the order of input and output sequences. In our work, we use the absolute positional encoding, but very recently the use of the relative positional information has been shown to improve performance (Shaw et al., 2018). The model is organized as a stack of encoder-decoder networks that works in an auto-regressive way, using the previously generated symbol as input for the next prediction. Both the decoder and encoder can be composed of uniform layers, each built of two sub-layers, i.e., a multi-head self-attention layer and a position wise feed-forward network (FFN) layer. The multi-head sub-layer enables the use of multiple attention functions with a similar cost of utilizing attention, while the FFN sub-layer is a fully connected network used to process the attention sublayers; as such, FFN applies two linear transformations on each position and a ReLU (Vaswani et al., 2017).

3.3 Multilingual NMT

Recent efforts in multilingual NMT using a single encoder-decoder and an attention mechanism (Johnson et al., 2016; Ha et al., 2016) have shown to improve translation performance with minimal complexity. Multilingual NMT models can be trained with parallel corpora of several language pairs in *many-to-one, one-to-many*, or *many-to-many* translation directions. The main idea that distinguishes multilingual NMT training and inference from a single language pair NMT is that in preprocessing, a *language-flag* is appended to the source side of each segment pair. The flag specifies the target language the source is paired with at training time. Moreover, it enables a zero-shot inference by directing the translation to a target language never seen at training time paired with the source. In addition to reducing training and maintenance complexity of several single language pair systems, the two main advantages of multilingual

	encoder-decoder type	embedding size	hidden units	encoder depth	decoder depth	batch size
Recurrent	LSTM	512	1024	4	4	128 seg
Transformer	Self-Attention	512	512	6	6	2048 tok

Table 1: Hyper-parameters used to train Recurrent and Transformer models, unless differently specified.

NMT is the performance gain for low-resource languages, and the possibility to perform a zero-shot translation.

However, the translations generated by multilingual and zero-shot systems have not been investigated in detail yet. This includes analyzing how the model behaves solely relying on a "language-flag" as a way to redirect the inference. Recent works have shown that the target language-flag is weaker in a low-resource language setting (Lakew et al., 2017). Thus, in addition to analyzing the behavior of bilingual and multilingual models, mainly, the zero-shot task requires a careful investigation.

4 Data and Experiments

4.1 Datasets and preprocessing

The experimental setting comprises seven languages; for each language pair, we use the ≈200,000 parallel sentences made publicly available by the IWSLT 2017 evaluation campaign (Cettolo et al., 2017), partitioned in training, development, and test sets. In the preprocessing pipeline, the raw data is first tokenized and cleaned by removing empty lines. Then, a shared byte pair encoding (BPE) model (Sennrich et al., 2015) is trained using the union of the source and target sides of the training data. The number of BPE segmentation rules is set to $8,000$, following the suggestion of Denkowski and Neubig (2017) for experiments in small training data condition. For the case of Transformer training, the internal sub-word segmentation (Wu et al., 2016) provided by the Tensor2Tensor library[1] is used. Note that prepending the "language-flag" on the source side of the corpus is specific to the multilingual and zero-shot models.

4.2 Evaluation data

For our investigation, we exploit the nine post-edits available from the IWSLT 2017 evaluation campaign. Post-editing regarded the bilingual, multilingual, and zero-shot runs of three different participants to the two tasks Dutch (Nl)→German (De) and Romanian (Ro)→Italian (It). Human evaluation was performed on a subset (603 sentences) of the nine runs, involving professional translators. Details on data preparation and the post-editing task can be found in Cettolo et al. (2017).

The translation directions we consider in this work are Nl/Ro→De and Nl/Ro→It. The choice of *German* and *Italian* as the target languages is motivated by (i) the availability of multiple post-edits for the fine-grained analysis and (ii) the possibility of varying the linguistic distance between the source and the target languages, allowing experimental configurations suitable to answer the research questions raised in Section §1.

As said, for Nl→De and Ro→It the human evaluation sets consist of 603 segments. Since post-editing involved only those two language pairs, for the other two directions considered in this work, namely Nl→It and Ro→De, we tried to exploit at best the available post-edits by looking for all and only the segment pairs of the Nl→It and Ro→De tst2017 sets for which the target side exactly matches (at least) one of the segment pairs of the Ro→It and Nl→De human evaluation sets. This way, we were able to find 478 matches on the Italian sides and 444 on the German sides, which therefore become the sizes of the human evaluation sets of Ro→De and Nl→It, respectively, for which we can re-use the available post-edits.

It is worth to note that in general, the post-edits from the evaluation campaign are not actual post-edits of MT outputs generated in our experiments, with some exceptions discussed later, therefore they should rather be considered as multiple external references.

Model	#Directions	System description
NMT	1	*Four pure bilingual models for the Nl→De/It and Ro→De/It directions*
M-NMT	20	*Multilingual, trained on all directions in the set {En,De,Nl,It,Ro}*
ZST	16	*Zero-shot, trained as multilingual but removing also Nl↔De and It↔Ro data*
ZST_A	12	*Zero-shot, trained as ZST but removing also De↔Ro and Nl↔It data*
ZST_B	16	*Zero-shot, trained as ZST_A but adding En↔Fr/Es data*

Table 2: The training setting of 4*bilingual, 1*multilingual, and 3*zero-shot systems.

4.3 Training setting

Each of the three system types, namely bilingual, multilingual and zero-shot, is trained using both Recurrent and Transformer architectures, with the proper training data provided in the IWSLT 2017 evaluation campaign. Meta training parameters were set in a preliminary stage with the aim of maximizing the quality of each approach. Recurrent NMT experiments are carried out using the open source OpenNMT-py[2] (Klein et al., 2017), whereas the Transformer models are trained using the Tensor2Tensor toolkit. Hence, we took the precaution of selecting the optimal training and inference parameters for both approaches and toolkits. For instance, for our low-resource setting characterized by a high data sparsity, the dropout (Srivastava et al., 2014) is set to 0.3 (Gal and Ghahramani, 2016) in Recurrent models and to 0.2 in Transformer models to prevent over-fitting. Similarly, Adam (Kingma and Ba, 2014) optimizer with an initial learning rate of either 0.001 (RNN) or 0.2 (Transformer) is used. If the perplexity does not decrease on the validation set or the number of epochs is above 7, a learning rate decay of 0.7 is applied in the Recurrent case. For the Transformer case, the learning rate is increased linearly in the early stages (*warmup_training_steps*=16000); after that, it is decreased with an inverse square root of training step (Vaswani et al., 2017). Table 1 summarizes the list of hyper-parameters.

4.4 Models

To address the research questions listed in Section §1, we train five types of models using either the Recurrent or the Transformer approaches. All models are trained up to convergence, eventually the best performing checkpoint on the dev set is selected. Table 2 summarizes the systems tested in our experiments. As references, we consider four bilingual systems (in short NMT) trained on the following directions: Nl→De/It and Ro→De/It. The first term of comparison is a many-to-many multilingual system (in short M-NMT) trained in all directions in the set {En,De,Nl,It,Ro}. Then, we test zero-shot translation (ZST) between related languages, namely Nl→De and Ro→It, by training a multilingual NMT without any data for these language pairs. We also test zero-shot translation between unrelated languages (ZST_A), namely Ro→De and Nl→It, by excluding parallel data between these languages. Finally, for the same unrelated zero-shot directions we also train multi-lingual systems (ZST_B) that include data related to Romanian and Italian, namely En↔Fr/Es.

4.5 Evaluation methods

Systems are compared in terms of BLEU (Papineni et al., 2002) (as implemented in *multi-bleu.perl* [3]) and TER (Snover et al., 2006) scores, on the single references of the official IWSLT test sets.
In addition, two TER-based scores are reported, namely the multiple-reference TER (mTER) and a lemma-based TER (lmmTER), which are instead computed on the nine post-edits of the IWSLT 2017 human evaluation set. In mTER, TER is computed by counting, for each segment of the MT output, the minimum number of edits across all the references and dividing by the average length of references. lmmTER is computed similarly to mTER but looking for matches at the lemma level instead of surface forms. Significance tests for all scores are reported using Multeval (Clark et al., 2011) tool.
Systems are also compared in terms of three well known and widely used error categories, that is lexical, morphological, and word order errors, exploiting TER and post-edits as follows. First, the MT outputs

Direction	System	Recurrent				Transformer			
		BLEU	TER	mTER	lmmTER	BLEU	TER	mTER	lmmTER
Nl→De	NMT	18.05	64.61	23.70	20.60	**18.37**	**63.74**	27.95	23.86
	M-NMT	17.79	66.18	21.75	18.28	↑**19.95**	**61.90**	23.62	20.05
	ZST	17.06	65.73	26.35	22.29	↑**19.13**	**62.69**	**25.19**	**21.53**
Ro→It	NMT	22.16	59.35	22.99	20.39	**22.48**	**57.34**	26.60	23.36
	M-NMT	21.69	59.50	21.12	18.46	↑**22.12**	**57.51**	25.05	21.57
	ZST	18.72	62.08	29.66	26.15	↑**21.29**	**59.08**	**26.93**	**23.33**

Table 3: Automatic scores on tasks involving related languages. BLEU and TER are computed on test2017, while mTER and lmmTER are reported for human evaluation sets. Best scores of the Transformer model against the Recurrent are highlighted in bold, whereas arrow ↑ indicates statistically significant differences ($p < 0.05$).

and the corresponding post-edits are lemmatized and POS-tagged; for that, we used ParZu (Sennrich et al., 2013) for German and TreeTagger (Schmid, 1994) for Italian. Then, the lemmatized outputs are evaluated against the corresponding post-edits via a variant of the *tercom* implementation[4] of TER: in addition to computing TER, the tool provides complete information about matching lemmas, as well as shift (matches after displacements), insertion, deletion, and substitution operations. Since for each lemma the tool keeps track of the corresponding original word form and POS tag, we are able to measure the number of errors falling in the three error categories, following the scheme described in detail in Bentivogli et al. (2018).

5 Translation Analysis

5.1 Related languages

First, we compare the bilingual (NMT), multilingual (M-NMT), and zero-shot (ZST) systems on the two tasks *Nl→De* and *Ro→It*, implemented as either Recurrent or Transformer networks, in terms of automatic metrics. As stated above, BLEU and TER exploit the official external reference of the whole test sets, while mTER and lmmTER are utilize the multiple post-edits of the (smaller) IWSLT human evaluation test set. Scores are given in Table 3.

Looking at the BLEU/TER scores, it is evident that Transformer performs better in all the three model variants. In particular, for the multilingual and the zero-shot models, the gain is statistically significant. On the contrary, the mTER and lmmTER scores are better for the Recurrent architecture; in this case, the outcome is misleading since the nine post-edits include those generated by correcting the outputs of the three Recurrent systems. As such, the translations of the Recurrent systems are rewarded over the translations produced by the Transformer systems, thus making the comparison not fair.

As far as the models are compared, the bilingual one is the best in three out of four cases, the exception being the Transformer/Nl→De. Nonetheless, it is worth to note the good performance of the multilingual model in terms of mTER and lmmTER. This result holds true in both Recurrent and Transformer approaches, regardless of the BLEU score. We hypothesize that the main reason behind this is the higher number of linguistic phenomena observed in training, thanks to the use of data from multiple languages, which makes the multilingual models more *robust* than the bilingual models.

5.2 Unrelated languages

In unrelated language directions, our experimental setting is aimed at evaluating the impact of source *language-relatedness* with the target. Particularly, we focus on the zero-shot setup given its intrinsic difficulty, by taking the bilingual systems as references. Table 4 provides BLEU and TER based scores for the Ro→De and Nl→It directions.

Concerning the ZST_A training condition, in one case (Recurrent Ro→De) it outstandingly allows to outperform the pure bilingual system, while in the other cases there is no significant difference between

Direction	System	Recurrent				Transformer			
		BLEU	TER	mTER	lmmTER	BLEU	TER	mTER	lmmTER
Ro→De	NMT	13.99	72.70	61.82	54.61	$^{\uparrow}$**16.52**	**66.71**	**55.68**	**48.44**
	ZST_A	14.93	69.38	58.26	51.08	$^{\uparrow}$**16.46**	**66.88**	**54.72**	**48.25**
	ZST_B	14.75	69.29	58.26	51.37	$^{\uparrow}$**16.55**	**67.18**	**55.29**	**48.03**
Nl→It	NMT	18.88	63.79	58.79	52.16	$^{\uparrow}$**20.22**	**60.88**	**55.52**	**48.56**
	ZST_A	18.77	62.97	58.80	51.32	$^{\uparrow}$**19.80**	**60.24**	**54.06**	**47.16**
	ZST_B	18.87	62.40	57.34	50.17	$^{\uparrow}$**20.61**	**59.41**	**53.04**	**46.17**

Table 4: Evaluation results for the unrelated language directions. BLEU and TER scores are computed with single references, while mTER and lmmTER are computed with nine post-edits. Best scores of the Transformer over the corresponding Recurrent architectures are highlighted in bold, whereas arrow $^{\uparrow}$ indicates statistically significant differences ($p < 0.05$).

ZST_A and NMT, proving once again that zero-shot translation built on the "language-flag" of M-NMT is really effective (Johnson et al., 2016): in fact, at most a slight performance degradation is recorded as the number of pairs used in training decreases (Lakew et al., 2017). Although gains are rather limited, adding training data involving Romance target languages (French and Spanish, ZST_B) close to Italian impacts as hoped: ZST_B scores are in general better than both NMT and ZST_A in Nl→It, while they do not degrade with respect to ZST_A in Ro→De.
Similarly to what is observed for related pairs (Table 3), the Transformer architecture shows definitely higher quality than the RNN one, confirming the capability of the approach to infer unseen directions.
The overall outcomes from Tables 3 and 4 are: (i) multilingual systems have the potential to effectively model the translation either in zero-shot or non zero-shot conditions; (ii) zero-shot translation is a viable option to enable translation without training samples; (iii) the Transformer is the best performing approach, particularly in the zero-shot directions.
The next section is devoted to a fine-grained analysis of errors made by the various systems at hand, with the aim of assessing the outcomes based on automatic metrics.

6 Fine-grained Analysis

Following the error classification defined in Section 4.5, now we focus on lexical, morphological, and reordering error distributions to characterize the behavior of the three types of models and the two sequence-to-sequence learning approaches considered in this work.
As anticipated in the previous section, it is expected that scores computed with reference to post-edits penalize Transformer over Recurrent systems because the outputs of the latter were post-edited, but not those of the former. We try to mitigate this bias by relying on the availability of multiple post-edits which likely allows to better match the Transformer runs than having a single reference would do. For the fine-grained analysis, we use instead the expedient of computing error distributions that are normalized with respect to the error counts observed in a bilingual reference system. In the next two sections, the fine-grained analysis is reported for related and unrelated languages pairs, consecutively.

6.1 Related languages

Table 5 provides the distribution over the error types by the bilingual (NMT), multi-lingual (M-NMT), and zero-shot (ZST) models, implemented either with Recurrent or Transformer architectures, for the Nl→De translation direction. We also report, for each error type and M-NMT and ZST system, the observed relative difference of errors with respect to the bilingual reference model (NMT).
Considering each error category, we observe the same general trend for all systems: the lexical errors represent by far the most frequent category (76-77%), followed by morphology (15-16%) and reordering (3-6%) errors; cases of words whose morphology and positioning are both wrong, represent about 1-2% of the total errors. Beyond the similar error distributions, it is worth to note the variation of errors made by M-NMT and ZST models with respect to those of the NMT model: for the Recurrent

Nl→De	Recurrent					Transformer

Table 7: Error distribution of ZST_A and ZST_B models for the Recurrent and Transformer variants. Transformer achieves the highest error reduction, particularly in the ZST_B model setting.

architecture, there is a decrease of 9.69 and an increase of 9.84 points, respectively. On the contrary, the Transformer architecture yields improvements for both models: total errors reduce by 14.88 and 9.40 points, respectively. The result for the Transformer ZST system is particularly valuable since the average error reduction comes from remarkable improvements across all error categories.

For the Ro→It direction, results are given in Table 6. Although to a different extent, we observe a picture similar to that of Nl→De discussed above: lexical errors is the type of error committed to a greater extent, multilingual models outperform their bilingual correspondents (more for the Recurrent than for the Transformer models), and ZST is competitive with bilingual NMT only if the Transformer architecture is adopted.

Training under the zero-shot conditions ZST_A and ZST_B assume less training data available and permit to measure the impact of introducing additional parallel data from related languages. We considered training conditions ZST_A and ZST_B here to perform Ro→It zero shot translation and report the outcomes in Table 7.

Results show error counts for each condition normalized with respect to the corresponding bilingual reference models (NMT). The most interesting aspect comes from the fact that global variations in the normalized error counts of the zero-shot translation can be here associated with the relatedness and variety of languages in the training data. As recently reported (Lakew et al., 2017), zero-shot performance

Ro→De	Recurrent					Transformer

Table 9: Error distribution of the bilingual (NMT), ZST_A and ZST_B model runs. Δ_{NMT} shows the relative change in the error distribution of the zero-shot models with respect to the bilingual reference models.

of Recurrent models in a low resource setting seems highly associated with the number of languages provided in the training data. This is also confirmed by comparing performance of Recurrent models across the ZST (Table 6), ZST_A and ZST_B conditions. In particular, variations from the bilingual reference model, show significant degradation when some language directions are removed (from +27.07 to +33.81) and a significant improvement when two related languages are added (from +33.81 to +26.00). Remarkably, the Transformer zero-shot model seems less sensitive to the removal or addition of languages: actually a slight improvement is observed after removing Nl→It and De→Ro (ZST_A), i.e., from +2.45 to +1.53, followed by a large improvement when En→Fr/Es (ZST_B) are added, i.e. from +1.53 to -5.04. Notice that the latter results outperform the bilingual model. Overall, across all experiments, we see slight changes in the distribution of errors types. On the other hand, increases or drops of specific error types with respect to the bilingual reference model show sharper differences across the different conditions. For instance, the best performing Transformer model (ZST_B in Table 7) seems to gain over the reference bilingual systems only in terms of lexical errors (-5.21). The zero-shot Transformer model trained under the ZST condition (Table 6) although globally worse than the bilingual reference, seems instead slightly better than the reference concerning reordering error (-0.54), which account for 5.35% of the total number of errors.

6.2 Unrelated languages

In our second scenario, we evaluate the relative changes in the error distribution for the unrelated language directions (Ro→De and Nl→It). This section complements the translation results reported in Table 4, analyzing the runs from the ZST_A and ZST_B models in a different manner.

In the Ro→De unrelated direction (Table 8), the Recurrent model shows a reduction in the error rate of 5.60 points (ZST_A) and 6.21 points (ZST_B) with respect to the bilingual (NMT) reference model, while for the Transformer no significant differences are observed. These results confirm what observed in the automatic evaluation on the reference translations (Table 4). The gain observed by the Recurrent model on the ZST_B condition is mainly on lexical (-4.76 points) and reordering errors (-1.17 points) is probably due to the poor performance of its bilingual counterpart.

As far as the the Nl→It unrelated direction (Table 9) is concerned, both Recurrent and Transformer

ZST models show to reduce the error counts over the bilingual reference model. Actually, a similar trend occurs in Ro→De (Table 8), but with a relatively higher error reduction in case of the Transformer model. In particular, the Transformer model shows reductions of -2.29 points for ZST_A and -4.53 for ZST_B, whereas for the Recurrent model the improvements are slightly lower, namely -1.11 (ZST_A) and -4.14 (ZST_B) points. Remarkably, both the Recurrent and Transformer models benefit from additional training data related to Italian (compare ZST_A and ZST_B).

In conclusion, we observe that error counts of the zero-shot models in unrelated directions can increase (Table 8) when compared to the bilingual model. However, in the related language direction the most interesting aspect is observed with the discount of error in the Nl→It direction (Table 9). In particular, the ZST_B zero-shot model showed $>2.0\%$ error reduction over the ZST_A model. This gain is directly related to the newly introduced training data (i.e., English↔French/Spanish) in case of ZST_B.

Summary and Conclusions

In this work, we showed how bilingual, multilingual, and zero-shot models perform in terms of overall translation quality, as well as the errors types produced by each system. Our analysis compared Recurrent models with the recently introduced Transformer architecture. Furthermore, we explored the impact of grouping related languages for a zero-shot translation task. In order to make the overall evaluation more sound, BLEU and TER scores were complemented with mTER and lmmTER, leveraging multiple professional post-edits. Our investigation on the translation quality and the results of the fine-grained analysis shows that:

- Multilingual models consistently outperform bilingual models with respect to all considered error types, i.e., lexical, morphological, and reordering.
- The Transformer approach delivers the best performing multilingual models, with a larger gain over corresponding bilingual models than observed with RNNs.
- Multilingual models between related languages achieve the best performance scores and relative gains over corresponding bilingual models.
- When comparing zero-shot and bilingual models, relatedness of the source and target languages does not play a crucial role.
- The Transformer model delivers the best quality in all considered zero-shot condition and translation directions.

Our fine-grained analysis looking at three types of errors (lexical, reordering, morphology) show significant differences in the error distributions across the different translation directions, even when switching the source language with another source language of the same family. No particular differences in the error distributions were observed across neural MT architectures (Recurrent vs. Transformer), while some marked differences were observed when comparing bilingual, multilingual, and zero-shot systems. A more in-depth analysis of these differences will be carried out in future work.

On Adversarial Examples for Character-Level Neural Machine Translation

Javid Ebrahimi, Daniel Lowd, Dejing Dou
Computer and Information Science Department, University of Oregon, USA
{javid, lowd, dou}@cs.uoregon.edu

Abstract

Evaluating on adversarial examples has become a standard procedure to measure robustness of deep learning models. Due to the difficulty of creating white-box adversarial examples for discrete text input, most analyses of the robustness of NLP models have been done through black-box adversarial examples. We investigate adversarial examples for character-level neural machine translation (NMT), and contrast black-box adversaries with a novel white-box adversary, which employs differentiable string-edit operations to rank adversarial changes. We propose two novel types of attacks which aim to remove or change a word in a translation, rather than simply break the NMT. We demonstrate that white-box adversarial examples are significantly stronger than their black-box counterparts in different attack scenarios, which show more serious vulnerabilities than previously known. In addition, after performing adversarial training, which takes only 3 times longer than regular training, we can improve the model's robustness significantly.

1 Introduction

Last year, a mistranslation by Facebook's machine translation (MT) system led to a wrongful arrest (Berger, 2017). Instead of translating an Arabic phrase to "good morning," Facebook's MT translated it as "attack them." Arabic is a morphologically-rich language, and the MT mistook the input word for another which differs from the input by only one character. As MT is used more and more, it is increasingly important to understand its worst-case failures to prevent incidents like this.

Adversarial examples are inputs designed to make a machine learning model perform poorly, and are often constructed by manipulating real-world examples (Goodfellow et al., 2015). Belinkov and Bisk (2018) investigate the sensitivity of neural machine translation (NMT) to synthetic and natural noise containing common misspellings. They show that state-of-the-art models are vulnerable to adversarial attacks even after a spell-checker is deployed. By performing ensemble adversarial training (Tramèr et al., 2018), they improve an NMT's robustness to adversarial noise.

We explore the space of adversarial examples for NMT in two directions: first, we study untargeted adversarial examples in a *white-box* setting, wherein the adversary has access to model parameters and can use its gradients to inflict more damaging manipulations for a larger decrease in the BLEU score; second, equipped with the developed machinery to do white-box attacks, we can perform more interesting attacks. We propose *controlled* and *targeted* adversaries which create adversarial examples with other goals, instead of merely decreasing the BLEU score. A controlled adversary aims to mute a word in the original translation, while a targeted adversary aims to push a word into it. Table 1 shows one example of each category. In both cases, the adversary, which has no word alignment model, has not drastically changed the rest of the translation, and has been able to reach its goals.

There is growing interest in understanding vulnerabilities of NLP systems (Jia and Liang, 2017; Zhao et al., 2018; Belinkov and Bisk, 2018). Previous work in NLP has focused on creating adversarial examples in a *black-box* setting, wherein the attacker can query a model but does not have access to its

parameters. Black-box attacks often rely on heuristic methods to create adversarial examples. In contrast, white-box attacks approximate the *worst-case* attack for a particular model and input, within some allowed set of perturbations. Therefore, white-box attacks can demonstrate and defend against a model's most serious vulnerabilities, which may not be discovered by black-box heuristics.

After exploring the space of adversarial examples for NMT and proposing new types of attacks, we focus on adversarial training to make our model more robust. We build on HotFlip (Ebrahimi et al., 2018), a recently-introduced white-box method for generating adversarial examples and performing adversarial training for text classification. At the core of HotFlip lies an atomic *flip* operation, which changes one character to another by using the gradients of the model with respect to the one-hot vector input. In this work, we extend it to include a broader set of attacks, and we also improve it with a better beam search heuristic and faster adversarial training.

Our contributions are as follows:

1. We use a gradient-based estimate, which ranks adversarial manipulations, and we search for adversarial examples using greedy search or beam search methods.

2. We propose two translation-specific types of attacks and provide a metric to evaluate adversaries in these scenarios. Our experiments show that white-box adversaries can be significantly stronger than black-box adversarial examples.

3. We investigate the robustness of models trained with white-box adversarial examples and compare their robustness with black-box trained models.

2 Related Work

The need to understand vulnerabilities of NLP systems is only growing. Companies such as Google are using text classifiers to detect abusive language[1], and concerns are increasing over deception (Zubiaga et al., 2016) and safety (Chancellor et al., 2016) in social media. In all of these cases, we need to to better understand the dynamics of how NLP models make mistakes on unusual inputs, in order to improve accuracy, increase robustness, and maintain security or privacy. While this line of research has recently received a lot of attention in the deep learning community, it has a long history in machine learning, going back to adversarial attacks on linear spam classifiers (Dalvi et al., 2004; Lowd and Meek, 2005).

Character-level NMT systems (Lee et al., 2017; Costa-Jussa and Fonollosa, 2016) and those based on sub-word units (Sennrich et al., 2016) are able to extract morphological features which can generalize unseen words. Belinkov and Bisk (2018) show that character-level machine translation systems are overly sensitive to random character manipulations, such as keyboard typos. They use black-box heuristics to generate character-level adversarial examples, without using the model parameters or gradients to generate adversarial examples. The major challenge in creating white-box adversarial examples for text is that optimizing over discrete input is difficult (Miyato et al., 2017), which is why previous work has focused on black-box adversarial examples. Zhao et al. (2018) search for black-box adversarial examples in the space of encoded sentences and generate adversarial examples by perturbing the latent representation until the model is tricked. However, it is not clear how many queries are sent to the model or what the

[1]https://www.perspectiveapi.com

success rate of the adversary is. We contrast black-box and white-box attacks and show how white-box attacks significantly outperform their black-box counterparts in controlled and targeted attack scenarios.

Adversarial training/regularization interleaves training with generation of adversarial examples (Goodfellow et al., 2015). Concretely, after every iteration of training, adversarial examples are created and added to the mini-batches. This technique has been used for text classification (Miyato et al., 2017) using adversarial noise on the word embeddings without creating real-world adversarial examples. Jia and Liang (2017) point out the difficulty of adversarial training with real-world adversarial examples, as it is not easy to create such examples efficiently. In this work, we improve the training time of HotFlip (Ebrahimi et al., 2018) by using a one-shot attack in our inner adversary, which makes the running time of adversarial training only 3 times slower than regular training.

3 White-Box Adversarial Examples

Editing text to trick an NLP model, constrained by the number of characters to change, r, is a combinatorial search problem. We develop a gradient-based optimization method to perform four text edit operations: namely, flip (replacing one character with another), swap (replacing two adjacent characters with each other), delete, and insert. We use derivatives with respect to one-hot representation of the input, to rank candidate changes to text, in order to search for an adversarial example which satisfies the adversary's goal. Compared with a black-box adversary, our method has the overhead of sorting or searching among derivatives, while being considerably more successful.

3.1 Definitions

We use $J(\mathbf{x}, \mathbf{y})$ to refer to the log-loss of the translation model on source sequence $\mathbf{x}$ and target sequence $\mathbf{y}$. Let V be the alphabet, $\mathbf{x}$ be a text of length L characters, and $x_{ij} \in \{0,1\}^{|V|}$ denote a one-hot vector representing the j-th character of the i-th word. The character sequence can be represented by

$$\mathbf{x} = [(x_{11},.. \; x_{1n});(x_{21},.. \; x_{2n});...(x_{m1},.. \; x_{mn})]$$

wherein a semicolon denotes explicit segmentation between words. The number of words is denoted by m, and n is the number of maximum characters allowed for a word[2].

3.2 Derivatives of Operations

We represent text edit operations as vectors in the input space, and estimate the change in loss by directional derivatives with respect to these operations. Based on these derivatives, the adversary can choose the best loss-increasing operation. Our algorithm requires just one function evaluation (forward pass) and one gradient computation (backward pass) to estimate the best possible flip.

A **flip** of the j-th character of the i-th word ($a \rightarrow b$) can be represented by this vector:

$$\vec{v}_{ijb} = (\vec{0},..;(\vec{0},..(0,..\text{-}1,0,..,1,0)_j,..\vec{0})_i; \vec{0},..)$$

where -1 and 1 are in the corresponding positions for the a-th and b-th characters of the alphabet, respectively, and $x_{ij}^{(a)} = 1$. A first-order approximation of change in loss can be obtained from a directional derivative along this vector:

$$\nabla_{\vec{v}_{ijb}} J(\mathbf{x}, \mathbf{y}) = \nabla_x J(\mathbf{x}, \mathbf{y})^T \cdot \vec{v}_{ijb} = \frac{\partial J}{\partial x_{ij}}^{(b)} - \frac{\partial J}{\partial x_{ij}}^{(a)} \quad (1)$$

Using the derivatives as a surrogate loss, we simply need to find the best change by **maximizing** eq. 1, to *estimate* the best character change ($a \rightarrow b$). This requires searching in $|V|mn$ values for a given text of m words with n characters each, in a vocabulary of size $|V|$.

Similarly, character **insertion**, **deletion**, and **swap** of adjacent characters can be represented as vectors which carry the information about the direction and number of flips. Since the magnitudes of operation vectors are different, we normalized them by both L_1 and L_2 norm but found it had little impact.

A black-box adversary can perform similar manipulations which would be randomly picked. For example, Belinkov and Bisk (2018) define `Key` operation, which flips one character with an adjacent one on the keyboard, at random.

[2]Padding is applied if the number of characters is fewer than the maximum.

3.3 Controlled and Targeted Attacks

The previous adversary was untargeted, and its only goal was to increase the loss of the model. However, some corruptions of the output may be much worse than others – translating "good morning" as "attack them" is much worse than translating it as "fish bicycle." By changing the loss function, we can force the adversary to focus on more specific goals.

In a *controlled attack*, the adversary tries to remove a specific word from the translation. This could be used to maintain privacy, by making more sensitive information harder to translate, or to corrupt meaning, by removing key modifiers like "not," "joked,"' or "kidding." Concretely, we maximize the loss function $J(x, y_t)$, where t is the target word. This way, the adversary ignores the rest of the output and focuses on parts of the input that would affect the target word most.

In a *targeted attack*, the adversary aims to not only mute a word but also replace it with another. For example, changing the translation from "good morning"' to "good attack" could lead to an investigation or an arrest. Making specific changes like this is much more dangerous, but also harder for the adversary to do. For this attack, we maximize the loss $-J(x, y_{t'})$, where $t^{'}$ is the new word chosen to replace t. Note that the negation makes this equivalent to minimizing the predictive loss $J(x, y_{t'})$ on $t^{'}$. We represent this as maximization so that it fits in the same framework as the other attacks. Our derivative-based approach from the previous subsection can be then used directly to generate these new attacks, simply by substituting the alternate loss function.

3.4 Multiple Changes

We explained how to estimate the best single change in text to get the maximum increase/decrease in loss. We now discuss approaches to perform multiple changes.

(a) **one-shot:** In this type of attack, the adversary manipulates all the words in the text with the best operation in parallel. That is, the best operation for each word is picked locally and independently of other words. This is efficient, as with only one forward and backward pass, we can collect the gradients for all operations for all words. In addition, compared with the global one-shot method of Ebrahimi et al. (2018), it does not require sorting the gradients globally, and can further reduce the time to create adversarial examples. It is less optimal than the next approaches, which apply changes one by one. Due to its efficiency, this is the approach we choose to do adversarial training. Our experiments in section 6, which are untargeted, follow this approach. We also investigate black-box and white-box variants of one-shot attacks in section 5.1. The budget for the adversary is the number of words, and it is spent in the first shot.

(b) **Greedy:** In this type of attack, after picking the best operation in the whole text, we make another forward and backward pass, and continue our search. Our controlled attack in section 5.2 follows this approach, where we allow a maximum of 20% of the characters in text as the budget for the adversary. As will be explained in 5.2, the adversary spends much less than this amount.

(c) **Beam Search**: And finally, we can strengthen our greedy search by beam search. Our beam search requires only $\mathcal{O}(br)$ forward passes and an equal number of backward passes, with r being the budget and b, the beam width. At every step, the beam will be sorted by the sum of the true loss up to that point, which we have computed, plus the gradient-based estimate of candidate operations. This showed better performance than using the sum of the gradients in the path for sorting the beam, as was previously done (Ebrahimi et al., 2018). Since targeted attacks are the most difficult type of attack, we use this strategy for targeted attacks, as described in section 5.3. We allow a maximum of 20% of the characters in text as the budget for the adversary, and set the beam width to 5.

4 Experiments

We use the TED talks parallel corpus prepared by IWSLT 2016 (Mauro et al., 2016) for three pairs of languages: German to English, Czech to English, and French to English. We use the development sets and test sets of previous years except 2015 as our development set. The statistics of the dataset can be

Pair	Train	Test	Target vocab.
FR-EN	235K	1.1k	69k
DE-EN	210K	1.1k	66k
CS-EN	122K	1.1k	49k

Table 2: Data Statistics

found in Table 2. Throughout our experiments, we only allow character changes if the new word does not exist in the vocabulary, to avoid changes that an MT would respond to as expected. For example, it is not surprising that changing the source German word "nacht" to "nackt" would cause an MT to introduce the word "nude" in the translation.

The architecture we study was first proposed by Kim et al. (2016) for language modeling, and later adapted by Costa-Jussa and Fonollosa (2016) for translation, and is also used by Belinkov and Bisk (2018) for their adversarially-trained models. In this architecture, feature extraction is performed by convolutions over characters, which are passed to layers of highway networks, and finally given to stacks of recurrent neural nets for modeling a sequence of words. Using this architecture, the BLEU scores on our datasets are competitive with the submissions to the IWSLT (Mauro et al., 2016). Our implementation[3] relies largely on Yoon Kim's seq2seq implementation[4], with similar hyper-parameters, which mostly follows the guidelines of Luong et al. (2015) for attentional translation.

For experiments in section 6, where we report the BLEU score for a vanilla model and several adversarially-trained models against different attackers, we use a decoder with a beam width of 4. However, our white-box attacker uses a model with greedy decoding to compute gradients. The reason is that in order to calculate correct gradients, we either need to use greedy decoding, or use models which incorporate beam search in the decoder architecture such that gradients could flow in the beam paths, too (Wiseman and Rush, 2016), which incur more computational cost. Correct gradients are more of an important issue for targeted attacks, where we want to achieve a goal beyond simply breaking the system. For the sake of consistency, we use greedy decoding for both the vanilla model which is being attacked, and the white-box attacker in all experiments of section 5, where we contrast white-box and black-box adversaries in different scenarios.

5 Analysis of Adversaries

We first study whether first-order approximation gives us a good estimator to be employed by white-box adversaries. Figure 1 compares the true increase in log-loss (i.e., $J(x+v) - J(x)$), with our gradient-based estimate (i.e., $\nabla_v J(x)$). We create adversarial examples using the best estimated character flip for every word, over the German test set. Then, we compare the true increase in loss for the created adversarial examples, with our gradient-based estimate. The log-loss is evaluated by summing the log-loss of individual words, and similarly, the gradient-based estimate is the sum of all gradients given by flips which are performed once on every word. Figure 1.a plots the histograms for both of these measures, and Figure 1.b shows a scatter plot of them with the least squares fitting line. Due to linearization bias of the first-order approximation, we have a distribution with smaller variance for the gradient-based estimate measure. We can also observe a moderately positive correlation between the two measures (Spearman coefficient $\rho = 0.61$), which shows we can use the gradient-based estimate for *ranking* adversarial manipulations.

Next, we contrast black-box and white-box adversaries in untargeted, controlled, and targeted scenarios, and demonstrate that white-box adversaries significantly outperform black-box adversaries especially in controlled and targeted scenarios.

5.1 Untargeted Attack

Table 3 shows the BLEU score after one-shot white-box and black-box attacks are performed. Unlike delete and swap, insert and flip have the advantage of making changes to one-letter words, so we expect

[3]https://github.com/jebivid/adversarial-nmt

[4]https://github.com/harvardnlp/seq2seq-attn

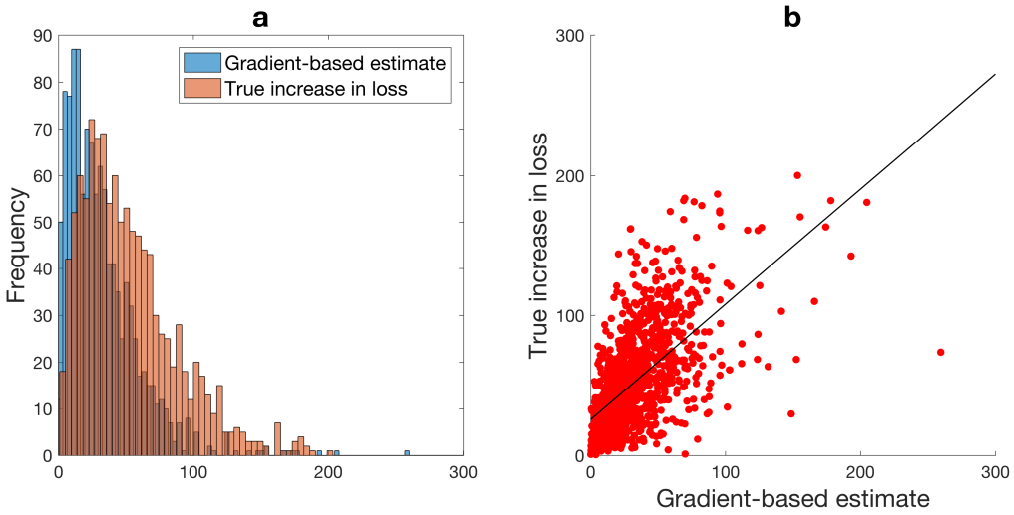

Figure 1: Comparing the distribution of the true increase in loss and its gradient-based estimate, and their correlation, using best flips for each word in a sentence of the German test set.

them to perform better. We see this for the white-box attacks which can pick the best change to every word using the gradients. On the contrary, a black-box adversary performs worst for flip, which is because the black-box attacker is not enabled to pick the best change when more options (possible character flips) are available, as opposed to swap and delete which are governed by the location of the change and contain no additional flip. Nevertheless, a black-box adversary has competitive performance with the white-box one, even though it is simply randomly manipulating words. We argue that evaluating adversaries, based on their performance in an untargeted setting on a brittle system, such as NMT, is not appropriate, and instead suggest using goal-based attacks for evaluation.

Attack	Flip		Insert		Delete		Swap	
	white	black	white	black	white	black	white	black
FR	**4.27**	6.98	**4.74**	4.85	**4.99**	5.86	**4.87**	5.20
DE	**4.50**	6.87	**3.91**	4.31	**5.63**	5.73	4.94	**4.74**
CS	**4.31**	6.09	**4.66**	5.86	**6.30**	6.62	6.05	**5.82**

Table 3: BLEU score after greedy decoding in the existence of different types of untargeted attacks.

5.2 Controlled Attack

We introduce more interesting attacks, in which the adversary targets the MT for more specific goals. A perfect *mute* attack removes a word successfully and keeps the rest of the sentence intact. For example, consider the translation T, containing words w_1, w_2,..., w_t, ...w_n, where w_t is the target word. A perfect mute attack will cause the NMT to create a translation T_p which contains words w_1, w_2,..., UNK, ...w_n, wherein w_t is replaced with UNK. With this observation in mind, we define the success rate of an attack, which generates T_{adv}, as follows:

$$\text{success}(T_{adv}) = \begin{cases} 1, & \text{if } \frac{\text{BLEU}(T, T_{adv})}{\text{BLEU}(T, T_p)} \geq \alpha \\ 0, & \text{otherwise} \end{cases}$$

We can control the quality of an attack with α, for which a larger value punishes the adversary for ad-hoc manipulations, which could cause the NMT to generate a radically different and possibly gibberish translation. Success rate is defined by the number of successful attacks divided by the number of total sentences in the test set. Figure 2 plots the success rate against α. As can be seen, the white-box adversary is significantly more successful than a black-box adversary. By taking advantage of the knowledge of

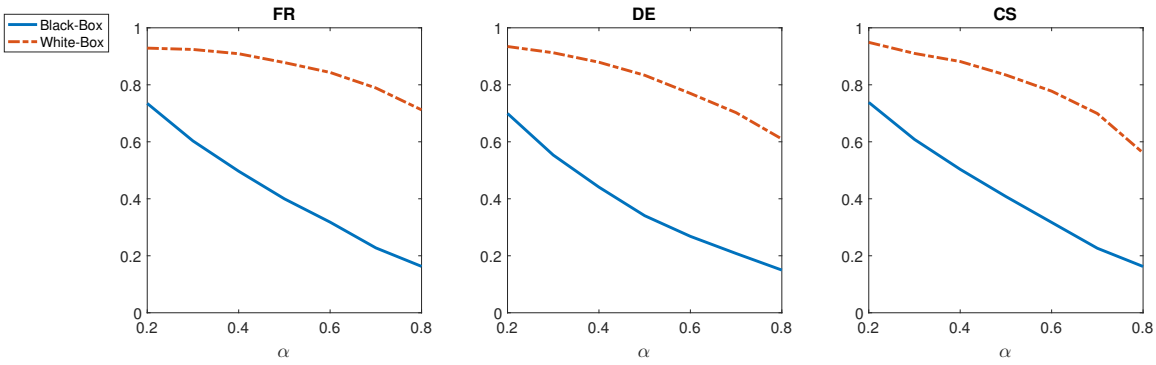

Figure 2: Success rate of white-box and black-box adversaries in a controlled setting as a function of α.

gradients of the model, a white-box adversary can perform better targeted attacks. For this experiment, the black-box attacker uniformly picks from the four possible changes and randomly applies them.

For this attack, we follow the greedy approach, and use a budget of 20% of the characters in text. Table 4 shows the average number of character changes and the number of queries made to the model. The reported character changes are for attacks wherein the attacker only muted a target word successfully, regardless of the quality of the translation. The reported number of queries takes the unsuccessful trials into account too. The white-box adversary is more efficient due to fewer queries and fewer manipulated characters, which can be crucial for a real-word adversary. Nevertheless, unlike a black-box adversary, a white-box adversary requires additional backward passes, and has the overhead of operations on the gradient values, mainly sorting. This makes the running times of the two comparable.

Compared with the results in the previous section, controlled attacks show a more convincing superiority of the white-box attacks over black-box attacks.

	Character Changes		Queries	
source	white	black	white	black
FR	**1.9**	7.7	**2.3k**	8.9k
DE	**1.9**	6.5	**1.9k**	7.8k
CS	**1.5**	5.3	**1.2k**	6.1k

Table 4: Efficiency of attacks.

5.3 Targeted Attack

A more challenging attack is to not only mute a word but also replace it with another one. The evaluation metric for targeted attack is similar to controlled attack with one difference that a perfect *push* attack produces a translation, T_p, which contains words w_1, w_2, $w_{t'}$,..w_n, wherein $w_{t'}$ has replaced w_t. In classification domains with few classes, targeted attacks are relatively simple, since an adversary can perturb the input to move it to the other side of a decision boundary. Whereas in MT, we deal with vocabulary sizes in the order of at least tens of thousands, and it is less likely for an adversary to be successful in targeted attacks for most possible target words. To address this, we evaluate our adversary with n^{th}-most likely class attacks. In the simplest case, we replace a target word with the second-most likely word at decoding time.

As can be seen in Table 3, targeted attacks are much more difficult with a much lower success rate for the adversary. Nevertheless, the white-box adversary still performs significantly better than the black-box adversary. The success rate dramatically goes down for large values of n. For example, for the value of 100, the success rate will be more than ten times smaller than second-most likely attack.

5.4 Some Adversarial Examples

Table 5 shows three adversarial examples. The first example shows a controlled attack, where the adversary has successfully removed a swear word from the sentence. The BLEU ratio, used in our success

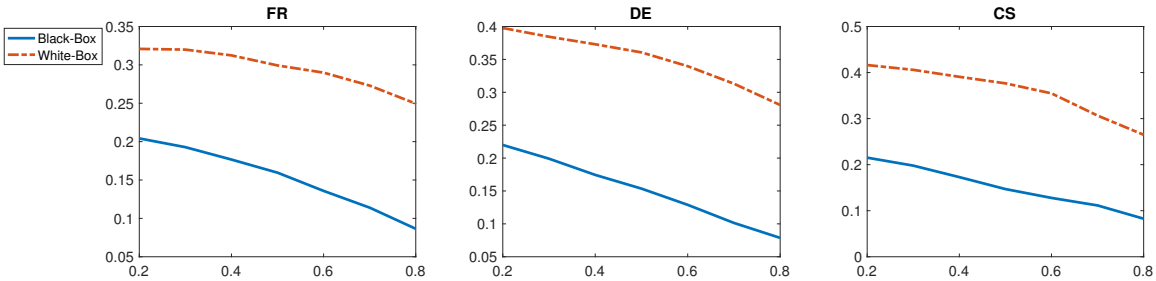

Figure 3: Success rate of white-box and black-box adversaries in the second-most likely targeted attack as a function of α.

src-output	A war is no longer a **competition** between states, like it used to be.
adv-output	A war is no longer a **throwaway** planet between states, as it used to be.

Table 5: A controlled attack and two targeted attacks on our DE-EN NMT. First example shows a controlled attack, the second and third examples show a second-most and a 100_{th}-most likely targeted attack, respectively.

rate measure, for this example is 0.52. The second example shows a second-most likely targeted attack where the new translation has managed to keep the rest of the translation intact and achieve its goal. The BLEU ratio for this example is 1.00. The third example, which has a BLEU ratio of 0.70, shows a 100^{th}-most likely attack, where the word *competition* is replaced with *throwaway*. Due to the difficulty of this change, the adversary has committed a considerably larger number of manipulations.

6 Robustness to Adversarial Examples

6.1 Baselines

We use the black-box training method of Belinkov and Bisk (2018) as our baseline. They train several models using inputs which include noise from different sources. We used their script[5] to generate random (`Rand`), keyboard (`Key`), and natural (`Nat`) noises. Their best model was one which incorporated noise from all three sources (`Rand+Key+Nat`).

Similar to their approach, we train a model which incorporates noisy input scrambled by Flips, Inserts, Deletes, and Swaps in training (`FIDS-B`). Since natural noise was shown to be the most elusive adversarial manipulation (Belinkov and Bisk, 2018), we used this source of noise to determine the proportion of each of the FIDS operations in training. Concretely we found that the majority of the natural noise can be generated by FIDS operations, and we used the ratio of each noise in the corpora to sample from these four operations. Figure 4 shows the distribution of manipulations for each language. A single swap is the least likely operation in all three languages[6]. FIDS operations account for 64%, 80%, and 70% of natural noise for Czech, German, and French, respectively. This can be regarded as a background knowledge incorporated into the adversary.

[5]https://github.com/ybisk/charNMT-noise

[6]Excluding single swaps from manipulations with two flips.

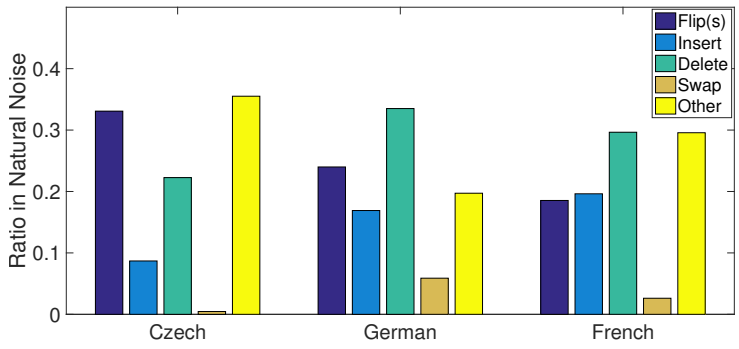

Figure 4: Distribution of types of noise in the natural noise corpora.

6.2 White-Box and Ensemble Methods

Our white-box adversary `FIDS-W` generates adversarial examples using our four text edit operations in accordance with the distribution of operations on the natural noise. At every epoch, adversarial examples are generated for every mini-batch using the one-shot approach. More precisely, all words in the sentence are changed by a single FIDS operation in parallel. While training on both clean and adversarial examples has been the standard approach in adversarial training, some evidence in computer vision (Madry et al., 2017; Shaham et al., 2015) suggests that training on white-box adversarial examples alone can boost models' robustness to adversarial examples, with a minor decrease in accuracy on clean examples. However, we found that in order to get a good BLEU score on the clean dataset, we need to train on both clean and white-box adversarial examples. We also train an ensemble model, `Ensemble`, which incorporates white-box and black-box adversarial examples, with 50/50 share for each. The black-box adversarial examples come from `Nat` and `Rand` sources.

When evaluating models against `White` adversarial examples at test-time, we use the test set which corresponds to their method of training. For instance, the `White` adversarial examples for the `Rand` model, come from the test set which has manipulated clean examples by `Rand` noise first. For `Vanilla`, `FIDS-W`, and `Ensemble` models, the adversarial examples are generated from clean data. This makes the comparison of models, which are trained on different types of data, fair. We use the one-shot attack for our white-box attack evaluation, using the same distribution based on natural noise.

6.3 Discussion

Table 6 shows the results for all models on all types of test data. Overall, our ensemble approach performs the best by a wide margin. As expected, adversarially-trained models usually perform best on the type of noise they have seen during training. However, we can notice that our `FIDS-W` model performs best on the `Nat` noise amongst models which have not been trained on this type of noise. Similarly, while `FIDS-W` has not directly been trained on `Key` noise, it is trained on a more general type of noise, particularly flip, and thus can perform significantly better on the `Key` than on other models which also have not been trained on this type of noise. However, it cannot generalize to `Rand`, which is an extreme case of attack, and we need to use an ensemble approach to perform well on it too. Nevertheless, `FIDS-W` performs best on the `Rand` noise, compared with models which are not trained on `Rand` either. This validates our earlier claim that training on white-box adversarial examples, which are harder adversarial examples, can make the model more robust to weaker types of noise. We also observe that `FIDS-B` performs better on the `White` examples compared with other baselines; although it has not been trained on white-box adversarial examples, it is trained on black-box adversarial examples of the same family of FIDS operations.

Figure 5 shows the training loss of white-box adversarially-trained model on adversarial examples. The model is getting more resilient to adversarial examples, which are created at the start of each epoch.

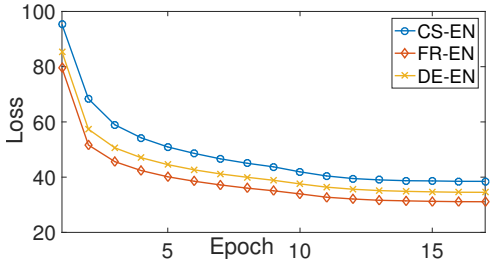

Figure 5: Training loss on adversarial examples for FIDS-W.

Training \ Test		Clean	Nat	Key	Rand	FIDS-B	FIDS-W	Avg.

Table 6: BLEU score of models on clean and adversarial examples, using a decoder with beam size of 4. The best result on each test set is shown in bold. FIDS-W performs best on all noisy test sets compared with models which have not been trained on that particular noise (shown in red). FIDS-B performs best on white-box adversarial examples compared with other black-box trained models (shown in blue).

7 Conclusion and Future Work

As MT methods become more effective, more people trust and rely on their translations. This makes the remaining limitations of MT even more critical. Previous work showed that NMT performs poorly in the presence of random noise, and that its performance can be improved through adversarial training. We consider stronger adversaries which are attacking a specific model and may also have specific goals, such as removing or changing words. Our white-box optimization, targeted attacks, and new evaluation methods are a step towards understanding and fixing the vulnerabilities in NMT: we're able to find more effective attacks and train more robust models than previous black-box methods. Next steps include exploring other types of targeted attacks, such as attacks that target more than one word, and other types of constraints, such as better characterizing which character changes affect intelligibility the least.

Systematic Study of Long Tail Phenomena in Entity Linking

Filip Ilievski, Piek Vossen, Stefan Schlobach

De Boelelaan 1105, 1081 HV Amsterdam
The Netherlands
{f.ilievski, piek.vossen, k.s.schlobach}@vu.nl

Abstract

State-of-the-art entity linkers achieve high accuracy scores with probabilistic methods. However, these scores should be considered in relation to the properties of the datasets they are evaluated on. Until now, there has not been a systematic investigation of the properties of entity linking datasets and their impact on system performance. In this paper we report on a series of hypotheses regarding the long tail phenomena in entity linking datasets, their interaction, and their impact on system performance. Our systematic study of these hypotheses shows that evaluation datasets mainly capture head entities and only incidentally cover data from the tail, thus encouraging systems to overfit to popular/frequent and non-ambiguous cases. We find the most difficult cases of entity linking among the infrequent candidates of ambiguous forms. With our findings, we hope to inspire future designs of both entity linking systems and evaluation datasets. To support this goal, we provide a list of recommended actions for better inclusion of tail cases.

1 Introduction

The task of Entity Linking (EL) anchors recognized entity mentions in text to their semantic representation, thus establishing identity and facilitating the exploitation of background knowledge, easy integration, and comparison and reuse of systems. The past years featured a plethora of EL systems: DBpedia Spotlight (Daiber et al., 2013), WAT (Piccinno and Ferragina, 2014), AGDISTIS MAG (Moussallem et al., 2017), to name a few. These systems propose various probabilistic algorithms for graph optimization or machine learning, in order to perform disambiguation, i.e., to pick the correct entity candidate for a surface form in a given context. The reported accuracy scores are fairly high, which gives an impression that the task of EL is both well-understood and fairly solved by existing systems.

At the same time, several papers (Ilievski et al., 2016; Van Erp et al., 2016; Esquivel et al., 2017; Ilievski et al., 2017) have argued that state-of-the-art EL systems base their performance on frequent 'head' cases, while performance drops significantly when moving towards the rare 'long tail' entities. This statement seems intuitively obvious, but no previous work has quantified what the 'head' and 'tail' of EL entails. In fact, the lack of definition of head and tail in this task prevents the (in)validation of the hypothesis that interpreting some (classes of) cases is more challenging for systems than others. This, in turn, means that we are currently unable to identify the difficult cases of EL for which current systems need to be adapted, or new approaches need to be developed. Previous linguistic studies which analyze words distributions can not be applied for this purpose, because they do not study reference, nor the relation of the head-tail distribution to system performance.

Understanding the tail cases better and explicitly addressing them in systems design will be beneficial because: 1. a lot of textual data and requirements for processing it are made up of long tail cases, 2. unlike the head entities, the knowledge about tail entities is less accessible (in structured or unstructured form), not redundant, and hard to obtain. 3. to perform well on the tail, systems are required to interpret entity references without relying on statistical priors, but by focusing on high-precision reasoning.

Proceedings of the 27th International Conference on Computational Linguistics, pages 664–674
Santa Fe, New Mexico, USA, August 20-26, 2018.

This paper addresses the question: **which data properties capture the distinction between the head and the tail in entity linking, and to what extent?** Its main contributions are the following:

1. We define the long tail properties of entity linking **(Section 3)**.[1] This is the first work that looks systematically into the relation of surface forms in datasets and their instances in DBpedia, and provides predictions in the form of a series of hypotheses about long tail phenomena.

2. We analyze existing entity linking datasets with respect to these long tail properties, demonstrating that data properties have certain inter-correlations that follow our hypotheses **(Section 4)**.

3. We describe how the performance of systems correlates with head and long tail cases, proving that the long tail phenomena and their interactions influence the performance of systems **(Section 5)**.

4. We provide recommendations on how to address the tail in future EL research (**Section 7**).

2 Related work

Analyzing well-known datasets for semantic tasks, Ilievski et al. (2016) measured very low ambiguity and variation, and a notable bias towards dominance. Overall, tasks and datasets show strong **semantic overfitting** to the head of the distribution (the popular part) and are not representative for the diversity of the long tail. In the related task of Word Sense Disambiguation, Postma et al. (2016) analyzed the impact of frequency on system accuracy, showing that the accuracy on the most frequent words is close to human performance, while the least frequent words can be disambiguated correctly in at most 20% of cases. According to Van Erp et al. (2016), EL datasets contain very little referential ambiguity and evaluation is focused on well-known entities (i.e., with high PageRank (Page et al., 1999) values).

NIL entities are entities without a representation in a knowledge base (Ji and Grishman, 2011). These are typically considered to have low frequencies within a corpus and/or to be domain-specific. Esquivel et al. (2017) report that around 50% of the people mentioned in news articles are not present in Wikipedia. Considering that Wikipedia and its structured data derivatives are almost exclusively used as an anchor in EL, this means that for half of all people mentions, the EL task is nonsensical. While NILs are a challenge that concerns the long tail of EL, in this work we focus on those entities that have been linked to Wikipedia, but are still infrequent, since this provides an entry for extensive analysis of their properties.

In this work, we distinguish dark, emerging, and domain entities. **Dark entities** are those for which no relevant information is present in a given knowledge base (Van Erp et al., 2015). Dark entities thus expand the notion of NIL entities to cases where an entity representation exists, but it is insufficient to reason over. **Emerging entities** are time-bound entities, recently unknown but potentially becoming popular in news in a short time (Hoffart et al., 2014). A body of work has dealt with **domain entities**, whose relevance is restricted within a topic, e.g. biomedical (Zheng et al., 2015), or historical domain (Heino et al., 2017). Dark, emerging, and domain entities mostly make up the tail in EL. Their definition is, however, orthogonal to our work: we strive to provide an umbrella theory of the tail in EL based on linguistic properties and avoid a discussion on defining the distinction between head or tail in a categorical way.

Finally, studying distributional properties of entity expressions and their linking, as we do in this study, is different from the classical linguistic studies on the distribution of words (Zipf, 1935; Corral et al., 2015; Kanwal et al., 2017). Linked entity data provides information on the surface forms, the meaning, and the referent of the surface form, whereas distributional studies on words only provide knowledge on the surface forms and to a limited extent on their sense, but never on their reference.

3 Approach

To address our research goal of **quantifying the long tail of EL**, we first explain the notions of ambiguity, variance, frequency, and popularity. Next, we formulate a set of hypotheses regarding their interaction and our expected influence on system performance. We also describe our choice of data collections and

[1] We consider the following properties: ambiguity of surface forms, variance of instances, frequency of surface forms, frequency of instances, and popularity of instances.

EL systems to analyze. The code of this analysis is available on Github at `https://github.com/cltl/EL-long-tail-phenomena`.

3.1 The long tail phenomena of the entity linking task

Each entity exists only once in the physical world. However, this is different in our communication where: 1. certain surface forms are very prominent and others occur only rarely; 2. certain instances are very prominent and others are mentioned incidentally. The task of EL covers a many-to-many relation between surface forms observed in text and their instances potentially found in a knowledge base. Surface forms and instances both have their own **frequency distribution**, pointing to the same underlying Grice (1975) mechanisms, governed by an envisioned trade-off between efficiency and effectiveness.

Surface forms have various frequency of occurrence in textual documents. Frequent surface forms include "U.S." and "Germany", but also "John Smith". The frequency of a surface form can be explained by its relation to one (or a few) very popular instances (`United States`), but it can also be a result of high **ambiguity** ("John Smith" is a common name, so it simply refers to many possible instances).[2]

Similarly, some **instances** are more popular and therefore more frequently mentioned than others. Note that *frequency* here refers to the number of occurrences in a corpus, while popularity refers to the frequency as a topic and can, for example, be measured by the volume of knowledge about an instance captured with its **PageRank** in a knowledge base. Frequent and popular instances are intuitively quite prominent and relevant, very often across many different circumstances, and are typically referred to by a relatively wide set of surface forms, resulting in a high **variance**. In addition, frequent/popular entities tend to participate in metonymy relations with other entities topically related to them. For instance, `United States` as a country relates to `United States Army` and to `United States Government` - two other entities of a different type, but possibly referenced by the same surface forms.

3.2 Hypotheses on the long tail phenomena of the entity linking task

We look systematically at the relation of surface forms in datasets and their instances in DBpedia, and provide a series of hypotheses regarding the long tail phenomena and their relation to system performance (Table 1). Some of these hypotheses, e.g., D1 and D2, are widely accepted as common knowledge but have rarely been investigated in EL datasets. Others, such as S4 and S5, are entirely new.

ID	Hypothesis	Sec
D1	Only a few forms and a few instances are very frequent in corpora, while most appear only incidentally.	4.1
D2	A few instances in corpora are much more popular (have much higher PageRank) compared to most other.	4.2
D3	Only a small portion of all forms in corpora are ambiguous.	4.3
D4	Only a small portion of all instances in corpora are referred to with multiple forms.	4.4
D5	There is a positive correlation between ambiguity of forms and their frequency.	4.5
D6	There is a positive correlation between variance of instances and their frequency.	4.5
D7	There is a positive correlation between variance of instances and their popularity.	4.5
D8	There is a positive correlation between popularity of instances and their frequency.	4.5
D9	The frequency distribution within all forms that refer to an instance is Zipfian.	4.6
D10	The frequency and the popularity distribution within all instances that refer to a form is Zipfian.	4.6
S1	Systems perform worse on forms that are ambiguous than overall.	5.1
S2	There is a positive correlation between system performance and frequency/popularity.	5.2
S3	Systems perform best on frequent, non-ambiguous forms, and worst on infrequent, highly ambiguous forms.	5.3
S4	Systems perform better on ambiguous forms with imbalanced, compared to balanced, instance distribution.	5.4
S5	Systems perform better on frequent instances of ambiguous forms, compared to their infrequent instances.	5.4
S6	Systems perform better on popular instances of ambiguous forms, compared to their unpopular instances.	5.4

Table 1: Hypotheses on the data properties (D*) and on their relation to system performance (S*)

[2]The notion of ambiguity captures the amount of instances to which a surface form has been observed to refer. Non-ambiguous forms are those that refer to a single instance, whereas ambiguous forms refer to at least two instances. Highly ambiguous forms refer to a wide array of instances.

3.3 Datasets and systems

We focus on well-known EL datasets with news documents, preferring larger sets with open licenses. Many customary EL datasets are however quite small ($< 1,000$ mentions). We opted to perform our analysis on the following two data collections, with five corpora in total:

AIDA-YAGO2 (Hoffart et al., 2011) - we consider its train, test A, and test B sets, summing up to 34,929 entity forms in 1,393 news documents, published by Reuters from August 1996 to August 1997.

N3 (Röder et al., 2014) is a collection of three corpora released under a free license. We consider the two N3 corpora in English: RSS-500 and Reuters-128. Reuters-128 contains economic news published by Reuters, while RSS-500 contains data from RSS feeds, covering various topics such as business, science, and world news. These two corpora consist of 628 documents with 1,880 entity forms in total.

We analyzed the EL performance of recent public and open-sourced entity linkers, as the state-of-the-art: 1. **AGDISTIS MAG** (Moussallem et al., 2017)[3] combines graph algorithms with context-based retrieval over knowledge bases. 2. **DBpedia Spotlight** (Daiber et al., 2013)[4] is based upon cosine similarities and a modification of TF-IDF weights. 3. **WAT** (Piccinno and Ferragina, 2014)[5] combines a set of algorithms, including graph- and vote-based ones.[6]

3.4 Evaluation

We apply the customary metrics of precision, recall, and F1-score to measure system performance in Section 5. In Table 2, we briefly describe the computation of true positives (TPs), false positives (FPs), and false negatives (FNs) per class. For example, if the gold instance belongs to C_1, then we count a TP when the system instance is also C_1. In case the system instance belongs to another class C_i, $i \neq 1$, this leads to a FN for C_1 and a FP for C_N. A special class are the NILs: predicting a NIL case incorrectly by the system results in a FN for the correct class; inversely, if the system was supposed to predict a NIL and it did not, then we count a FP. See the details in later sections for what constitutes a class. In our analysis we exclude the cases referring to NILs.

$G \backslash S$	C_1	...	C_N	NILL
C_1	TP(1)		FP(N), FN(1)	FN(1)
...				
C_N	FP(1), FN(N)		TP(N)	FN(N)
NILL	FP(1)		FP(N)	-

Table 2: Computation of TPs, FPs, and FNs per class C_1, ..., C_N. 'G'=gold instance, 'S'=system instance.

4 Analysis of data properties

4.1 Frequency distribution of forms and instances in datasets

We hypothesize that only a few forms and a few instances are very frequent in corpora, while most appear only incidentally (*D1*). This represents a variation of Zipf's law (Zipf, 1935) for the EL task.

The log-log frequency distributions of forms and instances (Figure 1a and 1b) show an almost ideal Zipfian distribution in the case of AIDA (with a slope coefficient of -0.9085 for forms and -0.9657 for instances) and to a lesser extent for N3 (a slope of -0.4291 for forms and -0.5419 for instances). The less Zipfian curves of N3 are probably because this data collection is significantly smaller than AIDA.

The similar shape of the form and the instance distribution per dataset can be explained by the dependency between the two aspects. Namely, the form 'U.S.' denoting the instance `United_States` 462 times is reflected in both the form and the instance distributions. However, these two distributions are only identical if the ambiguity and variance are both 1. In practice, the mapping between forms and instances is M-to-N, i.e., other forms also denote `United_States` (such as 'America') and there are other instances referred to by a form 'US' (such as `United_States_dollar`).

[3]AGDISTIS API: `http://akswnc9.informatik.uni-leipzig.de:8113/AGDISTIS`, used on 24/05/2018.

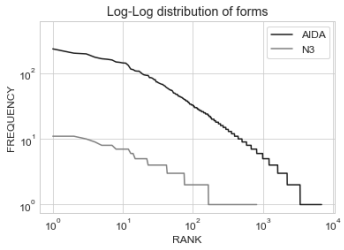
[4]Spotlight API: `http://spotlight.fii800.lod.labs.vu.nl/rest/disambiguate`, used on 24/05/2018.

[5]WAT API: `https://wat.d4science.org/wat/tag/json`, used on 24/05/2018.

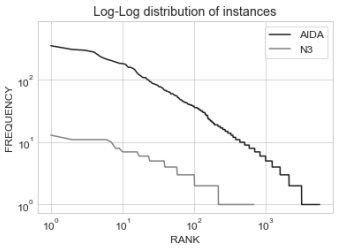
[6]All three APIs link to the Wikipedia dump from April 2016. Since the official DBpedia Spotlight endpoint at `http://model.dbpedia-spotlight.org/en/disambiguate` links to a newer Wikipedia version (February 2018 at the moment of writing of this paper), we set up our own endpoint that performs linking to the model 2016-04, to enable fair comparison with the other two systems. We reached similar conclusions with both versions of DBpedia Spotlight.

Figure 1: Log-log distribution of:

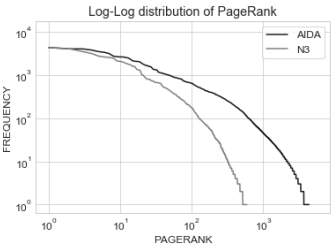
(a) form frequency



(b) instance frequency



(c) PageRank



4.2 PageRank distribution of instances in datasets

Similar to the instance frequency, we expect that a few instances in the corpora have an extremely high PageRank compared to most others (*D2*). Figure 1c shows the PageRank distribution of our both datasets. We observe that most entity mentions in text refer to instances with a low PageRank value, while only a few cases have a high PageRank value. Not surprisingly, the instance with the highest PageRank value (`United_States`) is at the same time the instance with the highest corpus frequency.

We inspect the effect of frequency and PageRank on system performance in Section 5.2.

4.3 Ambiguity distribution of forms

We hypothesize that only a small portion of all forms in a corpus are ambiguous (*D3*). As shown in Table 3, when both datasets are merged and NIL entities excluded, only 508 surface forms (6.73%) are ambiguous, as opposed to 7,037 monosemous forms (93.27%). This extremely high percentage validates our hypothesis. Moreover, in Sections 5.1, 5.3, and 5.4, we show that it also has a strong effect on systems performance.

	1	2	3	4	5	6	..	12
AIDA	6,400	359	78	29	7	3		1
N3	794	18	2	1	0	0		0
BOTH	7,037	381	84	29	10	3		1

Table 3: Ambiguity distribution per dataset, after NILs are excluded. Columns represent degrees of ambiguity.

4.4 Variance distribution of instances

We expect that only a small portion of all instances in a corpus are referred to with multiple forms (*D4*). The results of our variance analysis are given in Table 4. Over both datasets, 1,568 instances (25.61%) are referred to by multiple forms, as opposed to 4,555 instances (74.39%) which are always referred to by the same form. While the distribution of variance is much more even compared to that of ambiguity, we observe that most of the instances have a variance of 1.[7]

	1	2	3	4	5	6	7	8	9	10	11
AIDA	4,156	1,118	230	56	19	10	6	0	1	1	1
N3	550	106	15	7	1	0	0	0	0	0	0
BOTH	4,555	1,206	247	74	22	10	6	0	0	2	1

Table 4: Variance of instances with respect to the number of surface forms that reference them. Columns represent degrees of variance.

4.5 Interaction between frequency, PageRank, and ambiguity/variance

In the previous four Sections we analyzed the frequency distribution of individual data properties. Here we move forward to analyze their interaction. Figure 2 shows these results with mean as an estimator.[8]

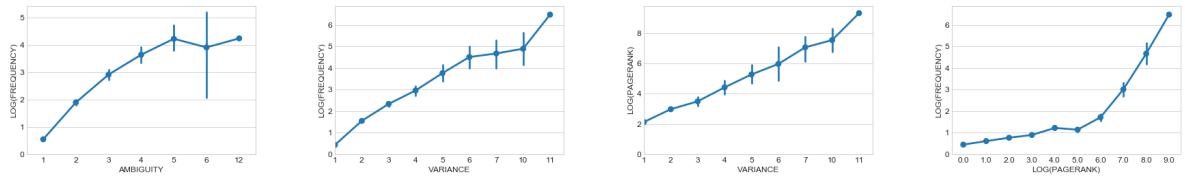
Firstly, we predict a positive dependency between ambiguity of forms and their frequency (*D5*). We expect that frequently used forms tend to receive new meanings, often as a result of metonymy or meronymy

[7] We expect that this skewness will also dominate system performance. For space reasons, we have not included this analysis.

[8] We observed comparable results with median as an estimator.

Figure 2: Correlations between long tail phenomena (estimator=mean):

(a) Ambiguity and frequency. (b) Variance and frequency. (c) Variance and PageRank. (d) PageRank and frequency.



of their dominant meaning. Figure 2a confirms this tendency, the Spearman correlation being 0.3772.

Secondly, we expect a positive correlation between variance of instances and their frequency (*D6*) or popularity (*D7*). Frequently mentioned and popular instances tend to be associated with more forms. Indeed, we observe that instances with higher frequency (Figure 2b) or PageRank (Figure 2c) typically have higher variance. The Spearman correlations are 0.6348 and 0.2542, respectively.

Thirdly, we compare the frequency of instances to their popularity measured with PageRank, predicting a positive correlation (*D8*). On average, this dependency holds (Figure 2d), though there are many frequent instances with low PageRank, or vice versa, leading to a Spearman correlation of 0.3281. The former are instances whose prominence coincides with the creation time of the corpus, but are not very well-known (e.g., the now-retired football player `Predrag_Mijatovic`). The latter are generally popular entities which were not captured sufficiently by the corpus, because their topical domain is marginal to this corpus (e.g., scientists), or they became relevant after the corpus release (emerging entities).

Hence, besides the high corpora skewness in terms of frequency, popularity, ambiguity, and variance, these factors also have positive interdependencies. Section 5 shows their effect on system performance.

4.6 Frequency distribution within a synset

We observed that the distribution of form frequency, instance frequency, and PageRank all have a Zipfian shape. But do we also see this behavior on a single form or instance level?

Supposedly, the frequency distribution within all forms that refer to an instance is Zipfian (*D9*). We test *D9* on the instance with highest variance and frequency, `United_States` (Figure 3). As expected, the vast majority of forms are used only seldom to refer to this instance, while in most cases a dominant short form "U.S." is used to make reference to this entity.

Figure 3: Form frequencies for the instance `United_States`

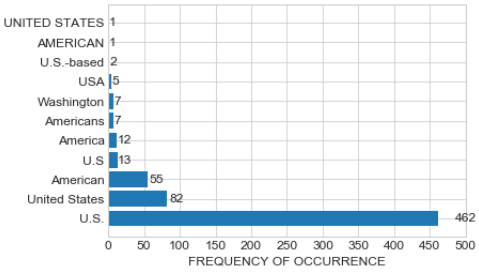


Figure 4a presents the frequency distribution of all instances that are referred to by the most ambiguous form in our data, "World cup". Figure 4b shows their PageRank distribution. In both cases, we observe a long-tail distribution among these instances (*D10*). Comparing them, we observe a clear match between frequency and PageRank, deviating only for instances that were prominent during the corpus creation, like `1998_FIFA_World_Cup`.

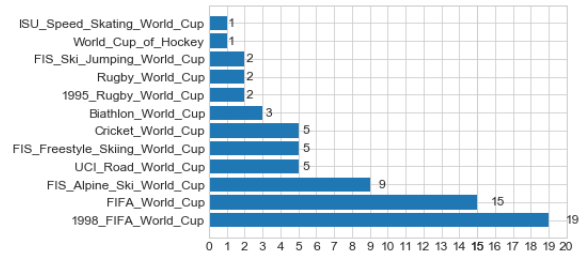
For analysis on the effect of frequency and popularity on system performance, please see Section 5.2.

5 Analysis of system performance and data properties

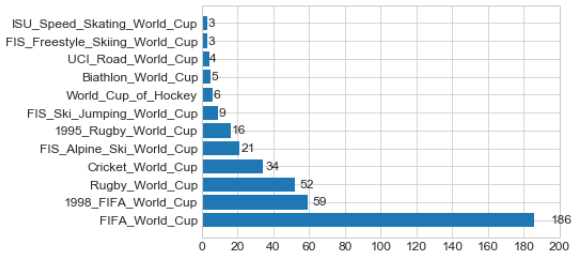
Next, we analyze systems performance in relation to the data properties: ambiguity (Section 5.1), form frequency, instance frequency, and PageRank (Section 5.2), as well as their combinations (5.3 and 5.4).

Figure 4: Distributions of the instances denoted by the most ambiguous form ("World Cup")

(a) Frequency distribution.



(b) PageRank distribution.

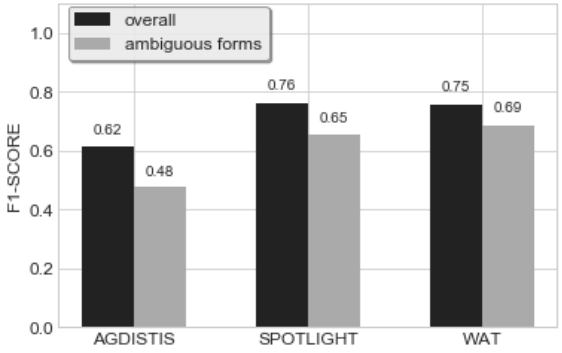


5.1 Correlating system performance with form ambiguity

Figure 5 displays the micro F1-scores of AGDISTIS MAG, Spotlight, and WAT on the two data collections jointly. For each system, we show its overall F1-score and F1-score on ambiguous forms only.

Section 4.3 showed that most of the forms in our corpora are not ambiguous. We expect that these forms lift the performance of systems, i.e., that they can resolve non-ambiguous forms easier than ambiguous ones (*S1*). Figure 5 confirms this for all systems: the F1-score on ambiguous forms is between 6 and 14 absolute points lower than the overall F1-score.

Figure 5: Micro F1-scores of systems: overall and on ambiguous subsets



When computing macro- instead of micro-F1 scores, we observe similar findings for *S1*. Interestingly, the macro-F1 scores are consistently lower than the micro-F1 scores, especially in case of the ambiguous subsets evaluation. Namely, the overall macro-F1 scores are between 0.44 and 0.52, and between 0.14 and 0.34 on the ambiguous forms. This suggests that frequent forms boost system performance, especially on ambiguous surface forms. We investigate this further in the next Sections.

5.2 Correlating system performance with form frequency, instance frequency, and PageRank

Next, we consider frequency of forms and instances, as well as PageRank values of instances in relation to system performance. For each of these, we expect a positive correlation with system performance (*S2*), suggesting that systems perform better on frequent and popular cases, compared to non-popular and infrequent ones.

	all forms			ambiguous forms only		
	FF-F1	**FI-F1**	**PR-F1**	**FF-F1**	**FI-F1**	**PR-F1**
AGDISTIS	0.2739	0.3812	0.1465	0.3550	0.4073	0.3969
Spotlight	0.1321	0.1847	0.1357	0.3986	0.4196	0.3108
WAT	0.4663	0.5050	0.3164	0.5831	0.5319	0.4214

Table 5: Correlation between F1-score and: frequency of forms (FF-F1), frequency of instances (FI-F1), and PageRank (PR-F1). Left: on all forms, right: only on ambiguous forms.

The Spearman correlation for each of the systems and properties, over all forms, are shown in Table 5 (left half). While most of the correlation for frequency and popularity is positive, the values are in general relatively low (WAT being an exception). This shows that frequency/popularity by itself contributes, but is not sufficient to explain system performance. The right half of the Table shows the same metrics when applied to the ambiguous forms. We observe an increase in all values, which means that frequency and popularity are most relevant when multiple instances 'compete' sharing a form. These findings are in line with those in Section 5.1.

5.3 Correlating system performance with ambiguity and frequency of forms jointly

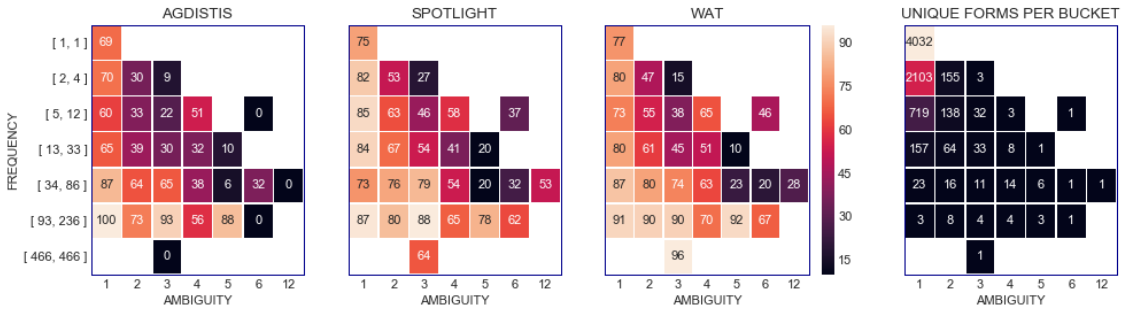


Figure 6: F1 per (ambiguity, frequency) pair. The first three heat maps show the F1-scores of systems per ambiguity degree and frequency range. The last plot shows the amount of unique forms in each cell.

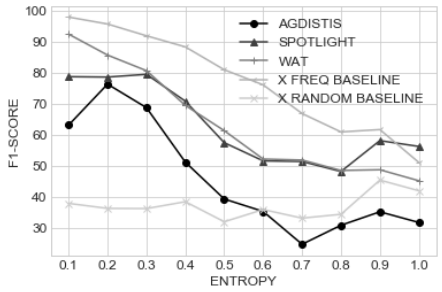
We have shown that system performance is lower on ambiguous than unambiguous forms. We also observed a tendency of systems to perform better on frequent forms and instances as compared to infrequent ones. But how does performance differ across different levels of ambiguity? How do ambiguity and form frequency interact as a joint predictor of performance? The heat maps in Figure 6 show the interplay between ambiguity, frequency, and micro F1-score for each of the systems. Generalizing over the discussion in Sections 5.1 and 5.2, we observe the best scores on frequent, non-ambiguous forms (bottom-left), and worst F1-scores on non-frequent, highly ambiguous forms (top-right) (*S3*).

In Section 5.4, we investigate if some instances within ambiguous forms are more difficult than others.

5.4 Correlating system performance with frequency of instances for ambiguous forms

Figure 7: Micro F1-score per entropy bucket.



To measure the instance distribution within individual forms, we employ the notion of *normalized entropy*, similarly as Ilievski et al. (2016). The entropy of a form i with n_i instances and N_i occurrences is: $H_i = (-\sum_{j=1}^{n_i} p_{i,j} log p_{i,j})/log_2 N_i$, where $p_{i,j}$ is the probability that the instance j is denoted by the form i. For non-ambiguous forms $H_i = 0$, while forms with uniform frequency distribution of instances have a maximum $H_i = 1$. We predict an inverse correlation between system performance and entropy (*S4*). The results in Figure 7 show a dramatic drop in micro F1-score for uniformly distributed cases (high entropy) compared to skewed ones (low entropy). We compare these shapes to two baselines: frequency baseline, that picks the most frequent instance for a form on the gold data, and a random baseline, choosing one of the gold instances for a form at random. All three systems have a similar curve shape to the frequency baseline, whereas out of the three systems Spotlight's curve comes closest to that of the random baseline.

We also compute the macro F1-score per entropy bucket to help us understand whether the drop in performance in Figure 7 is due to: 1. a qualitative difference between low and high entropy forms, or 2. an overfitting of systems to the frequent interpretations of ambiguous forms. The macro F1-score reduces the effect of frequency on performance, by evaluating each form-instance pair once. We observe that the macro F1-scores are much more balanced across the entropy buckets compared to the micro F1-scores, and especially lower on the buckets with higher skewness (low entropy). This suggests that the high micro F1-score for low entropies is heavily based on frequent instances.

As a final analysis, we seek to understand whether frequent/popular instances of a form are indeed resolved easier than less frequent/popular instances of the same form. For that purpose, we pick the set of all ambiguous forms, and we rank their instances by relative frequency/PageRank value.

Considering the most ambiguous form "World Cup" as an example and ranking by frequency, its $r1$ (rank 1) instance is `1998_FIFA_World_Cup`, $r2$ is `FIFA_World_Cup`, ..., and $r12$ is `ISU_Speed_Skating_World_Cup`. We expect systems to perform much better on frequent instances of ambiguous forms, compared to infrequent instances of ambiguous forms, i.e., we expect F1-scores to decrease when moving from higher to lower ranks (*S5*). Figure 8 shows that our hypothesis holds to a large extent for precision, recall, and F1-scores, except for the occasional peaks at $r6$ and $r9$.

Figure 8: Precision, recall, and micro F1-score per instance frequency rank, averaged over the systems.

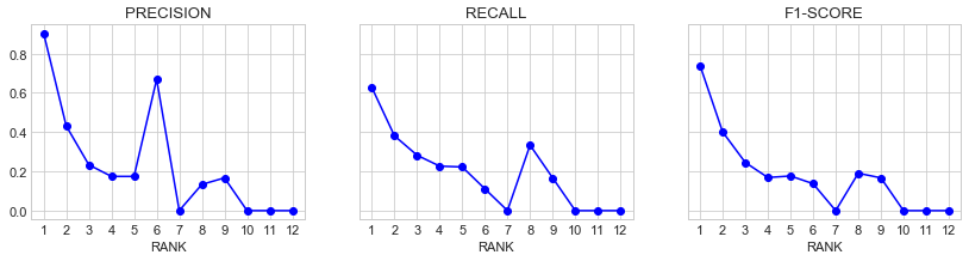


Figure 9: Precision, recall, and micro F1-score per PageRank-based rank, averaged over the systems.

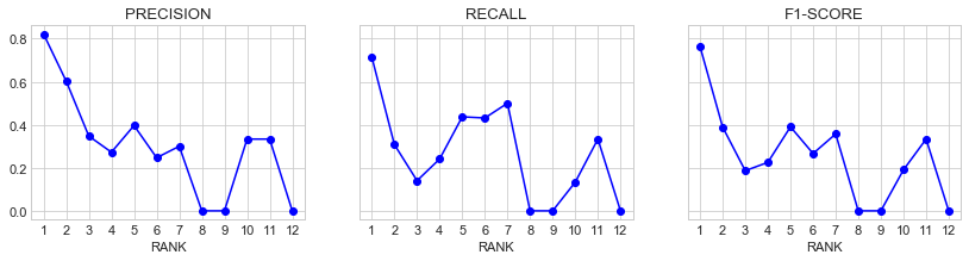

Similarly, we order the instances denoting a form based on their relative PageRank value. We hypothesize that systems perform better on popular instances of ambiguous forms, compared to their unpopular instances (*S6*). Although less monotonic than the frequency ones in Figure 8, the resulting shapes of this analysis in Figure 9 suggest that popularity can also be applied to estimate system performance.

6 Summary of findings

We noted a positive correlation between ambiguity and frequency of forms, as well as between variance and frequency of instances. We noticed that the distribution of instances overall, but also per form, has a Zipfian shape. Similarly, the distribution of forms, both on individual and on aggregated level, is Zipfian. While some of these distributions are well-known in the community for words, this is the first time they have been systematically analyzed for surface forms of entities, their meaning and reference, and empirically connected with the performance of systems.

We observed that ambiguity of forms leads to a notable decline in system performance. Coupling it with frequency, we measured that low-frequent, highly ambiguous forms yield the lowest performance, while very frequent, non-ambiguous forms yield the highest performance. The entropy of forms, capturing the frequency distribution of their denoted instances, revealed that balanced distributions tend to be harder for systems, with the micro F1-value dropping with 20-40 absolute points between the highest and lowest entropy. Finally, the higher performance on skewed cases was shown to be a result of overfitting to the most frequent/popular instances.

Based on these outcomes, we can conclude that the intersection of ambiguity and frequency/popularity is a good estimator of the complexity of the EL task. The hard cases of EL should be sought among the low-frequent and unpopular candidates of highly ambiguous forms.

7 Recommended actions

We have shown that there are systematic differences between the head and the tail of the EL task, and that these reflect on how systems perform. Provided that systems show a weakness on tail cases, and that this weakness is simultaneously hidden by averaged evaluation numbers, how can we overcome this obstacle in practice? Here we list three recommendations:

1. When **creating a dataset**, we propose authors to include statistics on the head and the tail properties (ambiguity, variance, frequency, and popularity) of the data, together with a most-frequent-value baseline. By doing so, the community would be informed about the hard cases in that dataset, as well as about the portion of the dataset that can be resolved by following simple statistical strategies.

2. When **evaluating** a system, we suggest splitting of all cases into head and tail ones. Afterwards, head and tail cases can be evaluated separately, as well as together. This provides a direct insight into the differences in scoring of the tail cases compared to the head cases, potentially signaling aspects of the EL tail that are challenging for the given system. In addition, the frequency skewness of head cases can be largely decreased by employing a macro instead of micro F1-score, as shown in this paper.

3. In addition to the suggestion in 2., when **developing or training** a system, it should be made explicit which heuristics target which cases, and to what extent resources and training data optimize for the target dataset in relation to the head and tail distributions.

8 Conclusions

Although past research has argued that the performance of EL systems declines when moving from the head to the tail of the entity distribution, the long tail has not been quantified so far, preventing one to distinguish head and tail cases in the EL task. Previous linguistic studies on words distributions can also not be applied for this purpose since they do not study reference. This paper is the first one that systematically looks into the relation of surface forms in EL corpora and instances in DBpedia, and provides a series of hypotheses on what long tail phenomena are. We analyzed existing EL datasets with respect to these long tail properties, demonstrating that data properties have certain inter-correlations that follow our hypotheses. Next, we investigated their effect on the performance of three state-of-the-art systems, proving that the long tail phenomena and their interaction consistently predict system performance. Namely, we noted a positive dependency of system performance on frequency and popularity of instances, and a negative one with ambiguity of forms. Our findings in this paper are meant to influence future designs of both EL systems and evaluation datasets. To support this goal, we listed three recommended actions to be considered when creating a dataset, evaluating a system, or developing a system in the future.

We see two directions for future improvement of our analysis: 1. To obtain a corpus-independent inventory of forms and their candidate instances, both with their corresponding frequencies, is a challenge in the case of EL and no existing resource can be assumed to be satisfactory in this regard (for Word Sense Disambiguation, this is usually WordNet). We approximated these based on the corpora we analyzed, but considering the fairly small size of most EL datasets, this poses a limitation to our current analysis. 2. Some of our current numbers are computed only on a handful of cases. This leads to unexpected disturbances in our results, like the occasional peaks for high ranks in Figure 8. We expect the outcome of this analysis to gain significance when more large EL datasets become available in the future.

Abstract

Entity Linking aims to link entity mentions in texts to knowledge bases, and neural models have achieved recent success in this task. However, most existing methods rely on local contexts to resolve entities independently, which may usually fail due to the data sparsity of local information. To address this issue, we propose a novel neural model for collective entity linking, named as NCEL. NCEL applies Graph Convolutional Network to integrate both local contextual features and global coherence information for entity linking. To improve the computation efficiency, we approximately perform graph convolution on a subgraph of adjacent entity mentions instead of those in the entire text. We further introduce an attention scheme to improve the robustness of NCEL to data noise and train the model on Wikipedia hyperlinks to avoid overfitting and domain bias. In experiments, we evaluate NCEL on five publicly available datasets to verify the linking performance as well as generalization ability. We also conduct an extensive analysis of time complexity, the impact of key modules, and qualitative results, which demonstrate the effectiveness and efficiency of our proposed method.

1 Introduction

Entity linking (EL), mapping entity mentions in texts to a given knowledge base (KB), serves as a fundamental role in many fields, such as question answering (Zhang et al., 2016), semantic search (Blanco et al., 2015), and information extraction (Ji et al., 2015; Ji et al., 2016). However, this task is non-trivial because entity mentions are usually ambiguous. As shown in Figure 1, the mention *England* refers to three entities in KB, and an entity linking system should be capable of identifying the correct entity as *England cricket team* rather than *England* and *England national football team*.

Entity linking is typically broken down into two main phases: (i) candidate generation obtains a set of referent entities in KB for each mention, and (ii) named entity disambiguation selects the possible candidate entity by solving a ranking problem. The key challenge lies in the ranking model that computes the relevance between candidates and the corresponding mentions based on the information both in texts and KBs (Nguyen et al., 2016). In terms of the features used for ranking, we classify existing EL models into two groups: **local models** to resolve mentions independently relying on textual context information from the surrounding words (Chen and Ji, 2011; Chisholm and Hachey, 2015; Lazic et al., 2015; Yamada et al., 2016), and **global (collective) models**, which are the main focus of this paper, that encourage the target entities of all mentions in a document to be topically coherent (Han et al., 2011; Cassidy et al., 2012; He et al., 2013b; Cheng and Roth, 2013; Durrett and Klein, 2014; Huang et al., 2014).

Global models usually build an entity graph based on KBs to capture coherent entities for all identified mentions in a document, where the nodes are entities, and edges denote their relations. The graph provides highly discriminative semantic signals (e.g., entity relatedness) that are unavailable to local model (Eshel et al., 2017). For example (Figure 1), an EL model seemly cannot find sufficient disambiguation clues for the mention *England* from its surrounding words, unless it utilizes the coherence

Santa Fe, New Mexico, USA, August 20-26, 2018.

information of consistent topic "cricket" among adjacent mentions *England*, *Hussain*, and *Essex*. Although the global model has achieved significant improvements, its limitation is threefold:

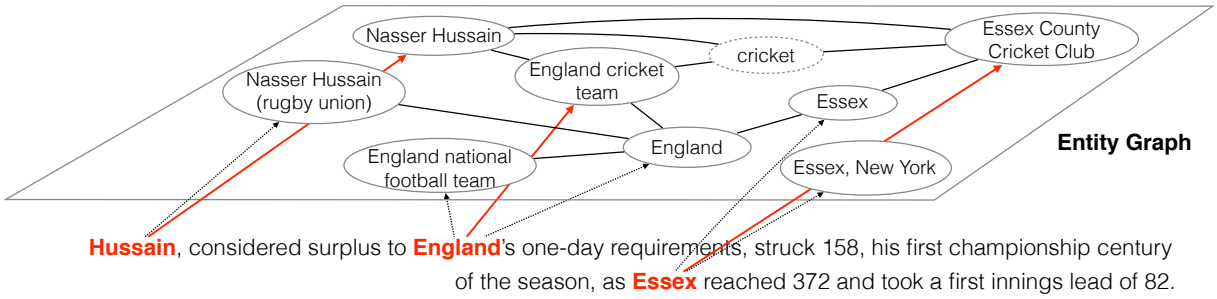

Figure 1: Illustration of named entity disambiguation for three mentions *England*, *Hussain*, and *Essex*. The nodes linked by arrowed lines are the candidate entities, where red solid lines denote target entities.

1. The global approach suffers from the data sparsity issue of unseen words/entities, and the failure to induce underlying discriminative features for EL.

2. The joint inference mechanism in the global approach leads to expensive computations, especially when the entity graph may contain hundreds of nodes in case of long documents.

3. The annotated EL training data is usually expensive to obtain or only available in narrow domains, which results in possible overfitting issue or domain bias.

To mitigate the first limitation, recent EL studies introduce neural network (NN) models due to its amazing feature abstraction and generalization ability. In such models, words/entities are represented by low dimensional vectors in a continuous space, and features for mention as well as candidate entities are automatically learned from data (Nguyen et al., 2016). However, existing NN-based methods for EL are either local models (Yamada et al., 2017; Gupta et al., 2017) or merely use word/entity embeddings for feature extraction and rely on another modules for collective disambiguation, which thus cannot fully utilize the power of NN models for collective EL (Globerson et al., 2016; Guo and Barbosa, 2017; Phan et al., 2018).

The second drawback of the global approach has been alleviated through approximate optimization techniques, such as PageRank/random walks (Pershina et al., 2015), graph pruning (Hoffart et al., 2011), ranking SVMs (Ratinov et al., 2011), or loopy belief propagation (LBP) (Globerson et al., 2016; Ganea and Hofmann, 2017). However, these methods are not differentiable and thus difficult to be integrated into neural network models (the solution for the first limitation).

To overcome the third issue of inadequate training data, (Gupta et al., 2017) has explored a massive amount of hyperlinks in Wikipedia, but these potential annotations for EL contain much noise, which may distract a naive disambiguation model (Chisholm and Hachey, 2015).

In this paper, we propose a novel **N**eural **C**ollective **E**ntity **L**inking model (NCEL), which performs global EL combining deep neural networks with Graph Convolutional Network (GCN) (Defferrard et al., 2016; Kipf and Welling, 2017) that allows flexible encoding of entity graphs. It integrates both local contextual information and global interdependence of mentions in a document, and is efficiently trainable in an end-to-end fashion. Particularly, we introduce attention mechanism to robustly model local contextual information by selecting informative words and filtering out the noise. On the other hand, we apply GCNs to improve discriminative signals of candidate entities by exploiting the rich structure underlying the correct entities. To alleviate the global computations, we propose to convolute on the subgraph of adjacent mentions. Thus, the overall coherence shall be achieved in a chain-like way via a sliding window over the document. To the best of our knowledge, this is the first effort to develop a unified model for neural collective entity linking.

In experiments, we first verify the efficiency of NCEL via theoretically comparing its time complexity with other collective alternatives. Afterwards, we train our neural model using collected Wikipedia hyperlinks instead of dataset-specific annotations, and perform evaluations on five public available benchmarks. The results show that NCEL consistently outperforms various baselines with a favorable generalization ability. Finally, we further present the performance on a challenging dataset WW (Guo and Barbosa, 2017) as well as qualitative results, investigating the effectiveness of each key module.

2 Preliminaries and Framework

We denote $M = \{m_i\}$ as a set of entity mentions in a document $D = \langle x_1, \ldots, x_i, \ldots, x_{|D|} \rangle$, where x_i is either a word w_i or a mention m_i. $G = (E, R)$ is the entity graph for document D derived from the given knowledge base, where $E = \{e_i\}$ is a set of entities, $R = \{r_j^i \in (0, 1]\}$ denotes the relatedness between $\langle e_i, e_j \rangle$ and higher values indicate stronger relations. Based on G, we extract a subgraph G^{ij} for $e_j \in \Phi(m_i)$, where $\Phi(m_i)$ denotes the set of candidate entities for m_i. Note that we don't include the relations among candidates of the same mention in G^{ij} because these candidates are mutually exclusive in disambiguation.

Formally, we define the entity linking problem as follows: Given a set of mentions M in a document D, and an entity graph G, the goal is to find an assignment[1] $\Gamma : M \rightarrow E$.

To collectively find the best assignment, NCEL aims to improve the discriminability of candidates' local features by using entity relatedness within a document via GCN, which is capable of learning a function of features on the graph through shared parameters over all nodes. Figure 2 shows the framework of NCEL including three main components:

1. **Candidate Generation**: we use a pre-built dictionary to generate a set of entities as candidates to be disambiguated for each mention, e.g., for mention *England*, we have $\Phi(m_i) = \{e_1^i, e_2^i, e_3^i\}$, in which the entities refer to *England national football team*, *England* and *England cricket team* in Figure 1, respectively.

2. **Feature Extraction**: based on the document and its entity graph, we extract both local features and global features for each candidate entity to feed our neural model. Concretely, local features reflect the compatibility between a candidate and its mention within the contexts, and global features are to capture the topical coherence among various mentions. These features, including vectorial representations of candidates and a subgraph indicating their relatedness, are highly discriminative for tackling ambiguity in EL.

3. **Neural Model**: given feature vectors and subgraphs of candidates, we first encode the features to represent nodes (i.e., candidates) in the graph, then improve them for disambiguation via multiple graph convolutions by exploiting the structure information, in which the features for correct candidates that are strongly connected (i.e., topical coherent) shall enhance each other, and features for incorrect candidates are weakened due to their sparse relations. Finally, we decode the features of nodes to output a probability indicating how possible the candidate refers to its mention.

Example As shown in Figure 2, for the current mention *England*, we utilize its surrounding words as local contexts (e.g., *surplus*), and adjacent mentions (e.g., *Hussian*) as global information. Collectively, we utilize the candidates of *England* $e_j^i \in \Phi(m_i), j = 1, 2, 3$ as well as those entities of its adjacencies $\Phi(m_{i-1}) \cup \Phi(m_{i+1})$ to construct feature vectors for e_j^i and the subgraph of relatedness as inputs of our neural model. Let darker blue indicate higher probability of being predicted, the correct candidate e_3^i becomes bluer due to its bluer neighbor nodes of other mentions m_{i-1}, m_{i+1}. The dashed lines denote entity relations that have indirect impacts through the sliding adjacent window , and the overall structure shall be achieved via multiple sub-graphs by traversing all mentions.

Before introducing our model, we first describe the component of candidate generation.

[1]Normally, an entity linking system outputs NIL for a mention when no assignment score is higher than a threshold. This is application-specific and thus outside of the scope of this work.

2.1 Candidate Generation

Similar to previous work (Ganea and Hofmann, 2017), we use the prior probability $\hat{p}(e_i|m_j)$ of entity e_i conditioned on mention m_j both as a local feature and to generate candidate entities: $\Phi(m_j) = \{e_i|\hat{p}(e_i|m_j) > 0\}$. We compute $\hat{p}(\cdot)$ based on statistics of mention-entity pairs from: (i) Wikipedia page titles, redirect titles and hyperlinks, (ii) the dictionary derived from a large Web Corpus (Spitkovsky and Chang, 2012), and (iii) the YAGO dictionary with a uniform distribution (Hoffart et al., 2011). We pick up the maximal prior if a mention-entity pair occurs in different resources. In experiments, to optimize for memory and run time, we keep only top n entities based on $\hat{p}(e_i|m_j)$. In the following two sections, we will present the key components of NECL, namely feature extraction and neural network for collective entity linking.

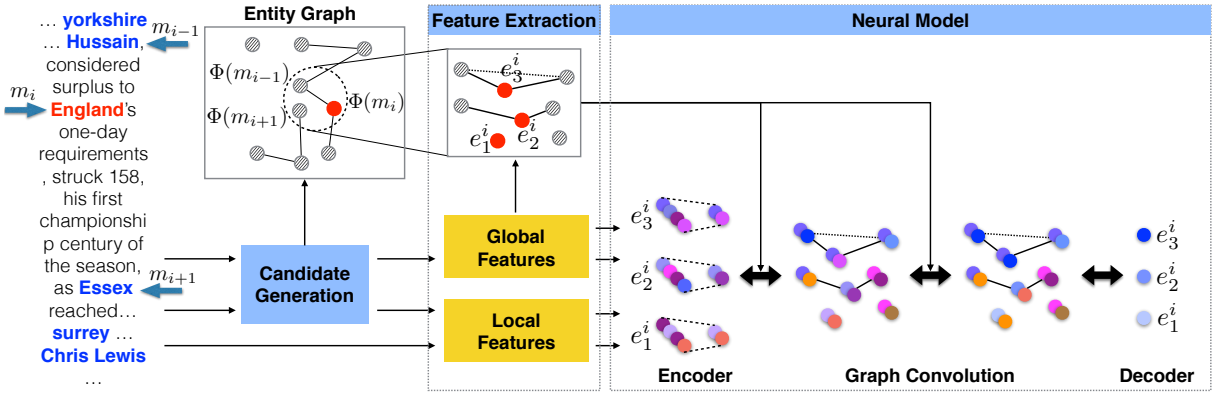

Figure 2: Framework of NCEL. The inputs of a set of mentions in a document are listed in the left side. The words in red indicate the current mention m_i, where m_{i-1}, m_{i+1} are neighbor mentions, and $\Phi(m_i) = \{e_1^i, e_2^i, e_3^i\}$ denotes the candidate entity set for m_i.

3 Feature Extraction

The main goal of NCEL is to find a solution for collective entity linking using an end-to-end neural model, rather than to improve the measurements of local textual similarity or global mention/entity relatedness. Therefore, we use joint embeddings of words and entities at sense level (Cao et al., 2017) to represent mentions and its contexts for feature extraction. In this section, we give a brief description of our embeddings followed by our features used in the neural model.

3.1 Learning Joint Embeddings of Word and Entity

Following (Cao et al., 2017), we use Wikipedia articles, hyperlinks, and entity outlinks to jointly learn word/mention and entity embeddings in a unified vector space, so that similar words/mentions and entities have similar vectors. To address the ambiguity of words/mentions, (Cao et al., 2017) represents each word/mention with multiple vectors, and each vector denotes a sense referring to an entity in KB. The quality of the embeddings is verified on both textual similarity and entity relatedness tasks.

Formally, each word/mention has a global embedding $\mathbf{w}_i/\mathbf{m}_i$, and multiple sense embeddings $\mathcal{S}(x_i) = \{\mathbf{s}_j\}$. Each sense embedding $\mathbf{s}_j$ refers to an entity embedding $\mathbf{e}_j$, while the difference between $\mathbf{s}_j$ and $\mathbf{e}_j$ is that $\mathbf{s}_j$ models the co-occurrence information of an entity in texts (via hyperlinks) and $\mathbf{e}_j$ encodes the structured entity relations in KBs. More details can be found in the original paper.

3.2 Local Features

Local features focus on how compatible the entity is mentioned in a piece of text (i.e., the mention and the context words). Except for the prior probability (Section 2.1), we define two types of local features for each candidate entity $e_j \in \Phi(m_i)$:

String Similarity Similar to (Yamada et al., 2017), we define string based features as follows: the edit distance between mention's surface form and entity title, and boolean features indicating whether they are equivalent, whether the mention is inside, starts with or ends with entity title and vice versa.

Compatibility We also measure the compatibility of e_j with the mention's context words $\mathcal{C}(m_i)$ by computing their similarities based on joint embeddings: $sim(\mathbf{e}_j, \mathbf{c}_{m_i,e_j})$ and $sim(\mathbf{s}_j, \mathbf{c}_{m_i,e_j})$, where $\mathbf{c}_{m_i,e_j}$ is the context embedding of m_i conditioned on candidate e_j and is defined as the average sum of word global vectors weighted by attentions:

$$\mathbf{c}_{m_i,e_j} = \sum_{w_k \in \mathcal{C}(m_i)} \alpha_{kj} \mathbf{w}_k$$

where α_{kj} is the k-th word's attention from e_j. In this way, we automatically select informative words by assigning higher attention weights, and filter out irrelevant noise through small weights. The attention α_{kj} is computed as follows:

$$\alpha_{kj} \propto sim(\mathbf{w}_k, \mathbf{e}_j)$$

where sim is the similarity measurement, and we use cosine similarity in the presented work. We concatenate the prior probability, string based similarities, compatibility similarities and the embeddings of contexts as well as the entity as the local feature vectors.

3.3 Global Features

The key idea of collective EL is to utilize the topical coherence throughout the entire document. The consistency assumption behind it is that: *all mentions in a document shall be on the same topic*. However, this leads to exhaustive computations if the number of mentions is large. Based on the observation that the consistency attenuates along with the distance between two mentions, we argue that the adjacent mentions might be sufficient for supporting the assumption efficiently.

Formally, we define neighbor mentions as q adjacent mentions before and after current mention m_i: $\mathcal{N}(m_i) = \{m_{i-q}, \ldots, m_{i-1}, m_{i+1}, \ldots, m_{i+q}\}$, where $2q$ is the pre-defined window size. Thus, the topical coherence at document level shall be achieved in a chain-like way. As shown in Figure 2 ($q = 1$), mentions *Hussain* and *Essex*, a cricket player and the cricket club, provide adequate disambiguation clues to induce the underlying topic "cricket" for the current mention *England*, which impacts positively on identifying the mention *surrey* as another cricket club via the common neighbor mention *Essex*.

A degraded case happens if q is large enough to cover the entire document, and the mentions used for global features become the same as the previous work, such as (Pershina et al., 2015). In experiments, we heuristically found a suitable $q = 3$ which is much smaller than the total number of mentions. The benefits of efficiency are in two ways: (i) to decrease time complexity, and (ii) to trim the entity graph into a fixed size of subgraph that facilitates computation acceleration through GPUs and batch techniques, which will be discussed in Section 5.2.

Given neighbor mentions $\mathcal{N}(m_i)$, we extract two types of vectorial global features and structured global features for each candidate $e_j \in \Phi(m_i)$:

Neighbor Mention Compatibility Suppose neighbor mentions are topical coherent, a candidate entity shall also be compatible with neighbor mentions if it has a high compatibility score with the current mention, otherwise not. That is, we extract the vectorial global features by computing the similarities between e_j and all neighbor mentions: $\{sim(\mathbf{e}_j, \mathbf{m}_i) | m_i \in \mathcal{N}(m_i)\}$, where $\mathbf{m}_i$ is the mention embedding by averaging the global vectors of words in its surface form: $\mathbf{m}_j = \sum_{w_l \in \mathcal{T}(m_j)} \mathbf{w}_l$, where $\mathcal{T}(m_j)$ are tokenized words of mention m_j.

Subgraph Structure The above features reflect the consistent semantics in texts (i.e., mentions). We now extract structured global features using the relations in KB, which facilitates the inference among candidates to find the most topical coherent subset. For each document, we obtain the entity graph G by taking candidate entities of all mentions $\Phi(M)$ as nodes, and using entity embeddings to compute their

similarities as edges $R = \{r_j^i | r_j^i = sim(\mathbf{e}_i, \mathbf{e}_j)\}$. Then, we extract the subgraph structured features $\mathbf{g}^{i*}$ for each entity $e_*^i \in \Phi(m_i), m_i \in M$ for efficiency.

Formally, we define the subgraph as: $G^{i*} = (e_*^i \bigcup \Phi(\mathcal{N}(m_i)), R^{i*})$, where $R^{i*} = \{r_{jk}^{i*} | e_k^j \in \Phi(m_j), j \in [i-q, i+q] \setminus i\}$. For example (Figure 1), for entity *England cricket team*, the subgraph contains the relation from it to all candidates of neighbor mentions: *England cricket team*, *Nasser Hussain (rugby union)*, *Nasser Hussain*, *Essex*, *Essex County Cricket Club* and *Essex, New York*. To support batch-wise acceleration, we represent G^{i*} in the form of adjacency table based vectors: $\mathbf{g}^{i*} = [r_{i-q,1}^{i*}, \cdots, r_{i+q,n}^{i*}]^T \in \mathbb{R}^{2qn}$, where n is the number of candidates per mention.

Finally, for each candidate e_j^i, we concatenate local features and neighbor mention compatibility scores as the feature vector $\mathbf{f}^{ij}$, and construct the subgraph structure representation $\mathbf{g}^{ij}$ as the inputs of NCEL.

4 Neural Collective Entity Linking

NCEL incorporates GCN into a deep neural network to utilize structured graph information for collectively feature abstraction, while differs from conventional GCN in the way of applying the graph. Instead of the entire graph, only a subset of nodes is "visible" to each node in our proposed method, and then the overall structured information shall be reached in a chain-like way. Fixing the size of the subset, NCEL is further speeded up by batch techniques and GPUs, and is efficient to large-scale data.

4.1 Graph Convolutional Network

GCNs are a type of neural network model that deals with structured data. It takes a graph as an input and output labels for each node. As a simplification of spectral graph convolutions, the main idea of (Kipf and Welling, 2017) is similar to a propagation model: to enhance the features of a node according to its neighbor nodes. The formulation is as follows:

$$H^{l+1} = \sigma(\tilde{A} H^l W^l)$$

where $\tilde{A}$ is a normalized adjacent matrix of the input graph with self-connection, H^l and W^l are the hidden states and weights in the l-th layer, and $\sigma(\cdot)$ is a non-linear activation, such as *ReLu*.

4.2 Model Architecture

As shown in Figure 2, NCEL identifies the correct candidate e_1^i for the mention m_i by using vectorial features as well as structured relatedness with candidates of neighbor mentions $\Phi(m_{i-1}), \Phi(m_{i+1})$. Given feature vector $\mathbf{f}^{ij} \in \mathbb{R}^{d_0}$ and subgraph representation $\mathbf{g}^{ij} \in \mathbb{R}^{2qn}$ of each candidate $e_j^i \in \Phi(m_i)$, we stack them as inputs for mention[2] m_i: $\mathbf{f} = [\mathbf{f}_{i1}, \cdots, \mathbf{f}_{in}]^T \in \mathbb{R}^{n \times d_0}$, and the adjacent matrix $A = [\hat{\mathbf{g}}^1, \cdots, \hat{\mathbf{g}}_n]^T \in \mathbb{R}^{n \times (2qn+1)}$, where $\hat{\mathbf{g}}^j = [\mathbf{g}^j, 1]^T \in \mathbb{R}^{2qn+1}$ denotes the subgraph with self-connection. We normalize A such that all rows sum to one, denoted as $\tilde{A}$, avoiding the change in the scale of the feature vectors.

Given $\mathbf{f}$ and $\tilde{A}$, the goal of NCEL is to find the best assignment:

$$\Gamma^*(m_i) = \underset{\hat{y}}{\text{argmax}}\ P(\hat{y}; \mathbf{f}, \tilde{A}, \omega)$$

where $\hat{y}$ is the output variable of candidates, and $P(\cdot)$ is a probability function as follows:

$$P(\hat{y}; \mathbf{f}, \tilde{A}, \omega) \propto \exp(F(\mathbf{f}, \tilde{A}, \hat{y}; \omega))$$

where $F(\mathbf{f}, \tilde{A}, \hat{y}; \omega)$ is the score function parameters by $\omega \in \mathbb{R}^\omega$. NCEL learns the mapping $F(\cdot)$ through a neural network including three main modules: encoder, sub-graph convolution network (sub-GCN) and decoder. Next, we introduce them in turn.

Encoder The function of this module is to integrate different features by a multi-layer perceptron (MLP):

$$h^1 = \sigma(\mathbf{f} W^1 + b^1)$$

[2]For clarity, we omit the superscripts indicating the mention.

where h^1 is the hidden states of the current mention, $W^1 \in \mathbb{R}^{d_0 \times d_1}$ and $b^1 \in \mathbb{R}^{d_1}$ are trainable parameters and bias. We use ReLu as the non-linear activation $\sigma(\cdot)$.

Sub-Graph Convolution Network Similar to GCN, this module learns to abstract features from the hidden state of the mention itself as well as its neighbors. Suppose $h^t_{m_k}$ is the hidden states of the neighbor m_k, we stack them to expand the current hidden states of m_i as $\tilde{h}^t \in \mathbb{R}^{(2qn+1)\times d_t}$, such that each row corresponds to that in the subgraph adjacent matrix $\tilde{A}$. We define sub-graph convolution as:

$$h^{t+1} = \sigma(\tilde{A}\tilde{h}^t W^t)$$

where $W^t \in \mathbb{R}^{d_t \times d_{t+1}}$ is a trainable parameter.

Decoder After T iterations of sub-graph convolution, the hidden states integrate both features of m_i and its neighbors. A fully connected decoder maps h^{t+1} to the number of candidates as follows:

$$F = h^{T+1} W^{T+1}$$

where $W^{T+1} \in \mathbb{R}^n$.

4.3 Training

The parameters of network are trained to minimize cross-entropy of the predicted and ground truth y^g:

$$\mathcal{L}_m = -\sum_{j=1}^{n} y^g_j log(P(\hat{y} = e_j; \mathbf{f}, \tilde{A}, \omega))$$

Suppose there are $D \in \mathcal{D}$ documents in training corpus, each document has a set of mentions M, leading to totally $M \in \mathcal{M}$ mention sets. The overall objective function is as follows:

$$\mathcal{L} = \sum_{M \in \mathcal{M}} \sum_{m \in M} \mathcal{L}_m$$

5 Experiments

To avoid overfitting with some dataset, we train NCEL using collected Wikipedia hyperlinks instead of specific annotated data. We then evaluate the trained model on five different benchmarks to verify the linking precision as well as the generalization ability. Furthermore, we investigate the effectiveness of key modules in NCEL and give qualitative results for comprehensive analysis[3].

5.1 Baselines and Datasets

We compare NCEL with the following state-of-the-art EL methods including three local models and three types of global models:

1. Local models: He (He et al., 2013a) and Chisholm (Chisholm and Hachey, 2015) beat many global models by using auto-encoders and web links, respectively, and NTEE (Yamada et al., 2017) achieves the best performance based on joint embeddings of words and entities.

2. Iterative model: AIDA (Hoffart et al., 2011) links entities by iteratively finding a dense subgraph.

3. Loopy Belief Propagation: Globerson (Globerson et al., 2016) and PBoH (Ganea et al., 2016) introduce LBP (Murphy et al., 1999) techniques for collective inference, and Ganea (Ganea and Hofmann, 2017) solves the global training problem via truncated fitting LBP.

4. PageRank/Random Walk: Boosting (Kulkarni et al., 2009), AGDISTISG (Usbeck et al., 2014), Babelfy (Moro et al., 2014), WAT (Piccinno and Ferragina, 2014), xLisa (Zhang and Rettinger, 2014) and WNED (Guo and Barbosa, 2017) performs PageRank (Page et al., 1999) or random walk (Tong et al., 2006) on the mention-entity graph and use the convergence score for disambiguation.

[3]Our codes can be found in `https://github.com/TaoMiner/NCEL`

For fairly comparison, we report the original scores of the baselines in the papers. Following these methods, we evaluate NCEL on the following five datasets: (1) **CoNLL-YAGO** (Hoffart et al., 2011): the CoNLL 2003 shared task including testa of 4791 mentions in 216 documents, and testb of 4485 mentions in 213 documents. (2) **TAC2010** (Ji et al., 2010): constructed for the Text Analysis Conference that comprises 676 mentions in 352 documents for testing. (3) **ACE2004** (Ratinov et al., 2011): a subset of ACE2004 co-reference documents including 248 mentions in 35 documents, which is annotated by Amazon Mechanical Turk. (4) **AQUAINT** (Milne and Witten, 2008): 50 news articles including 699 mentions from three different news agencies. (5) **WW** (Guo and Barbosa, 2017): a new benchmark with balanced prior distributions of mentions, leading to a hard case of disambiguation. It has 6374 mentions in 310 documents automatically extracted from Wikipedia.

5.2 Training Details and Running Time Analysis

Training We collect 50,000 Wikipedia articles according to the number of its hyperlinks as our training data. For efficiency, we trim the articles to the first three paragraphs leading to 1,035,665 mentions in total. Using CoNLL-Test A as the development set, we evaluate the trained NCEL on the above benchmarks. We set context window to 20, neighbor mention window to 6, and top $n = 10$ candidates for each mention. We use two layers with 2000 and 1 hidden units in MLP encoder, and 3 layers in sub-GCN. We use early stop and fine tune the embeddings. With a batch size of 16, nearly 3 epochs cost less than 15 minutes on the server with 20 core CPU and the GeForce GTX 1080Ti GPU with 12Gb memory. We use standard Precision, Recall and F1 at mention level (Micro) and at the document level (Macro) as measurements.

Complexity Analysis Compared with local methods, the main disadvantage of collective methods is high complexity and expensive costs. Suppose there are k mentions in documents on average, among these global models, NCEL not surprisingly has the lowest time complexity $\mathcal{O}(T * kn^2)$ since it only considers adjacent mentions, where T is the number of sub-GCN layers indicating the iterations until convergence. AIDA has the highest time complexity k^3n^3 in worst case due to exhaustive iteratively finding and sorting the graph. The LBP and PageRank/random walk based methods achieve similar high time complexity of $\mathcal{O}(T * k^2n^2)$ mainly because of the inference on the entire graph.

5.3 Results on GERBIL

GERBIL (Usbeck et al., 2015) is a benchmark entity annotation framework that aims to provide a unified comparison among different EL methods across datasets including ACE2004, AQUAINT and CoNLL. We compare NCEL with the global models that report the performance on GERBIL.

Datasets	AGDISTIS	AIDA	Babelfy	WAT	xLisa	PBoH	WNED	NCEL
ACE2004	0.66	0.80	0.61	0.76	0.81	0.79	0.81	**0.88**
	0.78	0.89	0.76	0.85	0.88	0.86	**0.90**	0.89
AQUAINT	0.73	0.57	0.70	0.75	0.79	0.84	0.83	**0.87**
	0.59	0.56	0.70	0.76	0.77	0.83	0.83	**0.88**
CoNLL-Test A	0.56	0.74	0.74	0.78	0.52	**0.80**	0.79	0.79
	0.49	0.71	0.68	0.76	0.48	**0.77**	0.76	**0.77**
CoNLL-Test B	0.55	0.77	0.76	**0.80**	0.54	**0.80**	0.79	**0.80**
	0.54	0.78	0.70	**0.80**	0.53	0.79	0.79	**0.80**
Average	0.63	0.72	0.70	0.77	0.67	0.81	0.81	**0.84**
	0.60	0.74	0.71	0.79	0.67	0.81	0.82	**0.84**

Table 1: Micro F1 (above) and Macro F1 (bottom) on GERBIL.

As shown in Table 1, NCEL achieves the best performance in most cases with an average gain of 2% on Micro F1 and 3% Macro F1. The baseline methods also achieve competitive results on some datasets but fail to adapt to the others. For example, AIDA and xLisa perform quite well on ACE2004 but poorly on other datasets, or WAT, PBoH, and WNED have a favorable performance on CoNLL but lower values on ACE2004 and AQUAINT. Our proposed method performs consistently well on all datasets that demonstrates the good generalization ability.

5.4 Results on TAC2010 and WW

In this section, we investigate the effectiveness of NCEL in the "easy" and "hard" datasets, respectively. Particularly, TAC2010, which has two mentions per document on average (Section 5.1) and high prior probabilities of correct candidates (Figure 3), is regarded as the "easy" case for EL, and WW is the "hard" case since it has the most mentions with balanced prior probabilities (Guo and Barbosa, 2017). Besides, we further compare the impact of key modules by removing the following part from NCEL: global features (NCEL-local), attention (NCEL-noatt), embedding features (NCEL-noemb), and the impact of the prior probability (prior).

Table 2: Precision on WW

AIDA	Ganea	WNED	NCEL-local	NCEL
0.63	0.78	0.84	0.81	**0.86**

	Prec	Micro F1	Macro F1
Chisholm	0.81	-	-
He	0.81	-	-
NTEE	0.88	-	-
NCEL-local	0.89	0.89	0.88
AIDA	-	0.55	0.51
Babelfy	-	0.63	0.62
WAT	-	0.75	0.73
Globerson	-	0.84	-
Boosting	-	0.86	0.85
NCEL	**0.91**	**0.91**	**0.92**

Table 3: Results on TAC2010

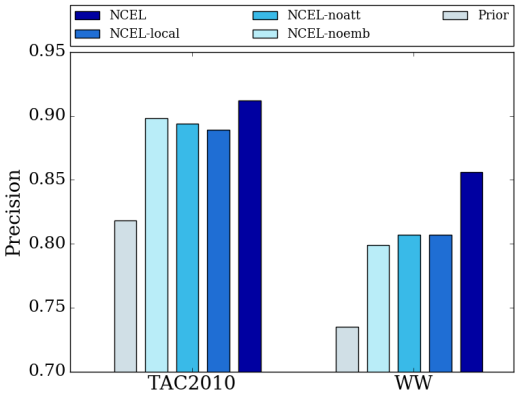

Figure 3: Impacts of NCEL modules

The results are shown in Table 2 and Table 3. We can see the average linking precision (Micro) of WW is lower than that of TAC2010, and NCEL outperforms all baseline methods in both easy and hard cases. In the "easy" case, local models have similar performance with global models since only little global information is available (2 mentions per document). Besides, NN-based models, NTEE and NCEL-local, perform significantly better than others including most global models, demonstrating that the effectiveness of neural models deals with the first limitation in the introduction.

Impact of NCEL Modules

As shown in Figure 3, the prior probability performs quite well in TAC2010 but poorly in WW. Compared with NCEL-local, the global module in NCEL brings more improvements in the "hard" case than that for "easy" dataset, because local features are discriminative enough in most cases of TAC2010, and global information becomes quite helpful when local features cannot handle. That is, our propose collective model is robust and shows a good generalization ability to difficult EL. The improvements by each main module are relatively small in TAC2010, while the modules of attention and embedding features show non-negligible impacts in WW (even worse than local model), mainly because WW contains much noise, and these two modules are effective in improving the robustness to noise and the ability of generalization by selecting informative words and providing more accurate semantics, respectively.

5.5 Qualitative Analysis

Hussain, considered surplus to Englands one-day requirements, struck 158, his first championship century of the season, as Essex reached 372 and took a first innings lead of 82.			
NCEL		NCEL-local	
England	0.23	England	0.42
England cricket team	0.72	England cricket team	0.20
Essex County Cricket Club	0.99	Essex County Cricket Club	0.97

Table 4: Qualitative Analysis of the Example *England*.

The results of example in Figure 1 are shown in Table 4, which is from CoNLL testa dataset. For mention *Essex*, although both NCEL and NCEL-local correctly identify entity *Essex County Cricket*

Club, NCEL outputs higher probability due to the enhancement of neighbor mentions. Moreover, for mention *England*, NCEL-local cannot find enough disambiguation clues from its context words, such as *surplus* and *requirements*, and thus assigns a higher probability of 0.42 to the country *England* according to the prior probability. Collectively, NCEL correctly identifies England cricket team with a probability of 0.72 as compared with 0.20 in NCEL-local with the help of its neighbor mention *Essex*.

6 Conclusion

In this paper, we propose a neural model for collective entity linking that is end-to-end trainable. It applies GCN on subgraphs instead of the entire entity graph to efficiently learn features from both local and global information. We design an attention mechanism that endows NCEL robust to noisy data. Trained on collected Wikipedia hyperlinks, NCEL outperforms the state-of-the-art collective methods across five different datasets. Besides, further analysis of the impacts of main modules as well as qualitative results demonstrates its effectiveness.

In the future, we will extend our method into cross-lingual settings to help link entities in low-resourced languages by exploiting rich knowledge from high-resourced languages, and deal with NIL entities to facilitate specific applications.

Abstract

Fundamental to several knowledge-centric applications is the need to identify named entities from their textual mentions. However, entities lack a unique representation and their mentions can differ greatly. These variations arise in complex ways that cannot be captured using textual similarity metrics. However, entities have underlying structures, typically shared by entities of the same entity type, that can help reason over their name variations. Discovering, learning and manipulating these structures typically requires high manual effort in the form of large amounts of labeled training data and handwritten transformation programs. In this work, we propose an active-learning based framework that drastically reduces the labeled data required to learn the structures of entities. We show that programs for mapping entity mentions to their structures can be automatically generated using human-comprehensible labels. Our experiments show that our framework consistently outperforms both handwritten programs and supervised learning models. We also demonstrate the utility of our framework in relation extraction and entity resolution tasks.

1 Introduction

Named entities are atomic objects of reference and reasoning in many cognitive applications and knowledge-centric services like deep question answering, text summarization and analytics. A real-world entity may have a great variety of representations (Galárraga et al., 2014; Nakashole et al., 2011). For example, University of California, Santa Cruz could have different string representations or *name variations*: UCSC, UC Santa Cruz, UC–Santa Cruz. Determining if two representations refer to the same entity is an important primitive in entity resolution and entity linking algorithms that drive these knowledge-centric applications (Shen et al., 2015; Arasu and Kaushik, 2009).

Unifying entity representations has been widely studied in record linkage (Christen, 2012), deduplication (Elmagarmid et al., 2007) and reference matching (McCallum et al., 2000). Typically, duplicates are identified using the attributes and/or the contextual information of entities (Zhang et al., 2010; Han et al., 2011; Shen et al., 2015). The string representation or *mention* of an entity forms key evidence: similar mentions likely refer to the same entity. Although deemed as crucial (Dredze et al., 2010), variations in mentions are typically handled using textual similarity like edit distance and cosine similarity (Zheng et al., 2010; Lehmann et al., 2010; Liu et al., 2013), which can be misleading.

Example. Consider the mentions: (a) General Electric Corporation, (b) General Electric China Corporation, (c) GE Corp. Mentions (a) and (b) are textually similar, differing in just one token. However, they refer to different entities, owing to the location detail 'China'. Conversely, textually dissimilar mentions (a) and (c) refer to the same entity.

An entity mention is not merely a sequence of characters (Arasu and Kaushik, 2009). It instead has an internal structure, specific to the type of entity. For example in Table 1, the company mentions have a $\langle name \rangle$, optionally followed by $\langle loc \rangle$ and $\langle suffix \rangle$. Such structural interpretation can help design similarity

Table 1: Example Structured Representations of Company and University Mentions

functions to capture the nuances in name variations of an entity that string similarity functions cannot. For instance, GE can be explained as a mention of General Electric Corporation using transformations like abbreviate $\langle name \rangle$ and drop $\langle suffix \rangle$. These transformations coupled with string similarity functions can augment existing entity linking algorithms (Qian et al., 2017).

The name variations and, consequently, the transformations are highly domain-dependent (Arasu et al., 2008). Designing similarity functions for an entity type that can reason over the structure of entities requires: (a) a comprehensive list of the structured representations (e.g. column 2 in Table 1), and (b) programs that can map mentions to these structures (e.g. column 3 in Table 1). Traditionally, a domain expert would scan a list of mentions of a target entity type to identify the different structured representations and handwrite programs. This requires specialized skills, and is error-prone and expensive, taking up to several person months to tune the programs for a single application (Campos et al., 2015).

To alleviate the high manual effort, some of the prior works (Arasu and Kaushik, 2009) use declarative, programmable frameworks that allow an expert to directly manipulate the mentions. The expert can provide a program as a set of grammar rules to generate the structured representations. While this equips the expert to manipulate the structure of a mention, it is only a partial solution. The rules are not generic, requiring the expert to specify how each mention is parsed to its structure. This is wasteful because a structure, shared by several mentions, can be captured with a generic rule. Another limitation of previous approaches is that they do not handle structural ambiguities. For instance, there can be multiple structures of Apple Inc. such as $\langle name \rangle \langle loc \rangle$ and $\langle name \rangle \langle suffix \rangle$, only one of which is correct.

Since several mentions of an entity type tend to have similar structures, it is possible to learn the various structures from a subset of mentions. Given a good query strategy, active learning offers a promising approach to efficiently select a small set of such mentions. Moreover, the expert need not provide programs that parse the selected mentions and generalize to unseen mentions. These programs can be induced from the labels for the structures of the mentions. Embodying these ideas, we propose LUSTRE, an active-learning based framework that learns structured representations for an entity type from human-comprehensible labels for a small set of mentions. It automatically synthesizes *generalizable* programs from the labels to map new mentions of the entity type to the learned structured representations. In addition, it allows the expert to incorporate domain knowledge and additional feedback to handle structural ambiguities. Our framework significantly reduces the manual effort in labeling mentions and writing programs for the structured representations. We also demonstrate how these structured representations help define similarity functions that benefit entity resolution, and string transformation functions that benefit relation extraction. The intellectual contributions of this work are as follows:

- *Structured Representations.* We present a framework to reason about name variations of entities based on their structured representations.
- *Active-learning.* We present an active-learning approach and a unified query strategy to learn structured representations for a target entity type with minimal human input.
- *Program Synthesis.* We propose to automatically synthesize *generalizable* programs from human-understandable labels to map mentions to their structured representations.
- *Experimental Evaluation.* Our experiments show that our framework achieves an average of 92% precision and 86% recall in predicting structured representations for several entity types, outperforming competing approaches that require high manual effort. We demonstrate the usefulness of the structured representations in two important tasks: entity resolution and relation extraction.

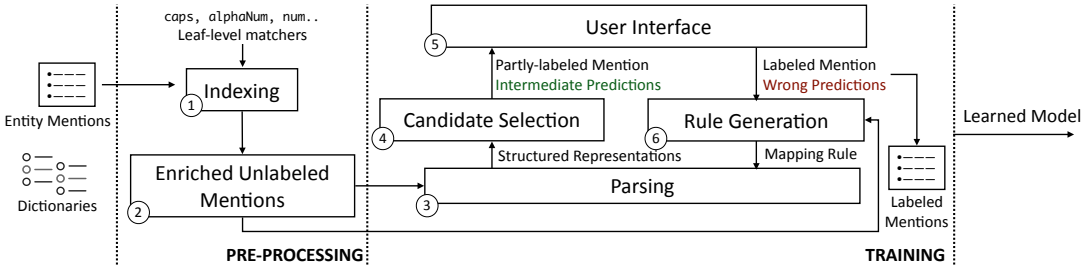

Figure 1: LUSTRE Architecture

2 Problem Formalization and Notations

Given a set of unlabeled mentions (i.e., raw strings) of a target entity type ϵ, our goal is to actively learn a high-quality model M_ϵ (with a small number of user labels) that can map a new mention of type ϵ to its structured representation. Key technical challenges in learning such a model include: (1) designing an effective query strategy to find representative mentions that are structurally similar to several other mentions and to find mentions with diverse structures; (2) automatically inferring mapping programs from the user labels to reduce the human effort, as in (Campos et al., 2015) and (Arasu and Kaushik, 2009); (3) handling ambiguities when an unlabeled mention has multiple candidate structured representations.

Mentions of a target entity type have internal *structured representations* consisting of atomic *semantic units*. Given the labels for the semantic units for a small set of mentions, we want to learn a model M of *mapping rules*. Each mapping rule converts a raw string mention into a structured representation.

Definition 1 (Structured Representation)**.** *A structured representation $\mathcal{S}$ of an entity mention is a sequence of atomic semantic units that compose its structure.*

Textually dissimilar mentions can have the same structure (e.g. Apple Inc. and Hewlett-Packard Co.).

Definition 2 (Semantic Unit)**.** *A semantic unit is a tuple $u = \langle l : p \rangle$ where l is a label for the unit and p is a pattern matching function (e.g., a regular expression), referred to as a **matcher**.*

A matcher describes how a substring in a mention matches a semantic unit. For instance, a matcher ([A-Z][A-Za-z]*[-']?)+ captures $\langle name \rangle$ in mentions Apple Inc. and GE Corp. Name variations of an entity can be explained as transformations on its semantic units (e.g. dropping suffix in Apple Inc. generates Apple).

Definition 3 (Mapping Rule)**.** *The mapping rule $r_\mathcal{S}$ for a structured representation $\mathcal{S}$ consists of matchers which decide how an unlabeled mention is mapped to $\mathcal{S}$, resulting in a **labeled entity mention**.*

Specifically, a mapping rule $r_\mathcal{S}$ is a sequence of matchers in the semantic units in $\mathcal{S}$, denoted by $r_\mathcal{S} = \{p_i \mid \langle l_i, p_i \rangle \in \mathcal{S}\}$. This mapping rule constitutes a program that maps unseen mentions to $\mathcal{S}$. Together the various mapping rules constitute a model M_ϵ for the entity type ϵ.

3 The LUSTRE System

We propose LUSTRE that addresses the aforementioned challenges in learning a model of mapping rules for an entity type by:

- adopting a unified query strategy that combines uncertainty sampling (i.e., selecting a mention whose current structured representation is unknown or uncertain) and density-weighted sampling (i.e., selecting a mention whose structured representation is representative of many unlabeled mentions).
- seeking human-comprehensible labels for the semantic units in the structure of an unlabeled mention, and deducing a mapping rule by combining the matchers for the semantic units.
- handling structural ambiguities of an unlabeled mention by ranking the candidate mapping rules based on their *reliability* and additional user feedback.

Figure 1 depicts the workflow of LUSTRE and Algorithm 1 shows our learning algorithm. It takes as input unlabeled mentions $\mathcal{U}_\epsilon$ and optionally dictionaries $\mathcal{D}_\epsilon$ of a target entity type ϵ. These dictionaries and a set of pre-defined matchers form the building blocks for the mapping rules. Before training, LUSTRE evaluates all the matchers against $\mathcal{U}_\epsilon$ to inform the query strategy and rule generation (Sec 3.1).

Algorithm 1 LUSTRE learning algorithm

input: $\mathcal{U}_\epsilon$ = a pool of unlabeled mentions $\{m\}$
output: $\mathcal{M}_\epsilon$ = a model of mapping rules $\{r_\mathcal{S}\}$

1: **function** TRAIN($\mathcal{U}_\epsilon$)
2: $\mathcal{L}_\epsilon$ = a set of labeled mentions $\{\langle m, l\rangle\}$
3: $\mathcal{F}$ = feedback $\{\langle m, l, f\rangle \mid m \in \mathcal{U}, f \in \{0, 1\}\}$
4: $\mathcal{M} = \varnothing$
5: **for** t = 1,2... **do**
6: $\mathcal{M}$ = UPDATE($\mathcal{M}, \mathcal{L}, \mathcal{F}$)
7: select $m^* \in \mathcal{U}$, mention with highest utility
8: select $\mathcal{F}$ with least confident predictions
9: query label l^* for mention m^*
10: query binary feedback on $\mathcal{F}$
11: $\mathcal{L} = \mathcal{L} \cup \langle m^*, l^*\rangle, \mathcal{U} = \mathcal{U} \backslash \{m^*\}$
12: **return** $\mathcal{M}$
13: **function** UPDATE($\mathcal{M}, \mathcal{L}, \mathcal{F}$)
14: **for** $\langle m, l\rangle \in \mathcal{L}$ **do**
15: $r_\mathcal{S} = generate\_rule(l)$
16: **if** $r_\mathcal{S} \notin \mathcal{M}$ **then**
17: $\mathcal{P}_{r_\mathcal{S}} = reliability(r_\mathcal{S})$
18: $\mathcal{M} = \mathcal{M} \cup \langle r_\mathcal{S}, \mathcal{P}_{r_\mathcal{S}}\rangle$
19: **for** $\langle r_\mathcal{S}, \mathcal{P}_{r_\mathcal{S}}\rangle \in \mathcal{M}$ **do**
20: $\mathcal{P}_{r_\mathcal{S}} = estimate(\mathcal{P}_{r_\mathcal{S}}, \mathcal{F})$
21: **return** $\mathcal{M}$

During training, in each iteration, LUSTRE selects a candidate mention for the user to label (Sec 3.2). Given the user-provided labels for semantic units of the selected mention, it derives a generic mapping rule for the structure of the mention (Sec 3.3). It then updates the model M with the new rule, and predicts the structures of unlabeled mentions (Sec 3.4). It presents a sample of these predictions to the user and integrates the user feedback in M (Sec 3.5). This iterative process continues until all the unlabeled mentions can be mapped to some structure or the user is satisfied with M.

3.1 Indexing

User-provided dictionaries and pre-defined regular expressions constitute the vocabulary of matchers for the mapping rules. The dictionaries help capture key domain-specific terminology but need not correspond to semantic units.

Example. *A suffix dictionary may contain 'Inc.', 'Corp', 'LLC', 'Pvt. Ltd.'* □

Additionally, we use type-independent regex matchers shown in Table 2. In a pre-processing step (Line 1 of Algorithm 1), we evaluate the unlabeled mentions against the matchers to save computational overhead. We refer to these *enriched unlabeled mentions* during training.

Example. *Given dictionaries for country and suffix and a mention IBM UK Ltd., the matchers yield matches UK→*$\langle country\rangle$*, Ltd.→*$\langle suffix\rangle$ *IBM→* $[\langle caps\rangle, \langle alphaNum\rangle]$*, UK→* $[\langle caps\rangle]$. □

Multiple matchers can match the same token (e.g. $\langle country\rangle$ and $\langle caps\rangle$ match 'UK'). We assume that more specific matchers offer higher precision than generic matchers. We further formalize this intuition in Section 3.3. We rank matchers in the following order based on their selectivity: $\mathcal{D}_\epsilon > caps > alphaNum > num > special > wild$[1].

Name	Regex
caps	[A-Z][A-Za-z]*[.-']?
alphaNum	[A-Za-z0-9]+[.-']?
num	[0-9]+
special	[^A-Za-z0-9]+
wild	.+

Table 2: Predefined Matchers

3.2 Candidate Selection

The query strategy to determine what constitutes an informative mention is the central challenge in our active-learning setting (Line 7 of Algorithm 1). We consider a mention *informative* if its represents the structure of several other unlabeled mentions and its current structure is unknown or uncertain. We adopt a unified approach, combining density-weighted sampling (Settles and Craven, 2008) and uncertainty sampling (Culotta and McCallum, 2005) as it is robust to outliers and input distribution.

For each unlabeled mention m_i, we compute a correlation score c_i (based on its structural similarity to other mentions) and an uncertainty score f_i (based on its predicted structure). We then compute a utility score u_i for m_i, combining its correlation and uncertainty scores, and select a mention m^* with the highest utility score for labeling.

To compute correlation score c_i, we need a reliable metric to measure the similarity of the structures of two mentions. Since surface-string similarity metrics won't suffice, we estimate structural similarity of two mentions as a function of the matchers that constitute their structures. Specifically, we compute structural similarity $c(i, j)$ of a pair of mentions (i, j) as the edit distance of their structures, $\mathcal{S}_i$ and $\mathcal{S}_j$.

[1]The order of preference can be inferred in a pre-processing step in which the system counts the selectivity of each matcher against the input mentions

Example. *'IBM Ltd.' and 'Apple Inc.' have the same structure* $\langle caps \rangle \langle suffix \rangle$*, and therefore, have an edit distance of 0. Each has edit distance 1 to 'Microsoft Asia Inc.' with structure* $\langle caps \rangle \langle loc \rangle \langle suffix \rangle$*.* □

Given the pair-wise structural similarity metric, the correlation score c_i of a mention m_i is its average structural similarity to other unlabeled mentions.

$$c_i = \frac{1}{|U|} \sum_{j \in U} c(i,j) \qquad f_i = \begin{cases} 1 & \text{if no rule maps } m_i \\ 1 - \mathcal{P}_{\hat{r}_\mathcal{S}} & \text{otherwise} \end{cases} \qquad u_i = c_i * f_i$$

$$c(i,j) = 1 - \frac{\text{edit distance}(\mathcal{S}_i, \mathcal{S}_j)}{\text{max edit distance}} \qquad \mathcal{P}_{\hat{r}_\mathcal{S}} = \operatorname*{argmax}_r \mathcal{P}_{r_\mathcal{S}} \qquad m^* = \operatorname*{argmax}_{m_i} u_i$$

To estimate the uncertainty score f_i of a mention, we use $\mathcal{P}_{r_\mathcal{S}}$, the reliability of the mapping rules that can parse the mention. If no mapping rule can parse a mention m_i, its structure is unknown i.e. f_i is simply 1. Otherwise, it is the uncertainty of the most reliable rule $\hat{r}_\mathcal{S}$ known to parse the mention. We discuss how the reliability $\mathcal{P}_{r_\mathcal{S}}$ of mapping rules are estimated in Sec. 3.4.

3.3 Rule Generation

Once the user labels a selected mention, LUSTRE next has to synthesize a generic program i.e. a mapping rule for the structure of the mention (Line 15 of Algorithm 1). Deriving a mapping rule is non-trivial as semantic units in the structure can potentially span multiple tokens and matchers. As a result, there are many ways to combine matchers and derive the rule.

Example. *A user can label 'General Motors' as semantic unit* $\langle name \rangle$ *in 'General Motors Co.' Tokens 'General' and 'Motors' map to matchers* $caps$ *and* $alphaNum$*. The most reliable interpretation for* $\langle name \rangle$ *is* $\langle name ::caps\{1,2\} \rangle$*, a combination of two adjacent matchers* $\langle caps \rangle$*.* □

LUSTRE derives a reliable rule as the sequence of most selective matchers, where *selectivity* is the expected number of matches of a matcher over the set of unlabeled mentions $\mathcal{U}$ (Li et al., 2008).

$$sel(p_i) = \mathrm{E}[match(p_i, m \in \mathcal{U})]$$

with $match(p_i, m)$ being number of matches of p_i over mention m.

3.4 Parsing

When a new mapping rule is learned, we want to estimate its reliability in predicting structures of mentions, and update the model M (Line 17-18 of Algorithm 1). These reliability scores are used for estimating utility scores at candidate selection and for resolving ambiguities when multiple rules can parse a mention (with preference given to the most reliable rule). Following the intuition that generic rules are less reliable, we estimate reliability of a rule based on its expected numbers of matches in the unlabeled mentions. Specifically, reliability $\mathcal{P}_{r_\mathcal{S}}$ is a function of the selectivity of the matchers in $r_\mathcal{S}$.

$$p^* = \operatorname*{argmin}_i \{sel(p_i) \mid \langle l_i, p_i \rangle \in \mathcal{S}\}$$

$$\mathcal{P}_{r_\mathcal{S}} = 1 - sel(p^*)$$

3.5 User Interface

LUSTRE uses an easy-to-use interface (Qian et al., 2018) to seek labels for a selected mention and additional feedback on intermediate predictions (Line 9 of Algorithm 1). To reduce the labeling effort, tokens in the mention that match an entry in the dictionary are pre-labeled with the name of the dictionary (e.g. 'IBM Corp' is presented with 'Corp' labeled as suffix). The user can keep these and/or provide new labels (e.g. user can label 'IBM' as name).

In addition, the interface presents the predictions of structures for a sample of unlabeled mentions. It selects 10 least confident predictions based on uncertainty scores (Section 3.2). The user can simply mark a prediction incorrect, without providing labels for its correct structure. LUSTRE effectively integrates this feedback to avoid over-estimating the reliability of learned rules, thereby improving the quality of model M. Specifically, it updates the reliability of a mapping rule $\mathcal{P}^i_{r_\mathcal{S}}$ as a function of number of incorrect predictions $\overline{m_r}$ for the rule in the set of 10 predictions presented to the user (Line 20 of Algorithm 1).

$$\mathcal{P}^j_{r_\mathcal{S}} = \mathcal{P}^i_{r_\mathcal{S}} * (1 - \alpha * \frac{|\overline{m_r}|}{10})$$

with α being the decay constant. We found such estimation, though simple, was effective in estimating the reliability of mapping rules. Training more powerful measures such as a discriminative model would require larger user feedback than is available in this setting.

4 Experiments

We assess the effectiveness of our learning algorithm, and the quality and usefulness of learned structures.[2]

4.1 Experimental Setup

Datasets. We conduct experiments on four entity types of varied complexity and ambiguity.

- Person: Focusing on subtype *Individual*, we randomly select 200 unique mentions for training and another 200 mentions for testing from the ACE 2005 dataset (Walker et al., 2006). For out-of-domain tests, we randomly select 200 person mentions from Freebase (Bollacker et al., 2008).
- Company: Focusing on subtype *Commercial*, we randomly select 200 mentions for training and use the remaining 100 mentions for testing from the ACE dataset. For out-of-domain test, we randomly select 200 company mentions from Freebase.
- Tournament: We use a 50/50 split for the 100 unique mentions of tournaments in Freebase.
- Academic Title: We use a 50/50 split for the 350 unique mentions of academic titles in Freebase.

For each mention, we ask two experts to manually annotate every token with a semantic label to produce the ground truth. The average inter-annotator agreement was 0.89 for Cohen's κ.

Baselines. We compare LUSTRE with the following methods.

- STG: A commercial system (Campos et al., 2015) which requires an expert (with domain knowledge and programming skills) to analyze the structures of an entity type and handwrite mapping programs.
- Linear-chain CRF[3]: A linear-chain CRF model that predicts a sequence of labels for the tokens in a mention. We use matches from the *Indexing* stage as features. We use two different training settings: CRF trained on the entire training set (to compare with best model), and CRF^{L} trained on the subset of training set selected via the query strategy in LUSTRE (to compare with same user effort).
- LUSTRE^{T}: LUSTRE with a native tf-idf based query strategy.

Evaluation Metric. We consider a prediction correct if the model and expert agree on the semantic labels for each token in the mention. We measure *precision* as the fraction of predictions that are correct and *recall* as the fraction of correct structures that are predicted. We define a new metric, which we call the α value, to estimate the role of manual effort on performance of various methods (definition is given below). Intuitively, higher the α value, higher the effectiveness of a method in learning from a user label.

$$\alpha(X,t) = \frac{\text{F-score of method } X \text{ on entity type } t}{\text{number of user labels requested by } X}, \text{where X} \in \{\text{LUSTRE, CRF, CRF}^{\text{L}}\}.$$

4.2 Quality Analysis

The performance results of the different methods are summarized in Table 3. For *Person* mentions, all methods achieve reasonably good results (F-scores are all above 0.85). This is not surprising as person mentions typically have simple structures with few semantic units. STG achieves lowest performance, indicating that manually-crafted programs are not as robust as learned models. CRF models, especially CRF^{L} trained on mentions selected using LUSTRE, show evident improvement over STG. LUSTRE achieves comparable performance. However, it outperforms all other methods on out-of-domain test data, suggesting it can capture the structures in mentions regardless of their data source.

Company mentions are more complex than *Person* mentions. They can have several semantic units such as core name, location, suffix and subsidiary, which can appear in different orders, be separated by special symbols etc. Consequently, capturing structures in company mentions is more difficult, as is reflected in the performance across methods. Learning a reliable model/program would require higher

[2]We will release the code and data from this work. Code is proprietary but can be licensed.

[3]http://mallet.cs.umass.edu/sequences.php

manual effort in STG and more training data in CRF. In contrast, LUSTRE, with small human input, achieves high precision and recall for both in-domain and out-of-domain data.

Tournament and *Academic Title* mentions have even more complex structures that exhibit more variations. Even for these complex types, LUSTRE outperforms CRF. We do not report results of STG for these two entity types because these were not considered when STG was developed. We do not provide an out-of-domain evaluation of the two entity types because only the Freebase data included mentions of these entity types.

In summary, LUSTRE outperforms STG and CRF-based methods in terms of overall F-score with the exception of *Person* where CRF^{L} has a small improvement over LUSTRE. Furthermore, its unified query strategy is more effective than a tf-idf based strategy, as is reflected in the performance of LUSTRE^{T}.

We found two main sources of errors made by LUSTRE. First, akin to all learning methods (such as CRF), it has low recall when the training data is not representative. Second, ranking mapping rules sometimes cannot effectively resolve structural ambiguities. For example, 'The Stanford University Professorship in Nephrology' can be interpreted as $\langle honorary\ \ prefix\rangle\langle title\rangle\langle specialty\rangle$ or $\langle institute\rangle\langle title\rangle\langle specialty\rangle$. The former is incorrect, but being more commonly observed in the training data, is ranked higher.

		In-Domain			Out-of-Domain		
Type	Algorithm	P	R	F_1	P	R	F_1
Person	STG	0.92	0.92	0.92	0.85	0.85	0.85

Table 3: Performances of LUSTRE, STG and CRF

4.3 Effectiveness

To assess how the quality of structured representations evolves in the learning process, we examine the precision and recall of LUSTRE after each iteration (as shown in Figure 2). We found that the precision remains nearly constant. There are a limited number of structures for the same types of entities. Every time LUSTRE learns a precise rule that improves coverage. There are slight drops in the precision due to the long tail of non-representative cases. The recall generally increases depending on whether the system prefers to gather additional evidence or to discover new structured representations.

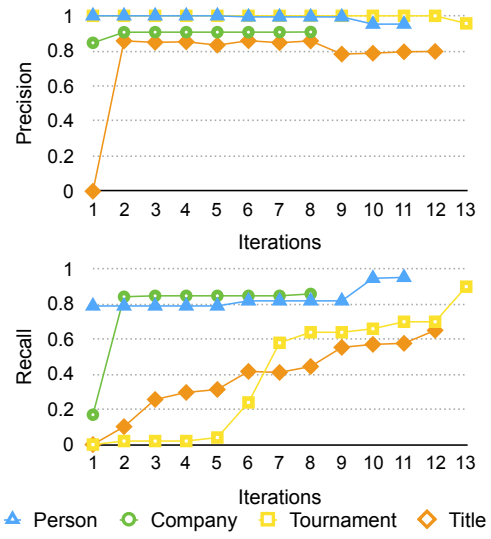

Figure 2: Performance of LUSTRE over iterations

We also examine the number of rules learned, number of incorrect intermediate predictions, and percentage of input training data covered after each learning iteration in LUSTRE (as shown in Figure 3). We found that it took 8-13 iterations to learn almost all different structures of an entity type. The fraction of training data that could be parsed using the mapping rules also generally increased, indicating that our query strategy selected structurally diverse mentions for labeling. Only a few (<5) predictions were

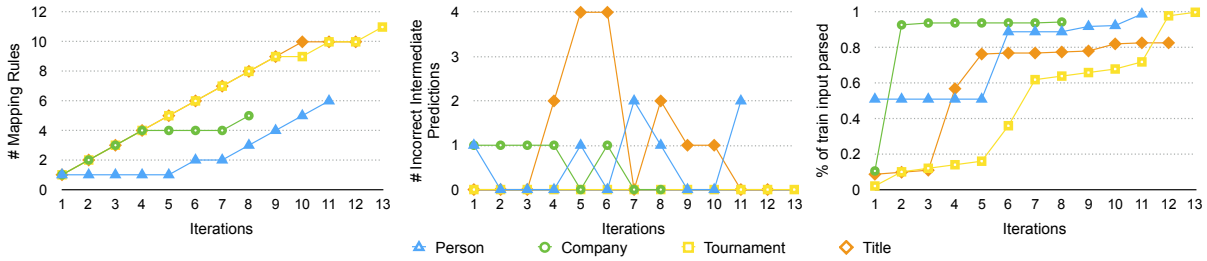

Figure 3: Number of mapping rules, number of incorrect predictions, fraction of training data parsed after each iteration

marked incorrect in each iteration. This suggests that LUSTRE, with a small set of labeled mentions and a little user feedback, learned reliable rules and ranked them correctly.

Next, we compare the nature and amount of human effort across different methods. STG requires high effort and high skill. Even for a simple entity type *Person*, it takes one skilled developer a few months to manually inspect the different structural patterns and write programs. Learned models such as LUSTRE and CRF reduce the skill level and require only human-readable labels for a mention. However, in contrast to CRF, LUSTRE does not require the user to collect and label a set of representative mentions. It guides the user to interactively and iteratively label a few mentions, with each iteration taking less 7 seconds. The optional feedback also is small (<5 predictions) and low-effort (boolean labels).

Quantitatively, we report the α values of the three learning methods. CRF has the lowest α value because it uses all labeled examples. Interestingly, benefiting from the informative mentions selected by LUSTRE, CRF^L have much higher α values. LUSTRE, however, has the highest α values.

	LUSTRE	CRF	CRF^L
`Person (in-domain)`	0.089	0.005	**0.090**
`Person (out-domain)`	**0.084**	0.005	**0.083**
`Company (in-domain)`	**0.125**	0.004	0.101
`Company (out-domain)`	**0.11**	0.004	0.091
`Tournament`	**0.072**	0.014	0.052
`Title`	**0.060**	0.004	0.055

Table 4: The α values of different methods

4.4 Usefulness

We present an extrinsic evaluation on entity resolution and relation extraction tasks, both of which require reasoning over name variations of entities. We implement a configurable variant generation program that uses structure of an entity to generate its name variations. It allows the user to configure a set of string transformation functions for the semantic units in a structure, which are then used to compose name variations. It supports four transformations: DROP (ignore a token), INITIAL (retain first character of a token), INITIAL$_{dot}$ (retain first character followed by a dot) and MAP (replace with user-provided string).

Entity Resolution

We use ERLearn (Qian et al., 2017), a state-of-the-art system for large-scale entity resolution (ER). ERLearn aims to learn a set of *matching rules*, each consisting of *matching functions* for different entity attributes (e.g., to determine duplicate names 'John Smith' and 'J. Smith'). The matching functions are mostly based on textual similarity of attributes. We replace these with matching functions created using LUSTRE[4]. We focus on two scenarios: (1) `Emp-Social` (matching ∼470k employee records with 50 million social network user profiles) (2) `Crystal` (de-duplicating ∼1.3 million company records). We include new matching functions for *person* names and *company* names for the two scenarios respectively.

Type	Algorithm	# links	Precision	# true links
EMP-SOCIAL	ERLearn-CIKM	1088	**0.93**	∼1015
	ERLearn-LUSTRE	**1178**	0.9	**∼1060**
CRYSTAL	ERLearn-CIKM	145,516	0.9	∼130,964
	ERLearn-LUSTRE	**147,232**	0.9	**∼132,508**

Table 5: ERLearn-CIKM vs. ERLearn-LUSTRE

As shown in Table 5, the new matching functions help ERLearn identify 4.40% and 1.17% more true links for `Emp-Social` and `Crystal` scenarios, respectively. This improvement is significant for

[4]Due to space constraints, we request readers to refer to the supplementary material for details

Emp-Social given the extreme low matching ratio for this dataset. ERLearn-CIKM already identifies a significant subset of the true links in such a sparse space that it is non-trivial for ERLearn-LUSTRE to have found additional 45 true links. In contrast, the ER task is more challenging for the Crystal scenario, with more matching functions (158 vs. 68) (Qian et al., 2017). ERLearn-LUSTRE could still identify additional 1544 true links, which is a significant improvement over 130k true links already identified by ERLearn-CIKM. [5]

Relation Extraction

We use MULTIR (Hoffmann et al., 2011), a state-of-the-art relation extractor trained on NY Times text (Riedel et al., 2010) with weak supervision from Freebase (Bollacker et al., 2008). The weak supervision data is generated by exactly matching the textual mentions to canonicalized entities in Freebase. We instead match to the variations of entities of types *Person* and *Company*, generated using the configurations in Table 6. We follow the approach of (Hoffmann et al., 2011) to generate supervision data, compute features and evaluate aggregate extraction.

For the 2 million entities, we generate 5.3 million variations. There were 24,882 sentences where textual mentions exactly matched a canonical Freebase entity and one of the specified relations existed between the entities. This increased to 34,197 sentences when named variations of entities were included, suggesting name variations are useful for entity recognition. By including the variations for only two entity types, we could generate a training data that improved the overall extractor performance (F-1 score increased by 3% from 0.485 to 0.499). The extractor could further benefit from variations for entities of other types.

5 Related Work

Exploiting the compositional structure of entities and attributes especially from query streams and text has received much attention in databases and NLP literature. It has mostly been used for understanding NL questions (Berant et al., 2013), noun-phrase queries (Li, 2010) or normalizing time expressions (Lee et al., 2014; Bethard, 2013). Consequently, structuring and linking information on the web (Bollacker et al., 2008; Auer et al., 2007) about entities and their attributes, has seen a rise in interest. With this information being automatically extracted from textual data (Fader et al., 2011; Carlson et al., 2010), reconciling variations in entities and attribute names has become an integral part of the effort. Some recent work (Halevy et al., 2016) has attempted to organize attribute names by learning their compositional structure. On the other hand, some have proposed complex normalization frameworks (D'Souza and Ng, 2015) for specific domains. However, we need methods that can learn structured representations for the large scale of entity types found on the web.

Named entities are not atomic units and often contain other entities (Finkel and Manning, 2009). However, entity resolution has relied largely on surface-level match of entity mentions (Riedel et al., 2010; Hoffmann et al., 2011; Xu et al., 2013). Variations are typically handled using similarity functions such as edit distance, jaccard similarity, which have limited customizability. While learning string transformation rules (Arasu et al., 2009; Singh and Gulwani, 2012) to reconcile variations has been studied in different contexts, it typically relies on a set of input-output examples. It is difficult to obtain such data for entities and their variations. We instead propose a different approach to first learn the internal structure of an entity and then enable configurable transformations on its structure to generate its variations.

We focus on the problem of reducing manual effort in selecting a set of representative examples for learning the regular expression patterns, which is different from the problem of synthesizing regular

[5] More results of the entity resolution experiment can be found in the appendix.

expressions from examples (Bartoli et al., 2012; Li et al., 2008).

6 Conclusion

This paper identifies a novel problem of understanding structured representations of entities for handling their name variations. We propose an active-learning based approach, LUSTRE, to iteratively learn the structured representations of an entity type from a few labeled mentions and a large set of unlabeled mentions. With small manual effort, it can learn these structured representations and automatically generate programs to map mentions to their structured representations. Reasoning over such structured representations is useful for entity resolution and relation extraction that require reasoning over name variations of entities. In the future, we plan to extend our approach to learn structures of nested entities, and use sophisticated variant generation algorithms that could rank the variations based on their reliability.

7 Appendix A. Experimental Setup of Entity Resolution

Our entity resolution experiments use ERLearn (Qian et al., 2017) on two scenarios `Emp-Social` and `Crystal`. We aim to provide it supplementary matching functions that reason over structured representations of entity names. To learn structured representations for the `Emp-Social` scenario, we randomly sample 1000 person names from the *Emp* records and 1000 person names from the online social network data. Using LUSTRE over the 2000 names, we learn the structures for *Person* with five different semantic units: $\langle first \rangle$, $\langle last \rangle$, $\langle middle \rangle$, $\langle suffix \rangle$, and $\langle title \rangle$. For the `Crystal` scenario, we learn structures for *Company* names using a sample of 2000 names. These structures have semantic units $\langle name \rangle$, $\langle industry \rangle$, $\langle suffix \rangle$, and $\langle location \rangle$.

Person

Table 7: Configurations with examples

To design matching functions that reason over structured representations to identify duplicates, we refer to the name variations of mentions generated using their representations. Intuitively, duplicate mentions are likely to share many name variations. Given a mention, we first generate its variations using the configurations in Table 7. We keep both the original string and the transformed string for a semantic unit modified using an operator from the configuration. For instance, dropping the title in a person name would generate Dr. Russell Nelson Sr. and Russell Nelson Sr. as variations of Dr. Russell Nelson Sr.. We define matching functions to identify two mentions as duplicates if they have at least r common variations.

matchPerson(Emp.name, social.name, r),
matchCompany(cp1.name, cp2.name, r),
matchCompany(cp1.parent.name, cp2.parent.name, r),

where $r = 1, 2, \ldots, 20$. These matching functions complement the matching functions used in the original study (Qian et al., 2017). We compare the ER rules learned by ERLearn in two different configurations, ERLearn-LUSTRE and ERLearn-CIKM, with and without the new matching functions respectively. The rules learned by ERLearn-LUSTRE had similar constituent matching functions as rules from ERLearn-CIKM. However, we found they additionally included the new matching functions and had relaxed some of the matching functions. For illustration, consider the following rules:

```
match Emp i, Social s By R:
  matchPerson(i.Name, s.name, 9)
  AND i.name.last = s.name.last
  AND lastNameFreqFilter(s.name.last, 50%)
  AND sameCity(i.CITY, s.city)
  AND countryIsInUS(i.COUNTRY, s.country)
```

(a) ERLearn-LUSTRE

```
match Emp i, Social s By R:
  nameMatch(i.Name.firstNameVars,s.name.first)
  AND i.Name.last = s.name.last
  AND lastNameFreqFilter(s.name.last, 60)
  AND upperCase(i.CITY)= upperCase(s.home.city)
  AND countryIsInUSA(i.COUNTRY)
```

(b) ERLearn-CIKM

There are to key differences: (1) the matching function for first names now uses the new matching function *matchPerson*, (2) the threshold value used in *lastNameFreqFilter* decreased from 60% to 50%. In contrast to the original rules, the lower threshold value for last names in the new rule makes it less conservative, potentially increasing the risk of identifying incorrect links. However, the matching function *matchPerson* makes the rule less susceptible to over-generalization. We found that by including matching functions that exploit the structured representations of entities, ERLearn could learn an ER model with appropriate generalization.

A Practical Incremental Learning Framework For Sparse Entity Extraction

Abstract

This work addresses challenges arising from extracting entities from textual data, including the high cost of data annotation, model accuracy, selecting appropriate evaluation criteria, and the overall quality of annotation. We present a framework that integrates Entity Set Expansion (ESE) and Active Learning (AL) to reduce the annotation cost of sparse data and provide an online evaluation method as feedback. This incremental and interactive learning framework allows for rapid annotation and subsequent extraction of sparse data while maintaining high accuracy.

We evaluate our framework on three publicly available datasets and show that it drastically reduces the cost of sparse entity annotation by an average of 85% and 45% to reach 0.9 and 1.0 F-Scores respectively. Moreover, the method exhibited robust performance across all datasets.

1 Introduction

Entity extraction methods delimit all mentions of an entity class (e.g., Location Names, Proteins, or Auto Parts IDs) in corpora of unstructured text. Supervised machine learning approaches have been effective in extracting such entity mentions, such as (Finkel et al., 2005). However, the prohibitive cost of obtaining a large volume of labeled data for training makes them unattractive and hard to use in realistic settings where resources may be scarce or costly to create (e.g., aviation engineer needing to annotate engine maintenance data). In this paper, we address the problem by developing a practical solution exploiting the strengths of the supervised sequence labeling techniques (Ye et al., 2009) while reducing the high cost of annotation.

Training data and the annotation approach are the two focal points of any supervised method. A model can be built from pre-annotated data or using *de novo annotations*. There are many pre-annotated and publicly available corpora such as CoNLL-2003 (Tjong Kim Sang and De Meulder, 2003), GENIA (Ohta et al., 2001), and BioCreative II (et. al., 2008). However, having such data leaves us with two challenges: (i) no training dataset can be found for many of the domain-specific entity classes in enterprise corpora due to data privacy concerns, IP restrictions, and problem specific use cases (needing *de novo annotations*), and (ii) data sparsity, which hinders the performance of supervised models on unseen data (needing *incrementally augmented annotations* to the annotated sentence pool).

We propose a practical solution to model building through (i) rapid auto-annotation, to create models with reduced cost, and (ii) flexible stopping criteria using an online evaluation method, which calculates the confidence of a model on unseen data without a need for a gold standard. Having such an online feedback method supports incremental learning which allows us to partially overcome the data sparsity problem (see Section 2).

Mainstream entity annotation approaches typically present a large body of text or full documents to annotators, which can be time-consuming as well as lead to low quality annotations. Additionally, the majority of these techniques require labeling for multiple entity classes which makes the annotation task

*Part of this work has been done during the author's internship at Maana Inc.

Proceedings of the 27th International Conference on Computational Linguistics, pages 700–710
Santa Fe, New Mexico, USA, August 20-26, 2018.

harder and more complex. Therefore, sentence-level and single-entity-class annotation are desirable to improve tractability and reduce cost. Imposing such requirements, however, causes a labeling starvation problem (i.e., querying annotators to label sentences containing a low frequency of entities from the desired class). In this work, we develop an Entity Set Expansion (ESE) approach to work side by side with Active Learning (AL) to reduce the labeling starvation problem and improve the learning rate.

Our framework is similar to the work proposed by (Tsuruoka et al., 2008) that aims to annotate all mentions of a single entity class in corpora while relaxing the requirement of full coverage. Our design choice lowers the annotation cost by using flexible stopping criteria, assisting in the corpus annotating procedure and removing the requirement for annotators to scan all sentences. Our approach differs from the above in that we perform ESE by learning the semantics and relevant context to retrieve similar entities by analogy, to accelerate the learning rate. Moreover, our approach provides Fast (FA), Hyper Fast (HFA), and Ultra Fast (UFA) auto-annotation modes for rapid annotation. Our contributions include:

1. A framework to annotate sparse entities rapidly in unstructured corpora using auto-annotation. We then use flexible stopping criteria to learn sequence labeling models incrementally from annotated sentences without compromising the quality of the learned models.

2. A comprehensive empirical evaluation of the proposed framework by testing it on six entity classes from three public datasets.

3. An open source implementation of the framework within the widely used Stanford CoreNLP package (Manning et al., 2014).[1]

In the upcoming sections, we describe our incremental learning solution developed using Active Learning, and how we use ESE to accelerate the annotation. Finally, we will evaluate the proposed method on publicly available datasets showing its effectiveness.

2 Incremental and Interactive Learning

In practical applications, domain experts have datasets from which they want to extract entities and then use these entities to build various applications like identifying the mentions of the same suppliers and materials referred to by similar entities in sourcing databases for the purpose of optimizing supply chains. Next, we will describe how we use AL to accelerate the learning rate, to auto-annotate sentences, and to provide feedback for flexible stopping criteria.

Active Learning (AL) We adopt the linear-chain Conditional Random Field (CRF) implementation by (Finkel et al., 2005) to learn a sequence labeling model to extract entities. However, we use pool-based AL for sequence labeling (Settles and Craven, 2008) to replace the sequential or random samplers during online corpus annotation.

Our iterative AL-enabled framework requires a pre-trained/base model to sample the next batch of sentences to be labeled. This iterative sampling allows us to reach higher accuracies with fewer data points by incrementally incorporating the new knowledge encoded in the trained models. This more informative sampling is achieved due to the added requirement on model training that uses all previously annotated sentences as well as new batches of annotated sentences[2]. In Section 3, we show how learning the base model by annotating sentences sampled using a method called Entity Set Expansion (ESE) is better than learning a model from a random sample.

While the default inductive behavior of CRF is to provide one label sequence (the most probable one), we instead use an n-best sequence method that uses the Viterbi algorithm to return, for each sentence, the top n sequences with their probabilities. We then query the annotator to annotate b number of sentences (equal to a pre-selected batch size) with the highest entropies (Kim et al., 2006; Settles and Craven, 2008) calculated using the following equation:

[1]Codes and data can be found at `https://github.com/halolimat/SpExtor`

[2]We train all CRF models using the default set of features for CoNLL 4 class - `https://rebrand.ly/corenlpProp`

$$nSE(m, s) = -\sum_{\hat{y} \in \hat{Y}} p_m(\hat{y}|s; \theta)\ log\ p_m(\hat{y}|s; \theta) \quad (1)$$

where m is the trained CRF model, s is a sentence, $\hat{Y}$ is the set of n sequences, and θ is the features' weights learned by the model m.

Annotation Modes We devise four AL-enabled annotation modes: **1.** ESE and AL (EAL), **2.** Fast (FA), **3.** Hyper Fast (HFA), and **4.** Ultra Fast (UFA) annotation mode. The EAL mode (which perform ESE to learn the base model, see Section 3) uses model confidence on sentences estimated using nSE for sampling while the rest use a thresholded auto-annotation method that we developed to accelerate the annotation procedure.

Auto-annotation employs a pre-trained CRF model m to annotate all unlabeled sentences in the pool. Then, we accept the most probable annotation of each sentence (i.e., the first label sequence) from the model if the first two label sequences satisfies the following condition: **if** $\frac{SE_1(s)}{SE_2(s)} \leq t$, where $SE_i(s)$ is the entropy of the sequence i of the sentence s and t is a predefined threshold representing the desired margin difference between the entropies of the two sequences 1 and 2. We chose t after running some experiments. What we found was that any threshold below 0.10 usually resulted in no auto-annotations, while a threshold above 0.20 resulted in many incorrect ones. Therefore, we chose 0.10, 0.15, and 0.20 for the FA, HFA, and UFA auto-annotation modes, respectively. In Section 4.4, we evaluate the effectiveness of the devised annotation modes.

Interactive Learning We designed an online evaluation method σ that provides feedback to annotators on the confidence of a model m on a given sentence pool S (Equation 2). This feedback is an alternative to the F-measure and is very valuable in the absence of a gold standard dataset that could otherwise provide this kind of a feedback.

$$\sigma = 1 - \frac{1}{|S|} \sum_{s \in S} nSE(m, s) \quad (2)$$

Typically, $\sigma \in [0, 1]$, where 1 is the highest confidence value. Hence, it gives the annotator a clearer picture of whether to keep the model as is or learn a new model, interactively, using the mean of all nSEs (i.e., $\frac{1}{|S|} \sum_{s \in S} nSE(m, s)$). We use σ both during the incremental learning steps from the same sentence pool and to test the model's accuracy/confidence on unseen sentences. Therefore, using this feedback, we can decide to stop annotating from a certain sentence pool and augment it with sentences from a new pool, or simply stop annotating and train a final model. Consequently, deciding to annotate new sentences that contain novel entities helps reduce the effect of data sparsity and increase the accuracy of models, which highlights the importance of this online feedback method.

We compare our online evaluation method with the Estimated Coverage (EC) method in (Tsuruoka et al., 2008) that computes the expected number of entities as follows:

$$EC = \frac{E}{E + \sum_{u \in U} E_u} \quad (3)$$

where E is the number of annotated entities in sentences, U is the set of all unlabeled sentences, and E_u is the expected number of entities in sentence u. E_u is calculated by summing the probability of each entity in all of the n-best sequences. As shown later in Section 4.4, our online method is more informative than the EC method.

3 Entity Set Expansion Framework

Since AL requires a base (pre-trained) model to work (Settles and Craven, 2008), learning that model from annotated sentences sampled using sequential or random sampling can be very expensive due to the labeling starvation problem mentioned before. Therefore, we developed an Entity Set Expansion (ESE)

method that incorporates and exploits the semantics and relevant context of the desired entity class to more informatively sample sentences that are likely to have entities of the desired class.

We assume that all noun phrases (NPs) are candidate entities and extract all of them from the unstructured text[3]. Then, we record five features for each noun phrase (np) and model the data as a bipartite graph with NPs on one side and features on the opposite side. Ultimately, modeling the edges from multi-modal edge weights allow us to calculate the similarity between NPs and retrieve all sentences containing the most similar ones.

3.1 Noun Phrase Extraction (NPEx)

We POS tag and parse sentences to the form ($[w_i/pos_i \; \forall w \in W]$). We then use the regular expressions below to extract NPs, where JJs are adjectives, NNs are nouns (singular, plural, proper, etc.), and CDs are cardinal numbers (Santorini, 1990).

```
NP = JJs + NNs + CDs
JJs = (?:(?:[A-Z]\\w+ JJ )*)
NNs = (?:[^\\s]* (?:N[A-Z]*)\\s*)+
CDs = (?:\\w+ CD)?
```

3.2 Featurization

We automatically extract and record five kinds of features for each extracted noun phrase from text to create relationships between noun phrases. Following is the list of the diverse lexical, syntactic, and semantic features we derive:

① **Lexical Features (LF):**

- **Orthographic Form (OF)**: We abstract OF features from the actual word and obtain its type (i.e., numeric, alpha, alphanumeric, or other). Additionally, we classify the word as: all upper case, all lower case, title case, or mixed case.
- **Word Shape (WS)**: We define WS to abstract the patterns of letters in a word as short/long word shape (SWS/LWS) features. In LWS, we map each letter to "L", each digit to "D", and retain the others unchanged. On the other hand, for SWS, we remove consecutive character types. For example, LWS("ABC-123") $\rightarrow$ "LLL-DDD" and SWS("ABC-123") $\rightarrow$ "L-D".

② **Lexico-Syntactic Features (LS):** We use a skip-gram method to record the explicit LS-patterns surrounding each NP, i.e., for each np in s we record the pattern $w_{i-1} + np + w_{i+1}$, where $w_{(.)}$ are the two words that precede and follow np.

③ **Syntactic Features (SF):** We use dependency patterns to abstract away from the word-order information that we can capture using contextual and lexico-syntactic features. We use Stanford's English_UD neural network-based dependency parser (Chen and Manning, 2014) to extract universal dependencies of NPs. For each np in s, we record two dependency patterns of the NP that serve in *governor* and *dependent* roles.

④ **Semantic Features (SeF):** To capture the lexical semantics, we use WordNet (Miller, 1995) to get word senses and draw sense relations between NPs if they have the same sense class.

⑤ **Contextual Features (CF):** To capture the latent features, we use a Word2Vec embedding model (Mikolov et al., 2013) trained on the sentence pool S as the only bottom-up distributional semantics method. We exploit the word-context co-occurrence patterns learned by the model to induce the relational similarities between NPs.

The use of semantic (i.e., word senses) and contextual (i.e., word embeddings) features for sparse or domain-specific data (such as enterprise data) is not enough and sometimes not even possible due to unavailability (Tao et al., 2015). Therefore, we tried to use diverse features in a complementary manner

[3]While not all candidate NPs are positive examples of an entity, a human-in-the-loop would interactively give feedback to the system by choosing the positive ones.

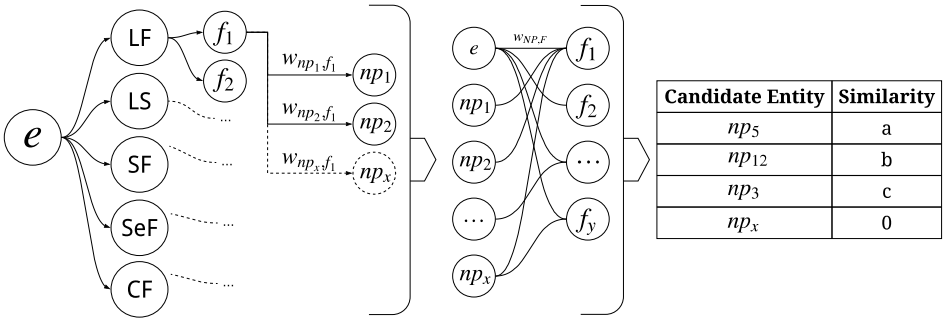

Figure 1: The three stages of graph embedding for candidate entities ranking.

to capture as many meaningful relations between potential entities as possible. For example, the absence of SeF for domain specific entities, such as protein molecules or parts numbers, is compensated by the use of WS features (e.g., by drawing a relation between the NPs "IL-2" and "AP-1" which have the same SWS and LWS features).

3.3 Feature-Graph Embedding

We model edges in the bipartite graph by assigning a weight w between each pair of a noun phrase n and a feature f using one of the following weights:

$$w1_{n,f} = C_{n,f} \tag{4}$$

$$w2_{n,f} = log(1 + C_{n,f})[log|N| - log(|N|_f)] \tag{5}$$

$$w3_{n,f} = log(1 + C_{n,f})[log|N| - log(\sum_{\hat{n}} C_{\hat{n},f})] \tag{6}$$

where $C_{n,f}$ is the co-occurrence count between n and f, $|N|$ is the number of NPs in our dataset, $|N|_f$ is the co-occurrence count of all NPs with f, and $\sum_{\hat{n}} C_{\hat{n},f}$ is the sum of all NP co-occurrences with the feature f. Equations 5 and 6 are two variations of TFIDF where the latter is adapted to weigh the edges in (Shen et al., 2017; Rong et al., 2016).

3.4 Set Expansion

Our method starts by taking a seed entity e from the annotator input, and returns a ranked list of similar NPs (see Algorithm 1). After constructing a graph using the embedding method mentioned in the previous section (see Figure 1), we calculate the similarity between the seed entity e and all other noun phrases NPs in the graph G using one of the following similarity methods:

$$Sim1(n_1, n_2|F) = \frac{\sum_{f \in F} w_{n_1,f} w_{n_2,f}}{\sqrt{\sum_{f \in F} w_{n_1,f}^2} \sqrt{\sum_{f \in F} w_{n_2,f}^2}} \tag{7}$$

$$Sim2(n_1, n_2|F) = \frac{\sum_{f \in F} \min(w_{n_1,f}, w_{n_2,f})}{\sum_{f \in F} \max(w_{n_1,f}, w_{n_2,f})} \tag{8}$$

Data: e: input seed; S: text sentences
Result: $N = \{n\}$: ranked similar noun phrases
Start
$\hat{N}$ = ∅; `// all noun phrases`
F = ∅; `// all features`
for $s \leftarrow S$ **do**
  $\hat{N} = \hat{N} \cup$ **ExtractNounPhrases**(s);
  $F = F \cup$ **Featurize**($\hat{N}$); `// Sec. 3.2`
end
$G =$ **BuildBipartiteGraph**($\hat{N}$, F);

return $rank(N)$;

Algorithm 1: Entity Set Expansion

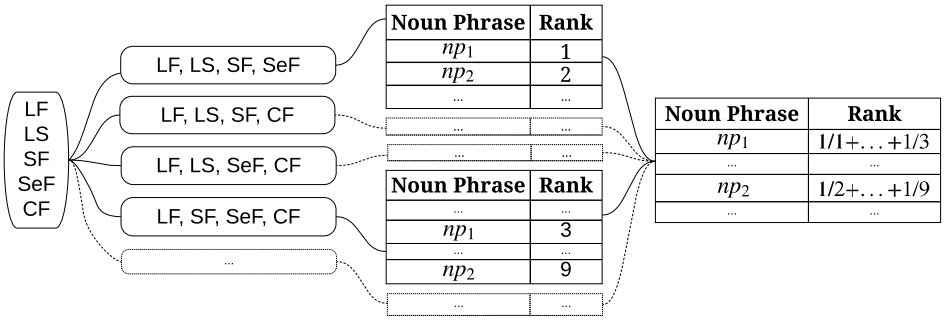

Figure 2: Coarse features ensemble method for ranking candidate entities.

Dataset Name	Entity Class	$\|S\|$ (with Entities)	# Entities	NPEx Precision	Seed Entity (Count)
CoNLL-2003	Location	13519 (36%)	1258	84%	U.S. (296), Washington (26)
	Person	13519 (31%)	3388	76%	Clinton (70), Von Heesen (1)
BioCreAtIvE II	Gene	12500 (51%)	10441	51%	insulin (64), GrpE (1)
GENIA 3.02	Protein Molecule	14838 (55%)	3413	60%	NF-kappa B (552), IL-1RA (1)
	Cell Type	14838 (27%)	1569	24%	T cells (489), MGC (2)
	Virus	14838 (8%)	324	50%	HIV-1 (336), adenovirus E1A (1)

Table 1: Evaluation dataset statistics, noun phrase extraction accuracies, and seed entity counts.

where $Sim(n_1, n_2|F)$ is the similarity between the two noun phrases n_1 and n_2 given the set of features F they have in common, and $w_{(.,.)}$ is the weight of the edge between the NPs and features (defined using one of the Equations 4-6). Equation 7 is the cosine similarity and Equation 8 is the context-dependent similarity by (Shen et al., 2017). The difference between these two similarity measure is that higher cosine similarities implies that the two NPs are better aligned on many feature dimensions, while higher context-dependent similarities implies that the two NPs are significantly similar on some feature dimensions compared to others.

3.5 Feature Ensemble Ranking

Similar to the use in SetExpan (Shen et al., 2017), we ensemble the coarse features[4] and rank NPs in sublists to reduce the effect of inferior features on the final ranking. The size of each sublist is equal to $|\hat{F}| - 1$, where $\hat{F}$ is the set of all features from Section 3.2.

$$MRR(n) = \sum_{q \in Q} \frac{1}{rank(n, q)} \tag{9}$$

We then use the mean reciprocal rank (MRR) from Equation 9 above, a form of rank aggregation, to find the final ranking of each noun phrase n using its rank in each sublist q (see Figure 2).

4 Experiments and Results

4.1 Data Preparation

To test our framework while emulating the full experience of annotators, we use three publicly available gold standard datasets labeled for several entity classes (CoNLL-2003, GENIA 3.02, and BioCreAtIvE II). We tokenize documents into sentences, then query the emulator (which plays the role of annotators) to label sentences, thus avoiding the required annotation of full documents for better user experience. We require the emulator to label only a single entity class from each dataset, to avoid the complexity of multiple class annotations. Therefore, we created six versions of the datasets where only one class is kept in each version. Table 1 includes some statistics about the datasets. The percentage of sentences with entities of a given class shows the sparsity of those entities.

[4]Coarse features are the five groups of features in Section 3.2 as opposed to the fine ones which are part of each of them.

		Location			Person			Gene			Protein			Cell Type			Virus		
		Eq.4	Eq.5	Eq.6	Eq.4	Eq.5	Eq.6	Eq.4	Eq.5	Eq.6	Eq.4	Eq.5	Eq.6	Eq.4	Eq.5	Eq.6	Eq.4	Eq.5	Eq.6
Seed 1	Eq.7	0.37	0.40	0.50	0.23	0.23	0.30	0.00	0.03	0.13	0.17	0.23	0.20	0.27	0.50	0.53	0.20	0.13	0.17
	Eq.8	0.63	**0.73**	0.73	0.03	**0.17**	0.20	0.03	**0.07**	0.07	0.43	**0.43**	0.53	0.17	**0.23**	0.23	0.07	**0.10**	0.07
Seed 2	Eq.7	0.33	0.33	0.57	0.53	0.40	0.30	0.63	0.63	0.63	0.17	0.60	0.27	0.10	0.20	0.13	0.07	0.03	0.03
	Eq.8	0.57	**0.70**	0.63	0.47	**0.37**	0.37	0.60	**0.57**	0.60	0.07	**0.30**	0.30	0.07	**0.07**	0.07	0.03	**0.10**	0.03

Table 2: ESE performance ($p@k$). The use of TFIDF variant without co-occurrence summation (Equation 5), to weight the graph edges, and the context-dependent similarity (Equation 8), to measure the similarity between NPs, led to the bold-faced best performing combination.

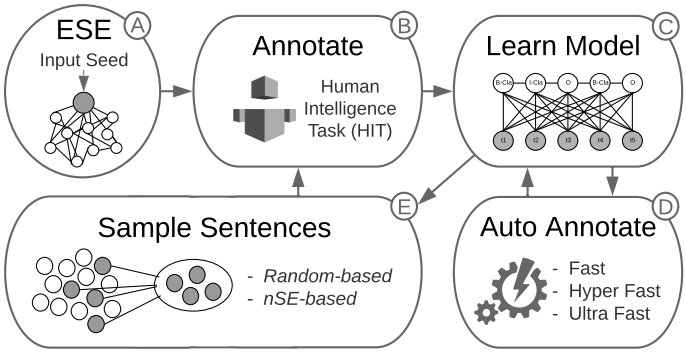

Figure 3: End-to-End system pipeline. Arrows represent paths can be followed to annotate text.

4.2 NPEx Evaluation

Since ESE method operates at an NP level, the performance of Noun Phrase Extraction (NPEx) significantly influences the overall performance of ESE. Table 1 includes the precision of NPEx method. In the future, ESE performance can be improved by enhancing the performance of candidate entities extraction through, for example, extracting noun phrases formed from typed-dependencies.

4.3 Entity Set Expansion (ESE) Evaluation

To test the influence of seed entity frequency on ESE performance, we manually picked two seeds, the most frequent and the least frequent among all noun phrases (See Table 1). Additionally, we varied the weighting measure of the graph edges to reflect different notions of feature relevance using one of Equations 4-6. Finally, we varied the similarity measure when ranking NPs (Equations 7 and 8).

We tested the performance of ESE with and without using the feature ensemble method in Section 3.5. We measured the precision of the method in ranking positive examples of entities similar to the seed entity (Seed 1 and Seed 2) in the top k NPs. We designed ESE to output thirty candidate entities (NPs) ranked based on the similarity to the seed term. Therefore, we calculated precision at k ($p@k$) where k is always 30. Table 2 shows the best results when using the feature ensemble method which is more stable than the non-ensemble one (due to lower standard deviation and non-zero precision). According to the results, the best combination in terms of the mean and standard deviation is obtained when using TFIDF (Eq.5) to weigh the edges and context-dependent similarity (Eq.8) to rank NPs. This shows that the uniqueness and the significant overlap of features between noun phrases were very important.

4.4 Full System Evaluation

We tested our pipeline on three different settings following three different paths in Figure 3:

1. All Random (AR): $(E, B, C)^*$, where E is a random-based sampler.
2. ESE and AL (EAL): $A, B, C, (E, B, C)^*$, where E is an nSE-based sampler.
3. EAL in addition to auto-annotation (EAA): $A, B, C, (D, C, E, B, C)^*$

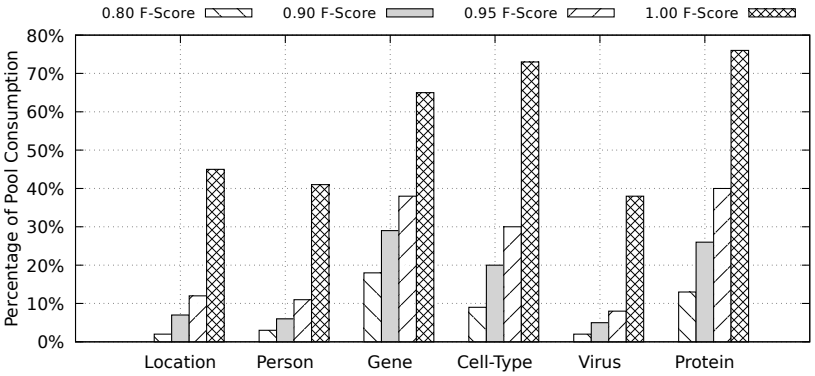

Figure 4: Percentage of sentences annotated while using EAL to reach different F-Scores.

Dataset Name	Entity Class	EAL		EAA Annotation Mode		
		@ 1.0 F		FA	HFA	UFA
		σ	% cut	F-Score (percentage cut)		
CoNLL-2003	Location	0.97	55%	0.99 (46%)	0.93 (83%)	0.82 (91%)
	Person	0.97	59%	0.99 (48%)	0.95 (81%)	0.85 (90%)
BioCreAtIvE II	Gene	0.94	35%	1.00 (35%)	0.96 (50%)	0.89 (69%)
GENIA 3.02	Protein Molecule	0.99	33%	0.98 (36%)	0.87 (71%)	0.74 (85%)
	Cell Type	0.99	62%	0.94 (70%)	0.82 (86%)	0.74 (91%)
	Virus	0.94	24%	0.97 (79%)	0.89 (94%)	0.84 (96%)
Average		0.97	45%	0.98 (52%)	0.90 (78%)	0.81 (87%)

Table 3: Pipeline testing results of EAL and EAA annotation modes (see Section 2) showing the model confidence (σ), F-Scores, and percentage cut from the pool of sentences.

We iterate through the loop paths in the starred parentheses while sampling 100 sentences each time until we finish all sentences in the pool or reach full F-Score. In Figure 5, we show the performance of the first two settings (i.e., AR and EAL) in terms of F-Score. The use of AL and ESE methods outperformed random sampling all the time. ESE increased the performance of the base model by 35% F-Score on average, allowing us to reach 0.5 F-Score while the random sampler reached only 0.37 F-Score.

As shown in Figure 4, the percentage consumption of the sentence pool to reach up to 0.95 F-Score follows almost a linear growth. However, this cost grows exponentially if we want to reach 1.0 F-Score (needing on average around 33% more sentences). Practically speaking, we might want to trade the 5% F-Score improvement to significantly reduce manual labor.[5]

We used Jensen-Shannon divergence (Lin, 1991) to compare the curves corresponding to the performance of the estimated coverage method (Equation 3) and our online evaluation metric σ (Equation 2) with the F-Score curve of EAL (see Figure 5). Our method σ outperformed the estimated coverage method with a decrease of 96% in dissimilarity, which makes our method more reliable. Additionally, as shown in Table 3, on average σ gives an accurate estimation of the F-Score without labeled data, with an error margin of 3% on average, when reaching 1.0 F-Score (i.e., @ 1.0 F).[6]

Our EAL method also outperformed (Tsuruoka et al., 2008) on the three overlapping entity classes we tested on from the two datasets (Genia and CoNLL-2003). EAL needed 2800, 2900, and 400 fewer sentences to reach the same coverage as (Tsuruoka et al., 2008) for the Location, Person, and Cell-Type datasets, respectively.

Finally, for the last setting, we tested the system using the three auto-annotation modes (i.e., FA, HFA,

[5]This would, therefore, make the annotated data a silver standard instead of a gold standard.

[6]The σ curves of GENIA-Cell-Type and GENIA-Virus show high overestimation of the F-Score curve in the first iterations. This is due to missing entity annotations we found in the gold standard, which mistakenly shows that we had many false positives. To list a few, GENIA-Cell-Type have missing annotations for "transformed T cells", "transformed cells", and "T cells", where GENIA-Virus have some missing annotations for "HIV-1" and "HIV-2".

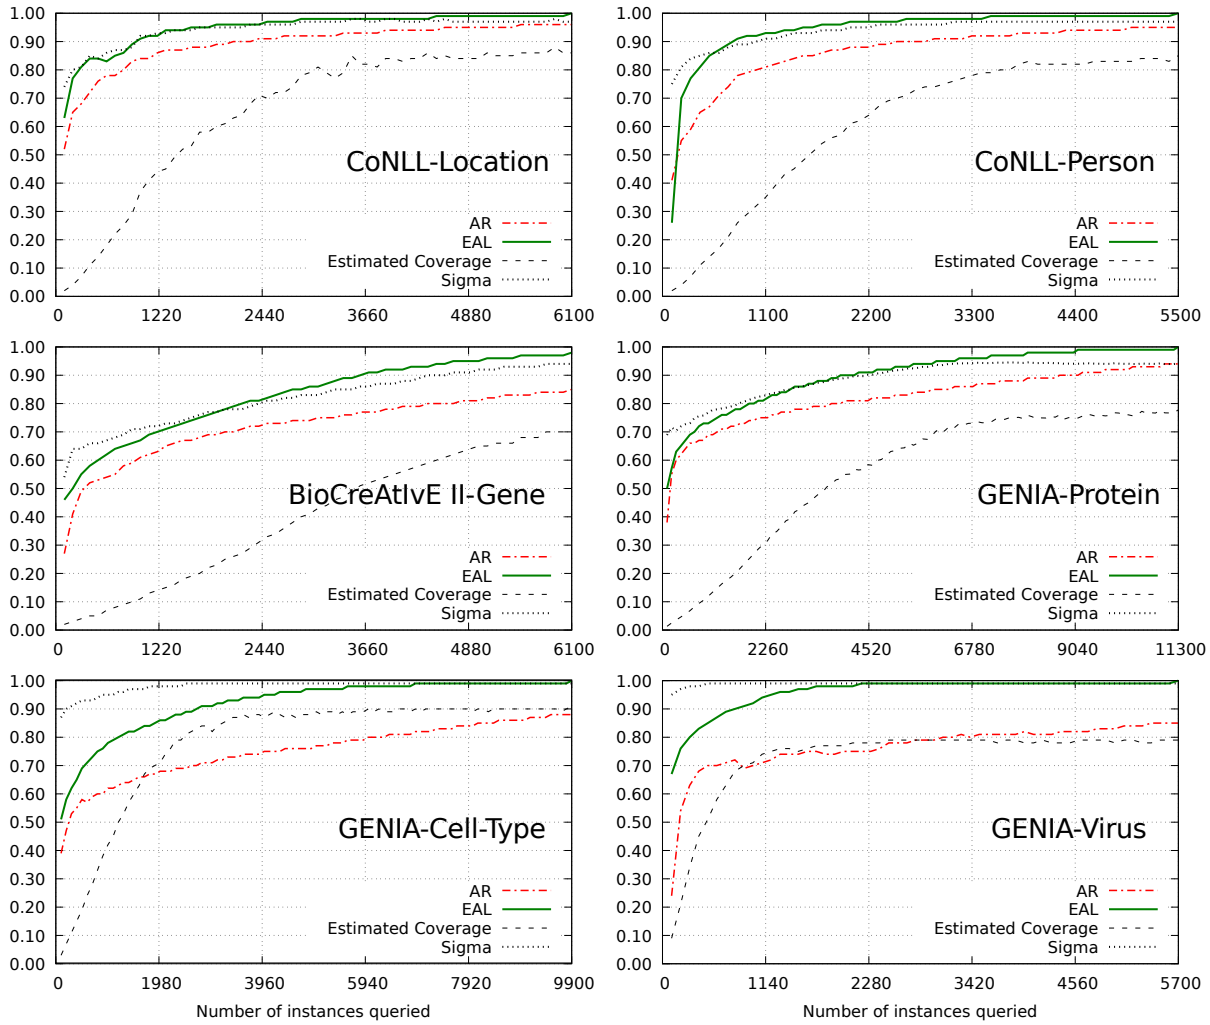

Figure 5: Learning curves with different query strategies. Y-axis value for AR and EAL is the F-Score, and for Sigma and Estimated Coverage is the value from Equations 2 and 3, respectively.

and UFA) as shown in Table 3. While the auto-annotation mode can allow us to reduce up to 87% of the data pool, this drastic saving also reduces the accuracy of the learned model, achieving, on average, around 81% F-Score. Overall, our framework presents a trade off between coverage and annotation cost. The HFA auto-annotation mode shows the benefit, especially in a realistic enterprise setting, when we need to annotate 33% of the data to increase F-Score by only 10% (when comparing the on average performance of HFA with ESA) is unreasonable.

Table 3 appears to show FA being inferior to EAL in terms of the percentage cut for the Location class, for example. In reality FA reduced sentence annotation by 65% to reach 0.99 F-Score. But as our testing criteria demanded that we either reach 1.0 F-Score or finish all sentences from the pool, FA tried to finish the pool without any further performance improvement on the 0.99 F-Score.

5 Related Work

To extract sparse entities from texts and learn sequence models faster, our practical framework uses Active Learning (AL) for sequence labeling (Tomanek and Hahn, 2009; Settles and Craven, 2008), both as a method of sampling and to auto-annotate sentences. Our work encompasses entity extraction, Entity Set Expansion (ESE), corpora pre-annotation, auto-annotation, and AL.

Using a pattern-based ESE (a.k.a., seed set expansion) technique on top of AL helped our approach in discovering rare patterns and rules which might have been hidden when using only a feature-based system (Chiticariu et al., 2013). Our ESE method is similar to (Shen et al., 2017; Tao et al., 2015;

Sadamitsu et al., 2012) where the system starts with a few positive examples of an entity class and tries to extract similar entities. Additionally, we use a richer set of features than those in (Gupta and Manning, 2014; Grishman and He, 2014; Min and Grishman, 2011) while training a CRF model and using it to find additional positive examples of a given entity class.

Methods such as (Sarmento et al., 2007) computes the degree of membership of an entity in a group of predefined entities called seed entities, where the class of each group is predefined. Their method does not focus on entity extraction, rather it focuses on detecting the class of entities during the evaluation step, which makes their method different from ours.

Regarding corpus annotation, many notable previous works such as (Lingren et al., 2013) use dictionaries to pre-annotate texts. However, inaccurate pre-annotations may harm more than improve since they require an added overhead of modifications and deletions (Rehbein et al., 2009). Kholghi et al. (2017) and Tsuruoka et al. (2008) propose AL-based annotation systems. However, their work differs from ours in the following ways: **(1)** we propose a more accurate online evaluation method than theirs, **(2)** we use ESE to bootstrap the learning framework collaboratively with a user-in-the-loop, and finally, **(3)** we provide auto-annotation modes which reduces the number of sentences to be considered for annotation and so allows for better usability of the framework.

6 Conclusions and Future Work

We presented a practical and effective solution to the problem of sparse entity extraction. Our framework builds supervised models and extracts entities with a reduced annotation cost using Entity Set Expansion (ESE), Active Learning (AL), and auto-annotation without compromising extraction quality. Additionally, we provided an online method for evaluating model confidence that enables flexible stopping criteria. In the future, we might consider evaluating different AL querying strategies and compare their performances and try a more sophisticated candidate entity extractors for entity set expansion.

Abstract

Named entity recognition (NER) has attracted a substantial amount of research. Recently, several neural network-based models have been proposed and achieved high performance. However, there is little research on fine-grained NER (FG-NER), in which hundreds of named entity categories must be recognized, especially for non-English languages. It is still an open question whether there is a model that is robust across various settings or the proper model varies depending on the language, the number of named entity categories, and the size of training datasets. This paper first presents an empirical comparison of FG-NER models for English and Japanese and demonstrates that LSTM+CNN+CRF (Ma and Hovy, 2016), one of the state-of-the-art methods for English NER, also works well for English FG-NER but does not work well for Japanese, a language that has a large number of character types. To tackle this problem, we propose a method to improve the neural network-based Japanese FG-NER performance by removing the CNN layer and utilizing dictionary and category embeddings. Experimental results show that the proposed method improves Japanese FG-NER F-score from 66.76% to 75.18%.

1 Introduction

Named entity recognition (NER) is a well studied topic in natural language processing. There have been many methods proposed for NER, including the conventional methods based on Conditional Random Fields (CRF) (McCallum and Li, 2003), Support Vector Machines (SVM) (Yamada et al., 2002; Takeuchi and Collier, 2002) and Hidden Markov Model (HMM) (Zhou and Su, 2002). Recently, neural network based methods, such as LSTM+CNN+CRF (Ma and Hovy, 2016) or BiLSTM/LSTM-CRF/Stack LSTMs (Lample et al., 2016; Misawa et al., 2017), have achieved state-of-the-art performance. However, while most existing studies mainly focus on recognizing a relatively small number of named entity (NE) categories (e.g., ten or twelve categories) such as Person, Organization, Location, Artifact, etc., modern NLP applications often require domain-specific and fine-grained (FG) NER with hundreds of NE categories. For example, a movie recommendation system might require the recognition of movie names, but does not need to recognize Locations. Similarly, a chatbot software might require not only the recognition of Organization, but also the fine-grained classification to recognize a music band name to answer the question "Which band was Paul in", from the information shown in Figure 1.

A fine-grained named entity recognition (FG-NER) model refers to a NER model that can recognize and classify a large number of entity categories (e.g., hundreds of NE categories). In classical coarse-grained named entity (NE) definition, often less than ten named entity categories are defined. For example, in the CoNLL-2003 Named Entity Recognition task, there are four NE categories: Person, Location, Organization and Miscellaneous (Sang and Meulder, 2003). Ritter et al. (2011) proposed a NER algorithm to recognize ten categories of entities from Twitter text. On the other hand, in FG-NER, there are hundreds of NE categories, which are fine-grained classification of coarse-grained categories.

(b) Fine-grained NER result

Figure 1: Example of NER and FG-NER

For example, Sekine (2008) divided the coarse-grained category Organization into the fine-grained categories such as Political_Party, Military, Sports_Organization, Show_Organization, as shown in Figure 2.

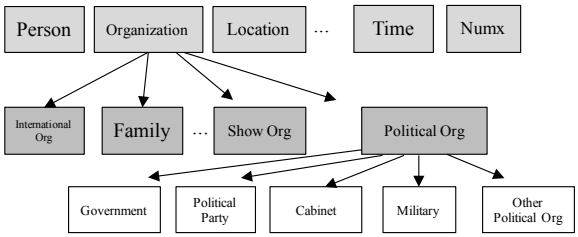

Figure 2: Sekine's Extended Named Entity (ENE) hierarchy

FG-NER is still an open research domain, with little information concerning the state-of-the-art performance, the relation between training data size and performance, and how to select the best model for different settings of training data size and target language. In FG-NER, because the number of NE categories is large, some categories might face with the data sparseness problem, whereas some other categories might have a large number of training samples in a dataset. Hence, it would be worth investigating the relation between dataset size and the performance of the system. The current state-of-the-art method for English NER (coarse-grained NER) is a neural network-based method, which uses convolutional neural network (CNN) to calculate the character level embeddings (Ma and Hovy, 2016). This leads to the question whether this method works well for languages with a large number of character types, such as Japanese.

In this paper, we first investigate the relationship between the F-score of various FG-NER algorithms with the size of training datasets for both English and Japanese. Second, we suggest the direction to choose an appropriate FG-NER algorithm for appropriate target language and training data size. We show that the state-of-the-art method for English NER also performs well for English FG-NER. On the other hand, for Japanese FG-NER, the state-of-the-art method does not work well. To solve this problem, we propose a method to significantly improve the neural network-based Japanese FG-NER performance by removing the CNN layer, as well as utilizing dictionary and category embeddings information. Experiments show that, the proposed method improves the F-score of the Japanese FG-NER system from 66.76% to 75.18%, which is a wide margin. We applied the proposed method to build an FG-NER system that can recognize 200 categories of named entities in the Sekine's Extended Named Entity Hierarchy (ENEH) (Sekine, 2008). To the best of our knowledge, the proposed system achieves the state-of-the-art performance in the task of recognizing 200 NE categories in the Sekine's ENEH. We publish the test dataset[1] and our FG-NER API on the Web to allow other researchers to freely use[2].

The rest of this paper is organized as follows. In Section 2, we describe the fine-grained named entity tag sets and datasets. We present various algorithms for FG-NER and show our proposal to achieve high performance for Japanese FG-NER in Section 3. We present detailed experimental results to find out the relationships between models, training data size and target languages in Section 4. Finally, Section 5 concludes the paper.

2 Fine-Grained Named Entity Tag Sets and Datasets

2.1 FG-NER tag set

The first challenge in FG-NER is defining a comprehensive tag set with a very large number of entity categories (Ling and Weld, 2012). There are two methods for defining a tag set (i.e., set of entity categories to recognize) in previous studies on FG-NER. The first method is to take the entity categories from a knowledge base such as Freebase (Bollacker et al., 2008) or YAGO (Suchanek et al., 2007), filtering out the categories with a small number of entities and merging the categories with similar semantic meaning into one FG-NER category (Ling and Weld, 2012; Yosef et al., 2012; Gillick et al., 2014). The second method is to manually build an entity hierarchy to cover important domains in the real world. Following the second method, Sekine et al. proposed an Extended Named Entity Hierarchy (ENEH), which contains 200 entity categories in a three-layer hierarchy, as shown in Figure 2 (Sekine et al., 2002; Sekine, 2008).

In this paper, we use the entity hierarchy described by Sekine (2008), which contains 200 NE categories at the leaf-level, as our tag set[3]. At the top level of the hierarchy, there are about twenty coarse-grained named entity categories, such as Person, Organization, Location, Facility, Product, Event, ... Each top-level categories is further divided into several second-level categories as shown in Figure 2. Each second-level category is in turn divided into several leaf-level categories.

We use this hierarchy because it is carefully designed by humans, it does not ignore important domains with small numbers of entities (e.g., Continental_Region) and it includes a systematic categorization of date/time and number. Moreover, for subsequent applications such as search engines or chatbot platforms to easily utilize the FG-NER results, we want to classify an entity to exactly one category in the hierarchy based on the context in which the entity appears. Consequently, we need an entity category hierarchy that does not allow overlap between the categories (Sekine, 2008). For all experiments in this paper, we will build Fine-grained NERs to recognize the leaf-level categories in this hierarchy. The parent level categories can be easily inferred once we recognize the leaf-level categories.

2.2 FG-NER Dataset

We hired several human annotators to annotate two text corpora to create FG-NER tagged datasets for English and Japanese. The number of annotators for English is ten and the number of annotators for Japanese is seven. All of the annotators are native speakers of the corresponding language.

For each category in the Sekine's Extended Named Entity (ENE) Hierarchy (Sekine, 2008), the human annotators are first asked to write down 100 entities that belong to each ENE category. We then search the Web for sentences that contain these entities. In the search result, we retrieve the sentences that include at least one entity of the corresponding category. The human annotators then tag the sentences with 200 ENE labels. For example, for the entity "Tokyo", the Web search results might contain the sentence "Tokyo is the capital of Japan". This sentence must then be tagged as "<City>Tokyo</City> is the capital of <Country>Japan</Country>". Consequently, we have 20,000 sentences for English and 20,000 sentences for Japanese (as the number of leaf-level categories defined in Sekine's ENEH is 200). Note that the number of entities is larger than the number of sentences because in one sentence we might have multiple entities, of different NE categories.

After filtering out erroneous sentences (sentences with invalid tag format, e.g., without closing the tag </City>), we obtain totally 19,800 well-formed English sentences and 19,594 well-formed Japanese sentences. Each category has at least 100 sentences containing the entities of that category. We divided the dataset into three subsets: the training set (70% of the total data), development set (10%) and test set (20%), as shown in Table 1. We use the development set to check the stop condition while training our LSTM model.

To have an estimation of the difficulty of the FG-NER annotation task, we measured the coherence between the annotators by calculating two coefficients for some categories in the English dataset: the Fleiss' kappa (κ) and the F-score of an annotator when assuming that another annotator created gold-

[3]The full tag set is here: https://nlp.cs.nyu.edu/ene/version7_1_0Beng.html

Table 1: Statistics of the datasets

Dataset	English		Japanese	
	Sents	Entities	Sents	Entities
Train	13,860	27,107	13,749	37,128
Dev	1,980	3,870	1,948	5,304
Test	3,960	7,739	3,897	10,485

Table 2: Agreement between annotators

Category	Fleiss' κ	F-score
Country	0.977	0.966
Dish	0.890	0.738
Car_Stop	0.873	0.672
Organization_Other	0.835	0.483

standard data[4]. The results are shown in Table 2. We choose these categories to calculate the coefficients because they represent typical categories in the dataset: a category with limited number of frequently used entities (*Country*), a category with entities that are often not proper nouns (*Dish*), a category with ambiguous and complicated location names (*Car_Stop*) and a category that is ambiguously defined (*Organization_Other*).

The κ coefficient is calculated on tokens so it is only slightly different between the four categories in Table 2. This is because the ratio between the number of tokens with label "Other" is very large, compared against the number of tokens with specific NE category labels. We calculated Fleiss' κ on tokens but not on entities because at entity level, there are some cases in which two annotators made overlapping tags, but not identical. For example, Annotator1 might tag "<City>Greater Tokyo Area</City>" and Annotator2 might tag "Greater <City>Tokyo</City> Area". If we calculate on entity level then the score would be 0 but if we calculate on token level, the score is greater than 0. Consequently, we calculate the κ based on B/I/O tags at token level.

On the other hand, when calculating the entity-based F-score, the difference is very large between the category *Country* and *Organization_Other*. This is because the category *Country* is very easy to recognize, as there are only about 200 entities frequently used in this category, whereas, recognizing *Organization_Other* or *Car_Stop* is very difficult because of the ambiguity. This also indicates that the performance of an FG-NER system tends to depend on the categories and we can confirm this in the experimental results in the next sections.

3 Fine-Grained Named Entity Recognition Methods

3.1 Dictionary and Rule-based FG-NER

The simplest method for FG-NER is using a dictionary and a set of rules. Sekine and Nobata (2004) presented a dictionary and rule-based Japanese FG-NER system that contains more than 1400 rules to recognize 140 entity categories.

In this work, we added 200 rules to the existing 1400 rules by Sekine and Nobata to create a rule set of 1600 rules to classify 200 NE categories in the Sekine's Extended Named Entity Hierarchy. We then built a rule-based Japanese FG-NER model to recognize 200 NE categories based on these 1600 rules.

We use a Japanese FG-NER dictionary containing 1.6 million Wikipedia entities in this model. In the 1.6 million entities in the dictionary, only 70 thousand entities are assigned NE tags by human, the rest are assigned by an existing Wikipedia NE labeling algorithm (Suzuki et al., 2016), which gives a score for each (entity, NE category) pair. We created similar rules for English FG-NER and we translated the Japanese dictionary into English by looking up parallel entries in Wikipedia.

We use this method as a baseline for performance evaluation of FG-NER systems.

3.2 CRF+SVM hierarchical classifier for FG-NER

Hierarchical classifiers have been successfully used in previous research for FG-NER (Ling and Weld, 2012; Yosef et al., 2012). Ling and Weld proposed FIGER, an FG-NER system with the entity categories taken from Freebase tags (Ling and Weld, 2012). In FIGER, the entity category is represented as a path, such as `/location/city` or `organization/company`. FIGER divides the entity categories into

[4]In this case, we only have two annotators for each categories, so Fleiss' kappa is equal to Cohen's kappa

a hierarchy of two layers: the categories in the first layer corresponding to the categories in coarse-grained NER systems, whereas, the second layer (the leaf-layer) contains fine-grained entity categories. FIGER uses a hierarchical classifier that contains a CRF at the top layer for sequence labelling and then a Perceptron at the second layer for classification of the entities into fine-grained categories.

In this work, we propose a hierarchical classification method in which CRF is used for sequence labelling at top-level and SVM is used for named entity classification at leaf-level of the Sekine's ENE Hierarchy, as shown in Figure 3. We use SVM at the leaf-level to classify an entity to fine-grained categories because SVM is good for classification tasks.

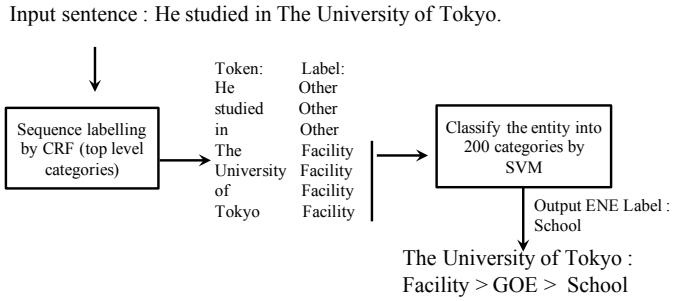

Figure 3: CRF+SVM based hierarchical classifier for FG-NER

Specifically, we use a training dataset (containing FG-NER tagged sentences) to train a CRF model to tag the input sentences with the top-level ENE categories in Figure 2. As illustrated in Figure 2, at the top level, we have only less than 20 categories of entities, thus using a CRF model here would achieve comparable performance with existing NER systems. We cannot directly use CRF for a large number of categories at leaf-level of the hierarchy, because with this number of classes, it would take a huge amount of memory and running time to train the CRF model. Actually, we have tried to use CRF for 200 classes, but the training process took a long time and did not finish. After tagging the sentences with the top-level categories, we can convert the FG-NER problem into a simple classification problem (not a sequence labeling problem anymore), thus we can use SVM to classify the extracted entities at the top level into leaf-level categories. Therefore, we have a CRF model to tag the input sentences with top-level categories, and several SVM models (each for a top-level category) to classify the entities into the leaf-level categories.

We use the following features for both SVM and CRF: bag-of-words, POS-tag, the number of digits in the word, the Brown cluster of the current word, the appearance of the word as a substring of a word in the Wikipedia ENE dictionary, the orthography features (the word is written in Kanji, Hiragana, Katakana or Romanji), is capital letter, and the last 2-3 characters. Those features are proved to be useful in previous work on named entity recognition (Ling and Weld, 2012; Yosef et al., 2012; Yogatama et al., 2015; Suzuki et al., 2016).

Once we have the sequence labelling result, we have already known the surfaces and the top-level categories of the entities in the input sentence. We then use SVM to classify the entities into leaf-level categories. Because the number of leaf-level categories in each top-level categories is also not too large (e.g., less than 15), SVM can achieve a reasonable performance at this step.

We also propose a method to incorporate dictionary information in both CRF and SVM step to improve the entire performance, as described in Section 3.4.

3.3 LSTM+CNN+CRF model for FG-NER

We re-implemented the LSTM+CNN+CRF NER model described by Ma and Hovy (2016) and adjust the model to work with FG-NER. The LSTM+CNN+CRF model originally described by (Ma and Hovy, 2016) is for NER problem with few NE categories. It first uses Convolutional Neural Network (CNN) to learn character level embeddings in the training process. For NLP tasks, previous works have shown that CNN is likely to extract morphological features such as prefix and suffix effectively (Ma and Hovy,

2016; dos Santos and Guimarães, 2015; Chiu and Nichols, 2016). The model then concatenates the character level embeddings with word embeddings to create a feature vector for each token in the input sentence. The input sentence is then fed to a BiLSTM network (Bi-directional Long-Short Term Memory network). Finally, CRF is used at the top layer of the BiLSTM to explore the correlations between outputs and jointly decode the best sequence of labels (i.e., NE categories).

For both English and Japanese FG-NER task, we use pre-trained word embeddings as input for our models. Previous studies have shown that GloVe achieves the best performance for English NER task (Reimers and Gurevych, 2017). Consequently, we use the embeddings based on GloVe for English[5]. For Japanese, we use pretrained word2vec[6] embeddings. The vector dimension is 300 for English and 200 for Japanese.

We use the default hyperparameters by Ma and Hovy (2016) in our model: $learning\_rate = 0.01$, $batch\_size = 10$ and $decay\_rate = 0.09$.

3.4 Incorporating dictionary information

Dictionary information (gazetteer feature) has been proved to be efficient in many NER and FG-NER tasks (McCallum and Li, 2003; Sekine and Nobata, 2004; Yosef et al., 2012). While there are previous studies that use dictionary for CRF (McCallum and Li, 2003) or SVM (Yosef et al., 2012) in the NER/FG-NER tasks, we believe that dictionary information would be useful in both sequence labelling and entity category disambiguation phase in the CRF+SVM method. Furthermore, the dictionary information can also be used in LSTM+CNN+CRF method. Consequently, we propose a method that efficiently utilizes dictionary information in the method LSTM+CNN+CRF and in both sequence labelling (CRF) and entity category disambiguation (SVM) phase of the method CRF+SVM.

We search the dictionary and assign a label in the set $\{B, I, O\}$ for each token in the input sentence $w_1 w_2 \dots w_n$, in which a token w_i is assigned the label *B* if it is a start token of an entity in the dictionary, label *I* if it is a token inside an entity in the dictionary, otherwise, it is assigned the label *O*. If there is a conflict (e.g., overlapping with two different entities in the dictionary) then we take the entities with the largest number of tokens. This is because we want to tag the longest sequence that could be an entity (e.g., if we have "United States" and "United States Army" then we take "United States Army"). We do not directly use these labels as the final results of the sequence labelling phase since they are not reliable as we drop all context information while assigning labels. Instead, we use these labels as features for CRF model for sequence labelling the entire input sentence or we add it to the additional dimensions of the vector representation of a token in the method LSTM+CNN+CRF.

Other than features from previous research on entity disambiguation (Yosef et al., 2012; Suzuki et al., 2016), we propose to use the following feature derived from the dictionary. We tokenize all the entities in the dictionary and calculate the probability that a token w is contained in an entity of type c :

$$P(c|w) = \frac{\text{count}(w, c)}{\text{count}(w, *)} \tag{1}$$

in which $\text{count}(w, c)$ is the number of occurences of w in an entity of type c, whereas, $\text{count}(w, *)$ is the total number of times that w appears. We then use this probability as a feature for SVM to classify the entities into leaf-level categories in the method CRF+SVM and we directly add this feature to the feature vector of a token in the LSTM+CNN+CRF method. This feature is helpful because it represents the likelihood that an entity e (which is a sequence of tokens $w_i w_{i+1} \dots w_{i+m}$) is contained in the category c.

We add these features to the CRF+SVM method to have the CRF+SVM+Dict method. Similarity, while using these features for LSTM+CNN+CRF, we obtained LSTM+CNN+CRF+Dict method.

3.5 Utilize entity category embeddings to improve Japanese FG-NER performance

For languages with a large number of character types such as Japanese, the CNN layer in the LSTM+CNN+CRF+Dict network architecture might not work well. This is because with a large

[5]https://nlp.stanford.edu/projects/glove/

[6]http://www.cl.ecei.tohoku.ac.jp/∼m-suzuki/jawiki_vector/

number of character types (e.g., 2000 frequently used characters in Japanese), it is difficult to calculate high quality character embeddings. Consequently, we propose a modification to the existing LSTM+CNN+CRF network architecture to alleviate this problem: We remove the CNN layer from the LSTM+CNN+CRF+Dict method to have the LSTM+CRF+Dict method. Moreover, we add another additional information concerning the entity category, as described below.

In the spirit of taking advantage of available dictionaries to improve our model as in CRF+SVM, we propose to integrate statistical information from the dictionary to improve the word embeddings. Specifically, for a word, we form a vector in which each element is the probability that this word is contained in an entity category, as follows:

$$C(w) = (x_1, x_2, \ldots, x_{n-1}, x_n) \tag{2}$$

where x_i is the probability that word w is contained in i^{th} category (c_i) :

$$x_i = P(c_i|w) = \frac{\text{count}(w, c_i)}{\text{count}(w, *)} \tag{3}$$

We call these "entity category embeddings". For new words or words that do not appear in any entity category in the dictionary, their entity embeddings are zero at all dimensions. We concatenate this entity category embedding vector with the original word embedding vector to form a new word embedding vector. We call the **LSTM+CRF+Dict** method that also utilizes entity category embeddings as **LSTM+CRF+Dict+Cate**.

4 Experiments

4.1 Performance comparison between FG-NER methods

We evaluated the performance of the FG-NER methods using the test dataset, as described in Table 1. We calculated the Precision, Recall and F1-score for each category and the micro-average Precision and Recall over all 200 entity categories. Finally, we derived the average F1-score from the average Precision and Recall.

Method	English F-score (%)	Japanese F-score (%)
Rule+Dict	24.43	48.29
FIGER(Ling and Weld, 2012)	23.41	-
CRF+SVM+Dict	72.58	**73.30**
LSTM+CNN+CRF (Ma and Hovy, 2016)	80.93	66.76
LSTM+CNN+CRF+Dict	**83.14**	70.34
LSTM+CRF+Dict	81.89	73.05

(a) Average F-score of the FG-NER methods

Method	English	Japanese
LSTM+CNN+CRF (Ma and Hovy, 2016)	80.93	66.76
LSTM+CNN+CRF+Dict	**83.14**	70.34
LSTM+CNN+CRF+Dict+Cate	82.29	-
LSTM+CRF+Dict	-	73.05
LSTM+CRF+Dict+Cate	-	**75.18**

(b) Average F-score of the FG-NER systems with and without entity category embeddings

Category	Precision (%)	Recall (%)	F-score (%)
URL	100.00	100.00	100.00
Phone_Number	100.00	100.0	100.00
Cabinet	95.24	100.00	97.56

Average	**83.25**	**83.04**	**83.14**

(c) Precision, Recall, F-score of the method LSTM+CNN+CRF+Dict on the English test dataset, sorted by F-score

Table 3: Performance of FG-NER methods

The evaluation results are shown in Table 3a. Rule and dictionary-based methods (**Rule+Dict**) can only achieve an F-score of less than 50%, even we used more than 1000 rules and a huge number of entries in the dictionaries. Because there are many Wikipedia entries that are in Japanese Wikipedia but they are not in English Wikipedia and we translated the dictionary from Japanese by looking up parallel

entries in English Wikipedia, these entities do not appear in the English dictionary. Consequently, the F-score of English **Rule+Dict** is very low.

The method **FIGER** is the CRF+Perceptron hierarchical classifier described by Ling and Weld (Ling and Weld, 2012). We use the published source code of **FIGER**[7] and our training dataset (identical to the training dataset of other methods in this paper) to get an FG-NER model. We evaluated this model with the test dataset described in the previous section. We can only evaluate **FIGER** with English because the source code of **FIGER** can only work with English (e.g., the feature extraction code can only work with English if we don't modify it). Although the architecture of the method **FIGER** is very similar to that of **CRF+SVM+Dict**, the performance is very different (the F-score is 24.43%, compared to 72.58%). This is because of several reasons. First, **FIGER** is designed for classifying the two-layer hierarchy of named entities based on Freebase. This hierarchy is different from the three-layer hierarchy of Sekine's Extended Named Entity Hierarchy (ENEH) that we use in this work. Second, we use SVM at the leaf-level, instead of Perceptron. We believe that SVM gives high performance than Perceptron in multi-class classification tasks. And finally, the training data size is not large enough for **FIGER** to work well. **FIGER** uses millions of training samples (which are automatically extracted from Wikipedia) to train the system (Ling and Weld, 2012), whereas, in our method, we only have about 13 thousand sentences in the training dataset. Automatically creating the NE tagged data is a reasonable approach for FG-NER definitions that are derived from existing knowledge bases like Freebase or Wikipedia. For FG-NER definitions that are not based on existing knowledge bases, it is difficult to automatically extract the NE tagged data from a large text corpus like Wikipedia. Consequently, for FG-NER system working with these definitions, we must design an algorithm that requires only a small amount of training data.

We can observe that the state-of-the-art method for English NER (Ma and Hovy, 2016) also works well with English FG-NER, as **LSTM+CNN+CRF** outperforms **CRF+SVM+Dict** by a wide margin (80.93%, compared to 72.58%). However, for Japanese FG-NER, the situation is different. The method **CRF+SVM+Dict** achieves the best performance, and it significantly outperforms the original **LSTM+CNN+CRF** model in (Ma and Hovy, 2016). Even when we add dictionary information, **CRF+SVM+Dict** still outperforms **LSTM+CNN+CRF+Dict** for Japanese FG-NER (the F-score is 73.30 and 70.34, respectively). We measured the statistical significance of the F-score difference by an approximate randomization test (Chinchor, 1992) with significance level $\alpha = 0.05$ and 99,999 iterations. The randomization test is used because we want to check the difference between the micro-average F-score over all ENE categories. The result of this test indicates that the difference in F-score is statistically significant (the p-value is 10^{-5}). The reason for this difference lies in the character level embeddings that **LSTM+CNN+CRF+Dict** creates in the CNN layer. For English, we only have less than 30 characters in the alphabet, whereas, in Japanese, we have more than 2,000 Hiragana, Katakana and Kanji characters that are frequently used (the total number of Japanese characters is above 10,000). Because the number of characters is large in Japanese, the CNN layer does not work well to create good quality character embeddings.

We verified the above reason by the following experiment: we removed the CNN layer from LSTM+CNN+CRF+Dict and we measured the performance on the test dataset. Removing the CNN layer means disabling the character level embedding features in the LSTM+CNN+CRF+Dict method. The result of this experiment is shown in the last row of Table 3a. We can observe that, removing the CNN layer boosts the performance of the neural network based method from 70.30% (**LSTM+CNN+CRF+Dict**) to 73.05% (**LSTM+CRF+Dict**), making it comparable with the performance of **CRF+SVM+Dict** (73.30%) for Japanese FG-NER. However, for English FG-NER, the performance decreased if we remove the CNN layer. This proves that the CNN layer works well for English, but it does not work for Japanese.

We also verify the difference between **CRF+SVM+Dict** and **LSTM+CRF+Dict** using a randomization test as described previously. For Japanese, the difference between **CRF+SVM+Dict** and **LSTM+CRF+Dict** is not statistically significant. This suggests that with enough amount of training data and dictionary information, we can use both CRF or LSTM for FG-NER problem.

[7] https://github.com/xiaoling/figer

4.2 Result of removing CNN and using entity category embeddings

To verify the effectiveness the proposed method for Japanese FG-NER, we compared the performance of the best neural network-based model for each language with and without the entity category embeddings. The results are shown in Table 3b.

Because removing the CNN layer does not improve the performance of English FG-NER, we compared **LSTM+CNN+CRF** with the method **LSTM+CNN+CRF+Dict** and **LSTM+CNN+CRF+Dict+Cate** for English. We observe that, by adding dictionary information, we can improve the F-score from 80.93% to 83.14%. This improvement is statistically significant under a randomization test (similar to the tests in Section 4.1). However, if we further add the entity category embedding information (in **LSTM+CNN+CRF+Dict+Cate**), the performance slightly decreased (from 83.14% to 82.29%, which is statistically significant under the randomization test). This is because the quality of the translated English dictionary is not good enough to have practical statistics information.

Table 3b also shows a series of improvements we made for Japanese FG-NER. First, if we add the dictionary information, we obtained a similar result with that of English FG-NER (we boost the performance from 66.76% to 70.34%, as shown in the 1st and 2nd row of Table 3b). Second, if we remove the CNN layer from the network, we improve the performance from 70.34% to 73.05%, as described in the previous section. Finally, if we add category entity embeddings, we further improve the performance from 73.05% to 75.18%. This makes the method **LSTM+CRF+Dict+Cate** significantly outperforms the method **CRF+SVM+Dict** (the randomization test result shows that the improvement is statistically significant). This proves the effectiveness of the newly added entity category embedding feature for Japanese FG-NER.

With this result, we can unify the FG-NER model for both English and Japanese: we don't need to use **CRF+SVM** anymore, but we can utilize neural network-based models for both languages. We can have an identical system for both English and Japanese FG-NER by simply setting an option to enable/disable the CNN layer and the entity category embedding information to switch between English and Japanese. This makes the engineering of the system easier and helps to cut the maintenance cost of the FG-NER system.

4.3 Performance of each category

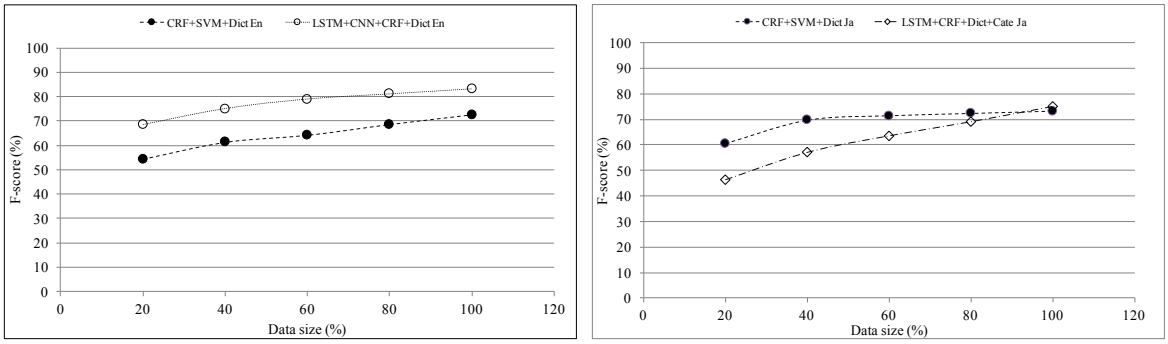
In the 200 NE categories in the Sekine's ENEH (Sekine, 2008), there are several categories that can be recognized by rule-based method (such as URL or Email). There are also some categories that are actually not named entities, and difficult to recognize, such as Mollusk_Arthropod (cellar spider, turbinidae,...) or Art_Other (e.g., "the Venus of Milo", "Genji Monogatari Emaki",...). Consequently, the performance of the FG-NER models for each category will be different. In this section, we investigate the performance some typical entity categories in the method **LSTM+CNN+CRF+Dict** (the best method for English).

Table 3c shows the Precision, Recall and F-score of the **LSTM+CNN+CRF+Dict** method on some specific categories as well as the average evaluation results of the entire 200 categories (in the last row). We achieved very high performance on the categories with a small number of known entities (such as Country) or the categories that the rules can capture almost all entities (such as Intensity, Volume, URL, and Email). For categories with free text names (e.g, printing names) or very short name (e.g., AK-47, a type of weapon) the system can not predict the NE tag very well because these names might appear in various contexts. This result is consistent with the difficulty of the tasks as described in Section 2.2 and in Table 2.

4.4 Training data size and performance

To find out the relation between the training data size with the FG-NER models, we varied the training data size and measured the F-score of each model on the test dataset.

Specifically, we randomly sample the training dataset by the rates of 20%, 40%, 60%, 80% and 100% (i.e., using the entire training dataset). We then use the sampled training dataset to train the FG-NER models and evaluated these models with the test dataset. The results of this experiment are shown in



(a) For English FG-NER models

(b) For Japanese FG-NER models

Figure 4: Relation between training data size and F-score

Figure 4a and Figure 4b.

For English, we observe that the neural network-based method (**LSTM+CNN+CRF+Dict**) consistently outperforms the method **CRF+SVM+Dict** by a wide margin, irrespective of the training data size. If we only use 20% of the training data (i.e., about 4000 training sentences), we can get the F-score of 68.49%, whereas, using the entire of the training dataset (100%), we get the F-score of 83.14%. However, from 60% of the data size, the F-score increases gradually. This indicates that, we can still get a comparable performance even if we do not have a large amount of training data (an F-score of 78.68% for 60% of training data size).

For Japanese, the situation is totally different. When the training data size is small, **CRF+SVM+Dict** outperforms **LSTM+CRF+Dict+Cate** by a wide margin (F-score of 60.60%, compared to 45.43%). However, when the training data size is increased to 100%, **LSTM+CRF+Dict+Cate** is the best method (it achieves an F-score of 75.18%, compared to 73.30% of **CRF+SVM+Dict**). Therefore, if we only have a small amount of training data (e.g., 4,000 sentences), we must use **CRF+SVM+Dict**. If we have a larger amount of training data (e.g., 20,000 sentences), we can use the neural network-based model **LSTM+CRF+Dict+Cate** to achieve the best performance. When the amount of training data is large enough, the LSTM layer can learn the relation between the NE tags and the underlying words (tokens) as well as the grammatical structures. Consequently, it can precisely model the NE tagging problem.

These comparison results give us a suggestion to choose the appropriate model for each setting of target language and training data size: if the target language is English then we should use the neural network-based methods; if the language is Japanese then we should use **CRF+SVM+Dict** if we only have little amount of training data and we use the neural network-based method when we have enough amount of training data.

5 Conclusion

We presented an empirical study of fine-grained named entity recognition (FG-NER) methods. We investigated the relation between the performance of the methods with various settings of target languages and training data sizes. We found that the state-of-the-art method for English NER, which is based on neural network architecture, also works well with English FG-NER. However, for Japanese FG-NER, it does not achieve state-of-the-art performance. We proposed two additional features to the existing method: first, incorporating dictionary information to the model and second, utilizing entity category embeddings. Moreover, we proposed a modification to the architecture of the neural network-based model, that is removing the CNN layer for Japanese FG-NER to alleviate problem concerning a large number of characters in the Japanese alphabet. Experimental results show that, the proposed additional features and network architecture modification improve the performance of Japanese FG-NER by a wide margin.

Abstract

Existing neural models usually predict the tag of the current token independent of the neighboring tags. The popular LSTM-CRF model considers the tag dependencies between every two consecutive tags. However, it is hard for existing neural models to take longer distance dependencies of tags into consideration. The scalability is mainly limited by the complex model structures and the cost of dynamic programming during training. In our work, we first design a new model called "high order LSTM" to predict multiple tags for the current token which contains not only the current tag but also the previous several tags. We call the number of tags in one prediction as "order". Then we propose a new method called Multi-Order BiLSTM (MO-BiLSTM) which combines low order and high order LSTMs together. MO-BiLSTM keeps the scalability to high order models with a pruning technique. We evaluate MO-BiLSTM on all-phrase chunking and NER datasets. Experiment results show that MO-BiLSTM achieves the state-of-the-art result in chunking and highly competitive results in two NER datasets. [1]

1 Introduction

Chunking and named entity recognition are sequence labeling tasks whose target is to find the correct segments and give them the correct labels. The tags inside a segment have internal dependencies. The tags in consecutive segments may have dependencies, too. Therefore, it is natural to take the tag dependencies into consideration when making a prediction in such sequence labeling tasks.

Recently, methods have been proposed to capture tag dependencies for neural networks. Collobert et al. (2011) proposed a method based on convolutional neural networks, which can use dynamic programming in training and testing stage (like a CRF layer) to capture tag dependencies. Furthermore, Huang et al. (2015) proposed LSTM-CRF by combining LSTM and CRF for structured learning. They use a transition matrix to model the tag dependencies. A similar structure is adopted by Ma and Hovy (2016). Their model also involves an external layer to extract some character level features.

However, it is not explicit how to model the dependencies of more tags or use the dependency information in these lines of work. We then propose a solution to capture long distance tag dependencies and use them for dependency-aware prediction of tags. For clarity, we first give some detailed explanations of the related terms in our work. "order" means the number of tags that a prediction involves in a model. An order-2 tag is a bigram which contains the previous tag and the current tag at a certain time step, as shown in Figure 1. Higher order tags are defined in a similar way.

We first develop a simple method to implement high order models. But these models, which are supposed to capture more tag dependency information, perform worse and worse as the order of models increases. One possible reason is that trying to capture more tag dependencies raises the difficulty of prediction. We name these models as single order models and propose a new method based on them. The proposed **M**ulti-**O**rder **LSTM** (MO-LSTM) combines multi-order information from these single order models to decode. It keeps the scalability with a proposed pruning technique and performs well in our

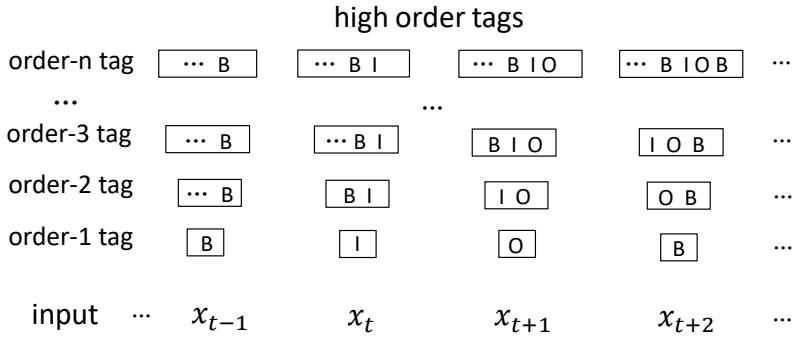

Figure 1: An illustration of tags of different orders.

tasks. Experiments show that MO-LSTM achieves the state-of-the-art F1 score in all-phrase chunking and competitive scores in two NER datasets.

The contributions of this work are as follows:

- We extend the LSTM model to higher order models. However, the performance of the high order models which are supposed to capture longer tag dependencies is getting worse when increasing the order.
- We propose a model integrating low order and high order models. It keeps the scalability in both training and testing stage with a pruning technique.
- The proposed MO-LSTM achieves an evident error reduction in chunking and NER tasks. It produces the state-of-the-art F1 score in chunking and highly competitive results in two NER datasets.

2 Single Order LSTM

We first propose a simple training and decoding method which enables the existing models to extend to higher order models. Take the order-2 model as an example, for each word we combine its previous tag and its current tag to produce a bigram tag as its new tag to predict. Hence, the model can be trained with the "new" bigram (order-2) tag set.

Formally, given an input sequence $\boldsymbol{x} = \{x_1, x_2, \cdots, x_T\}$, where x_t denotes the t-th word in a sentence and T denotes the sentence length. The sequence $\boldsymbol{y} = \{y_1, y_2, \cdots, y_T\}$ represents a possible label sequence for $\boldsymbol{x}$. We denote $\mathcal{Y}^{(1)}$ as the set of all possible order-1 labels, and $y_t \in \mathcal{Y}^{(1)}$. The order-1 model can be represented as:

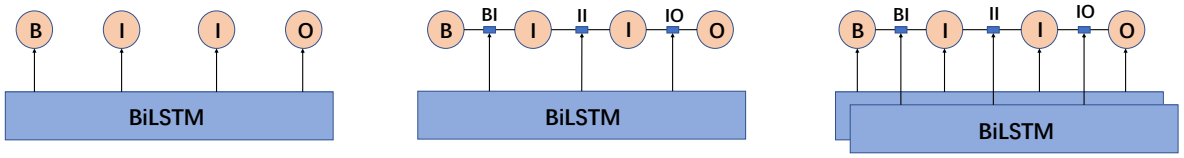
$$s_1(y_1, y_2, \cdots, y_T|\boldsymbol{x}; \theta) = \prod_{t=1}^{T} s(y_t|\boldsymbol{x}; \theta) \tag{1}$$

where θ is the parameters of the model. In implementation, we use a Bi-LSTM with a softmax layer to compute the score $s(y_t|\boldsymbol{x}; \theta)$.

To extend the order-1 model to an order-2 model, we transform the unigram label sequence into a bigram label sequence $y_0y_1, y_1y_2, \cdots, y_{T-1}y_T$, where y_0 is a special START symbol. The bigram label is defined as a combination of two consecutive label y_{t-1} and y_t, and $\mathcal{Y}^{(2)}$ is the set of all possible bigram labels that appear in the training set. The order-2 model can then be written as:

$$s_2(y_1, y_2, \cdots, y_T|\boldsymbol{x}; \theta) = \prod_{t=1}^{T} s(y_{t-1}y_t|\boldsymbol{x}; \theta) \tag{2}$$

Similar to the order-1 model, the score $s(y_{t-1}y_t|\boldsymbol{x}; \theta)$ is computed by a Bi-LSTM with a softmax layer. In implementation, the difference with the order-1 model is that the unigram label is replaced with the



(a) Single Order-1 Model (b) Single Order-2 Model (c) Multi-Order-2 Model

Figure 2: An illustration of the single order model and the multi-order model. The single order-1 model is a BiLSTM.

bigram label. In this way, the model can be further extended to order-n:

$$s_n(y_1, y_2, \cdots, y_T|\boldsymbol{x}; \theta) = \prod_{t=1}^{T} s(y_{t-n+1} \cdots y_t|\boldsymbol{x}; \theta) \tag{3}$$

As the order of the models increases, the models are supposed to learn more tag dependencies. However, according to our experiments, the performance of these models is getting worse, and the detailed results are shown in Section 4. An intuitive reason to explain the experimental phenomena is that the increasing size of the label set makes it more difficult to predict a correct label of the input word. Another potential reason is that the complex structure leads to overfitting problem. Sun (2014) suggests that complex structures are actually harmful to the generalization ability in structured prediction.

3 Multi-Order BiLSTM

The performance of single high order models deteriorates as the order increases. But they might capture some kinds of useful dependency information. To make use of these dependency information, we introduce a multi-order model which combines the low-order and high-order information. The proposed multi-order model consists of several single order models (as described in Section 2) of different orders. At the training stage, these models are trained separately as usual. At the decoding stage, we propose a new decoding method to combine the low order model and the high order model. Since both low order information and high order information is used when decoding, the proposed method is named Multi-Order BiLSTM (MO-BiLSTM). In this section, we first give the details of the training and the decoding process, and then introduce a pruning technique to improve the efficiency of MO-BiLSTM.

3.1 Multi-Order Training

Our proposed multi-order-n model is a mixture of k single order models with different orders, where n is the maximum order of the single order models. When $n = 1$, the multi-order model becomes a single order-1 model, i.e. a BiLSTM. The order set of the single order models is the subset of $\{1, 2, \cdots, n\}$. For example, if the maximum order n is 3, the combination of the single order models can be $[1, 2]$, $[1, 3]$, $[2, 3]$, or $[1, 2, 3]$. Formally, we denote the order set as $\{o_1, o_2, \cdots, o_k\}$, where $o_i < o_j$ and $i < j$. In our implementation, n is equal to k in both training and decoding stage.

At the training stage, we train k single order models separately following Eq. 3:

$$\theta_i = \underset{\theta}{\operatorname{argmax}}\, s_{o_i}(y_1, y_2, \cdots, y_T|\boldsymbol{x}; \theta) = \underset{\theta}{\operatorname{argmax}} \prod_{t=1}^{T} s(y_{t-o_i+1} \cdots y_t|\boldsymbol{x}; \theta) \tag{4}$$

where θ_i is the parameters of the i-th single order model of the order o_i. After training, we obtain a set of k independent models: $\{s(y_{t-o_1+1} \cdots y_t|\boldsymbol{x}; \theta_1), \cdots, s(y_{t-o_i+1} \cdots y_t|\boldsymbol{x}; \theta_i)\}$, which learns the label dependency of different orders.

3.2 Multi-Order Decoding

For the purpose of simplicity and clarity, we first describe the proposed decoding method of MO-BiLSTM in the order-2 case, and then we extend it to the general order-n case.

Algorithm 1 Multi-order decoding with pruning in the order-n case

Input: sentence $\boldsymbol{x}$, trained order-1 LSTM $s_1(y|x)$ in Eq. 1, multi-order-n LSTM $s_n(y|x)$ in Eq. 6
for $t = 1...T$ **do**
  Select the top-k uni-labels by the order-1 scores:
    $\tilde{Y_1} = \text{topkTag}(s_1(y_t|x)), \tilde{Y_2} = \text{topkTag}(s_1(y_{t-1}|x)), \cdots, \tilde{Y_n} = \text{topkTag}(s_1(y_{t-n+1}|x))$
  Combine n top-k uni-label sets into a n-gram label set:
    $Y = \tilde{Y_1} \times \tilde{Y_2} \times \cdots \times \tilde{Y_n}$
  for each $(y^1, y^2, \cdots, y^n) \in Y$ **do**
    Previous tag state $d_{t-1} = y^1 y^2 \cdots y^{n-1}$
    Current tag state $d_t = y^2 y^3 \cdots y^n$
    Compute the transition score $s = s_n(y^1, y^2, \cdots, y^n|x)$ by multi-order-n LSTM
    Compute the maximum score at current state $A[t][d_t] = max(A[t][d_t], A[t-1][d_{t-1}] * s)$
Output: The optimal tag sequence y^* by backtracking the path of the maximum score $A[T][d_T]$

As shown in Figure 2, in the order-2 case the multi-order model is a mixture of 2 single order models, i.e. single order-1 model (Eq. 1) and single order-2 model (Eq. 2). At the decoding stage, the multi-order model takes account of both the order-1 model and the order-2 model. We need a new decoding approach to unify the decisions of both models. Since the order-1 model and order-2 model predict the label sequence independently, we choose to multiply the scores of order-1 model and order-2 model to get a global score, and use a dynamic programming algorithm to search for the label sequence with the maximum score:

$$\begin{aligned} y_1^*, y_2^*, \cdots, y_T^* &= \underset{\boldsymbol{y}}{\text{argmax}}\, s_1(y_1, y_2, \cdots, y_T|\boldsymbol{x}; \theta_1) \times s_2(y_1, y_2, \cdots, y_T|\boldsymbol{x}; \theta_2) \\ &= \underset{\boldsymbol{y}}{\text{argmax}} \prod_{t=1}^{T} s(y_t|\boldsymbol{x}; \theta_1) \times s(y_{t-1}, y_t|\boldsymbol{x}; \theta_2) \end{aligned} \tag{5}$$

where $s(y_t|\boldsymbol{x}; \theta_1)$ and $s(y_{t-1}, y_t|\boldsymbol{x}; \theta_2)$ are the score predictions of the single order-1 model and the single order-2 model, respectively. The details of the dynamic programming algorithm are shown in Section 3.3.

Further, we extend the order-2 case to a general order-n case. The difference with the order-2 case is that there are k single order models to approximate the scores of the generated label sequence. We approximate the scores by multiplying all the scores of these trained single order models, and then decode the sequence with the maximum score. Formally, it can be written as:

$$\begin{aligned} y_1^*, y_2^*, \cdots, y_T^* &= \underset{\boldsymbol{y}}{\text{argmax}} \prod_{i=1}^{k} s_{o_i}(y_1, y_2, \cdots, y_T|\boldsymbol{x}; \theta_i) \\ &= \underset{\boldsymbol{y}}{\text{argmax}} \prod_{i=1}^{k} \prod_{t=1}^{T} s(y_{t-o_i+1} \cdots y_t|\boldsymbol{x}; \theta_i) \end{aligned} \tag{6}$$

where $s(y_{t-o_i+1} \cdots y_t|\boldsymbol{x}; \theta_i)$ is the score prediction of the i-th single order model of the order o_i.

3.3 Scalable Decoding with Pruning

Here, we introduce an efficient dynamic programming algorithm to search for the label sequence with the maximum score. The scores of different n-gram labels are jointly considered in our model. Originally, we should consider all possible n-gram labels at every position of the sentence during dynamic programming. However, it will lead to a huge search space and a lot of time. In order to reduce the time cost, we can prune the unnecessary searching branches. For example, an order-1 model assigns a very low probability to the uni-label "I" of the t-th word, which means the order-1 model is confident that the t-th word can hardly be labeled as "I". Therefore, it is unnecessary to take account of the bi-gram labels "I-B", "I-I", and "I-O" at the next time step.

Model	All-Chunking	English-NER	Dutch-NER
Single Order-1 BiLSTM	93.89	88.23	77.20
Single Order-2 BiLSTM	93.71 (-0.18)	87.61 (-0.62)	76.61 (-0.59)
Single Order-3 BiLSTM	93.34 (-0.55)	87.47 (-0.76)	76.47 (-0.73)
Multi-Order-1 BiLSTM	93.89	88.23	77.20
Multi-Order-2 BiLSTM	94.93 (+1.04)	90.23 (+2.00)	80.95 (+3.75)
Multi-Order-3 BiLSTM	**95.01 (+1.12)**	**90.70 (+2.47)**	**81.76 (+4.56)**

Table 1: Results of single order models and MO-BiLSTM. The number in parentheses means the improvements or reductions compared to the results of order-1 models. All-Chunking denotes All-Phrase-Chunking.

In implementation, we use the order-1 labels with high scores to evaluate whether to prune the high order labels. More precisely, we simply keep the top-k order-1 labels at each position. The order-n labels for a specific position is generated by the top-k labels of n tokens around the position. Suppose a task has totally 50 labels. The order-1 model should compute 50 scores of these labels at each time step. As for the order-3 model, the number of the scores to be computed becomes 50^3. The original search space before pruning for dynamic programming at each time step is 50^3. But if we only keep top-5 order-1 labels at each position and prune the order-n labels, the search space will be reduced from 50^3 to 5^3.

According to our experiments, the pruning technique saves a lot of time in the decoding stage and results in no loss of accuracy, and we find top-5 pruning works the best in order to balance the accuracy and the time cost. Details of the experiments can be found in Section 4. Algorithm 1 shows the detailed process of multi-order decoding with pruning in the order-n case.

4 Experiments

4.1 Datasets

Chunking and named entity recognition are sequence labeling tasks that are sensitive to tag dependencies. The tags inside a segment have internal dependencies. The tags in consecutive segments may have dependencies, too. Thus, we conduct experiments on the chunking and NER tasks to evaluate the proposed method. The test metric is F1-score. The chunking data is from CoNLL-2000 shared task (Sang and Buchholz, 2000), where we need to identify constituent parts of sentences (nouns, verbs, adjectives, etc.). To distinguish it from NP-chunking, it is referred to as the all-phrase chunking. We use the English NER data from the CoNLL-2003 shared task (Sang and Meulder, 2003). There are four types of entities to be recognized: PERSON, LOCATION, ORGANIZATION, and MISC. The other NER dataset is the Dutch-NER dataset from the shared task of CoNLL-2002. The types of entities are the same as the English NER dataset.

4.2 Experimental Details

Our model uses a single layer for the forward and backward LSTMs whose dimensions are set to 200. We use the Adam learning method (Kingma and Ba, 2014) with the default hyper parameters. We set the dropout (Srivastava et al., 2014) rate to 0.5.

Following previous work (Huang et al., 2015), we extract some spelling features and context features. We did not use extra resources, with the exception of using Senna embeddings[2] in Chunking and English-NER tasks. The embeddings in Dutch-NER tasks are randomly initialized with a size of 50. The code is implemented with the python package *Tensorflow* (Abadi et al., 2016).

4.3 Effect of Multi-Order Setting

For simplicity, the single order model of order-n is denoted as single order-n model and the multi-order model in the order-n case is denoted as multi-order-n model. To verify the effectiveness of MO-BiLSTM,

Model	All-Chunking	English-NER	Dutch-NER
Order-1	14	10	11
Order-2	154	39	44
Order-3	832	138	158

Table 2: The sizes of tag set of different order.

we conduct comparison experiments of single order models and multi-order models. The results are shown in Table 1. The performance of single order BiLSTM models is getting worse with the growing of the order. An intuitive reason is that the increasing size of tag set raises the difficulty to make a correct tag prediction of a word. Although the performance of single high order models is far from satisfactory, the multi-order models perform well with consistent growth of F1-score on three datasets. In chunking, the MO-BiLSTM at order-3 obtains a 18.3% error reduction compared to BiLSTM. It also performs well in the NER tasks, resulting in a 21.6% and a 20.0% error reductions in English-NER and Dutch-NER compared to BiLSTM baselines, respectively.

The results suggest that high order dependency information is indeed beneficial to the prediction. Furthermore, the adopted multi-order setting makes the learned tag dependency specific to the input words. The reason is that the proposed high order model encodes the tag dependency into a single "output tag", and model the "output tag" relations using a BiLSTM conditioned on the input words. The tag dependency in previous work is represented by a transition matrix, which cannot capture the relations of tag dependencies with respect to the input words. Moreover, MO-BiLSTM can take advantage of the subtle tag dependencies captured by single-order models and naturally integrate multi-order information to make tag prediction. The decoding process of MO-BiLSTM finds a global optimum tag sequence, which significantly reduces the risk of mistakes.

MO-BiLSTM also results in a growing size of tag set. The sizes of tag set from order-1 model to order-3 model are given in Table 2 respectively. The tag size of the model is beyond a hundred at order-3 case. Although the size of tag set grows as the order of model increases, it is acceptable in such sequence labeling problems compared to the vocabulary size in machine translation which can be over millions.

4.4 Effect of Pruning

The effect of pruning on speeding up the decoding is presented in Table 3. As shown, the pruning technique has shown a great ability to save time with no loss of accuracy. We then give a detailed analysis of the pruning technique. Original search process of dynamic programming considers all possible high order dependencies. However, most low-order tags have been assigned very low probabilities by low-order models and they will form almost impossible high-order tags. Thus, we only keep a small subset of all low-order tags, which makes the possible combinations shrink rapidly so that the cost of dynamic programing is greatly reduced. We also find that the pruned search space has no effect on the performance of the models. We suppose it is almost unlikely that the best tag sequence is out of the pruned search space. Hence, the accuracy is kept to the full extent, as shown in our experiments.

4.5 Comparison with State-of-the-art Systems

Table 4 shows the results on all-phrase chunking task compared with previous work. We achieve the state-of-the-art performance in all-phrase chunking. Our model outperforms the popular method BiLSTM-CRF (Huang et al., 2015) by a large margin. Shen and Sarkar (2005) also reported a 95.23 F1-score in their paper. However, this result is based on noun phrase chunking (NP-chunking). All phrase chunking task contains much more tags to predict than NP-chunking, so it is more difficult.

Table 7: Examples of the predictions of BiLSTM and MO-BiLSTM of order-3.

Table 5 shows the comparison results on the English-NER dataset. Ma and Hovy (2016) reported the best result of English NER. The main architecture of their network is BiLSTM-CRF equipped with a CNN layer to extract character-level representations of words. Our model performs slightly worse than it but outperforms BiLSTM-CRFs reported in other papers (Huang et al., 2015; Lample et al., 2016).

The comparison results on Dutch NER are shown in Table 6. Gillick et al. (2015) keeps the best result of Dutch NER. However, the model is trained on four languages. With the monolingual setting, their model achieves 78.08 on F1 score. Another competitive result is reported in the work of Lample et al. (2016). Their model is a BiLSTM-CRF model with an external LSTM layer to extract character-level representations of words. Our model gets the best score when there is no extra resources.

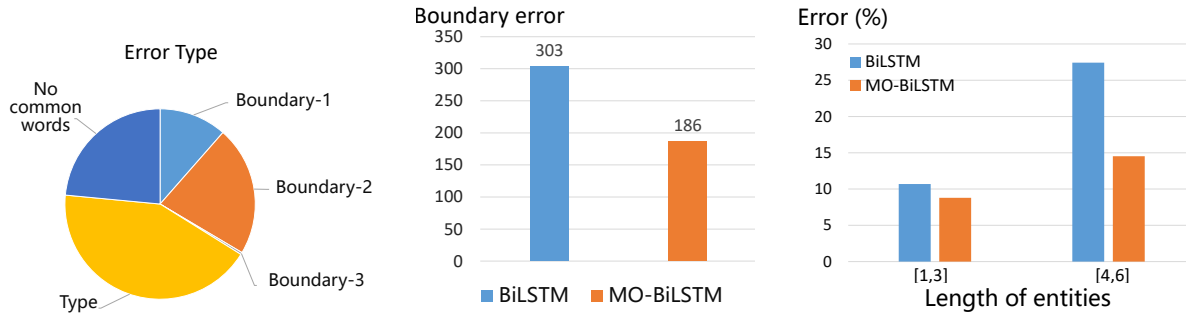
4.6 Case Study

We observe that MO-BiLSTM mainly helps in two aspects: the prediction of boundaries of a segment and the recognition of long segments. Table 7 shows two cases that MO-BiLSTM model predicts correctly but BiLSTM fails to recognize the entities. In the first case, "Gulf of Mexico" should be recognized as the entity "Location". BiLSTM recognizes "Gulf" and "Mexico" as locations, but fails to recognize "of" as a part of the entity, so that an entire entity is split. The reason is that BiLSTM model predicts the tag independently, and it predicts "O" as the tag of "of" regardless of the neighboring tags. On the contrary, MO-BiLSTM takes account of the neighboring tags, and works well in this case. Considering that both the left tag and the right tag are labeled "LOC", the word "of" has a larger probability to be a part of the entity.

The second case contains an entity of type "LOC". BiLSTM succeeds in recognizing the boundary of the entity but predicts a wrong entity type for the word "Yongon". Although "Yangon" is a city, it should not be recognized as a location because it is a part of an organization. BiLSTM does not consider the neighboring tag, and makes a wrong prediction, while MO-BiLSTM succeeds in predicting a correct entity by considering the neighboring tag.

4.7 Error Analysis

To better analyze the basic model and the MO-BiLSTM, we investigate the cases that can not be handled well in English-NER dataset, and the result is summarized in Figure 3. All the unrecognized entities are classified into five categories, which are "boundary-1", "boundary-2", "boundary-3", "type", and "no common words". "Boundary-1" denotes the cases that the gold entity contains a predicted entity, and "boundary-2" means the gold entity is contained by a prediction. "Boundary-3" represents the case that the gold entity and our prediction overlap. "Type" means a entity's boundaries are recognized correctly but its entity type is misclassified. When there are no common words between the predicted entity and any gold entity, it is denoted as "no common words". We count the number of wrongly predicted entities of these different categories, and the result is shown in Figure 3a. The "boundary" error (the



(a) Error types of the predicted entities of MO-BiLSTM.

(b) Number of predicted entities belonging to boundary error.

(c) Percentage of error entities regarding the length of entities.

Figure 3: Error analysis of BiLSTM and MO-BiLSTM on English-NER.

sum of "boundary-1", "boundary-2", and "boundary-3"), which represents the model misidentifies the entity's boundaries, is the major error type of BiLSTM. The reason is that the boundary is made up of two tags, but BiLSTM model predicts each tag independently. Our MO-BiLSTM is able to capture the dependencies between two tags, so it can significantly decrease the number of boundary recognition error. That is also the reason why "boundary" error is not the major error of MO-BiLSTM.

We further compare the number of entities belonging to "boundary" error between BiLSTM and MO-BiLSTM. According to Figure 3b, it shows that the "boundary" error of MO-BiLSTM has a reduction rate of nearly 40% compared with BiLSTM. In order to analyze the influence of the length of entities, we divide the entities into 2 groups according to their lengths, and calculate the recognition error rate of different lengths of entities. The result is shown in Figure 3c. We observe that the MO-BiLSTM model has a significant reduction in the recognition error of long entities from 27.42% to 14.52%. The large reduction in error rate proves that the MO-BiLSTM model is able to capture longer distance tag dependencies compared with BiLSTM.

5 Related Work

Huang et al. (2015) and Lample et al. (2016) stacked a CRF layer on BiLSTM to capture the global tag dependencies. The difference between their work is the way to capture character-level information. Their proposed BiLSTM-CRF performs well in sequence labeling tasks. However, the dynamic programming must be done in both training and testing stage. The MO-BiLSTM does not need dynamic programming during training. Muller et al. (2013) proposed a model that also prunes the tag set using a lower order model, but dynamic programming is required in both training and testing stage like prior work. Besides the difference that we do not need dynamic programing in training stage, the pruning technique is different. We directly model the high order states in the training stage, while Muller et al. (2013) merges lower order states to get higher order states. Soltani and Jiang (2016) propose a model called higher order recurrent neural networks (HORNNs). They proposed to use more memory units to keep track of more preceding RNN states, which are all recurrently fed to the hidden layers as feedback. These structures of Soltani's work are also termed "higher order" models, but the definition is different from ours.

There are several other neural networks that use new techniques to improve sequence labeling. Ling et al. (2015) and Yang et al. (2016) used BiSLTM to compose character embeddings to words representation. Martins and Kreutzer (2017) used an attention mechanism to decide what is the "best" word to focus on next in sequence labeling tasks. Zhai et al. (2017) proposed to separate the segmenting and labeling in chunking. Segmentation is done by a pointer network and a decoder LSTM is used for labeling. Shen et al. (2018) used active learning to strategically choose most useful examples in NER datasets.

6 Conclusions

In this paper, we focus on extending LSTM to higher order models in order to capture more tag dependencies for segmenting and labeling sequence data. We introduce a single order model, which is supposed

to capture more tag dependencies. However, the performance of the single order model is getting worse when increasing the order. To address this problem, we propose to integrate dependency information of different orders to decode. The proposed method, which is called MO-BiLSTM, keeps the scalability to high order models with a pruning technique. Experiments show that MO-BiLSTM achieves better performance than many existing popular methods. It produces the state-of-the-art result in chunking and competitive results in two NER datasets. At the end, we analyze the advantage and limitation of the MO-BiLSTM. We find that MO-BiLSTM mainly helps in the prediction of segment boundaries and the recognition of long segments.

Abstract

This paper proposes an extractive multi-document summarization approach based on an ant colony system to optimize the information coverage of summary sentences. The implemented system was evaluated on both English and Arabic versions of the corpus of the Text Analysis Conference 2011 MultiLing Pilot by using ROUGE metrics. The evaluation results are promising in comparison to those of the participating systems. Indeed, our system achieved the best scores based on several ROUGE metrics.

1 Introduction

Multi-document summarization (MDS) is a type of summarization in which the contents of a set of documents are represented as a single summary. Today, this type of summarization has become a necessity due to the existence of enormous amounts of information. It reduces the quantity of text by providing a summary that contains the most relevant and important parts. The automatic summarization problem has been studied since the middle of the 20th century. Therefore, the application of several summarization approaches, such as statistical (Radev et al., 2004; Alguliev et al., 2013; Rautray and Balabantaray, 2017) and graph-based (Erkan and Radev, 2004; Shen and Li, 2010; Mosa et al., 2017b) approaches, have been described in the literature.

An extractive summary represents a combination of the most important sentences from the source without modifying them. Summary sentences are selected according to the two following approaches. The first is the greedy selection approach, in which the best textual units (e.g., sentences) are selected one item at a time. This approach is widely used in text summarization and is simple and fast; however, it rarely produces the best summaries (Huang et al., 2010). The second approach is the global optimal selection approach, which searches for the best summary rather than for the best sentences. It reduces the summarization task, or at least the step of selecting sentences, to an optimization problem in which the overall score of the output summary is optimized by searching for the best mixture of sentences. In the literature, several summarization objectives have been studied and optimized, such as information coverage, text diversity, and readability. In addition, different meta-heuristics have been applied in the studies to approximate the solution of the summarization problem. One group of such meta-heuristics is swarm intelligence (SI). SI is a nature-inspired population-based type of meta-heuristics that has been applied successfully to the summarization problem (Alguliev et al., 2013; Peyrard and Eckle-Kohler, 2016). Additionally, ant colony optimization (ACO) algorithms have been successfully applied to short text (Mosa et al., 2017a; Mosa et al., 2017b) and single document summarization (Tefrie and Sohn, 2018).

Motivated by the importance of the summarization task as well as by the promising results of the studies mentioned above, this paper investigates the application of the ACO algorithms to MDS for both the English and Arabic languages. It proposes an extractive MDS algorithm that maximizes the information coverage and saliency and minimizes the redundancy in the resulting summary using ACO. Specifically, it uses an ant colony system (ACS) to search for a good summary that optimizes these

Proceedings of the 27th International Conference on Computational Linguistics, pages 734–744
Santa Fe, New Mexico, USA, August 20-26, 2018.

objectives. The implemented system (called MDS-ACS) has been evaluated on both English and Arabic versions of the corpus of the Text Analysis Conference (TAC) 2011 MultiLing Pilot (hereafter referred to as the 2011 MultiLing Pilot) and using ROUGE metrics (Lin, 2004). The results of the proposed algorithm are promising compared to those of the top-ranked participated systems. The outline of the paper is as follows: Section 2 briefly presents some related studies; Section 3 briefly describes the ACS algorithm; Section 4 presents the formulation of the MDS problem; Section 5 describes the proposed algorithm and its main steps; Section 6 presents the experimental results; and finally, Section 7 presents the main conclusion and considerations for future work.

2 Related Work

Due to space limitations, this section only covers text summarization studies that use SI meta-heuristics. In addition, since the results of the proposed algorithm are compared to the results of the systems that participated in the 2011 MultiLing Pilot, these systems will be briefly presented. During the last decade, SI has accompanied the other meta-heuristics used to solve the text summarization problem. Examples of these meta-heuristics are particle swarm optimization (PSO), which simulates the behavior of a fish school or a bird flock; ACO, which was inspired by the ant society; and the artificial bee colony (ABC) algorithm, which simulates the behavior of honey bees. Recently, new SI meta-heuristics such as cuckoo search (CS) has also been used in the summarization field (see Table 1.)

PSO has been used by several summarization studies. For example, they have been used to assign weights for features extracted from the text to be summarized in Binwahlan et al. (2010) and as a feature selection method for Arabic single document summarization in Al-Zahrani et al. (2015). Aliguliyev (2010) proposed a multi-document method based on sentence clustering, which has been solved using a modified PSO algorithm. PSO has also been used in several summarization studies to perform the actual summary extraction process. Alguliev et al. (2013) proposed an optimization model that uses a discrete PSO algorithm to generate multi-document summaries by maximizing their content coverage and diversity. Asgari et al. (2014) proposed an extractive summarization method based on a multi-agent PSO (Ahmad et al., 2007). Foong and Oxley (2011) proposed an extractive summarization model that combines two kinds of algorithms: PSO and harmony search. PSO has also been included in summarization studies with languages other than English, such as Arabic (Al-Abdallah and Al-Taani, 2017) and Hindi (Dalal and Malik, 2018).

ACO is another SI meta-heuristics that has been used in summarization. Tefrie and Sohn (2018) proposed a summarization model that incorporates several features to calculate the heuristic value of each sentence. There are several differences between Tefrie and Sohn (2018) algorithm and our algorithm. Besides using different extracted features, several aspects related to the ACO are also different, such as the initial pheromone values, the calculated heuristics, the pheromone updating method, and the termination condition. Unfortunately, we could not compare the performance of our algorithm and of their algorithm because the exact values of the results are not provided in their paper. ACO has also been used with short text summarization problems. Mosa et al. (2017a) proposed a technique based on the use of ACO and Jensen-Shannon divergence to summarize a large number of Arabic user-contributed comments. Mosa et al. (2017b) proposed another technique to summarize comments using ACO along with graph coloring and local search to extract the summaries. Peyrard and Eckle-Kohler (2016) used ABC meta-heuristic to create an extractive multi-documents summarizer. They proposed a general optimization framework in which any objective function of input documents and an output summary can be used. Another ABC based summarizer was proposed by Sanchez-Gomez et al. (2017). The main difference between this study and all the previous ones is that the summarization problem is formulated as a multi-objective one. Finally, Rautray and Balabantaray (2017) used the CS for multi-document summarization.

The remainder of this section is devoted to describing the eight systems that participated in the 2011 MultiLing Pilot, in which they were given IDs from 1 to 8. All these systems were applied to both English and Arabic languages except system 5, which was not applied to Arabic. Liu et al. (2011) proposed a solution (ID 1) based on using the hierarchical latent Dirichlet allocation (LDA) topic model along with other traditional features to score the sentences. The CLASSY model (ID 2) (Conroy et al.,

2011), used a naïve Bayes classifier to give a weight for each term and summary sentences were selected using one of two methods: non-negative matrix factorization and integer programming. Steinberger et al. (2011) proposed a system (ID 3) based on the use of latent semantic analysis (LSA). Hmida and Favre (2011) proposed a summarizer (ID 4) that uses the Maximal Marginal Relevance (MMR) model to select a summary. Varma et al. (2011) proposed a system (ID 5) that uses the hyperspace analogue to language (Lund and Burgess, 1996) model to estimate the probability for each word w that another word w' occurs with w within a window of size K. Based on these probabilities, the system gives a score for each sentence, and the summary is created by selecting the sentences with the highest scores. Saggion (2011) proposed system (ID 6) in which summary sentences are selected based on their similarity to the centroid of the set of documents to be summarized. Das and Srihari (2011) proposed a solution (ID 7) based on the use of LDA. The solution combines several models to solve the summarization problems, including global tag-topic models (i.e., on a corpus- level) and local models (i.e., on a document set level). Finally, El-Haj et al. (2011) proposed a centroid-based summarizer (ID 8) whereby the sentences are ordered and selected based on their similarity to its centroid.

3 Ant Colony System

Ant colony optimization (ACO) is a family of SI meta-heuristics that mimics the collective behavior of real ants. Communication among ants in their colonies is realized by means of pheromone trails laid down while the ants search for food. Because these trails evaporate over time, the shortest path from the colony to the food source attracts more ants because it has a greater amount of pheromone. An example of an ACO method is the ant colony system (ACS) algorithm. Dorigo and Gambardella (1997) proposed this algorithm and applied it to the traveling salesman problems (TSP.) They made three modifications to the ant system (AS) algorithm, which is another example of ACO. The first modification concerns to the state transition rule that balances between the exploration of new paths and the exploitation of old ones. Formally, an ant k moves from city r to city s by following this rule:

$$s = \begin{cases} arg\ max_{u \in J_k(r)}\{[\tau(r,u)].[\eta(r,u)]^{\beta}\} & if \quad q \leq q_0 \ \ (exploitation) \\ S & if \quad q > q_0 \ \ (biased\ exploration), \end{cases} \tag{1}$$

where τ and η represent the pheromone value and the heuristic value, respectively. $J_k(r)$ is a set of cities that can be reached by the ant k. q is a random number that is uniformly distributed over [0,1]. The relative importance of exploration versus exploitation in the algorithm is controlled by the parameter q_0. β is another parameter used to control the relative weight of the pheromone verses the heuristic. S is a

city that is randomly selected according to the following probability distribution:

$$P_k(r,s) = \begin{cases} \frac{[\tau(r,s)].[\eta(r,s)]^\beta}{\sum_{u \in J_k(r)}[\tau(r,u)].[\eta(r,u)]^\beta} & if \quad s \in J_k(r) \\ 0 & otherwise. \end{cases} \tag{2}$$

The second and third modifications concern the pheromone-trail updating process. The second modification adds a local updating rule that is applied to the pheromones of the visited edges while constructing the solutions. The third modification is applied to the global updating rule so only the ant with the best tour is allowed to deposit pheromone.

4 Formulating the MDS Problem

In this step, MDS problem is formulated into an optimization problem and summary sentences are selected in a way that maximizes its overall content coverage score using ACS algorithm. This optimization problem can be formulated as follows. Let D be a set of input documents to be summarized and each of these document is split into sentences. Thus, D can be written as $D = \{s_1, \ldots, s_{|D|}\}$ where $|D|$ is the total number of sentences in D and s_i represents sentence i ($1 \leq k \leq |D|$.) The extractive MDS problem imposes the generation of a sequence of sentences; summary S, with a maximum length L by selecting a number of sentences from D such that the overall information coverage of S is maximized. Formally, it asks to optimize the main objective below:

$$S = max(\sum_{s_k \in D}(c_k.z_k)) \tag{3}$$

$$s.t. \sum_{s_k \in D}(l_k.z_k) \leq L,$$

where c_k and l_k stand for the content coverage score and the length of of sentence k, respectively. The binary variable z_k is equals to 1 if s_k is part of the summary and zero otherwise. The content score of each sentence is based on the weight of the words it contains. However, to maximize the information coverage and saliency as well as to minimize the redundancies, only the weight of the words that have not been covered by other sentences that already selected as a part of S will be considered and the other words are ignored. Thus, even if a word j occurs more than once in S, its weight w_j is added only once to the total content coverage score. Therefore, the overall content coverage score of S can be calculated by summing the weights of words it covers:

$$\sum_{s_k \in D}(c_k.z_k) = \sum_j (b_j.w_j), \tag{4}$$

The binary variable b_j is defined as:

$$b_j = \begin{cases} 1 & if \sum_{s_k \in D}(d_{kj}.z_k) \geq 1 \\ 0 & otherwise. \end{cases} \tag{5}$$

where d_{kj} is a constant that equals 1 if sentence k contains word j and 0 otherwise.

5 The Proposed Algorithm

This study proposes a summarization algorithm that generates extractive MDS summaries where its overall content score is maximized. It starts by preparing the input text using four preprocessing steps. After that, it gives a score for each word. Finally, these scores are used to generate the summary by selecting the sentences that maximize its information coverage score by using an ACS algorithm. The proposed algorithm (denoted as MDS-ACS) is outlined by Algorithm 1.

input: a set of related documents
the maximum summary length
output: a summary
begin
1 Preprocessing
1.1 Segment the text into a set of sentences
1.2 Tokenize the set of sentences
1.3 Remove the stop words
1.4 Replace each word by its stem
2 Scoring of words
2.1 Build the sentence-to-sentence, word-to-word, and sentence-to-word graphs
2.2 Apply the reinforcement algorithm (Wan et al., 2007)
3 Extracting of summary sentences
3.1 Build the graph of the input documents
3.2 Optimize the information coverage of the summary sentences by ACS
end

Algorithm 1: MDS-ACS

5.1 Preprocessing

Four preprocessing steps are applied to the text before conducting the summarization process. First, Stanford CoreNLP[1] (Manning et al., 2014) is used for text segmentation and sentence tokenization. The text segmentation step breaks up the text into sentences while the sentence tokenization step specifies the words in each of these sentences. After that, a stop word elimination step is applied to the text to remove the frequently occurring words that have low semantic weight (Jurafsky and Martin, 2009). A stop word list from the SMART information retrieval system [2] is used for the English text and the general stop-word list provided in El-Khair (2006) is used for the Arabic text. Finally, a stemming step is applied to obtain the stem of each word, using the Porter stemmer[3] and Khoja's stemmer[4] for English and Arabic text, respectively.

5.2 Scoring of words

In this step, the score of each word is computed by following the approach proposed by Wan et al. (2007). This iterative reinforcement approach merges ideas similar to those of two graph-ranking algorithms: PageRank (Brin and Page, 1998) and the HITS (Kleinberg, 1999). It starts by building three graphs. The first one is a bipartite graph that links each word with the sentences in which it appears and its edges are given a score based on the TF-ISF scores and cosine similarity measure. The second graph represents the relationship between each pair of sentences using also the TF-ISF scores and cosine similarity measure while the third one represents the relationship between each pair of words using the longest common substring.

The reinforcement algorithm is then applied to the graphs. Specifically, the score of each word is computed by applying a method similar to that of the HITS algorithm is applied to the first graph and a method similar to that of the PageRank algorithm is applied to the second and third graphs. Formally, each graph is represented by a matrix: W for the first graph, U for the second graph, and V for the third graph. In addition, this approach has two outputs; the score of each word and the score of each sentence. These scores are computed by applying repeatedly the following equations:

$$u^{(n)} = \alpha \widetilde{U}^T u^{(n-1)} + \beta \widehat{W}^T v^{(n-1)} \tag{6}$$

[1] https://stanfordnlp.github.io/CoreNLP/
[2] http://jmlr.csail.mit.edu/papers/volume5/lewis04a/a11-smart-stop-list/english.stop
[3] https://tartarus.org/martin/PorterStemmer/
[4] http://zeus.cs.pacificu.edu/shereen/research.htm

$$v^{(n)} = \alpha \widetilde{V}^T u^{(n-1)} + \beta \widetilde{W}^T u^{(n-1)}, \tag{7}$$

where v and u are two matrices that hold the scores of the words and the score of the sentences, respectively. $\widetilde{W}$, $\widetilde{U}$, and $\widetilde{V}$ are the normalized versions of W, U, and V, respectively, $\widehat{W}$ is the normalized transposed version of W. $u^{(n)}$ and $v^{(n)}$ are the values of matrix u and matrix v at the iteration n. Finally, $u^{(n-1)}$ and $v^{(n-1)}$ are the values of matrix u and matrix v at the iteration $n-1$. At this point, the score of each word is computed and ready to be used to generate the summary. However, due to the importance of the first sentences in the summarization, the proposed algorithm doubles the weight of the words that exist in the first sentences. Several differences exist between the proposed algorithm and the reinforcement approach. First, the proposed algorithm generates multi-document summaries while the reinforcement approach creates single document summaries. Second, while the reinforcement approach depends on the scores of the sentences to create the summary, the proposed algorithm uses the scores of the words to generate a summary that maximizes information coverage and saliency and minimizes redundancy. Third, the proposed algorithm uses the longest common substring to compute the similarities among the words. Forth, the words of the first sentences are given more weight than the other words. Finally, an ACS algorithm is used to extract summary sentences.

5.3 Extracting of summary sentences

A modified version of the ACS algorithm is used to extract summary sentences (see Algorithm 2.)

```
input : the graph representation of input documents
        the maximum summary length
output: summary sentences
begin
    Initialize the pheromone trails and parameters
    while the maximum number of iterations is not reached do
        Create and position an ant on each node (i.e., sentence)
        Activate the ants
        repeat
            for each active ant do
                Choose the next sentence according to Equation (1) and Equation (2)
                if ant cannot include more sentences then
                    Deactivate the ant
                end
                else
                    Update the ant's current scores of the unvisited sentences
                    Update the current length and score of the ant's partial summary
                end
            end
            for each active ant do
                Apply pheromone local updating rule
            end
        until all ants become inactive;
        Increase the current number of iterations
    end
    Apply pheromone global updating rule using the best solution found in the current iteration
    if a summary with a new higher score is found then
        Update the best-so-far summary
    end
    return the best-so-far summary
end
```

Algorithm 2: ACS

This step begins by building a connected graph from the text to be summarized by adding a node to represent each sentence. Then, a modified version of the ACS algorithm proposed by Dorigo and Gambardella (1997)), adapted to work for MDS instead of TSP, is applied to the graph. In this study, the ACS algorithm starts by creating and placing an ant on each node (i.e., sentence). After each iteration, each ant generates a solution (i.e. a summary) which is a path of nodes that represent the extracted sentences. Regarding the summary length constraint, each ant keeps its own length and stops when it reaches the maximum summary length. Therefore, MDS-ACS assigns a state for each ant; active ant if it can include more sentences to its summary and inactive ant otherwise.

Regarding the maximization of the coverage objective (i.e., minimization of the travel distance), the heuristic value to include a new sentence (i.e., to go to a new node) is the inverse of the content score of this sentence. In other words, the heuristic value to travel from sentence r to sentence u is computed as follows:

$$\eta(r, u) = \frac{1}{c_u} \tag{8}$$

where c_u represents the content score of sentence u. In addition, each ant updates the current scores of its unvisited nodes (i.e., sentences) while constructing its solution based on the words that it has covered so far. Finally, the ACS parameters were set to the same values recommended by Dorigo and Gambardella (1997), except the number of ants, which was set to the total number of sentences in the documents to be summarized.

6 Experiments

The proposed algorithm was implemented in Java programming language and is available online[5]. The evaluations were performed on a machine running Windows 10 with with 12 GB RAM and an Intel(R) Core(TM) i7-6500U CPU 2.5 GHz processor. The corpus of the 2011 MultiLing Pilot was chosen to evaluate MDS-ACS on both English and Arabic languages. The 2011 MultiLing Pilot is a multilingual MDS corpus written in seven languages, including English and Arabic. This pilot asked the participants to test their systems on at least two languages to create multi-document summaries of between 240 and 250 words. In this study, MDS-ACS was applied to the English and Arabic versions of this corpus, each consisting of 10 clusters including 10 documents. The results of the present study were compared to the results of participating systems (eight systems for the English version and seven for the Arabic version, see Table 2) as well as to those of the topline and the baseline summaries. Topline summaries were created using a genetic algorithm with the models (human) summaries, whereas the baseline summaries were created based on the similarity between the text and the cluster centroid.

Table 3: F-measure values of ROUGE -1 (R-1), ROUGE-2 (R-2), ROUGE-SU4 (R-SU4), and ROUGE-L (R-L) for the participating systems, the baseline, the topline, and the proposed algorithm (MDS-ACS) for the English version of the corpus of the 2011 MultiLing Pilot. The highest values among those of participants and MDS-ACS are written in bold.

scores. MDS-ACS scores are reported in terms of mean F-measure of five independent runs. These scores, those of participating systems, baseline, and topline summaries of the English and Arabic versions of the corpus are presented in Tables 3 and 4, respectively. Relative improvements of MDS-ACS over the other systems are also reported in these tables. The relative improvement of MDS-ACS over another system, X, was computed as follows:

$$Relative\ Improvement = \frac{score(MDS - ACS) - score(X)}{score(X)} \times 100 \quad (9)$$

The results of MDS-ACS were promising. When tested on the English version of the corpus, MDS-ACS outperformed all the eight systems based on ROUGE-1, ROUGE-SU4, and ROUGE-L scores. MDS-ACS showed improvements of 2.9%, 0.49%, and 1.31% over the top ranked systems in terms of these metrics, respectively. In addition, MDS-ACS was ranked second among other systems based on ROUGE-2 scores. It outperformed the baseline in terms of ROUGE-1, ROUGE-2, ROUGE-SU4, and ROUGE-L metrics with relative improvements of 25.02%, 62.73%, 43.09%, and 24.24%, respectively. When tested on the Arabic version of the corpus, MDS-ACS outperformed all the participating systems based on ROUGE-1 and ROUGE-L scores. In comparison to the top ranked systems ID3 and ID2, MDS-ACS showed relative improvements of 3.98% and 4.09%, respectively. The former comparison used ROUGE-1 and the latter ROUGE-L. MDS-ACS was ranked second among other systems based on ROUGE-2 scores and third based on ROUGE-SU4 scores. MDS-ACS outperformed baseline summaries based on all four ROUGE metrics used in this study. The relative improvement of MDS-ACS over the baseline was 35% (ROUGE-1), 26.56% (ROUGE-2), 33.12% (ROUGE-SU4), and 34.04% (ROUGE-L).

Paired t-tests (p-value = 0.05) were conducted to check whether performance differences between MDS-ACS and the other systems were statistically significant. The results showed that on the English version of the corpus, MDS-ACS significantly outperformed the systems ID1, ID6, ID7, and ID8 as well as the baseline in terms of all metrics used in this study. MDS-ACS outperformed the ID5 system according to ROUGE-1, ROUGE-2, and ROUGE-L metrics. However, there was no significant difference between MDS-ACS and ID5 according to ROUGE-SU4. In addition, MDS-ACS was significantly outperformed by the topline system (ID10), and there were no statistically significant differences between MDS-ACS and the ID2, ID3, and ID4 systems. Regarding the Arabic version, t-tests showed that the only significant difference was between MDS-ACS and ID9 (the baseline) in terms of ROUGE-L. This may be because ROUGE 1.5.5 has not been adapted to the Arabic language. Overall, these experiments showed that adding more weight to words occurring in the first sentences of input documents signifi-

System ID	R-1	R-2	R-SU4	R-L	Improvement of MDS-ACS (%)

Table 4: F-measure values of ROUGE -1 (R-1), ROUGE-2 (R-2), ROUGE-SU4 (R-SU4), and ROUGE-L (R-L) for the participating systems, the baseline, the topline, and the proposed algorithm (MDS-ACS) for the Arabic version of the corpus of the 2011 MultiLing Pilot. The highest values among those of participants and MDS-ACS are written in bold.

cantly improved the performance of MDS-ACS. We think that these results could be enhanced by adding other semantic and language-dependent features.

7 Conclusion and Future Work

This study proposed a generic extractive MDS approach based on ACO. The original ACS algorithm was adapted to search for the sentences maximizing the information coverage of the summary generated. The implemented system, MDS-ACS, was evaluated using the corpus of the 2011 MultiLing Pilot (English and Arabic versions) based on four ROUGE metrics. The results show that the performance of MDS-ACS was comparable to the performance of the best participating systems. It outperformed all participating systems based on ROUGE-1, ROUGE-SU4, and ROUGE-L for the English version and ROUGE-1 and ROUGE-L for the Arabic version. As a future work, we plan to study the influence of other semantic features on the performance of MDS-ACS. We also intend to explore other SI meta-heuristics for maximizing the information coverage in the generated summaries.

Multi-task dialog act and sentiment recognition on Mastodon

Abstract

Because of license restrictions, it often becomes impossible to strictly reproduce most research results on Twitter data already a few months after the creation of the corpus. This situation worsened gradually as time passes and tweets become inaccessible. This is a critical issue for reproducible and accountable research on social media. We partly solve this challenge by annotating a new Twitter-like corpus from an alternative large social medium with licenses that are compatible with reproducible experiments: Mastodon. We manually annotate both dialogues and sentiments on this corpus, and train a multi-task hierarchical recurrent network on joint sentiment and dialog act recognition. We experimentally demonstrate that transfer learning may be efficiently achieved between both tasks, and further analyze some specific correlations between sentiments and dialogues on social media. Both the annotated corpus and deep network are released with an open-source license.

1 Introduction

Social media are a gold mine for researchers in many domains and especially in natural language processing, because of the endless stream of linguistic content produced every day. However, a major issue faced by every researcher working with Twitter data concerns the accessibility of datasets previously extracted. Indeed, license restrictions limit the possibility to store tweets in a database for a long period of time, and the proportion of tweets that are continuously deleted from the Twitter company servers makes any Twitter corpus quickly obsolete and impossible to retrieve after a few months. This is a very serious issue for the ethics of experimental research, of which reproducibility is a foundational feature. Despite these limitations, many research and development works use Twitter data for a wide variety of applications.

We propose in this work to exploit another social medium with language data, the Mastodon network, which closely resembles Twitter, except for two important differences: Mastodon is a decentralized social network, and it adopts permissive licenses that are compatible with reproducible research. In particular, everyone may create his own Mastodon server with his cohort of registered users, and have his server automatically federated within the worldwide social network. To enable this, the Mastodon software is released with the open-source AGPL license, and the user-generated content in the Mastodon network typically follows a Creative Commons license[1], which allows redistribution of posts.

Mastodon is very similar to Twitter with regard to content and usage, except that the user posts are limited by default to 500 characters, which gives the user the possibility to write longer sentences than on Twitter. From a sociological point of view, Mastodon users are mostly composed of people who are either attracted by the technical challenge of setting up their own server, or who have been disappointed by Twitter, sometimes because of advertisements, changes of policies and privacy threats, or who feel a strong sense of belonging to a minority group, such as LGBT, because Mastodon naturally enables

Proceedings of the 27th International Conference on Computational Linguistics, pages 745–754
Santa Fe, New Mexico, USA, August 20-26, 2018.

and favors the emergence of local communities. Another difference, which is relevant for researchers in Linguistics and Natural Language Processing, is that Mastodon is more international than Twitter, in the sense that the majority of Mastodon servers are located in Japan and in the West of Europe (France, Spain and Germany in particular), and although these servers are federated together, each of them brings together a community, which is often linguistic. It is thus frequent to observe on some server a majority of posts that are not written in English.

In terms of the amount of language data produced every day, Mastodon is still less developed than Twitter, but it is growing and is already large enough (with one and a half million of users as of February 2018) to be useful for most research works. We demonstrate this by scrapping and annotating a corpus of dialogues in English from Mastodon and training and validating a deep learning model on this data. Both the corpus and software described in this work are distributed freely at `https://github.com/cerisara/DialogSentimentMastodon`. We focus in this work on two aspects of Mastodon posts: dialog acts and sentiment recognition, and on the correlations between both of these tasks.

One of the most studied natural language processing task on Twitter is sentiment recognition, which is for example a recurrent task every year at the SEMEVAL evaluation campaign (Nakov et al., 2016; Bethard et al., 2017). We thus have also annotated our Mastodon corpus with sentiments, in order to maximize the potential impact and usage of this new corpus. Conversely, there are fewer works that study dialogues on Twitter. Dialogues on social media have quite a different form than on other media, such as vocal, sms and meetings interactions, because the participants in the dialogue are often unknown in advance, they may come and leave at any time and live in different time zones. The structure of social media dialogues thus typically forms a tree, or a directed acyclic graph if we take into account @-mentions. We focus next on dialog acts, also known as speech acts, which characterize the function of a phrase in the course of a dialog. Typical dialog acts are questions, answers, disagreements...

The scientific hypothesis that is studied in this work is that sentiments are correlated to dialog acts on social media, and that this correlation may be exploited to enable transfer learning between both tasks. Intuitively, consider a dialog where user A writes something *positive* (sentiment) about a given smart phone brand. Then, user B *disagrees* (dialog act) and points out a *negative* aspect of this brand. An obvious correlation between dialog acts and sentiments can be found on this trivial example. Surprisingly, the majority of works about sentiment analysis ignores such relations between dialog acts and sentiments. We propose next to demonstrate experimentally that this correlation is strong enough to enable transfer learning between both tasks, and we further analyze both quantitatively and qualitatively some of the observed correlation patterns.

2 Corpus annotation

We hereafter call *post* the Mastodon equivalent of a tweet, i.e., a single message that is limited to 500 chars maximum. From the user perspective, Mastodon is very similar to Twitter, and we can thus find the same type of content that is found on Twitter. We have crawled about 800,000 posts from the *octodon.social* Mastodon instance, which is one amongst thousands of existing instances, and have filtered out non English posts automatically with the *langdetect* python library. We have then followed the *reply-to* links to structure all posts into dialog trees: dialogues in social media are structured as trees, because anyone can get involved in a dialog from any post that composes the dialog so far. About half of the dialogues have two posts, $1/4$ three, and so on. The longest dialog is composed of 44 posts. The tree-dialogues are then split into a training and test set.

Before annotation, all dialogues are linearized, following the work of Zarisheva and Scheffler (2015), which means that each branch of the tree forms a unique dialog. Two students with a Master degree in linguistics and fluent in English independently assigned two tags to each post in a dialog:

- A sentiment tag with 3 possible values: positive (26% of the corpus), negative (31%) and neutral (43%); The baseline performances, when always classifying posts as neutral, are F1=24.4%.
- A dialog act with 27 possible values (the bold labels on the right of Table 2).

A typical dialog is shown in table 1.

	Sent	DA	Textual content of segment
0	-	I	because this is getting way too much attention it wasn't even that funny URL
1	+	I	LMAO
2	*	O	why you still on twitter though ?
3	-	W	i'm trying to get all my other friends to get on here before i deactivate !
4	-	I	I might have to do that too . Some ain't migrated yet . It's an issue .
5	-	I	some of my mutuals are waiting for more leftists go get on here
6	*	O	and i'm like what are you waiting for ? ? ?
7	-	I	then again i did have to spend hours to figure out how to work this site haha
8	-	Q	lol was it that hard ? ?
9	-	W	i'm not that good with technology or websites
10	-	A	so yeah ..
11	-	A	well yeah , the whole instances thing is kind of confusing tbh .

Table 1: Example of a typical dialog from the Mastodon corpus.

The dialog act tags have been derived from the seminal work on the Switchboard corpus (Core and Allen, 1997) and have been adapted to take into account specificities of social media, taking inspiration from the work of Zarisheva and Scheffler (2015). The recently proposed ISO standard (Bunt et al., 2017) has also been taken into account in the design phase of the annotation guide. This process has lead to the definition of the tags listed in Table 2. After a first round of annotations and in order to avoid rare labels, these 27 tags have been further merged into 15 tags, whose distribution is shown in Table 2.

The inter-annotator agreement is 88.6% for dialog acts and 90.2% for sentiments. The Cohen's kappa coefficient is 85.1% for dialog acts and 90.2% for sentiments.

The final training corpus is composed of 239 dialogues for a total of 1075 posts, and the test corpus of 266 dialogues for a total of 1142 posts. The vocabulary size is 5330 words.

3 Multi-task model

3.1 Model description

The proposed model is shown in Figure 1. It is a two-level hierarchical recurrent network similar to the one proposed in Sordoni et al. (2015):

- The first level (*post level*) takes as input the sequence of word embeddings in a post. This first level is composed of a bi-LSTM, which outputs a single vector per post.
- The second level (*dialog level*) takes as input the sequence of vectors produced at the first level, i.e., one vector per post for every post within a dialog. The second level is composed of a standard RNN, because the length of dialogues rarely exceeds 10 posts and so the LSTM cells do not offer a clear advantage over standard recurrent cells. The output of this RNN at every post is passed to two MLPs, one for dialog acts and another for sentiment labels.

3.2 Training procedure

Two cross-entropy losses are used to train the model, one for dialog act recognition and another for sentiment classification. In our corpus, every post is manually annotated with both a sentiment and dialog act labels. So standard multi-task training simply consists in backpropagating the gradient of both losses with equal weights. However, we also realize some transfer learning experiments with fewer annotations in one of the tasks. In such cases, we artificially remove the gold sentiment label for training and only backpropagate the gradient of the dialog act loss, and vice versa when transferring from the sentiment to the dialog act task.

A development corpus is extracted using 10-fold cross-validation. Three values of the learning rate (0.1, 0.01 and 0.001) have been tried on this development corpus and the best one has been kept. The number of epochs, up to a maximum of 500 epochs, is also tuned on this development corpus for each experiment. Furthermore, because some badly initialized weights may fail to converge, every experiment

Table 2: List of dialog acts with the 27 labels used by annotators (letters in bold) and their distribution in the corpus (percentage within parentheses). Some labels have been merged a priori (before the annotation process), in order to simplify the annotation process. Very rare labels have been merged after the annotation process. The remaining 15 labels used to compute the F1 metric are the ones with a distribution percentage. The baseline recognition performance obtained when always answering **I** is F1=35%.

on the development corpus is run twice with different random initializations, and the best one on the development set is kept. Running only twice does not guarantee that at least one training is correct, but it reduces the chances of failure, without increasing too much the computation requirements. All other hyper-parameters have been set a priori to reasonable values: 100-dim LSTM hidden state size, 100-dim word embeddings, 0.4 dropout, ReLU activations.

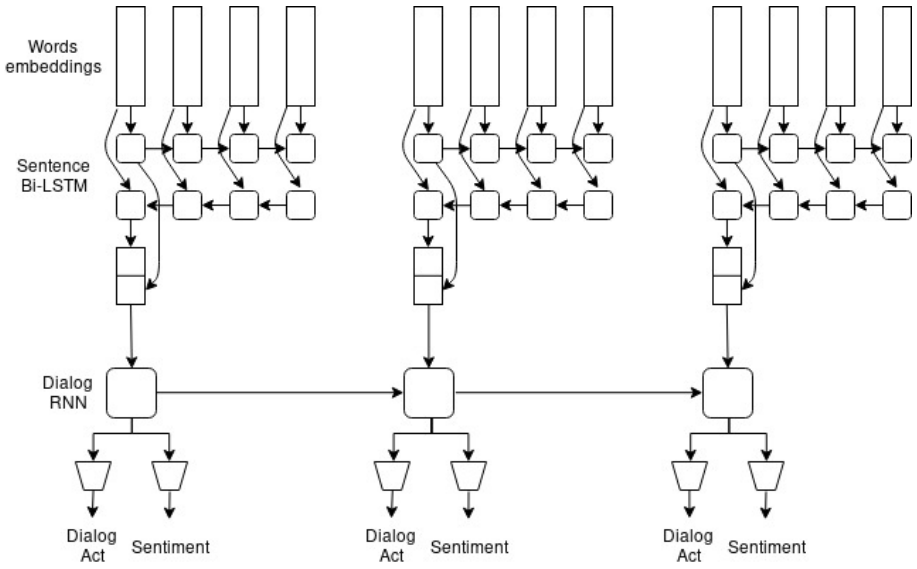

Figure 1: Multi-task hierarchical recurrent model. The number of posts per dialog and the number of words per post may vary and are handled dynamically without any padding.

4 Related work

Pluwak (2016) demonstrates that some expressions of sentiments might not be detected with traditional methods of opinion mining, and that exploiting dialog acts may partly solve this challenge. Nevertheless, very few works have investigated this joint modeling of dialog acts and opinion mining: Clavel and Callejas (2016) study the impact and usage of both dialog act recognition and sentiment analysis in human-agent conversational platforms and affective conversational interfaces, while Novielli and Strapparava (2013) perform a dialog act clustering of a lexicon and study the emotional load of dialog acts. The authors further try to improve dialog act recognition by exploiting affective lexicon, but without convincing results. Conversely, Herzig et al. (2016) include dialog features (e.g., time elapsed between turns...) into an emotion classifier, but do not model the dialog and emotion jointly. Boyer et al. (2011) exploit affects that are visually expressed on faces to better classify dialog acts.

While many works have investigated sentiment analysis on Twitter (Bethard et al., 2017), a few works only handle dialog act recognition on Twitter, such as in (Vosoughi and Roy, 2016), (Ritter et al., 2010), (Forsythand and Martell, 2007) and (Zarisheva and Scheffler, 2015). Each of these works have annotated their own corpus, because, to the best of our knowledge, no large corpus with dialog act annotations on Twitter exist. Zarisheva and Scheffler (2015) describe a detailed and precise procedure for annotating and evaluating dialog acts on German tweets, which we have tried to reproduce as closely as possible for English. Hence, we have manually segmented our own corpus into functional segments - following the ISO definition of a functional segment (Bunt et al., 2017) - and assumed that this gold segmentation is known during training and testing of our models. We have also linearized the dialog trees on Mastodon by splitting and reforming every branch of a dialog tree from the root of the tree as a complete independent dialog. However, because several such dialogues may share some posts at the beginning of dialogues, we have paid attention that our train, dev and test splits never contain the same sub-dialog, and are thus completely independent. We finally took inspiration from the conclusions of (Zarisheva and Scheffler, 2015), where it is shown that dialog act recognition is quite reliable for small taxonomies to design our own taxonomy adapted from the new ISO-standard (Bunt et al., 2017).

A joint model of sentiments and dialog acts is proposed in (Kim and Kim, 2018). It exploits one convolutional network per task, which output vectors are concatenated and passed to one classifier per task. It makes strong simplifying assumptions to merge the tasks, in particular:

- The dialog act at time t does not depend on sentiments, but does depend on the dialog act at time

$t-1$;

- The sentiment at time t only depends on the sentiment and dialog act at time t (no Markov hypothesis);

Despite these strong hypothesis, the authors report better results when considering jointly dialog acts and sentiments on a Korean corpus. As far as we know, their corpus and code is not distributed, which makes comparative evaluations with this model difficult. Compared to this work, our proposed network jointly models both tasks at deeper layers, just after the word embeddings layer. Furthermore, our hypothesis are weaker, because both labels at time t depend on both tasks at time t and $t-1$, and recurrence is applied at both word and dialog levels. Finally, we distribute our corpus and software under an open-source and free license to make future comparison easier.

5 Experimental validation

Model evaluation is performed with metrics used in related works:

- For sentiment recognition, following SemEval 2016 (Nakov et al., 2016), this is the macro-average of the positive and negative F1 scores;
- For dialog act recognition, following (Zarisheva and Scheffler, 2015), this is the average of the dialog-act specific F1 scores weighted by the prevalence of each dialog act.

The model has been written in pytorch. The source code, along with all the data used in this work, is released as open-source and is available at `https://github.com/cerisara/DialogSentimentMastodon`.

5.1 Multi-task experiments

The development corpus is composed of 28 dialogues (average size across all 10 folds). We experiment next with a training corpus of varying size: 1, 10, 50, 100, 150, 200 and the full set of 239 dialogues. The x-axis in Figures 2 and 3 are labeled with the total number of annotated dialogues used at training time (train + dev set). The number of epochs for training is tuned on the development set by optimizing either the sentiment loss (**target sentiment**) or the dialog act loss (**target dialog act**).

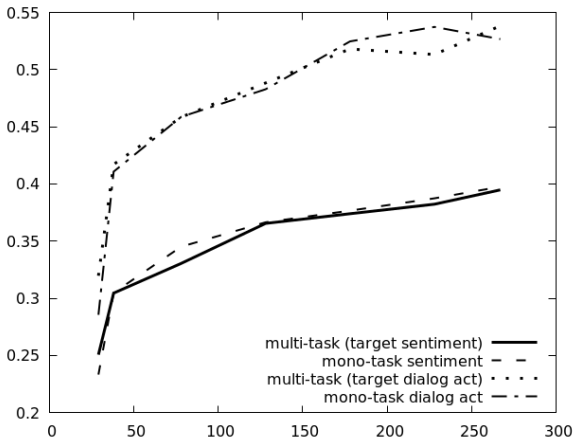

Figure 2: Sentiment and dialog act F1s as a function of the number of dialogues used for training.

In Figure 2, both the mono-task and multi-task models have similar performance. So considering an additional label for the second task does not help, as compared to when only the label of the target task is given. This might be due to the fact that the model already captures all available information with a single task, and the auxiliary label does not bring enough new information to help recognition of the target label.

5.2 Transfer between tasks

We study next unbalanced cases, when the number of annotations differ between tasks. Figure 3 compares the evolution of the sentiment analysis F1 score when:

- Both tasks are trained on the same number of annotated dialogues (**both-rich**); this is the same experiment as realized in Section 5.1.
- The sentiment recognition task is limited to a maximum of 38 (10 dialogues for training plus the development corpus) annotated dialogues, while the training size of the dialog act task is not limited (**sentiment-poor**);
- Both tasks are limited to only 38 annotated dialogues (**both-poor**).

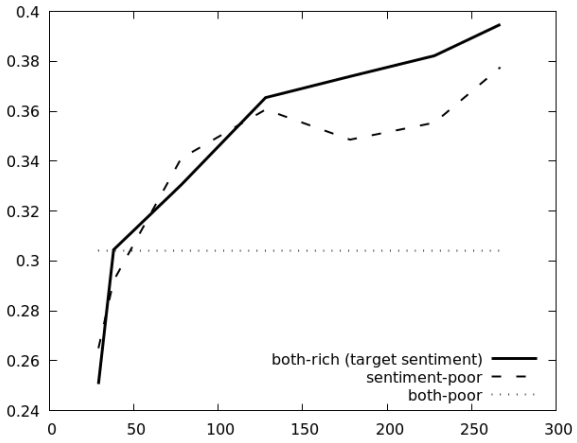

Figure 3: Sentiment F1 as a function of the number of dialogues used for training. **both-rich:** both tasks have the same training size; **sentiment-poor:** only 38 dialogues maximum are annotated with sentiment labels; **both-poor:** both tasks are limited to 38 training dialogues.

The curves show that information is largely transferred from the richer dialog act recognition task to the target sentiment classification task. Hence, although the **sentiment-poor** and **both-poor** systems have only access to 38 dialogues annotated with sentiment labels, the accuracy of the **sentiment-poor** model keeps on increasing when additional dialog act labels are considered. On the right, when the full dialog act training corpus is used, its accuracy is quite close to the one obtained with all sentiment labels, and is better than the **both-poor** model by a large margin, thanks to multi-task transfer learning.

Conversely, we also validate transfer learning from a rich sentiment recognition task to a poor dialog act recognition task. The resulting curves are shown in Figure 4.

Similar gains in performance are obtained through transfer learning for the dialog act recognition task than for the sentiment analysis task. We can thus conclude that transfer learning is efficient between both tasks in both directions.

6 Analysis

Beyond quantitative experiments that demonstrate transfer learning between dialog act and sentiment recognition, we analyze next some properties of our Mastodon corpus.

6.1 Dynamics of sentiments and dialog acts

In the course of a dialog, the sentiment globally changes at a slower rate than the dialog act. While dialog acts change nearly at every segment, often, a single sentiment is expressed per dialog, sometimes two or three, but rarely more. This is understandable, but this also implies that the correlation between both tasks is not very strong, otherwise, they would have a much similar dynamic. On the other hand, they are

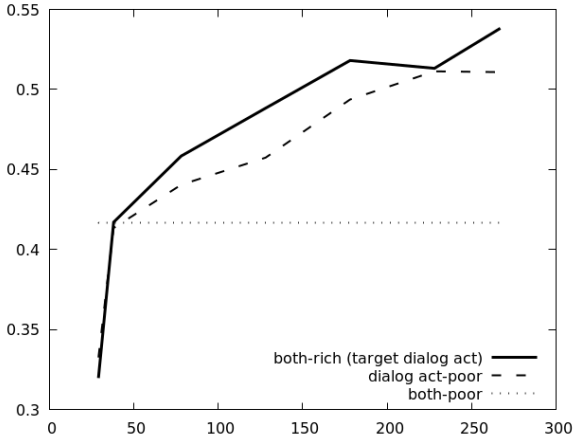

Figure 4: Dialog act F1 as a function of the number of dialogues used for training. **both-rich:** both tasks have the same training size; **dialog act-poor:** only 38 dialogues maximum are annotated with dialog act labels; **both-poor:** both tasks are limited to 38 training dialogues.

not completely independent, as shown in the transfer learning experiments. So we try and exhibit next some patterns where correlation between tasks is explicit in the corpus.

6.2 Both tasks are sparsely correlated

In order to validate our initial hypothesis that, in the course of a dialog, sentiments may be correlated to agreements and disagreements, we have computed the transition log-probabilities between the previous sentiment s_{t-1} and the current sentiment s_t as a function of the current dialog act d_t. These log-probabilities are shown respectively for $s_{t-1} =$ neutral, positive and negative in Figures 5 and 6.

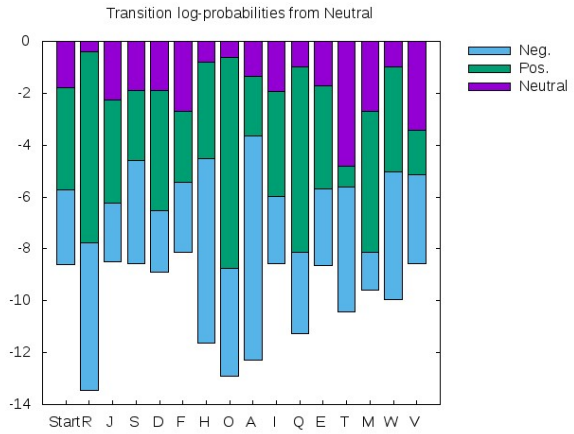

Figure 5: $\log p(s_t|d_t, s_{t-1} = neutral)$. The dialog acts d_t are listed at the bottom of each histogram column. Because log-probabilities are plotted, boxes with the smallest height are the most likely. The start of a dialog, which has no previous sentiment, is a special case that is added on the left.

We observe that:

- With agreements (**A**), a positive sentiment mainly stays positive and a negative sentiment mainly stays negative.
- With disagreements (**D**), a positive sentiment becomes either neutral or negative, a negative sentiment becomes either positive or stays negative, a neutral sentiment either stays neutral or becomes negative.

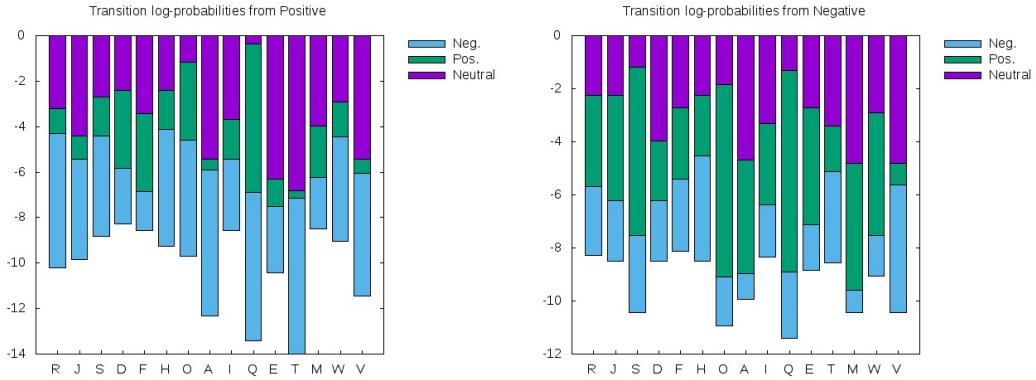

Figure 6: $\log p(s_t|d_t, s_{t-1} = positive)$ (left) and $\log p(s_t|d_t, s_{t-1} = negative)$ (right)

These observations globally follow our intuition, even though more complex patterns than expected seem to occur.

Another observation concerns the evolution of sentiments from the start to the end of a dialog. Previous studies have shown that, with regard to dialogues, the sentiment on social media is related to:

- The topic of discussion: for instance, discussions about politics tend to have more negative sentiments (Thelwall et al., 2012a);
- The length of the dialog: negative sentiments tend to lead to longer dialogues (Thelwall et al., 2012b), which we suggest may be also related to the correlation between sentiments and disagreements that we have observed in this work; indeed, an increased proportion of disagreements may lead to longer dialogues.

Based on our corpus, another pattern seems to emerge, which is in favor of negative sentiments at the beginning of dialogues and positive sentiments at the end. This is intuitively plausible, as at least a small proportion of the sources of discords are likely to be resolved during dialogues, but this interpretation is still to be confirmed on a more diverse set of corpora.

7 Conclusion

We have studied a multi-task model for joint sentiment and dialog act recognition on social media. We have shown that transfer learning is quite efficient when the number of annotated labels for one task is smaller than for the other task. We have further analyzed the correlation between both tasks and shown that although there is enough mutual information to enable transfer learning, both tasks are not strongly correlated globally. They are actually characterized by different dynamics, but we have nevertheless found a few specific patterns that exhibit a strong correlation. All these studies are realized on a new corpus extracted from the Mastodon social network. Conversely to other corpora based on Twitter, this corpus enables reproducible experiments and both the annotated corpus and source code of our model are available with an open-source license on github. Obviously, the privacy issues concerned with extracting corpora from social media are not only related to licenses, and other aspects must be considered, including dissemination, usage and ethical considerations with respect to citizen privacy. Even though the proposed approach does not totally solve all such issues, it initiates an original alternative to the current dominant experimental methodology that hopefully leads to a better experimental reproducibility for natural language researches.

Acknowledgments

The authors thank the “Programme d’Investissements d’Avenir” of the French government, the French National Research Agency (ANR) and the Lorraine Université d’Excellence (LUE) initiative for funding. Experiments presented in this paper were carried out using the Grid’5000 testbed, supported by a

scientific interest group hosted by Inria and including CNRS, RENATER and several Universities as well as other organizations (see `https://www.grid5000.fr`).

Abstract

This paper presents RuSentiment, a new dataset for sentiment analysis of social media posts in Russian, and a new set of comprehensive annotation guidelines that are extensible to other languages. RuSentiment is currently the largest in its class for Russian, with 31,185 posts annotated with Fleiss' kappa of 0.58 (3 annotations per post). To diversify the dataset, 6,950 posts were pre-selected with an active learning-style strategy. We report baseline classification results, and we also release the best-performing word embeddings trained on 3.2B corpus of Russian social media posts.

1 Introduction

Over the past several years sentiment analysis has been increasingly important in political science (Ceron et al., 2015) and journalism (Jiang et al., 2017). Such applications necessitate resources for languages spoken in the conflict zones. Our study focuses on Russian, which to date has little annotated data (Loukachevitch and Rubtsova, 2016; Koltsova et al., 2016), and no openly available sentiment detection systems beyond the dictionary-based ones. However, lexical features have time and again shown inferior performance compared to the supervised learning approaches using annotated data (Gombar et al., 2017), and lack of such a resource severely limits sentiment analysis applications for Russian.

We present RuSentiment, a dataset of public posts on VKontakte (VK), the largest Russian social network that currently boasts about 100M monthly active users.[1] RuSentiment was developed with new comprehensive guidelines that enabled light and speedy annotation while maintaining consistent coverage of a wide range of explicitly and implicitly expressed sentiment. The overall inter-annotator agreement in terms of Fleiss' kappa stands at 0.58. In total, 31,185 posts were annotated, 21,268 of which were selected randomly (including 2,967 for the test set). 6,950 posts were pre-selected with an active learning-style strategy in order to diversify the data. This makes RuSentiment the largest openly available sentiment dataset for social media, and the largest general domain sentiment dataset for this relatively low-resource language.

We also present baseline classification results on the new dataset. The best results were achieved with a neural network model that made use of word embeddings trained on the VKontakte corpus, which we also release to enable a fair comparison with our baselines in future work. This model achieved an F1 score of 0.728 in a 5-class classification setup. The dataset, the source code for the baseline classifiers, and the in-domain word embeddings are available at the project website[2].

2 Related Work

Russian is generally not as well resourced as English, and that includes the sentiment analysis data. RuSentiLex, the largest sentiment lexicon for Russian[3] (Loukachevitch and Levchik, 2016), currently contains 16,057 words, which exceeds the size of such manually constructed English resources as, for example, SentiStrength (Thelwall and Buckley, 2013). However, there is nothing like SentiWordNet (Baccianella et al., 2010), SentiWords, (Gatti et al., 2016), or SenticNet (Cambria et al., 2018) for Russian.

There are also few annotated datasets. The datasets from the SentiRuEval 2015 and 2016 competitions are the largest resource that has been available to date (Loukachevitch and Rubtsova, 2016). The SentiRuEval 2016 dataset is comprised by 10,890 tweets from the telecom domain and 12,705 from the banking domain. The Linis project (Koltsova et al., 2016) reports to have crowdsourced annotation for 19,831 blog excerpts, but only 3,327 are currently available on the project website.

The choice of VK social network makes RuSentiment qualitatively different from the above resources. Unlike Linis, it contains standalone mini-texts, and unlike SentiRuEval, the postings vary by length and were not pre-selected by topic. We also found the VK data used for our RuSentiment to be more noisy than SentiRuEval tweets.[4] RuSentiment thus fills an existing gap, providing a large annotated dataset of general-domain posts from the largest Russian social network.

3 Annotation

Our VK data was originally collected for research on political bias, and contained the posts from the personal "walls" (i.e., posts on personal pages) of the users that were members of anti-Maidan and pro-Maidan communities during the 2014 Maidan conflict in Ukraine. RuSentiment only includes the posts that were posted outside these communities, and do not contain political keywords.[5] No pre-selection by topic makes RuSentiment currently the largest manually annotated general domain sentiment dataset for Russian, exceeded in size only by automatically annotated silver dataset by Rubtsova (2015).

To remove noisy posts, we used the following selection criteria. The posts included in the dataset were 10-800 characters in length, at least 50% of which were alphabetical, and at least 30% used the Russian Cyrillic alphabet. URLs and VK postcards were excluded. To ensure the meaningfulness of the posts, we also excluded any posts with over 4 hashtags or less than 2 comments. RuSentiment is distributed without VK post ids, and only includes posts that were posted publicly.[6] The annotation was performed by six native speakers with backgrounds in linguistics over the course of 5 months. The average annotation speed was 250-350 posts per hour. A screenshot of our custom web-interface is shown in Figure 1.

3.1 Annotation Policy

Despite the popularity of the sentiment task, the problem of developing comprehensive, yet easy to follow and "light" guidelines that would ensure high enough agreement is far from being solved. Sentiment is an extremely multi-faceted phenomenon, and each research team in the end has to make its own choices about how it would prefer to treat implicit vs. explicit sentiment, subjective feeling and emotion vs. evaluation, and also irony, sarcasm, and other types of mixed sentiment.

We aimed to develop comprehensive guidelines that would cover the most frequent potentially ambiguous cases and would be easy to apply consistently. Most of the categories we have used have been defined and used before (Liu, 2015; Toprak et al., 2010; Wiebe et al., 2005; Thelwall et al., 2010), and our contribution is mainly their combination that enabled the right balance between coverage and ease of application.

[3]There are at least two more projects that attempt to crowdsource sentiment lexicons: SentiBase (`http://web-corpora.net/wsgi/senti\_game.wsgi/rules`), and Sentimeter (`http://sentimeter.ru/assess/instruction/`). At the moment, both appear to be unfinished.

[4]Baldwin et al. (2013) did not find significant grammatical or spelling differences between Twitter, Youtube comments, or blogs, but domain (telecom in SentiRuEval) could impact the ratio of professionally edited commercial or news-like texts.

[5]The list comprised 169 keywords, including political entities (such as *Moscow* or *Putin*) and words coined and used during the Maidan conflict (such as *ukrop* "dill", a Russian derogatory term for Ukrainians).

[6]This work is covered by an IRB protocol at the authors' institution.

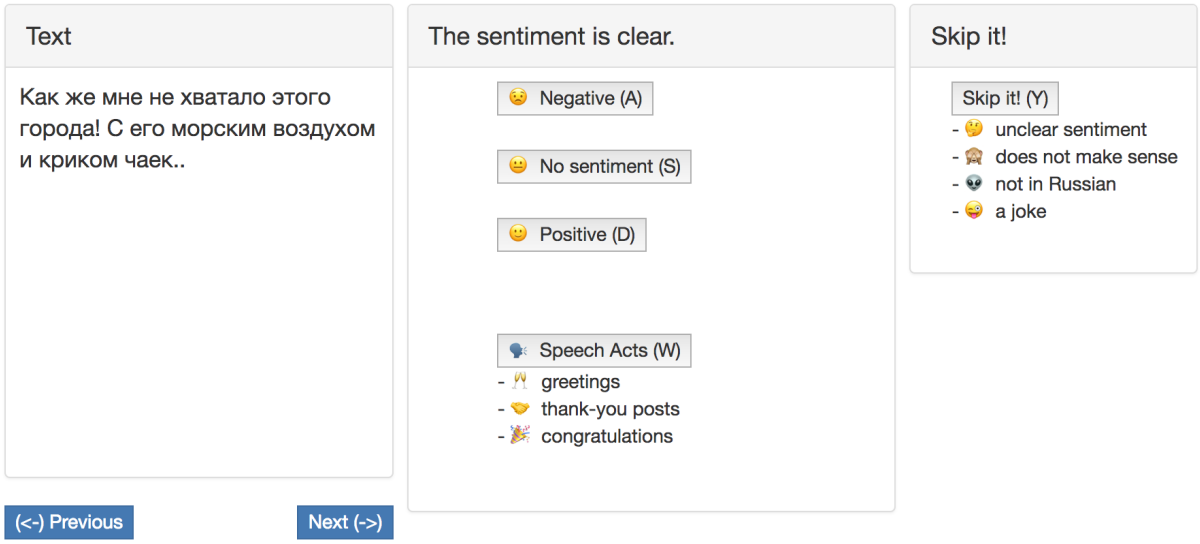

Figure 1: Annotation web-interface.

Finding this point of balance required multiple pilots and extensive linguistic analysis. This difficulty is likely the reason why many sentiment annotation projects, including the Russian crowdsourced initiatives mentioned in Section 2, provide only minimal annotation instructions. Such instructions often yield very inconsistent data. Our guidelines are available at the project website in English, with Russian examples.[7] We hope that they would be useful for subsequent work in other languages and domains.

We prioritized the speed of annotation over detail, opting for a 3-point scale rather than e.g., the 5-point scale in SemEval Twitter datasets (Rosenthal et al., 2017). Thus, the task was to rate the prevailing sentiment in complete posts from VK on a three-point scale ("negative", "neutral", and "positive"). We also defined the "skip" class for excluding the posts that were too noisy, unclear, or not in Russian (e.g., in Ukrainian). We also made the decision to exclude jokes, poems, song lyrics, and other such content that was not generated by the users themselves. It could be argued that posting jokes on social media should be interpreted as an expression of positive mood, but such data is easy to import from existing web collections.

Although the only sentiment classes we annotated are "positive" and "negative", RuSentiment guidelines address both explicit and implicit forms of expressions for the speaker's *internal emotional state* (mood) and *external attitude* (evaluation), as shown in Table 1. These distinctions are often not accounted for in sentiment data, including many of the English datasets (Volkova et al., 2013; Abdul-Mageed and Ungar, 2017). The guidelines cover such cases of implicit sentiment as rhetorical questions, (non-)desirability, recommendations, and descriptions or mentions of the experiences that most people would consider positive or negative.

Additionally, we defined a subcategory of positive posts that covers frequent speech acts, such as expressions of gratitude, greetings, and congratulations. They are very frequent in VK data, and the sentiment they express is overtly positive, but they are also very formulaic. The separate subcategory enables excluding them from the category of positive posts, depending on the practical goals of the analysis. In our binary classification experiments, we chose to exclude this category.

The neutral posts were defined as those that describe something in a matter-of-fact way, without clear sentiment (e.g., *That's a girl I know.*) They also included factual questions, commercial information, plot summaries, descriptions, etc..

We opted to not define a separate "mixed sentiment" class, as this would not be particularly useful, and is also difficult for models to capture (Liu, 2015, p. 77). All cases of mixed sentiment were annotated as either negative or positive. To improve consistency, the guidelines covered 7 frequent cases of mixed sentiment. For example, irony was annotated with the dominant (usually negative) sentiment (e.g. *I*

[7] http://text-machine.cs.uml.edu/projects/rusentiment/

Mode \ Target	Emotional state	Attitude towards some entity
Explicit	• direct statement of one's mood, emotions, feelings - either positive or negative e.g., УРРРРАААААААА!!!!!!)))) *Hooray!!!!!!))))*	• direct statement of one's positive or negative attitude towards the target e.g., годный дабстеп, очень годный. *That's fairly decent dubstep.*
Implicit	• descriptions of experience that most people would consider positive or negative e.g., 15 дней к окончанию сессии... *15 more days of exams...* • rhetorical questions e.g., Вот как я теперь её найду?(((*So how am I supposed to find it now?*	• expressing (non-)desirability of the target, (non-)recommending it e.g., Обязательно попробуй шампусик. *Do taste the champagne.* • rhetorical questions e.g., НАТАШ ТЕБЕ НЕ КАЖЕТСЯ ШО ТЕБЕ ПОРА ЗАНИМАТЬСЯ УЧЕБОЙ? *Natasha, don't you think you should be studying?*

Table 1: Types of positive and negative sentiment covered by RuSentiment annotation guidelines.

broke my heels and got drenched on the way back. What a great day.) Generally neutral posts with some positive formulaic language were annotated as neutral (e.g. *Looking to buy a used electric guitar. Please share this post. Thank you, and have a great day!*) In cases of conflict between a speaker's emotional state and their attitude towards something, we annotated the mood of the speaker. For example, *I miss you* expresses the sadness of the speaker while also implying their high opinion of the addressee, and is annotated as negative.

Hashtags such as *#epicentr* (company name) were considered neutral, but those that could agree or disagree with the general sentiment of the post were treated as sentiment markers. This concerned the hashtags that expressed the sentiment explicitly (e.g. #ihate, #sad) or implicitly, via experiences that most people would consider positive or negative (e.g. #beach, #party).

The annotators were instructed to *not* treat the emoticons as automatic sentiment labels, as done by Go et al. (2009), Davidov et al. (2010), Sahni et al. (2017), and others. Some emoticons do indeed strengthen the message (Derks et al., 2008), but others serve to soften its illocutionary force without changing its content (Ernst and Huschens, 2018).[8] A user may end a post with a "hedging" emoticon just to express friendliness or politeness, and we found that often to be the case for VK data. Therefore, emoticons were not taken into account when no sentiment was expressed verbally or when they aligned with the content of the message. Emoticons were considered relevant only when they contradicted the verbal clues of sentiment. In that case, the annotators were instructed to annotate the dominant overall sentiment of the post, including the emoticons.

In total, five categories were annotated: "Neutral", "Negative", "Positive", "Speech Act", and "Skip".

3.2 Annotating Randomly Selected Posts

In the first stage, 18,453 randomly selected posts were annotated. Fleiss' kappa for three annotators in this sample constituted 0.654. A post was deemed to belong to a class if at least 2 of 3 annotators attributed it to that class. The class distribution is as follows: 41.3% neutral posts, 10.3% negative and 20.5% positive posts, and 9.4% skipped, with an additional 13.9% posts in the speech acts category. In 4.6% cases, all three annotators disagreed, and we included them in the skipped class as unclear. Furthermore, we annotated 2,967 random posts to create a test set (Fleiss' kappa is 0.604).

4 Experiments

4.1 Baseline model selection

We experimented with several classifiers of different types, including logistic regression, linear SVM, and gradient boosting classifier (Pedregosa et al., 2011). We also implemented a simple neural network classifier (NNC) consisting of four fully-connected layers with non-linear activation functions between

[8]This also concurs with classifications drawn in pragmatics and discource analysis, among others, by Kavanagh (2010; Yus and Yus (2014).

(a) Negative posts vs. the rest

(b) Positive posts vs. the rest

Figure 2: Distribution of true labels in probability bins of NNC binary classifier.

them. We used the PyTorch library to implement it.[9] The selected models cover most types of commonly used models, spanning from simple linear models to ensembles and neural networks. The source code for these baselines is available on the project page[10].

The posts were represented either with a sparse TF-IDF representation (Manning et al., 2008) or as an average of word vectors for the constituent tokens. Averaging is by no means the only way to combine word vectors to obtain a representation of a sentence (Mitchell and Lapata, 2010; Baroni et al., 2014; Socher et al., 2012; Hill et al., 2016), but it is one of the computationally cheapest options that still encodes a non-trivial amount of information about the sentences (Adi et al., 2016). FastText (Bojanowski et al., 2017) was chosen for its capacity to represent subword information. This is beneficial for a morphologically rich language such as Russian, especially with a corpus that is as noisy and full of misspellings as our VK corpus.

	Wiki	0.661	0.658	0.666
	TF-IDF	0.593	0.599	0.589

Table 2: Classifier performance with different post representations on 5-class classification (20,896 random posts).

We performed experiments using the published FastText embeddings trained on CommonCrawl (CC)[11] and on Russian Wikipedia[12] (Wiki). We also trained our own embeddings on 3.2B tokens of VK data. The training corpus included the posts that are part of RuSentiment, but they constitute less than 0.001% of the data. We trained these embeddings with the default FastText parameters, with vector size 300 and minimum frequency 100. Table 2 shows the performance in 5-way classification, for the models trained using the 20,896 posts annotated without active learning. The best accuracy was achieved by the NNC classifier. The in-domain VK embeddings consistently improved performance of all models, as could be expected.

4.2 Active Learning Data Selection Strategy

Unbalanced datasets present difficulties in classification, especially when the classes of interest – in this case, positive and negative sentiment – are in the minority. With the setup described in Section 4.1

[9] http://pytorch.org
[10] http://text-machine.cs.uml.edu/projects/rusentiment/
[11] https://github.com/facebookresearch/fastText/blob/master/docs/crawl-vectors.md
[12] https://github.com/facebookresearch/fastText/blob/master/pretrained-vectors.md

we conducted preliminary experiments with 13,764 posts for training and 3,441 for testing[13]. In these preliminary experiments, the best-performing model (NNC) reached an F1 of 0.637 for the positive class vs. the rest and F1 of 0.550 for negative vs. the rest in binary classification. The recall was very low, 0.477 and 0.587, respectively). Figure 2 shows that the distribution of correct labels in each probability bin was nearly even, which suggests that the classifier did not have a well-formed representation of the target class. For example, the number of examples correctly assigned to the negative polarity class with probability of 0.9 was nearly equal to the number of misclassified negative polarity examples which were assigned the probability of 0.1. Although there were twice as many training examples, the same trend was present for the positive polarity posts.

To provide the classifier with more examples that it was unsure about, we used NNC to pre-select additional 3,500 "negative" and 2,500 "positive" posts with certainty sampling (Koncz and Paralič, 2013; Fu et al., 2013). We drew an equal number of samples from the probability bins 0.3-0.7, annotating additional 6,950 posts.

4.3 Active Learning Effect

Figure 3 shows that the distribution of positive posts in the pre-selected sample turned out to be similar to the original one. However, the classifier was successful in reducing the number of skipped and speech act posts, and the ratio of negative posts increased.

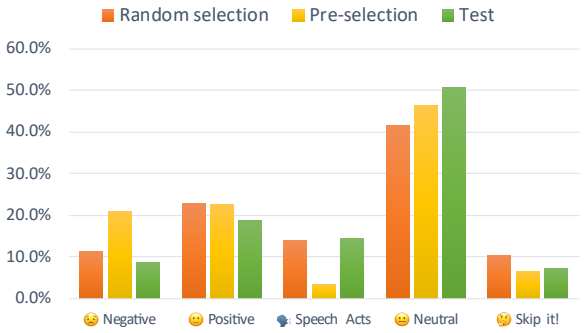

Figure 3: Sentiment class distribution in RuSentiment.

Fleiss' kappa for the pre-selected sample was much lower (0.449), bringing the overall number down. The reason was the higher ratio of posts with agreement of two, rather than three annotators. We interpret this as success in bringing more borderline and diverse cases into the dataset, even at the cost of the overall agreement.

In order to investigate the effects of adding the pre-selected sample to the dataset, we conducted additional 5-way classification experiments using NNC and VK embeddings. Table 3 shows the comparison between the model trained on all the randomly selected examples and the model trained on the data in which 6,950 randomly selected examples were replaced with the ones pre-selected with the active learning strategy described above.[14] Replacing randomly selected examples with pre-selected ones yielded consistent, albeit small, improvement, with the recall being affected the most. Table 3 also shows that the 5-way classification results using the full training data, including the pre-selected sample, produces the best results. The performance is averaged across three runs.

Input data	F1	Prec.	Rec.
Randomly selected posts only (21,268)	0.717	0.718	0.717
6,950 out of 21,268 random posts replaced with pre-selected	0.720	0.722	0.730
21,268 random + 6,950 pre-selected posts	**0.728**	**0.729**	**0.736**

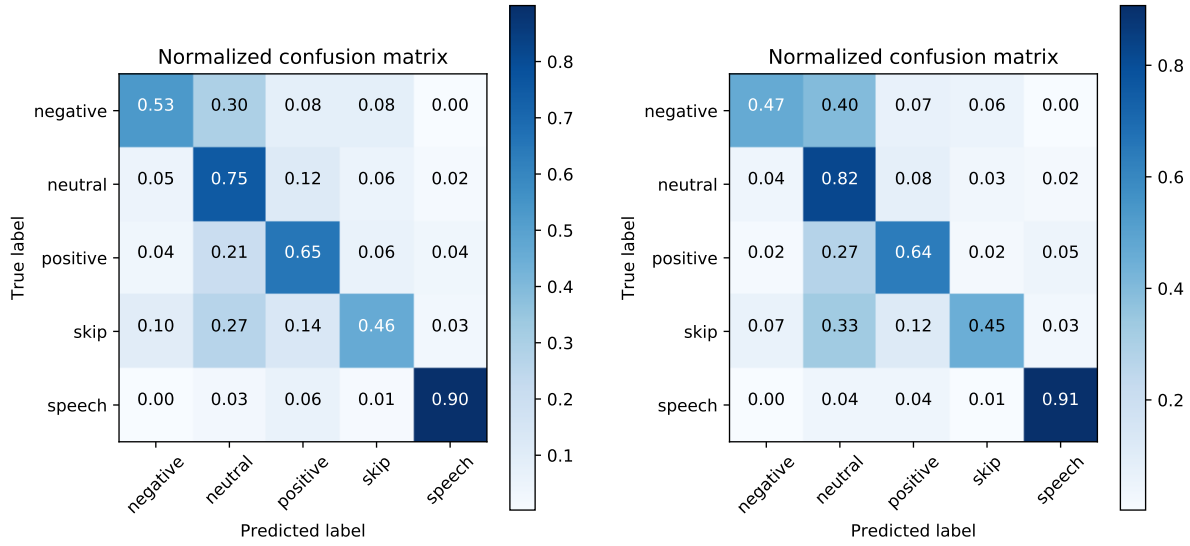
Table 3: 5-class classification with NNC and VK embeddings: the effect of pre-selected posts.

4.4 Error Analysis

Figure 4 presents the confusion matrices for RuSentiment test set with the NNC classifier trained in two settings: (a) using the base randomly selected posts only, and (b) using the additional posts pre-selected with active learning. There is a clear shift in the distribution of neutral and negative posts. Compared to

[13]These samples do not intersect with the final test set.

[14]An additional 463 randomly selected examples were included in this experiment and are released in the final dataset. Out of these, 372 examples were added to the training set and 91 to the test set. These data came in late from the annotation team, and additional experiments confirmed that they did not affect the overall pattern of model performance.



(a) Random posts only

(b) Random and pre-selected posts

Figure 4: Confusion matrix for the RuSentiment test set with different training sets (true labels in rows, predicted labels in columns).

the classifier trained only on randomly selected posts, the classifier trained on the entire dataset makes more errors misclassifying neutral and, to a lesser degree, skipped posts as negative. This suggests that the pre-selected sample makes the classifier more sensitive to borderline cases, since their amount is increased. Interestingly, the positive posts category was not affected in the same way, presumably due to the larger amount of positive posts in the base data.

5 Conclusion

We presented RuSentiment, a new general domain sentiment dataset for Russian social media, built with data from VK, Russia's largest social network. RuSentiment includes 31,185 posts, each carrying 3 annotations with Fleiss' kappa of 0.58, and is currently the largest openly available dataset of its class for Russian. RuSentiment was developed with new guidelines that enabled light, speedy and consistent 5-class annotation of explicit and implicit sentiment, and could be adapted for other languages.

We also presented 4 baseline models using FastText word embeddings as well as TF-IDF representation. The best performance was F1 of 0.728 in 5-class classification. It was achieved by a neural net classifier with in-domain FastText embeddings, which we release to enable fair comparison with future systems.

Abstract

Self-normalizing discriminative models approximate the normalized probability of a class without having to compute the partition function. In the context of language modeling, this property is particularly appealing as it may significantly reduce run-times due to large word vocabularies. In this study, we provide a comprehensive investigation of language modeling self-normalization. First, we theoretically analyze the inherent self-normalization properties of Noise Contrastive Estimation (NCE) language models. Then, we compare them empirically to softmax-based approaches, which are self-normalized using explicit regularization, and suggest a hybrid model with compelling properties. Finally, we uncover a surprising negative correlation between self-normalization and perplexity across the board, as well as some regularity in the observed errors, which may potentially be used for improving self-normalization algorithms in the future.

1 Introduction

The ability of statistical language models (LMs) to estimate the probability of a word given a context of preceding words, plays an important role in many NLP tasks, such as speech recognition and machine translation. Recurrent Neural Network (RNN) language models have recently become the preferred method of choice, having outperformed traditional n-gram LMs across a range of tasks (Jozefowicz et al., 2016). Unfortunately however, they suffer from scalability issues incurred by the computation of the softmax normalization term, which is required to guarantee proper probability predictions. The cost of this computation is linearly proportional to the size of the word vocabulary and has a significant impact on both training and testing run-times.

Several methods have been proposed to cope with this scaling issue by replacing the softmax with a more computationally efficient component at train time. [1] These include importance sampling (Bengio and et al, 2003), hierarchical softmax (Minh and Hinton, 2008), BlackOut (Ji et al., 2016) and Noise Contrastive Estimation (NCE) (Gutmann and Hyvarinen, 2012). NCE has been applied to train neural LMs with large vocabularies (Mnih and Teh, 2012) and more recently was also successfully used to train LSTM-RNN LMs (Vaswani et al., 2013; Chen et al., 2015; Zoph et al., 2016), achieving near state-of-the-art performance on language modeling tasks (Jozefowicz et al., 2016; Chen et al., 2016). All the above works focused on reducing the complexity at train time. However, at test time, the assumption was that one still needs to compute the costly softmax normalization term to obtain a normalized score fit as an estimate for the probability of a word.

Self-normalization was recently proposed to address the test time complexity. A self-normalized discriminative model is trained to produce near-normalized scores in the sense that the sum over the scores of all words is approximately one. If this approximation is close enough, the assumption is that the costly exact normalization can be waived at test time without significantly sacrificing prediction accuracy (Devlin et al., 2014). Two main approaches were proposed to train self-normalizing models. Regularized softmax self-normalization is based on using softmax for training and explicitly encouraging the normalization term of the softmax to be as close to one as possible, thus making its computation redundant

[1] Alleviating this problem using sub-word representations is a parallel line of research not discussed here.

Proceedings of the 27th International Conference on Computational Linguistics, pages 764–773
Santa Fe, New Mexico, USA, August 20-26, 2018.

at test time (Devlin et al., 2014; Andreas and Klein, 2015; Chen et al., 2016). The alternative approach is based on NCE. The original formulation of NCE included a parametrized normalization term Z_c for every context c. However, the first work that applied NCE to language modeling (Mnih and Teh, 2012) discovered empirically that fixing Z_c to a constant did not affect the performance. More recent studies (Vaswani et al., 2013; Zoph et al., 2016; Chen et al., 2015; Oualil and Klakow, 2017) empirically found that models trained using NCE with a fixed Z_c, exhibit self-normalization at test time. This behavior is facilitated by inherent self-normalization properties of NCE LMs that we analyze in this work.

The main contribution of this study is in providing a first comprehensive investigation of self-normalizing language models. This includes a theoretical analysis of the inherent self-normalizing properties of NCE language models, followed by an extensive empirical evaluation of NCE against softmax-based self-normalizing methods. Our results suggest that regularized softmax models perform competitively as long as we are only interested in low test time complexity. However, when train time is also a factor, NCE has a notable advantage. Furthermore, we find, somewhat surprisingly, that larger models that achieve better perplexities tend to have worse self-normalization properties, and perform further analysis in an attempt to better understand this behavior. Finally, we show that downstream tasks may not all be as sensitive to self-normalization as might be expected.

The rest of this paper is organized as follows. In sections 2 and 3, we provide theoretical background and analysis of NCE language modeling that justifies its inherent self-normalizing properties. In Section 4, we review the alternative regularized softmax-based self-normalization methods and introduce a novel regularized NCE hybrid approach. In Section 5, we report on an empirical intrinsic investigation of all the methods above, and finally, in Section 6, we evaluate the compared methods on the Microsoft's Sentence Completion Challenge and compare these results with the intrinsic measures of perplexity and self-normalization.

2 NCE as a Matrix Factorization

In this section, we review the NCE algorithm for language modeling (Gutmann and Hyvarinen, 2012; Mnih and Teh, 2012) and focus on its interpretation as a matrix factorization procedure. This analysis is analogous to the one proposed by Melamud et al. (2017) for their PMI language model. Let $p(w|c)$ be the probability of a word w given a preceding context c, and let $p(w)$ be the word unigram distribution. Assume the distribution $p(w|c)$ has the following parametric form:

$$p_{nce}(w|c) = \frac{1}{Z_c} \exp(m(w, c)) \tag{1}$$

such that $m(w, c) = \vec{w} \cdot \vec{c} + b_w$, where $\vec{w}$ and $\vec{c}$ are d-dimensional vector representations of the word w and its context c, and Z_c is a normalization term.

We can use a simple lookup table for the word representation $\vec{w}$, and a recurrent neural network (RNN) model to obtain a low dimensional representation of the entire preceding context $\vec{c}$. Given a text corpus D, the NCE objective function is:

$$S(m) = \sum_{w,c \in D} \Big[\log \sigma(m(w, c) - \log(p(w)k)) \tag{2}$$

$$+ \sum_{i=1}^{k} \log(1 - \sigma(m(w_i, c) - \log(p(w_i)k))) \Big]$$

such that w, c go over all the word-context co-occurrences in the learning corpus D and $w_1, ..., w_k$ are 'noise' samples drawn from the word unigram distribution. σ denotes the sigmoid function.

Let $\text{pce}(w, c) = \log p(w|c)$ be the Pointwise Conditional Entropy (PCE) matrix, which is the true log probability we are trying to estimate. Gutmann and Hyvarinen (2012) proved that $S(m) \leq S(\text{pce})$ for every matrix m. The rank of the matrix m is at most $d + 1$. Thus, the NCE training goal is finding the best low-rank decomposition of the PCE matrix in the sense that it minimizes the difference $S(\text{pce}) -$

$S(m)$. Following Melamud and Goldberger (2017), we can explicitly write this difference as a Kullback-Leibler (KL) divergence. The NCE derivation was originally based on sampling w and c either from the joint distribution or from the product of marginals according to a binary r.v. denoted by z. For every matrix m, the conditional distribution of z given w and c is:

$$p_m(z{=}1|w,c) = \sigma(m(w,c) - \log(kp(w))).$$

The difference between the NCE score at the PCE matrix and the NCE score at a given matrix m can be written as:

$$S(\text{pce}) - S(m) = \text{KL}(p_{\text{pce}}(z|w,c)||p_m(z|w,c)) \tag{3}$$

$$= \sum_{w,c} p(w,c) \sum_{z=0,1} p_{\text{pce}}(z|w,c) \log \frac{p_{\text{pce}}(z|w,c)}{p_m(z|w,c)}.$$

This view of NCE as a matrix factorization instead of a distribution estimation, makes the normalization factor redundant during training, thereby justifying the heuristics of setting $Z_c = 1$ used by Mnih and Teh (2012). The crux of the matrix decomposition view of NCE is that although the normalization term is not explicitly included here, the optimal low-dimensional model attempts to approximate the true conditional probabilities, which are normalized, and therefore we expect that it will be almost self-normalized. Indeed, in the next section we provide formal guarantees for that.

3 The NCE Self-Normalization property

We now address the test time efficiency of language models, which is the focus of this study. As is the case with other language models, at test time, when we use the low-dimensional matrix learned by NCE to compute the conditional probability $p_{nce}(w|c)$ (1), we need to compute the normalization factor to obtain a valid distribution:

$$Z_c = \sum_w \exp(m(w,c)) = \sum_w \exp(\vec{w} \cdot \vec{c} + b_w). \tag{4}$$

Unfortunately, this computation of Z_c is often very expensive due to the typical large vocabulary size. However, as we next show, for NCE language models this computation may be avoided not only at train time, but also at test time due to self-normalization.

A matrix m is called self-normalized if $\sum_w(\exp(m(w,c)) = 1$ for every c. The full-rank optimal LM obtained from the PCE matrix $\text{pce}(w,c) = \log p(w|c)$, is clearly self normalized:

$$Z_c = \sum_w \exp(\text{pce}(w,c)) = \sum_w p(w|c) = 1.$$

The NCE algorithm seeks the best low-rank unnormalized matrix approximation of the PCE matrix. Hence, we can assume that the matrix m is close to the PCE matrix and therefore defines a LM that should also be close to self-normalized:

$$\sum_w \exp(m(w,c)) \approx \sum_w \exp(\text{pce}(w,c)) = 1. \tag{5}$$

We next formally show that if the matrix m is close to the PCE matrix then the NCE model defined by m is approximately self-normalized.

Theorem 1: Assume that for a given context c there is an $0 < \epsilon$ such that

$$\log \sum_{w \in V} p(w|c) \exp(|m(w,c) - \log p(w|c)|) \leq \epsilon.$$

Let $Z_c = \sum_w \exp(m(w,c))$ be the normalization factor. Then $|\log Z_c| \leq \epsilon$.

Proof:

$$\log Z_c = \log \sum_w \exp(\vec{w} \cdot \vec{c} + b_w)$$

$$= \log \sum_w (p(w|c) \exp(m(w,c) - \log p(w|c)))$$

$$\leq \log \sum_w p(w|c) \exp(|m(w,c) - \log p(w|c)|) \leq \epsilon. \quad (6)$$

The concavity of the log function implies that:

$$-\log Z_c \leq -\sum_w p(w|c)(m(w,c) - \log p(w|c)) \quad (7)$$

$$= \sum_w p(w|c)(-(m(w,c) - \log p(w|c)))$$

The convexity of the exp function implies that:

$$\leq \log \sum_w p(w|c) \exp(-(m(w,c) - \log p(w|c)))$$

$$\leq \log \sum_w p(w|c) \exp(|m(w,c) - \log p(w|c)|) \leq \epsilon$$

Combining Eq. (6) and Eq. (7) we finally obtain that $|\log Z_c| \leq \epsilon$. □

We can also state a global version of Theorem 1 and its proof is similar.

Theorem 2: Assume there is an $0 < \epsilon$ such that

$$\log \sum_{w,c} p(w,c) \exp(|m(w,c) - \log p(w|c)|) \leq \epsilon.$$

Then $|\sum_c p(c) \log Z_c| \leq \epsilon$.

4 Explicit Self-normalization

In this section, we review the two recently proposed language modeling methods that achieve self-normalization via explicit regularization, and then borrow from them to derive an novel regularized version of NCE.

The standard language modeling learning method, which is based on a softmax output layer, is not self-normalized. To encourage its self-normalization, Devlin et al. (2014) proposed to add to its training objective function, an explicit penalty for deviating from self-normalization:

$$S_{Dev} = \sum_{w,c \in D} \left[(\vec{w} \cdot \vec{c} + b_w - \log Z_c) - \alpha (\log Z_c)^2 \right] \quad (8)$$

where $Z_c = \sum_{v \in V} \exp(\vec{v} \cdot \vec{c} + b_v)$ and α is a constant. The drawback of this approach is that at train time you still need to explicitly compute the costly Z_c. Andreas and Klein (2015) proposed a more computationally efficient approximation of (8) that eliminates Z_c in the first term and computes the second term only on a sampled subset D' of the corpus D:

$$S_{And} = \sum_{w,c \in D} (\vec{w} \cdot \vec{c} + b_w) - \frac{\alpha}{\gamma} \sum_{c \in D'} (\log Z_c)^2 \quad (9)$$

where $\gamma < 1$ is an additional constant that determines the sampling rate, i.e. $|D'| = \gamma |D|$. They also provided analysis that justifies computing Z_c only on a subset of the corpus by showing that if a given LM is exactly self-normalized on a dense set of contexts (i.e. each context c is close to a context c' s.t. $\log Z_{c'} = 0$) then $E|\log Z_c|$ is small.

Inspired by this work, we propose a regularized variant of the NCE objective function (2):

$$S_{nce-r}(m) = S_{nce}(m) - \frac{\alpha}{\gamma} \sum_{c \in D'} (\log Z_c)^2 \quad (10)$$

This formulation allows us to further encourage the NCE self-normalization, still without incurring the cost of computing Z_c for every word in the learning corpus.

5 Intrinsic Evaluation

We report here on an empirical investigation of the self-normalization properties of NCE language modeling as compared to the alternative methods described in the previous sections.

5.1 Experimental Settings

We investigated the following language modeling methods:

- *DEV-LM* - the language model proposed by Devlin et al. (2014) (Eq. 8)
- *SM-LM* - a standard softmax language model (DEV-LM with $\alpha = 0$)
- *AND-LM* - the light-weight approximation of DEV-LM proposed by Andreas and Klein (2015) (Eq. 9)
- *NCE-LM* - NCE language model (Eq. 2)
- *NCE-R-LM* - our light-weight regularized NCE method (Eq. 10)

Following Devlin et al. (2014), to make all of the above methods approximately self-normalized at init time, we initialized their output bias terms to $b_w = -\log|V|$, where V is the word vocabulary. We set the negative sampling parameter for the NCE-based LMs to $k = 100$, following Zoph et al. (2016), who showed highly competitive performance with NCE LMs trained with this number of samples, and following Melamud et al. (2017) who used the same with PMI language models. We note that in early experiments with PMI LMs, which can be viewed as a close variant of NCE-LMs, we got very similar results for both of these types of models and therefore did not include PMI-LMs in our final investigation.

All of the compared methods use standard LSTM to represent the preceding (left-side) sequence of words as the context vector $\vec{c}$, and a simple word embedding lookup table to represent the predicted next word as $\vec{w}$. The LSTM hyperparameters and training regimen are similar to Zaremba et al. (2014) who achieved strong perplexity results compared to other standard LSTM-based neural language models. Specifically, we used a 2-layer LSTM with a 50% dropout ratio. During training, we performed truncated back-propagation-through-time, unrolling the LSTM for 20 steps at a time without ever resetting the LSTM state. We trained our model for 20 epochs using Stochastic Gradient Descent (SGD) with a learning rate of 1, which is decreased by a factor of 1.2 after every epoch starting after epoch 6. We clip the norms of the gradient to 5 and use mini-batch size of 20. All models were implemented using the Chainer toolkit ((Tokui et al., 2015)).

We used two popular language modeling datasets in the evaluation. The first dataset, denoted *PTB*, is a version of the Penn Tree Bank, commonly used to evaluate language models.[2] It consists of 929K/73K/82K training/validation/test words respectively and has a 10K word vocabulary. The second dataset, denoted *WIKI*, is the WikiText-2, more recently introduced by Merity et al. (2016). This dataset was extracted from Wikipedia articles and is somewhat larger, with 2,088K/217K/245K train/validation/test tokens, respectively, and a vocabulary size of 33K.

To evaluate self-normalization, we look at two metrics: (1) $\mu_z = E(\log(Z_c))$, which is the mean log value of the normalization term, across the contexts in the evaluated dataset; and (2) $\sigma_z = \sigma(\log(Z_c))$, which is the corresponding standard deviation. The closer these two metrics are to zero, the more self-normalizing the model is considered to be. We note that a model with an observed $|\mu_z| >> 0$ on a dev set, can be 'corrected' to a large extent (as we show later) by subtracting this dev μ_z from the unnormalized scores at test time. However, this is not the case for σ_z. Therefore, from a practical point of view, we consider σ_z to be the more important metric of the two. In addition, we also look at the classic perplexity metric, which is considered a standard intrinsic measure for the quality of the model predictions. Importantly, when measuring perplexity, except where noted otherwise, we first perform exact normalization of the models' unnormalized scores by computing the normalization term.

Table 1: Self-normalization and perplexity results of NCE-LM against the standard softmax language model, SM-LM. d denotes the size of the compared models (units).

5.2 Results

We begin by comparing the results obtained by the two methods that do not include any explicit self-normalization component in their objectives, namely NCE-LM and the standard softmax SM-LM. Table 1 shows that consistent with previous works, NCE-LM is approximately self-normalized as apparent by relatively low $|\mu_z|$ and σ_z values. On the other hand, SM-LM, as expected, is much less self-normalized. In terms of perplexity, we see that SM-LM performs a little better than NCE-LM when model dimensionality is low, but the gap closes entirely at $d = 650$. Curiously, while perplexity improves with higher dimensionality, we see that the quality of NCE-LM's self-normalization, as evident particularly by σ_z, actually degrades. This is surprising, as we would expect that stronger models with more parameters would approximate the true $p(w|c)$ more closely and hence be more self-normalized. A similar behavior was recorded for SM-LM. We further investigate this in Section 5.3.

We also measured model test run-times, running on a single Tesla K20 GPU. We compared run-times for normalized scores that were produced by applying exact normalization versus unnormalized scores. For both SM-LM and NCE-LM, which perform the same operations at test time, we get $\sim$9 seconds for normalized scores vs. $\sim$8 seconds for unnormalized ones on the PTB validation set. Run-times on the x3 larger Wiki validation set are $\sim$38 seconds for normalized and $\sim$24 seconds for unnormalized. We see that the run-time of the unnormalized models seems to scale linearly with the size of the dataset. However, the normalized run-time scales super-linearly, arguably since it depends heavily on the vocabulary size, which is greater for Wiki than for PTB. With typical vocabulary sizes reaching much higher than Wiki's 33K word types, this reinforces the computational motivation for self-normalized language models.

Next, Table 2 compares the self-normalization and perplexity performance of DEV-LM for varied values of the constant α on the validation sets. As could be expected, the larger the value of α is, the better the self-normalization becomes, reaching very good self-normalization for $\alpha = 10.0$. On the other hand, the improvement in self-normalization seems to occur at the expense of perplexity. This is particularly true for the smaller models, but is still evident even for $d = 650$. Interestingly, as with NCE-LM, we see that σ_z grows (i.e. self-normalization becomes worse) with the size of the model, and is negatively correlated with the improvement in perplexity.

Finally, in Table 3, we compare AND-LM against our proposed NCE-R-LM, using a sampling rate of $\gamma = 0.1$ to avoid computing Z_c most of the time, and varied values of α. As can be seen, AND-LM exhibits relatively bad performance. In particular, to make the model converge when trained on the WIKI dataset, we had to follow the heuristic suggested by Chen et al. (2016), applying the following conversion to all of AND-LM's unnormalized scores, $x \rightarrow 10 \tanh(x/5)$. In contrast, we see that NCE-R-LM is able to use the explicit regularization to improve self-normalization at the cost of a relatively small degradation in perplexity.

Table 3: Self-normalization and perplexity results of the self-normalizing DEV-LM for different values of the normalization factor α. d = 650 and γ = 0.1.

Switching to the test-set evaluation, we propose a simple technique to center the $\log(Z)$ values of a self-normalizing model's scores around zero. Let μ_z^{valid} be $E(\log(Z))$ observed on the validation set at train time. The probability estimates of the 'shifted' model at test time are $\log p(w|c) = \vec{w}\cdot\vec{c}+b_w-\mu_z^{valid}$. Table 4 shows the results that we get when evaluating the shifted versions of DEV-LM, NCE-R-LM, NCE-LM and AND-LM with $d = 650$. For each compared model, we chose the α value that showed the best self-normalization performance without sacrificing significant perplexity performance. Specifically, we used $\alpha_{\text{DEV-LM}} = 1.0$ and $\alpha_{\text{NCE-R-LM}} = 10.0$ for both PTB and WIKI datasets, and then $\alpha_{\text{AND-LM}} = 1.0$ and $\alpha_{\text{AND-LM}} = 0.1$ for the PTB and WIKI datasets, respectively. Following Oualil and Klakow (2017), in addition to perplexity, we also report 'unnormalized perplexity', which is computed with the unnormalized model scores. When the unnormalized perplexity measure is close to the real perplexity, this suggests that the unnormalized scores are in fact nearly normalized.

As can be seen, with the shifting method, all models achieve near perfect (zero) μ_z value, and their unnormalized perplexities are almost identical to their respective real perplexities. Also, with the exception of AND-LM, the perplexities of all models are nearly identical. Finally, the standard deviation of the normalization term of DEV-LM and NCE-R-LM is notably better than that of NCE-LM and AND-LM. DEV-LM and NCE-R-LM perform very similar in all respects. However, we note that NCE-R-LM's advantage is that during training, it performs sparse computations of the costly normalization term and therefore its training time depends much less on the size of the vocabulary.

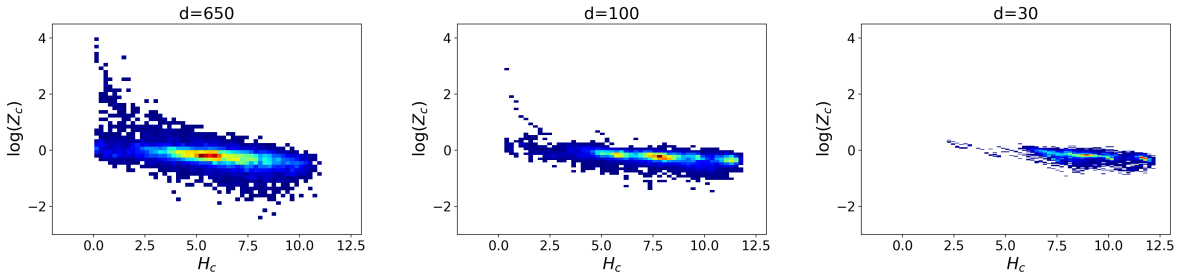

Figure 1: A 2-dimensional histogram of the normalization term of a predicted distribution as a function of its entropy, as measured over a sample from NCE-LM predictions on the WIKI validation set. Brighter colors denote denser areas.

5.3 Analysis

The entropy of the distributions predicted by a language model is a measure of how uncertain it is regarding the identity of the predicted word. Low-entropy distributions would be concentrated around few possible words, while high-entropy ones would be much more spread out. To more carefully analyze the self-normalization properties of NCE-LM and DEV-LM, we computed the Pearson's correlation between the entropy of a predicted distribution $H_c = -\sum_v p(v|c) \log p(v|c)$ and its normalization term, $\log(Z_c)$. As can be seen in Table 5, it appears that a regularity exists, where the value of $\log(Z_c)$ is negatively correlated with entropy. Furthermore, it seems that, to an extent, the correlation is stronger for larger models. To further illustrate this regularity, Figure 1 shows a 2-dimensional histogram of a sample of distributions predicted by NCE-LM . We can see there that particularly low entropy distributions can be associated with very high values of $\log(Z_c)$, deviating a lot from the self-normalization objective of $\log(Z_c) = 0$. Examples for contexts with such low-entropy distributions are: "During the American Civil [War]" and "The United [States]", where the actual word following the preceding context appears in parenthesis. This phenomenon is less evident for smaller models, which tend to produce fewer low entropy predictions.

We hypothesize that the above observations could be a contributing factor to our earlier finding that larger models have larger variance in their normalization terms, though it seems to account only for some of that at best. Furthermore, we hope that this regularity could be exploited to improve self-normalization algorithms in the future.

	2 training iterations				5 training iterations			
	acc-n	Δacc	perp	σ_z	acc-n	Δacc	perp	σ_z

Table 6: Microsoft Sentence Completion Challenge (MSCC) results for models with $d = 650$ that were trained with 2 and 5 iterations. 'acc-n' denotes the accuracy measure obtained when language model scores are precisely normalized. 'Δacc' denotes the delta in accuracy when unnormalized scores are used instead. 'perp' and σ_z denote the mean perplexity and standard deviation of $log(Z_c)$ recorded for the 1,040 answer sentences.

6 Sentence Completion Challenge

In Section 5, we've seen that there may be some trade-offs between perplexity, self-normalization and run-time complexity of language models. While the language modeling method should ultimately to be optimized for each downstream task individually, we follow Mnih and Teh (2012) and use the Microsoft Sentence Completion Challenge (Zweig and Burges, 2011) as an example use case.

The Microsoft Sentence Completion Challenge (MSCC) (Zweig and Burges, 2011) includes 1,040 items. Each item is a sentence with one word replaced by a gap, and the challenge is to identify the word, out of five choices, that is most meaningful and coherent as the gap-filler. The MSCC includes a learning corpus of approximately 50 million words. To use this corpus for training our language models, we split it into sentences, shuffled the sentence order and considered all words with frequency less than 10 as unknown, yielding a vocabulary of about 50K word types. We used the same settings described in Section 5.1 to train the language models except that due to the larger size of the data, we ran fewer training iterations. [3] Finally, as the gap-filler, we choose the word that maximizes the score of the entire sentence, where a sentence score is the sum of its words' scores. For a normalized language model this score can be interpreted as the estimated log-likelihood of the sentence.

The results of the MSCC experiment appear in Table 6. Accuracy is the standard evaluation metric for this benchmark (simply the proportion of questions answered correctly). We report this metric when performing the costly test-time score normalization and then the delta observed when using unnormalized scores instead. First, we note that given the same number of training iterations, all methods achieved fairly similar normalized-scores accuracies, as well as perplexity values. At the same time, we do see a notable improvement in both accuracies and perplexities when more training iterations are performed. Next, with the exception of SM-LM, all of the compared models exhibit good self-normalization properties, as is evident from the low σ_z values. There does not seem to be a meaningful accuracy performance hit when using unnormalized-scores for these models, suggesting that this level of self-normalization is adequate for the MSCC task. Finally, as expected, SM-LM exhibits worse self-normalization properties. However, somewhat surprisingly, even in this case, we see a relatively small (though more noticeable) hit in accuracy. This suggests that in some use cases, the level of the language model's self-normalization may have a relatively low impact on the performance of a down-stream task.

7 Conclusions

We reviewed and analyzed the two alternative approaches for self-normalization of language models, namely, using Noise Contrastive Estimation (NCE) that is inherently self-normalized, versus adding explicit self-normalizing regularization to a softmax objective function. Our empirical investigation compared these approaches, and by extending NCE language modeling with a light-weight explicit self-normalization, we also introduced a hybrid model that achieved both good self-normalization and perplexity performance, as well as little dependence of train-time on the size of the vocabulary. To put our

[3] We started with a learning rate of 1 and reduced it by a factor of 2 after each iteration beginning with the very first one.

intrinsic evaluation results in perspective, we used the Sentence Completion Challenge as an example use-case. The results suggest that it would be wise to test the sensitivity of the downstream task to self-normalization, in order to choose the most appropriate method. Finally, further analysis revealed unexpected correlations between self-normalization and perplexity performance, as well as between the partition function of self-normalized predictions and the entropy of the respective distribution. We hope that these insights would be useful for improving self-normalizing models in future work.

A Position-aware Bidirectional Attention Network for Aspect-level Sentiment Analysis

Abstract

Aspect-level sentiment analysis aims to distinguish the sentiment polarity of each specific aspect term in a given sentence. Both industry and academia have realized the importance of the relationship between aspect term and sentence, and made attempts to model the relationship by designing a series of attention models. However, most existing methods usually neglect the fact that the position information is also crucial for identifying the sentiment polarity of the aspect term. When an aspect term occurs in a sentence, its neighboring words should be given more attention than other words with long distance. Therefore, we propose a position-aware bidirectional attention network (PBAN) based on bidirectional GRU. PBAN not only concentrates on the position information of aspect terms, but also mutually models the relation between aspect term and sentence by employing bidirectional attention mechanism. The experimental results on SemEval 2014 Datasets demonstrate the effectiveness of our proposed PBAN model.

1 Introduction

Sentiment analysis, also known as opinion mining (Liu, 2012; Pang et al., 2008), is a vital task in Natural Language Processing (NLP). It divides the text into two or more classes according to the affective states and the subjective information of the text, and has received plenty of attention from both industry and academia. In this paper, we address the aspect-level sentiment analysis, which is a fine-grained task in the field of sentiment analysis. For instance, given the mentioned aspect terms $\{menu, server, specials\}$, and the sentence is *"The menu looked good, except for offering the Chilean Sea Bass, but the server does not offer up the specials that were written on the board outside."*. For aspect term *menu*, the sentiment polarity is *positive*, but for aspect term *server*, the polarity is *negative* while for *specials*, the polarity is *neutral*.

One important challenge in aspect-level sentiment analysis is how to model the semantic relationship between aspect terms and sentences. Traditional approaches have defined rich features about content and syntactic structures so as to capture the sentiment polarity (Jiang et al., 2011). However this kind of feature-based method is labor-intensive and highly depends on the quality of the features. Compared with these methods, neural network architectures are capable of learning features without feature engineering, and have been widely used in a variety of NLP tasks such as machine translation (Cho et al., 2014), question answering (Andreas et al., 2016) and text classification (Lai et al., 2015). Recently, with the development of the neural networks, they are also applied to target-dependent sentiment analysis[1], such as Target-Dependent LSTM (TD-LSTM) (Tang et al., 2015) and Target-Connection LSTM (TC-LSTM) (Tang et al., 2015). However, these neural network-based methods can not effectively identify which words in the sentence are more important. Fortunately, attention mechanisms are an effective way to solve this problem.

*Corresponding author: Yuexian Hou.

[1]The aim of the target-dependent sentiment analysis is similar to aspect-level sentiment analysis. Given a sentence and target/aspect term, the task calls for inferring the sentiment polarity of the sentence towards the target/aspect term.

Proceedings of the 27th International Conference on Computational Linguistics, pages 774–784
Santa Fe, New Mexico, USA, August 20-26, 2018.

Attention, which is widely applied to Computer Vision (CV) and NLP fields, is an effective mechanism and has been demonstrated in image recognition (Mnih et al., 2014), machine translation (Bahdanau et al., 2014; Luong et al., 2015) and reading comprehension (Hermann et al., 2015; Cui et al., 2016). Therefore, some researchers have designed attention networks to address the aspect-level sentiment analysis and have obtained comparable results, such as AE-LSTM (Wang et al., 2016), ATAE-LSTM (Wang et al., 2016) and IAN (Ma et al., 2017).

However, these existing work ignores or does not explicitly model the position information of the aspect term in a sentence, which has been studied for improving performance in information retrieval (IR). In (Liu et al., 2015), the occurrence positions of the query terms were modeled via kernel functions and then integrated into traditional IR models to boost the retrieval performance. By analyzing this aspect-level sentiment analysis task and the corresponding dataset, we find that when an aspect term occurs in a sentence, its neighboring words in the sentence should be given more attention than other words with long distance. Let us take *"It's a perfect place to have an amazing indian food."* as an example, when the aspect term is *indian food*, its corresponding sentiment polarity is *positive*. Intuitively, we can see that the neighboring word of the *indian food* (i.e. *"amazing"*) has a greater contribution to judge the sentiment polarity of the aspect term than other words with long distance such as *"to"* and *"have"*. Sometimes this intuitive idea of judging the sentiment polarity may be interpreted as a cognitive activity, which also can be rephrased in a quantum-like language model (Niu et al., 2017). To be specific, sentiment polarity may be interpreted as a quantum-like cognition state. Inspired by this, we go one step further and propose a position-aware bidirectional attention network (PBAN) based on bidirectional Gated Recurrent Units (Bi-GRU) (Cho et al., 2014).

In addition to utilizing the position information, PBAN also mutually models the relationship between the sentence and different words in the aspect term by adopting a bidirectional attention mechanism. To be specific, our model consists of three components: 1) Obtaining position information of each word in corresponding sentence based on the current aspect term, then converting the position information into position embedding. 2) The PBAN composes of two Bi-GRU networks focusing on extracting the aspect-level features and sentence-level features respectively. 3) Using the bidirectional attention mechanism to model the mutual relation between aspect term and its corresponding sentence. We evaluate our models on SemEval 2014 Datasets, and the results show that our models are more effective than other previous methods.

The main contributions of our work can be summarized as follows: (1) We attempt to explicitly investigate the effectiveness of the position information of aspect term for aspect-level sentiment analysis. (2) We propose a position-aware bidirectional attention network (PBAN) based on Bi-GRU, which has been proved to be effective to improve the sentiment analysis performance. (3) We apply a bidirectional attention mechanism, which can enhance the mutual relation between the aspect term and its corresponding sentence, and prevent the irrelevant words from getting more attention.

2 Model Overview

In this section, we describe the proposed model position-aware bidirectional attention network (PBAN) for aspect-level sentiment analysis and PBAN is shown in Figure 1. In this paper, the set of sentiment polarity of the aspect term is $\{positive, negative, neutral\}$.

2.1 Position Representation

As for how to model the position information of the aspect term in its corresponding sentence, inspired by the position encoding vectors used in (Collobert et al., 2011; Zeng et al., 2014), we define a position index sequence whose length is equal to the length of corresponding sentence. Suppose that if a word in the aspect term occurs in the sentence, then its position index will be marked as "0", and the position index of other words will be represented as the relative distance to the current aspect term.

$$p_i = \begin{cases} \mid i - j_s \mid, & i < j_s \\ 0, & j_s \leq i \leq j_e \\ \mid i - j_e \mid, & i > j_e \end{cases} \tag{1}$$

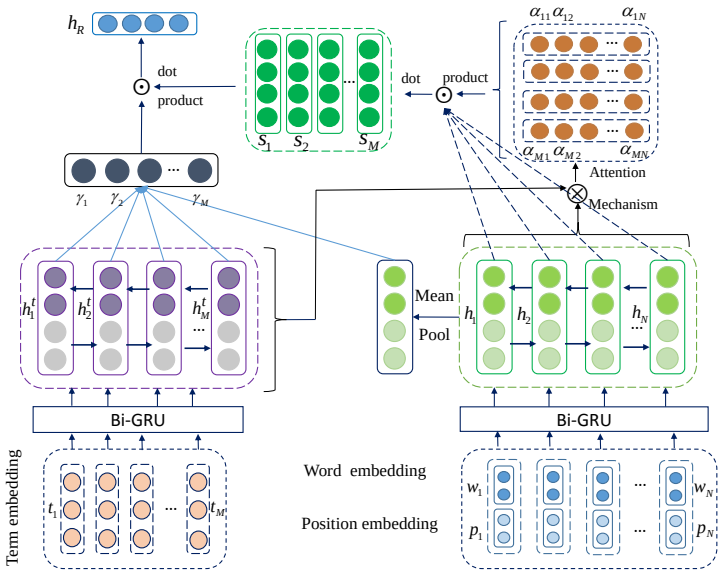

Figure 1: The architecture of position-aware bidirectional attention network for aspect-level sentiment analysis (PBAN). $\{w_1, w_2, ..., w_N\}$ represents the word embedding in a sentence whose length is N, and $\{t_1, t_2, ..., t_M\}$ represents the aspect term embedding whose length is M. $\{p_1, p_2, ..., p_N\}$ is the position embedding of the aspect term, which is concatenated to the word embedding. $\{\mathbf{h}_1, \mathbf{h}_2, ..., \mathbf{h}_N\}$ denotes the hidden representation of inputs and $\{\mathbf{h}_1^t, \mathbf{h}_2^t, ..., \mathbf{h}_M^t\}$ indicates the hidden representation of aspect term.

where, j_s and j_e denote the starting and ending indices of the aspect term respectively, and p_i can be viewed as the relative distance of the $i\text{-}th$ word in sentence to the aspect term. For example, given a sentence *"not only was the food outstanding but the little perks were great."*, and the aspect term is *food*, then the position index sequence is represented as $\mathbf{p} = [4, 3, 2, 1, 0, 1, 2, 3, 4, 5, 6, 7]$. And its corresponding position embedding are obtained by looking up a position embedding matrix $\mathbf{P} \in \mathbb{R}^{d_p \times N}$, which is randomly initialized, and updated during the training process. Here, d_p denotes the dimension of position embedding and N indicates the length of the sentence. After the position index is converted to the embedding, the position embedding can model the different weights of words with different distance. From this example, it is obvious that the words with smaller relative distances (such as *"outstanding"*) play an more important role in judging the sentiment polarity of *food*. We can find that this process is basically consistent with the way people judge the sentiment polarity of the aspect term. Because we usually first observe the neighboring words of the aspect term, judging whether the neighboring words can show its sentiment polarity, after that we will focus on those words with long distance.

2.2 Word Representation

Bidirectional LSTMs have been successfully applied to various NLP tasks (Bahdanau et al., 2014), and it models the context dependency with the forward LSTM and the backward LSTM. The forward L-STM handles the sentence from left to right, and the backward LSTM processes it in the reverse order. Therefore, we can obtain two hidden representation, and then concatenate the forward hidden state and backward hidden state of each word. In this paper, we choose to use bidirectional GRU since it performs similarly to bidirectional LSTM but has fewer parameters and lower computational complexity.

Concretely, we firstly obtain the representation of each word in aspect term and sentence, and formalize the notations in our work. We suppose that a sentence consists of N words $[w_1, w_2, ..., w_N]$ and an aspect term contains M words $[t_1, t_2, ..., t_M]$, then we get sentence embedding and aspect term embedding by looking up a word embedding matrix $\mathbf{E} \in \mathbb{R}^{d \times v}$ respectively, where d denotes the dimension of the embedding, and v indicates the vocabulary size.

Then we input aspect term embeddings into the left Bi-GRU to get the hidden contextual representa-

tion, which consists of forward hidden state $\overrightarrow{\mathbf{h}_i^t} \in \mathbb{R}^{d_h}$ and backward hidden state $\overleftarrow{\mathbf{h}_i^t} \in \mathbb{R}^{d_h}$, where d_h denotes the number of hidden units. Finally, the hidden contextual representation of aspect term $\mathbf{h}_i^t$ is obtained by concatenating $\overrightarrow{\mathbf{h}_i^t}$ and $\overleftarrow{\mathbf{h}_i^t}$, i.e., $\mathbf{h}_i^t = [\overrightarrow{\mathbf{h}_i^t}; \overleftarrow{\mathbf{h}_i^t}] \in \mathbb{R}^{2d_h}$. For the right Bi-GRU structure, we take the concatenation of the position embedding and word embedding as the inputs, then we can obtain the final hidden contextual representation of the inputs, i.e., $\mathbf{h}_i = [\overrightarrow{\mathbf{h}_i}; \overleftarrow{\mathbf{h}_i}] \in \mathbb{R}^{2d_h}$.

2.3 Position-aware Bidirectional Attention Network Model (PBAN)

As shown in Figure 1, attention model in PBAN consists of two parts: including the aspect term to the position-aware sentence part and a position-aware sentence to the aspect term part. For the former part, we can obtain the different hidden contextual representation of a sentence according to different word in aspect term. For the later part, we can obtain the attention weights of the words in aspect term according to the position information, which is used for getting the final representation of a sentence. Details will be described in follwing sections.

Aspect term to position-aware sentence attention: A sentence should be represented differently based on different words in aspect term, because different words may have different effects on the final representation of the sentence. We firstly get the hidden contextual representation of the aspect term by the left Bi-GRU, and get the hidden contextual representation of inputs (i.e., the concatenation of word embedding and position embedding) by the right Bi-GRU structure. Here, we regard the position embedding as the part of the inputs, because it intuitively represents the relative distance of words in a sentence to the current aspect term as mentioned in section 2.1. Then we calculate the attention weights by adopting hidden contextual representation of aspect term and inputs, obtaining the attention weight distribution of sentence corresponding to each word in this aspect term. It can be formulated as follows:

$$\mathbf{s}_i = \sum_{j=1}^{N} \alpha_{ij} \mathbf{h}_j \tag{2}$$

$$\alpha_{ij} = \frac{exp(f(\mathbf{h}_j, \mathbf{h}_i^t))}{\sum_{k=1}^{N} exp(f(\mathbf{h}_k, \mathbf{h}_i^t))} \tag{3}$$

$$f(\mathbf{h}_j, \mathbf{h}_i^t) = \tanh(\mathbf{h}_j^T \mathbf{W}_m \mathbf{h}_i^t + b_m) \tag{4}$$

where α_{ij} indicates the attention weights from the word $\mathbf{h}_i^t$ in the aspect term to the j-th word in the inputs, and $tanh$ is a non-liner activation function. $\mathbf{W}_m$ is the weight matrix and b_m is the bias. Subsequently, α_{ij} is used to compute a weighted sum of the hidden representation $\mathbf{s}_i$, producing a semantic vector that represents the input sequence.

Position-aware sentence attention to aspect term: As we mentioned above, different words in aspect term will play different role in judging the sentiment polarity of aspect term. Since we obtain the hidden contextual representation of the inputs by the right Bi-GRU, we utilize both the position and semantic information for calculating the attention weights of different words in aspect term. The process can be formulated as follows:

$$\mathbf{h}_R = \sum_{i=1}^{M} \gamma_i \mathbf{s}_i \tag{5}$$

$$\gamma_i = \frac{exp(f(\overline{\mathbf{h}}, \mathbf{h}_i^t))}{\sum_{k=1}^{M} exp(f(\overline{\mathbf{h}}, \mathbf{h}_k^t))} \tag{6}$$

$$f(\overline{\mathbf{h}}, \mathbf{h}_i^t) = \tanh(\overline{\mathbf{h}}^T \mathbf{W}_n \mathbf{h}_i^t + b_n) \tag{7}$$

$$\overline{\mathbf{h}} = \frac{1}{N} \sum_{i=1}^{N} \mathbf{h}_i \tag{8}$$

where γ_i stands for the attention weights from inputs to the words in aspect term, denoting which word in aspect term should be more focused. $\overline{\mathbf{h}}$ is calculated by averagely pooling all Bi-GRU hidden states. Later, the sequence representation $\mathbf{x}$ is obtained by using a non-linear layer:

$$\mathbf{x} = \tanh(\mathbf{W}_R\mathbf{h}_R + \mathbf{b}_R) \tag{9}$$

where $\mathbf{W}_R$ and $\mathbf{b}_R$ are weight matrix and bias respectively.

We feed $\mathbf{x}$ into a linear layer, the length of whose output equals to the number of class labels $\|S\|$. Finally, we add a *softmax* layer to compute the probability distribution for judging the sentiment polarities as *positive*, *negative* or *neutral*:

$$\mathbf{y} = softmax(\mathbf{W}_s\mathbf{x} + \mathbf{b}_s) \tag{10}$$

where $\mathbf{W}_s$ and $\mathbf{b}_s$ are the weight matrix and bias respectively for *softmax* layer.

2.4 Model training

The PBAN model can be trained in an end-to-end way in a supervised learning framework, the aim of the training is to optimize all the parameters so as to minimize the objective function (loss function) as much as possible. In our work, let y_i be the correct sentiment polarity, which is represented by one-hot vector, and $\widehat{y}_i$ denotes the predicted sentiment polarity for the given sentence. We regard the cross-entropy as the loss function, and the formula is as follows:

$$loss = -\sum_{i=1}^{S} y_i log(\widehat{y}_i) + \frac{1}{2}\lambda \parallel \theta \parallel^2 \tag{11}$$

where λ is the regularization factor and θ contains all the parameters. Furthermore, in order to avoid over-fitting, we adopt the dropout strategy to enhance our PBAN model.

3 Experiments

3.1 Experiments Setting

Parameters Setting: In our experiments, all word embedding are initialized by the pre-trained Glove vector[2] (Pennington et al., 2014). All the weight matrices are given the initial value by sampling from the uniform distribution $U(-0.1, 0.1)$, and all the biases are set to zero. The dimension of the word embedding and aspect term embedding are set to 300, and the number of the hidden units are set to 200. The dimension of position embedding is set to 100, which is randomly initialized and updated during the training process. We use Tensorflow (Abadi et al., 2016) to implement our proposed model and employ the Momentum as the training method, whose momentum parameter γ is set to 0.9, λ is set to 10^{-6}, and the initial learning rate is set to 0.01.

Dataset: To evaluate our proposed methods, we conduct experiments on the dataset of SemEval 2014 Task4[3], the SemEval 2014 dataset consists of reviews in *Restaurant* and *Laptop* datasets. Each review contains a list of aspect terms and corresponding polarities, which are labeled with $\{positive, negative, neutral\}$. Particularly, each aspect term has its character index in the sentence, so that when different aspect term have the same word in a sentence, we can mark the relative position distance of a sentence according to the current aspect term without confusion. Table 1 shows the training and test sample numbers in each sentiment polarity.

3.2 Model Comparison

In order to evaluate the performance of our model, we compare our model with several baseline models, including LSTM (Wang et al., 2016), AE-LSTM (Wang et al., 2016), ATAE-LSTM (Wang et al., 2016), IAN (Ma et al., 2017) and MemNet (Tang et al., 2016).

[2]Pre-trained word vectors of Glove can be obtained from http://nlp.stanford.edu/projects/glove/

[3]The detail introduction of this dataset can be seen at: http://alt.qcri.org/semeval2014/task4/

Datasets	Positive		Negative		Neutral	
	Train	Test	Train	Test	Train	Test
Restaurant	2164	728	807	196	637	196
Laptop	994	341	870	128	464	169

Table 1: Samples of SemEval 2014 Dataset.

LSTM: LSTM takes the sentence as input so as to get the hidden representation of each word. Then it regards the average value of all hidden states as the representation of sentence, and puts it into *softmax* layer to predict the probability of each sentiment polarity. However, it can not capture any information of aspect term in sentence (Wang et al., 2016).

AE-LSTM: AE-LSTM first models the words in sentence via LSTM network and concatenate the aspect embedding to the hidden contextual representation for calculating the attention weights, which are employed to produce the final representation for the input sentence to judge the sentiment polarity (Wang et al., 2016).

ATAE-LSTM: ATAE-LSTM extended AE-LSTM by appending the aspect embedding to each word embedding so as to represent the input sentence, which highlights the role of aspect embedding. The other design of ATAE-LSTM is the same as AE-LSTM (Wang et al., 2016).

IAN: IAN considers the separate modeling of aspect terms and sentences respectively. IAN is able to interactively learn attentions in the contexts and aspect terms, and generates the representations for aspect terms and contexts separately. Finally, it concatenates the aspect term representation and context representation for predicting the sentiment polarity of the aspect terms within its contexts (Ma et al., 2017).

MemNet: MemNet applies attention multiple times on the word embedding, so that more abstractive evidences could be selected from the external memory. The output of the last attention layer is fed to a *softmax* layer for predictions (Tang et al., 2016).

Datasets	Restaurant		Laptop	
	Three-class	Two-class	Three-class	Two-class
LSTM	74.28	—	66.45	—
AE-LSTM	76.60	89.60	68.90	87.40
ATAE-LSTM	77.20	90.90	68.70	87.60
IAN	78.60	—	72.10	—
MemNet(9)	80.95	—	72.21	—
PBAN	**81.16**	**91.67**	**74.12**	**87.81**

Table 2: Comparison with baselines. Accuracy on Three-class and Two-class prediction about *Restaurant* and *Laptop* dataset, and Two-class denotes $\{positive, negative\}$. MemNet(9) indicates that MemNet with nine computational layers. Best scores are in bold.

Table 2 shows the performance of our model and other baseline models on datasets *Restaurant* and *Laptop* respectively. We can observe that our proposed PBAN model achieves the best performance among all methods. It is obvious that LSTM method gets the worst performance, because it treats aspect term and other words as the same, so that it can not take full advantage of the aspect term information and predicts the same polarity for different aspect terms in a sentence.

Furthermore, both AE-LSTM and ATAE-LSTM perform better than LSTM model, because they all consider the importance of the aspect term, and utilize the attention mechanism. Specifically, ATAE-LSTM outperforms AE-LSTM since it appends the aspect embedding to each word embedding and takes them as inputs, which helps the model obtain more semantic information related to aspect term. IAN realizes the importance of interaction between aspect term and context, and models aspect term and context using two connected attention networks. Thus, IAN performs better than ATAE-LSTM, and achieves an improvement of 1.40 points and 3.40 points on *Restaurant* and *Laptop* datasets in *Three-class*

respectively. MemNet(9) utilizes a more complex structure that containing nine computational layers, and it achieves better results compared to IAN since MemNet reads the useful information from external memory repeatedly.

Although both IAN and MemNet models performance better than other methods, they all perform less competitive than our PBAN both on *Restaurant* and *Laptop* datasets. For IAN model, it interactively learns the attentions between the aspect term and its corresponding sentence, but this attention mechanism is coarse-grained and it does not fully consider the influence of different words in aspect term on the sentence. For MemNet model, although it utilizes the location information, it is mainly used for calculating the memory vectors. Nevertheless, PBAN utilizes the character index of the aspect term (provided in the raw dataset) and adopts relative distance to represent the position sequence. As we have mentioned in previous sections, an aspect term contains several words and different words in aspect term should have different contributions to the final representation of sentence. In PBAN, the position information is regarded as the inputs of the Bi-GRU, so it can help calculate the weights of different words in aspect term and improve the final representation of the sentence. Moreover, when different aspect terms contain the same word, our proposed position information can effectively identify the current aspect term without confusion while MemNet can not.

Generally speaking, by integrating the position information and the bidirectional attention mechanism, PBAN achieves the state-of-the-art performances, and it can effectively judge the sentiment polarity of different aspect term in its corresponding sentence so as to improve the classification accuracy.

3.3 Analysis of PBAN Model

In this section, we design a series of models to demonstrate the effectiveness of our PBAN model. Firstly, we design an ATAE-Bi-GRU model, whose structure is similar with ATAE-LSTM. The only difference between these two models is that ATAE-Bi-GRU uses the Bi-GRU structure rather than LSTM, and other design is the same as ATAE-LSTM. Next we design a BAN model without modeling position embedding, and it just utilizes the representation of aspect term and sentence. In BAN, we still adopt bidirectional attention mechanism to model the relation between aspect term and sentence as PBAN does. The only difference between BAN and PBAN is that BAN without taking the position embedding as a part of inputs. Moreover, we also design a PAN model, whose structure is similar with the ATAE-Bi-GRU model. PAN takes the concatenation of the aspect term embedding and the word embedding as the inputs of the Bi-GRU structure to obtain the hidden contextual representation, and then PAN utilizes this representation and the position embedding of the aspect term to calculate the attention weights, so as to effectively judge the sentiment polarity of an aspect term. From Table 3, we can find that PBAN achieves the best performance among these models.

Dataset	Restaurant	Laptop
ATAE-LSTM	77.20	68.70
ATAE-Bi-GRU	77.68	69.47
PAN	78.07	71.13
IAN	78.60	72.10
BAN	78.74	72.61
PBAN	**81.16**	**74.12**

Table 3: Analysis of PBAN model.

Because Bi-GRU structure has a big advantage over LSTM, it is obvious that ATAE-Bi-GRU model performs better than ATAE-LSTM model. For PAN model, it outperforms ATAE-LSTM and ATAE-Bi-GRU models, but it is worse than BAN model. Compared with ATAE-Bi-GRU, the most difference is that PAN utilizes the position embedding to calculate the attention weights rather than the aspect term embedding like ATAE-Bi-GRU. Therefore, according to these three experimental results, we can prove the importance of the position information in aspect-level sentiment analysis task.

As for BAN model, it outperforms IAN model while performs worse than PBAN model. Because

Aspect term	Sentence	Polarity
pizza	This is one great place to eat pizza more out but not a good place for take-out pizza.	positive
take-out pizza	This is one great place to eat pizza more out but not a good place for take-out pizza.	negative

Figure 2: Case Study: The visualized attention weights for sentence and aspect term by PBAN.

compared with IAN model, BAN model can learn more semantic relationship between aspect term and sentence via bidirectional attention mechanism. However, it ignores the position information of aspect term when compared with PBAN model.

As we expect, PBAN achieves the best performance among all these models. This is because in addition to fully considering the position information of the aspect term in its corresponding sentence, PBAN also considers the mutual relationship between aspect term and sentence, which is mainly achieved by a bidirectional attention mechanism.

3.4 A Case Study

To have an intuitive understanding of our proposed model, we visualize the attention weights on the aspect term and sentence in Figure 2. The color depth indicates the importance degree of the weight, the darker the more important. In Figure 2, the sentence is *"**This is one great place to eat pizza more out but not a good place for take-out pizza.**"*, the polarities are *positive* and *negative* for ***pizza*** and ***take-out pizza*** respectively. From Figure 2, we can find that our model is more inclined to consider the neighboring words of the aspect term. For example, when the current aspect term is ***pizza***, obviously, its neighboring words such as *"great"*, *"place"* and *"more"* get more attention and play a great role for judging sentiment polarity of ***pizza***. However, those words that are far from the current aspect term such as *"but"*, *"not"* and *"take-out"* obtain less attention, which demonstrates the effectiveness of the position information. For aspect term ***take-out pizza***, it is obvious that the word *"take-out"* is more important to express the aspect term than the word *"pizza"*. From Figure 2, it is worth noting that some words such as *"good"* and *"place"* get less attention even they are closer to the current aspect term than *"but"* and *"not"*. This is because different words in aspect term have different effect on a sentence, and we apply the bidirectional attention mechanism to choose more useful words. For instance, in this case, PBAN should pay more attention on the word *"take-out"*. Therefore, PBAN is capable of figuring out the important part in a sentence for judging the sentiment polarity by modeling the mutual relation between sentence and different words in aspect term.

4 Related Work

In this section, we will briefly review some research on sentiment analysis in recent years. The previous research can be divided into three directions: traditional machine learning methods, neural network methods and attention network methods.

4.1 Machine Learning for Sentiment Analysis

Traditional machine learning approaches mainly involve text representation and feature extraction, such as bag-of-words models and sentiment lexicons features, then training a sentiment classifier (Prez-Rosas et al., 2012). Rao et al. (2010) demonstrated the utility of graph-based semi-supervised learning framework for building sentiment lexicons. Kaji et al. (2007) explored to use structural clues that could extract polar sentences from HTML documents, and built lexicon from the extracted polar sentences. However, these methods are labor-intensive, and usually results in high dimensional and high sparse phenomenon for the text representation.

4.2 Neural Network for Target-dependent Sentiment Analysis

Since a simple and effective method to learn distributed representation was proposed (Mikolov et al., 2013), neural networks enhance target-dependent sentiment analysis significantly. Vo and Zhang (2015) split a tweet into a left context and a right context according to a given target, using distributed word representations and neural pooling functions to extract features. Tang et al. (2015) proposed TD-LSTM and TC-LSTM, where target information is automatically taken into account. These two models integrated the connections between target words and context words so as to significantly boost the classification accuracy. Zhang et al. (2016) proposed two gated neural networks, one was used to capture tweet-level syntactic and semantic information, and the other was used to model the interactions between the left context and the right context of a given target. With the gating mechanism, the target influenced the selection of sentiment signals over the context.

4.3 Attention Network for Aspect-level Sentiment Analysis

With the successful application of the attention mechanism in machine translation and reading comprehension, it is also applied to aspect-level sentiment analysis in recent years. Wang et al. (2016) examined the latent relatedness of the aspect term and sentiment polarity for aspect-level sentiment analysis. They designed an attention-based LSTM to learn aspect term embedding, and let the aspect term embedding participate in calculating the attention weights. Ma et al. (2017) proposed a new attention model IAN, which considered the separate modeling of aspect terms and could interactively learn attention in the contexts and aspect terms.

Despite the effectiveness of these attention mechanisms, they are coarse-grained and it is still challenging to identify different sentiment polarity at a fine-grained aspect level. However, our PBAN model makes full use of the position information of the aspect term, and PBAN uses a fine-grained bidirectional attention mechanism to model the mutual relationship between the sentence and each word in the aspect term, identifying the importance of the word in the aspect term to obtain a more effective sentence representation as described in Section 1.

5 Conclusion

In this paper, we have proposed a position-aware bidirectional network (PBAN) based on Bi-GRU for aspect-level sentiment analysis. The main idea of PBAN is to utilize the position embedding of aspect term for calculating the attention weights. Moreover, PBAN adopts a bidirectional attention mechanism, which is not only capable of mutually modeling the relation between sentence and different words in aspect term, but also takes advantage of the position information to better judge the sentiment polarity of aspect term. Experimental results on SemEval 2014 Datasets demonstrate that our proposed models can learn effective features and obtain superior performance over the baseline models.

Abstract

One main challenge for incremental transition-based parsers, when future inputs are invisible, is to extract good features from a limited local context. In this work, we present a simple technique to maximally utilize the local features with an attention mechanism, which works as context-dependent dynamic feature selection. Our model learns, for example, which tokens should a parser focus on, to decide the next action. Our multilingual experiment shows its effectiveness across many languages. We also present an experiment with augmented test dataset and demonstrate it helps to understand the model's behavior on locally ambiguous points.

1 Introduction

This paper explores better feature representations for incremental dependency parsing. We focus on a system that builds a parse tree incrementally receiving each word of a sentence, which is crucial for interactive systems to achieve fast response or human-like behavior such as understanding from partial input (Baumann, 2013). The most natural way to achieve incremental parsing is using a transition system (Nivre, 2008), and for such parsers, the main challenge is to choose an appropriate action with only the local context information. While some recent transition-based parsers alleviate this difficulty by exploiting the entire input sentence with recurrent neural networks (Kiperwasser and Goldberg, 2016; Shi et al., 2017), one possible disadvantage is to require that all inputs are visible from the beginning, which should be problem when we try more strict incremental conditions such as simultaneous translation. Therefore there are still demands to explore the effective way to extract better feature representation from incomplete inputs.

In this paper, we incorporate a simple attention mechanism (Bahdanau et al., 2015) with an incremental parser and investigate its effectiveness during the feature extraction. Attention mechanism itself has firstly succeeded in machine translation, capturing relative importances of tokens on a certain step for a proper output (Bahdanau et al., 2015; Luong et al., 2015). The characteristic to weight on some features automatically and effectively can be applied to various tasks such as seq-to-seq parsing model (Vinyals et al., 2015), text summarization (Rush et al., 2015), dialogue generation (Shang et al., 2015), image captioning (Xu et al., 2015) in which the systems can enjoy performance gain by attending to specific clues depending on a given situation. We can also expect this behavior is helpful to fix the error which transition-based parsers often commits due to local ambiguities.

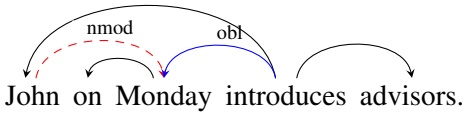

Figure 1: A locally ambiguous sentence. "*Monday*" should be analyzed as oblique of "*introduce*" while tends to be analyzed as a noun modifier of "*John*".

Proceedings of the 27th International Conference on Computational Linguistics, pages 785–794
Santa Fe, New Mexico, USA, August 20-26, 2018.

Figure 1 shows our motivating example, on which the standard transition-based parser fails and attaches "*Monday*" to "*John*", since on the POS level and the usual behavior of "*on*", this sequence is misleading as a typical noun phrase. By introducing attention on feature extraction, we expect the model to attend to important tokens, in this case "*Monday*", which is not likely to attach to a person and suggests the parser to anticipate the following predicate. Our technique can be applied to any models with feed-forward networks on concatenated feature embeddings, and in this work, we apply it on the standard transition-based parser of Chen and Manning (2014).

On the multilingual experiment on Universal Dependencies (UD) 2.0 (Zeman et al., 2017), we find our attention brings performance gain for most languages. To inspect the model's behavior, we also introduce a controlled experiment with manually created data. For this experiment, we prepare a set of sentences for which the parser must attend to the key points for correct disambiguation, as in Figure 1, and see whether the model behaves as expected. There we give detailed error analysis to suggest what makes it difficult to solve the local ambiguities and how attention achieves it. This type of analysis is common in psycholinguistics (Levy, 2008), and a similar idea has recently begun to be explored in NLP neural models (Shekhar et al., 2017).

2 Model

2.1 Base model

Our base model is a transition-based neural parser of Chen and Manning (2014).[1] For each step, this parser first creates feature vectors of words ($\mathbf{x}^w$), POS tags ($\mathbf{x}^p$), and labels ($\mathbf{x}^l$), each of which is a concatenation of embeddings around a stack and a buffer. These vectors are transformed with corresponding weights, i.e., $\mathbf{h} = \mathbf{W}^w\mathbf{x}^w + \mathbf{W}^p\mathbf{x}^p + \mathbf{W}^l\mathbf{x}^l + \mathbf{b}$, followed by nonlinearity. A next softmax layer then provides action probabilities.

Although this method is actually old, the approach which creates the feature vector from independent embeddings becomes useful in our second experiment inspecting our attention behaviors (See section 3.3 in detail). In addition, UDPipe (Straka et al., 2016) which is the baseline parser in the latest shared task (Zeman et al., 2017) also adopts this approach and holds good performance compared to others using recent techniques.

2.2 Attention on local features

We introduce attention in feature computation from the input embeddings to $\mathbf{h}$. Note that three components $\mathbf{W}^w\mathbf{x}^w$, $\mathbf{W}^p\mathbf{w}^p$, and $\mathbf{W}^l\mathbf{x}^l$ are independent; in the following we focus on just one part, abstracted by $\mathbf{W}\mathbf{x}$, and describe how attention is applied for this computation.

Our attention calculates the importance of input elements. First, note that $\mathbf{x}$ is a concatenation of embeddings of input elements, and when the number of elements is n, $\mathbf{W}$ can also be divided into n blocks as in Figure 2. When these parts are denoted by $\mathbf{W}_i$ and $\mathbf{x}_i$, $\mathbf{W}\mathbf{x} = \sum_i \mathbf{W}_i\mathbf{x}_i$ holds. We define $\mathbf{c}_i = \mathbf{W}_i\mathbf{x}_i$, which corresponds to the hidden representation for the i-th input element.

Our core idea is to apply attention on decomposed hidden vectors $\{\mathbf{c}_i\}$. Using attention vector $\mathbf{a} = (a_1, a_2, \cdots, a_n)$, the new hidden representation becomes $\mathbf{h}_g = \sum_i a_i\mathbf{c}_i$. We obtain attention a_i using $\mathbf{c}_i$ and parameters $\mathbf{q}$ as follows:

$$a_i = \frac{\exp(\sigma(\mathbf{q} \cdot \mathbf{c}_i))}{\sum_{i=1}^{n} \exp(\sigma(\mathbf{q} \cdot \mathbf{c}_i))},$$

where σ is a sigmoid function. We use different attention parameters $\mathbf{q}^w$, $\mathbf{q}^p$, and $\mathbf{q}^l$ for word, POS, and label inputs, respectively.

3 Experiments

Our first experiment is on the multilingual UD treebanks used in CoNLL 2017 shared task (Zeman et al., 2017). In addition to this, we present another experiment using augmented test data. This is a set of

[1] As described in Section 3.1 we slightly extend their parser to use additional features. In this section, we first present our model with the original features for simplicity.

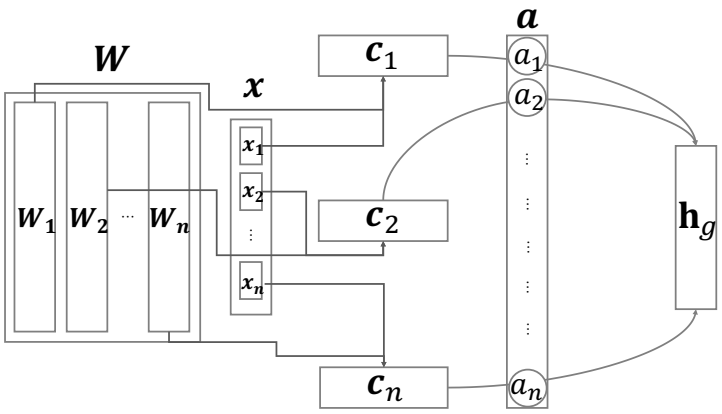

Figure 2: Our attention mechanism on the decomposed hidden vectors $\mathbf{c}_i$, obtained by $\mathbf{W}_i\mathbf{x}_i$.

sentences for which there is a key token for correct disambiguation. We will see whether our model is capable of disambiguating them by attending to the critical points.

For both experiments, our baselines are our parser without attention, and UDPipe v1.1 (Straka et al., 2016), which was the state-of-the-art among transition-based parsers with local features on the shared task.[2]

3.1 Parser

We extract features from the same positions as Chen and Manning (2014); top three tokens from the stack and the buffer, the first and second leftmost or rightmost children of the top two tokens on the stack, and the leftmost or rightmost children of leftmost or rightmost children of the top two tokens on the stack. However, from each position we extract more information such as LEMMA (see also footnote 1). The embedding sizes are: 50 dimensions for WORD, 20 dimensions for LEMMA, UPOS, XPOS, FEATS, and DEPREL. We also extract 32 dimensional character encoding of a token by bi-LSTMs (Ling et al., 2015), though we do not apply attention on this. The size of the hidden dimension is 200, on which we apply 50% dropout. We use pre-trained embeddings used in the baseline UDPipe.[3] To handle non-projectivity, we employ the arc-standard swap algorithm (Nivre et al., 2009). We also use beam search with width 5. To learn the representation for unknown words, we stochastically replace singletons with the dummy token (Dyer et al., 2015). These hyperparameters are the same across languages except Kazakh. This is apart from UDPipe, which tunes the setting for each language. For Kazakh, which is extremely small, we find increasing the model size as 100, 50, and 50 dimensions for WORD, UPOS, and XPOS embeddings works well so we choose this setting.

3.2 Multilingual evaluation

We use 63 treebanks in 45 languages on Universal Dependencies v2.0 (Nivre et al., 2017), with the same data split as the setting of official UDPipe.[3] We evaluate F1 LAS of each treebank and their macro average. For the development sets, we use the gold preprocessed data while for the test sets, we parse the raw text preprocessed by UDPipe.

With respect to the macro averaged score, in the Table 1 below, we can see that our model without attention (w/o Att.) is comparable to UDPipe; with attention, it outperforms both. When inspecting in detail, we see that our attention improves the scores on 54 treebanks on the development set and 57 treebanks on the test set. We also see that the treebanks for which our attention degrades the performance are relatively small, e.g., `en_partut` (1,035 sentences) and `hu` (864 sentences), which indicates our attention may be more data-hungry.

[2]There are three systems (Straka and Straková, 2017; Kanerva et al., 2017; Yu et al., 2017) that outperform UDPipe v1.1 but the improvements come not from parsing models but from preprocessing, such as improvements to the POS tagger.

[a] The test set of it_partut treebank was excluded in the shared task as well.
[b] The UDPipe's official score is 68.35 because it includes the scores for extra treebanks in the shared task, called *surprise language*.

Table 1: Labeled attachment scores of 63 treebanks in UD v2.0

3.3 Augmented data evaluation

Why does attention help for disambiguation? To inspect this, now we perform a controlled experiment by parsing a set of sentences that for correct disambiguation may require attending to some specific points. We present two different sets on English, which differ in the points where the model should attend.

Oblique vs. noun modifier The first set is related to the difficulty of the left of Figure 3, where as we discussed the parser may be confused and attach "*Monday*" to "*John*" as a noun modifier since the POS sequence of "*John on Monday*" and the usual behavior of "*on*" are typical for a noun phrase. The right of Figure 3 shows the step where the parser must decide the head of "*Monday*"; here the correct action is shift and right-arc leads to the wrong analysis. At this step, though the important token for a typical NP is "*on*", we expect the parser to focus more on "*Monday*", which is likely to attach to a subsequent predicate as oblique.

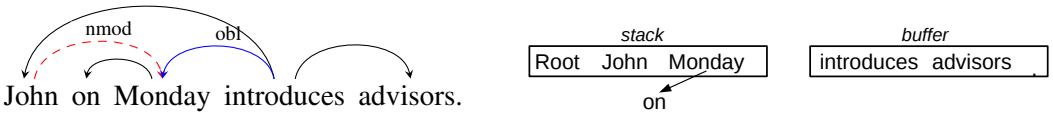

Figure 3: Left - An local ambiguous sentence, reprint of Figure 1. Right - The configuration on which the parser must decide whether "*Monday*" works as an oblique or a modifier.

To inspect the model's ability for correctly handling these ambiguities, we prepare 14 pairs of sentences.[4] Each pair differs minimally, as in "*John on Monday introduces advisors*" and "*John on a balcony introduces advisors*", in which the former should be analyzed as oblique (obl) while the latter as a modifier (nmod). Table 2 contrasts the inputs to parsers when gold preprocessing is given, where the differences always appear at third and forth tokens ("*Monday*" in obl vs. "*a*" and "*balcony*" in nmod). All words in these items occur at least one in the training corpus, therefore no unknown words are used.

	1	2	3	4	5	6	7
obl	John	on	Monday		introduces	advisors	.
	PROPN	ADP	PROPN		VERB	NOUN	PUNCT
	NNP	IN	NNP		VBZ	NNS	.

nmod	John	on	a	balcony	introduces	advisors	.
	PROPN	ADP	DET	NOUN	VERB	NOUN	PUNCT
	NNP	IN	DT	NN	VBZ	NNS	.
	Sing	_	Ind	Sing	Ind	Plur	_

Table 2: Minimal pair in oblique ("*John on Monday introduces advisors*") vs. noun modifier ("*John on a balcony introduces advisors*") experiment

The result is summarized in Table 3, where we count the number of sentences on which the parser outputs are perfect. We can see that nmod sentences are analyzed near perfectly, which is intuitive as this structure is typical. obl sentences are more difficult, but the system with attention is capable of handling them. The other systems fail, even assuming gold tags. For pred tags, all systems receive the same inputs tagged by UDPipe. The accuracy for obl decreases, and we find the errors are due to incorrect POS tags for the predicate at 5th word, which are sometimes tagged as a noun. This suggests our attention parser can handle these local ambiguities unless a crucial tag error occurs, while the other systems cannot at all.

Finally, we show in Figure 4 the attention weights on features at a branching step (The right of Figure 3) for the sample sentences in Table 2. We can see that for the obl sentence the parser attends more

[4] All items are shown in Appendix A.

	Gold tags		Pred tags	
	obl	nmod	obl	nmod
UDPipe	0 / 14	14 / 14	0 / 14	13 / 14
w/o Att.	0 / 14	14 / 14	0 / 14	13 / 14
w/ Att.	**12** / 14	14 / 14	**6** / 14	13 / 14

Table 3: # of correct analysis for obl vs. nmod pairs.

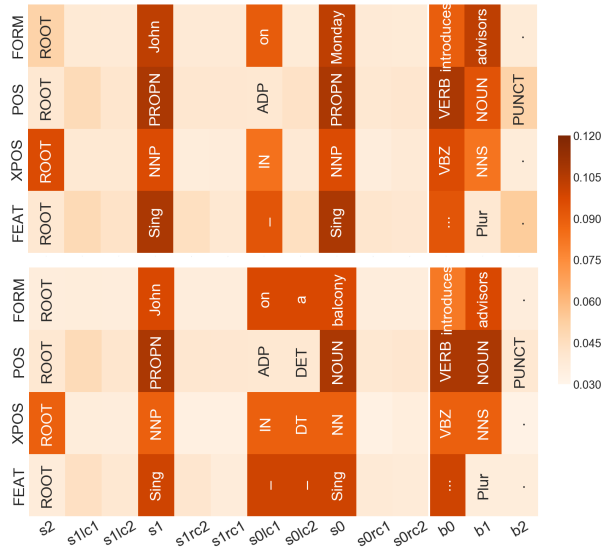

Figure 4: Attention weights on obl sentence (above) and nmod sentence (below). s_i and b_i are the i-th top-most position on the stack and buffer, respectively. lc_i and rc_i are their (inward) i-th left and right child.

on the key tokens of "*Monday*" on the stack and "*introduces*" on the buffer. This suggests the attention mechanism works as we expected and its behavior matches our intuition.

Object complement vs. that clause The second set is about different ambiguities from the previous experiment; an example pair is shown in the left of Figure 5, where to correctly parse the lower one, the parser must recognize the implicit that clause (that), rather than an object-complement (oc). The right of the figure shows the configuration on which the parser must choose the structure, by shift or right-arc. The key token for correct analysis is at the last, which can be accessed as the second token on the buffer.

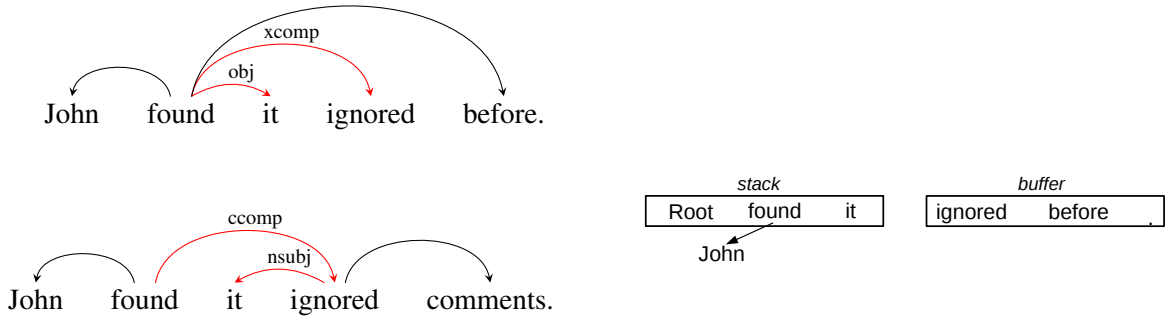

Figure 5: The representative pair for the second set: object-complement (left above) vs. that clause (left below) and the branching configuration (right).

We prepare 24 pairs of sentences. Table 4 shows an example of differences of a pair. In these sentences, tokens from third to fifth differ. Note that contrary to Table 2 these two condition are distinctive with

POS tags (e.g., VBN or VBD), so the main challenge is whether the model can attend to the key tokens when the predicted noisy tags are used.

	1	2	3	4	5	6
oc	John	found	it	ignored	before	.
	PROPN	VERB	PRON	VERB	ADV	PUNCT
	NNP	VBD	PRP	VBN	RB	.
	Sing	Ind	Acc	Past	_	_
that	John	found	it	ignored	comments	.
	PROPN	VERB	PRON	VERB	NOUN	PUNCT
	NNP	VBD	PRP	VBD	NNS	.
	Sing	Ind	Nom	Ind	Plur	_

Table 4: Minimal pair in object-complement ("*John found it ignored before*") vs. that-clause experiment ("*John found it ignored comments*")

Table 5 summarizes the results. As we expected, all systems succeed with gold tags, but perform badly in particular on that sentences, with predicted tags. Inspecting errors, we find that this is due to error propagation from an incorrect tag for *it* (3rd token), on which UDPipe assigns Acc(suative) feature due to that-omission. By this error, another error is induced on the POS tag of the next token (e.g., *ignored*), which becomes participle or adjective. These erroneous tags make it hard for parsers to recognize an implicit *that*.

Though all models fail, we notice that for 30% of sentences (7/24), our attention parser recognizes the existence of that-clause, by wrongly analyzing the last noun (e.g., comments) as the head of the clause (*it* becomes nsubj of the noun). Inspecting the attention weights for succeeded and failed cases (Figure 6), we find the last noun is slightly attended more in the succeeded case (above), which may lead the parser to predict a ccomp arc (but to a wrong word).

	Gold tags		Pred tags	
	oc	that	oc	that
UDPipe	23 / 24	24 / 24	19 / 24	0 (0) / 24
w/o Att.	24 / 24	24 / 24	16 / 24	1 (2) / 24
w/ Att.	23 / 24	24 / 24	18 / 24	1 (7) / 24

Table 5: # of correct sentences for oc vs. that. Numbers in brackets mean the cases where that-omission is correctly predicted but other errors exist (see body).

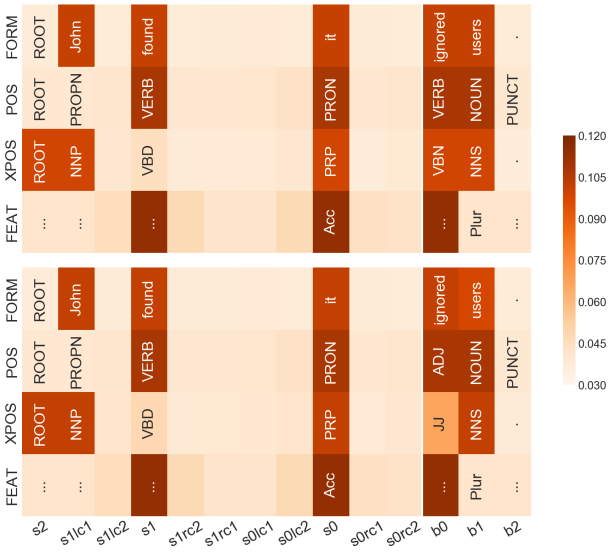

Figure 6: Attention weights on that sentences when that-omission is predicted (above) or failed (below).

4 Conclusion

We have presented an simple attention mechanism for dynamic feature selection, which can be applied to any feed-forward networks on concatenated feature embeddings. When applying to an incremental parser, the parser performance increased across many languages. Also our augmented-data experiment showed that the parser successfully learns where to focus on each context, and becomes more robust to erroneously tagged sentences.

Abstract

Neural sequence-to-sequence models have been successfully extended for summary generation. However, existing frameworks generate a single summary for a given input and do not tune the summaries towards any additional constraints/preferences. Such a tunable framework is desirable to account for linguistic preferences of the specific audience who will consume the summary. In this paper, we propose a neural framework to generate summaries constrained to vocabulary-defined linguistic preferences of a target audience. The proposed method accounts for the generation context by tuning the summary words at the time of generation. Our evaluations indicate that the proposed approach tunes summaries to the target vocabulary while still maintaining a superior summary quality against a state-of-the-art word embedding based lexical substitution algorithm, suggesting the feasibility of the proposed approach. We demonstrate two applications of the proposed approach - to generate understandable summaries with simpler words, and readable summaries with shorter words.

1 Introduction

Automatic text summarization (Nenkova and McKeown, 2011) is the task of generating summaries of an input document while retaining the important points. These summaries are used for presenting the most relevant and important information in a long text in a succinct form. They are useful in places where a quick consumption of the information in a long article is preferred. Earlier works in summarization select sentences/textual units from the input article and put them together into an "extractive" summary. However, humans summarize an article by understanding the content and paraphrasing the understood content into the desired summary. Therefore, extractive summarization is unable to produce "human-like" summaries. This has led to efforts towards "abstractive" summarization which paraphrases summaries the input article. Several models have been proposed, with the most recent ones based on neural networks.

Often, it is desirable to tune the summaries to the linguistic preferences of the readers. For example, a medical report may contain a lot of technical jargon beyond the understanding of the common population. When such a report is consumed by a patient, it makes sense to use lesser jargon to suit a patient's knowledge level. Similarly, while reading articles, teenagers would prefer more informal and trendy words, while older people might like a more formal vocabulary. Summaries which are tuned to such "linguistic" preferences of the target population segment are likely to appeal better and catch their attention.

A standard approach to incorporate vocabulary tuning would be to post-process a generated summary to achieve the desired goal by replacing a few words (e.g. replacing words with their simpler alternatives). However, such an approach might not preserve the context and hence can result in a complete change in the meaning of the content. Consider the sentence *"The baseball **pitcher** was seen with a **pitcher** of beer in his hand."* The word *pitcher* means different things in its two occurrences here. The sentence can be rephrased as *"The baseball **player** was seen with a **jug** of beer in his hand."* Since *pitcher* can mean both *player* and *jug* in two independent senses, it is not easy to decide the right replacement without looking

Proceedings of the 27th International Conference on Computational Linguistics, pages 795–805
Santa Fe, New Mexico, USA, August 20-26, 2018.

at the respective context. Post-processing based approaches lose the contextual information from the source article once the summary has been constructed. This is because the algorithm only sees the short snippet of text (summary), and not the large source article. This is a lost opportunity to utilize all that contextual information to make better word substitutions.

In this paper, we propose a neural network based summary generator that generates summaries imposing the desired vocabulary preferences while also maintaining the context and meaning of the content. Neural network based summarizers encode the entire source article, and generate the summary word-by-word. They are trained to predict the next word in a summary given the words in the summary generated so far, as well as the encoded article. This will allow the network to better judge which words will fit in context at any position in the sentence. In our proposed approach, we modify the generation probability of the next word in accordance with the vocabulary-based preferences. A key advantage of the proposed approach is that it does not require re-training a neural network, and relies on modifying the summary generation procedure on a pre-trained network.

2 Related Work

Traditional methods for summarization (Nenkova and McKeown, 2011) extract key sentences from the source text to construct the summary based on various features like descriptiveness of words, word frequencies, etc. Early attempts at abstractive summarization created summary sentences based on templates (Wang and Cardie, 2013; Genest and Lapalme, 2011) or used ILP-based sentence compression to collect parts from various sentences to generate the summary (Filippova, 2010; Berg-Kirkpatrick et al., 2011; Banerjee et al., 2015).

With the advent of deep sequence to sequence networks (Sutskever et al., 2014), attention based models have been proposed for summarizing long sentences (Rush et al., 2015; Chopra et al., 2016). Gulcehre et al. (2016) incorporated the ability to copy out-of-vocabulary words from the article to incorporate rarely seen words like names in the generated text. Tu et al. (2016) included the concept of coverage, to prevent the models from repeating the same phrases while generating a sentence. See et al. (2017) proposed a summarization model which incorporates these improvements, and also learns to switch between generating new words and copying words from the source article. We use this summarization framework as the starting point for our work. However, none of the existing works attempt to tune the summaries to suit preferences of a reader.

One naive way to solve this problem could be to impose the preferences after the summary generation as a post-processing step. As we will show later, this can result in out-of-context replacements while tuning. The words can be substituted based on a standard thesaurus (Bott et al., 2012) using one of the synonyms of the target word. However, since a word can be used in multiple senses, not all of its synonyms can be used in its place, and therefore such an approach is prone to errors. We address these challenges in the proposed approach by optimizing for the vocabulary preferences at the time of summary generation by looking for potential replacements in the synonyms weighted by their contribution to the context (computed from the attention models). As we will show later, such an approach generates better quality summaries and reduces substitution errors.

Lexical substitution deals with deciding textual substitutions that will preserve the meaning and grammatical correctness of the sentence by modeling the overall sentence context and using it for word substitutions. Early methods used co-occurrence statistics of the possible substitutions and the context words to predict whether a substitution is valid in a given context (Szarvas et al., 2013).

Melamud et al. (2015) use the proximity of words in an embedding space to measure the appropriateness of a candidate substitution to replace the target word. They use the embeddings of the dependency relations (De Marneffe and Manning, 2008) of the target word in the same embedding space called 'context embeddings'. The cosine similarity between the embedding of a candidate substitution with embeddings of these dependency relations along with the target was shown to improve substitution performance. Roller and Erk (2016) extended this work further by incorporating a linear transformation of the context embeddings and learning the parameters of the transformation to rank possible substitutions.

These methods work on the hypothesis that words closer to the target word in the embedding space are

its viable replacements. We believe that this hypothesis might not always hold. While it is true that the proximity of word embeddings of two words implies their usage in similar contexts (similar neighboring words or dependency relations), two different words having opposite meanings can also occur nearby in the word embedding space. For example, *good* and *bad* have very close embeddings in the space trained on the Google News corpus[1] by Mikolov et al. (2013), because both are adjectives and used around similar contexts. In this embedding space, the cosine similarity between *good* and *bad* is 0.72, whereas similarity between *good* and *wonderful* is 0.57. However, replacing good with bad will certainly change the meaning of the sentence and despite having a lower similarity, *wonderful* is the better substitute in most cases. Our method does not suffer from such incorrect substitutions because we couple the information from a thesaurus with the contextual information from the neural decoder to generate the summary by picking the appropriate words. We show that compared to contextual word vectors, the neural decoder is able to capture the context better and so our method generates better summaries.

Another related line of work is **text adaptation** which deals with modification of the textual content to suit the needs of a particular audience segment. Text simplification (Paetzold and Specia, 2015; Paetzold and Specia, 2016) is a popular variant of text adaptation where the objective is to modify text to have simpler words so that it is easier to comprehend. Linguistic personalization is another variant of the problem which looks at modifying messages to suit a target segment's linguistic style (Roy et al., 2015). However, all these approaches adapt the text as a post-processing task, and hence do not account for the context with which the text was generated. Our proposed approach is generic and can be extended to address these variants of text adaptation while accounting for the context of generation. In particular, we show the application to the tasks of text simplification and text readability enhancement.

3 Summary Generation with Vocabulary Tuning (VoTing)

Given an input text article as a sequence of n tokens $A = a_1, a_2, ..., a_n$, a vocabulary $V = \{w_1, w_2, ..., w_k\}$ of words with scores indicating the preference of each word given by $q : V \rightarrow \mathbb{R}^+$, the objective is to generate a summary as a sequence of tokens $S = s_1, s_2, ..., s_m$ tuned to the preferences indicated by the vocabulary while preserving the contextual sense.

We extend the **pointer generator network** by See et al. (2017) to generate the summary in a word-by-word fashion. At each step, the algorithm runs a trained decoder neural network to output the probability of each word $w \in V$ being the next generated word. This generation probability of any word is also an indicator of its contextual appropriateness in the current generation.

Our primary contribution in this paper is a **modified decoding algorithm** to incorporate vocabulary preferences. At each decoding step of the trained neural network, instead of adding the word w having the highest generation probability to the summary, we tune it by replacing it with a better preferred word that is also contextually appropriate. We take all synonyms of w and score their contextual appropriateness based on their generation probabilities. We combine the contextual appropriateness with the "vocabulary" scores of the synonyms based on the vocabulary metric q (e.g. simplicity) to select the contextually best candidate that is preferred in the vocabulary, and append it to the summary. Iteratively repeating this builds the complete summary.

3.1 Pointer Generator Network

For the sake of completeness and introducing the notations, we first give an overview of the pointer generator architecture (See et al., 2017) before introducing our vocabulary tuning approach in Section 3.2. The pointer generator network consists of an encoder and a decoder, both based on LSTM architecture. Given an input article, the encoder takes the word embedding vectors of the source text $A = a_1 a_2 ... a_n$ and computes a sequence of encoder hidden states $h_1, h_2, ..h_n$. The final hidden state is passed to a decoder. The decoder computes a hidden state s_t at each decoding time step, and an attention distribution a^t is over all words in the source text,

$$e_i^t = v^T \tanh(W_h h_i + W_s s_t + b_{att});\ a^t = \text{softmax}(e^t) \quad (1)$$

[1]Pretrained word embeddings available at `https://code.google.com/archive/p/word2vec/`

where v, W_h, W_s and b_{att} are trained model parameters. The attention model is a probability distribution over the words in the source text, which aids the decoder in generating the next word in the summary using words with higher attention. The context vector h_t^* is a weighted sum of the encoder hidden states and is used to determine the next word that is to be generated.

$$h_t^* = \sum_{i=1}^{n} a_i^t h_i, \tag{2}$$

At each decoding time step, the decoder uses the last word y_t in the summary generated so far and computes a scalar p_{gen} denoting the probability of the network generating a new word from the vocabulary.

$$p_{gen} = \sigma(w_h^T h_t^* + w_s^T s_t + w_y^T y_t + b_{gen}) \tag{3}$$

where w_h, w_s, w_y, b_{gen} are trained vectors. The network probabilistically decides based on p_{gen}, whether to generate a new word from the vocabulary or copy a word from the source text using the attention distribution. For each word w in the vocabulary, the model calculates $P_{vocab}(w)$, the probability of the word getting newly generated next. P_{vocab} is calculated by passing a concatenation s_t and h_t^* through a linear transformation with softmax activation. On the other hand, for each word w' in the input article, its total attention received yields its probability of being copied. The total probability of w being the next word generated in the summary, denoted by $\mathbf{p}$ is given by,

$$\mathbf{p}(w) = p_{gen} P_{vocab}(w) + (1 - p_{gen}) \sum_{i:w_i=w} a_i^t \tag{4}$$

The second term allows the framework to choose a word to copy from the input text using the attention distribution. For our experiments, we utilized the model trained using back-propagation and the Adagrad gradient descent algorithm (Duchi et al., 2011).

3.2 Vocabulary Tuning (VoTing)

We assume that there exists a scoring function $q(w)$ that computes a quality/preference score of a word w in the target vocabulary. The preference can be along different criteria like simplicity, readability, commonality etc. There have been several approaches explored (Paetzold and Specia, 2015) to compute such a score for a target corpus/vocabulary, e.g. normalized word counts in the target vocabulary. Our primary contribution is a method to integrate such preference scores with the generation process for tuning the generated summary.

We encourage the decoder to pick a different word w' in place of w if it has a higher preference score and similar contextual appropriateness ($\mathbf{p}()$). To preserve the meaning in the generation, we restrict the possible replacements to synonyms of w, $w' \in Syn(w)$, where $Syn(w)$ represents the set of synonyms of w. Since the replacement is done to tune the summary to the target vocabulary, it implicitly attempts to maximize the aggregated quality/preference score of the generated summary. We therefore, define the probability of replacement $p(w'|w)$ to be non-zero only when the new word(w') has a higher quality/preference score than the old one(w). We calculate $p(w'|w)$ for each pair of words (w', w) in the vocabulary which is given by,

$$p(w'|w) = \begin{cases} \frac{q(w')}{N(w)} & \text{if } q(w') \geq q(w) \text{ and } w' \in Syn(w) \\ 0 & \text{otherwise} \end{cases} ; \text{ where } N(w) = \sum_{q(w'') \geq q(w), w'' \in Syn(w)} q(w'')$$

$p(w'|w)$ can be seen as the replacement affinities for a word w with respect to other words in the vocabulary. Whenever the decoder adds a token w (the token with the highest generation probability from the network) to the summary, we calculate,

$$w_{tuned} = \underset{w':p(w'|w)>0}{\arg\max} \hat{\mathbf{p}}(w') p(w'|w) \tag{5}$$

$$\hat{\mathbf{p}}(w') = \frac{e^{(\ln \mathbf{p}(w'))/r}}{\sum_{\bar{w}:p(\bar{w}|w)>0} e^{(\ln \mathbf{p}(\bar{w}))/r}} \tag{6}$$

where $\mathbf{p}$ is the distribution from the network in the latest time step, which contains the generation probabilities for each word in the vocabulary. This is an indicator of the current contextual appropriateness of the words in the vocabulary. The vocabulary preferences from $p(w'|w)$ is thus combined with the contextual appropriateness from $\hat{\mathbf{p}}(w')$ (a function of $\mathbf{p}$). The token w_{tuned} thus obtained from Eq. 5 is added to the tuned summary by replacing w. Eq. 6 (inspired by the softmax activation function with temperature often used in reinforcement learning (Sutton and Barto, 1998)) includes a replacement strength parameter r that can be used to tune the replacement levels for the algorithm. The value of r is always kept positive.

When r is close to 0, the distribution of $\hat{\mathbf{p}}(w')$ is more peaked and the value of $\hat{\mathbf{p}}(w')$ is almost 1 for the w' having highest $\mathbf{p}(w')$ and almost 0 for others. Hence $w_{tuned} = \arg\max_{w'} \mathbf{p}(w')$, and there are no replacements to tune for vocabulary. As r increases to 1, we see more replacements. When r goes much higher than 1, $\hat{\mathbf{p}}(w')$ tend to be almost same across all w'. Hence, the output would depend more on the target vocabulary preferences $p(w'|w)$, leading to more aggressive replacements at the cost of contextual appropriateness.

The proposed decoder has a better understanding of context because of the awareness of past words produced in the summary. Besides, attention based decoding has been shown to generate new words while preserving context, like generating the word *beat* by paying attention to words like *victorious* and *win* from the source text of an article about a football match (See et al., 2017). This suggests that there are high probabilities of generation for novel synonyms which can actually be used in the summary while preserving context.

As we will show later in our experiments in Section 4.2, the source article itself might have more than one word appropriate for a given context, which can be used by the decoder. For example, an article about "crime" can have both words - *inexplicable* and *mysterious*. Since generation probabilities of the pointer generator network are influenced partly by its tendency of copying words from source text, these words have a high probability of generation($\mathbf{p}()$). Now if our algorithm has to choose an alternative word for *inexplicable*, it is more likely to generate *mysterious* (if it is better suited for the target vocabulary), because of its higher generation probability than other synonyms of *inexplicable* which are not in the text and may or may not be usable in the given context.

4 Experiments

The proposed approach can be used in applications where the audience's linguistic preference can be quantified. Here, we evaluate the framework on two such applications: enhancing **text simplicity** and enhancing **text readability** of generated summaries. In the former experiment, our objective is to generate a "simple" summary that contains more commonly used words. In the latter, we adapt the summary to use shorter words thereby making it more readable. In both applications, we test the proposed framework against several baselines that are described below.

Pointer-Generator Summary (PGS): These are the summaries generated by the vanilla pointer-generator network (See et al., 2017) without any optimization for vocabulary. Note that the proposed algorithm is aimed at producing summaries with comparable quality to this vanilla generator and better tuned to the vocabulary.

Non-Contextual Post-processed Summary (NCP): Here, we replace a given word with its synonym which has the highest score. All replacements are carried out after the summaries have been generated by the network. Note that this does not consider the context for the summary generation.

Contextual Word Embedding (CWE): This method is based on the hypothesis that cosine similarities in the word/dependency embedding space capture the extent to which a word can contextually replace another as proposed by Melamud et al. (2015). Given a target word t to be replaced in a sentence, $\mathbf{p}(w'|t)$ defines a measure of the appropriateness of the word w' replacing t. If t has m dependency relations $r_1, r_2, ...r_m$ with words $w_1, w_2, .., w_m$, then $\mathbf{p}(w'|t)$ is given by,

$$\mathbf{p}(w'|t) = \frac{1}{2m}(m\langle v(w'), v(t)\rangle + \sum_{i=1}^{m}\langle v(w'), v(r_i, w_i)\rangle) \tag{7}$$

where, $v(w)$ is the embedding vector for word w and $v(r_i, w_i)$ is the embedding vector for a dependency in the same embedding space. We extend this towards our problem by replacing each word w by w_{CWE} in the generated summary S based on,

$$w_{\text{CWE}} = \underset{w':p(w'|w)>0}{\arg\max}\ \hat{\mathbf{p}}(w'|w)p(w'|w) \tag{8}$$

We define $\hat{\mathbf{p}}(w'|w)$ similar to our formulation in Eq. 6 as,

$$\hat{\mathbf{p}}(w'|w) = \frac{e^{\mathbf{p}(w'|w)/r}}{\sum\limits_{\bar{w}:p(\bar{w}|w)>0} e^{\mathbf{p}(\bar{w}|w)/r}} \tag{9}$$

where r is the replacement strength parameter. To enhance the overall quality of replacements and for unbiased comparisons, all compared approaches were set to not replace stopwords.

4.1 Dataset & Evaluation Metric

We use the CNN/Daily Mail dataset (Hermann et al., 2015; Nallapati et al., 2016) which consists of $312,084$ news articles from the CNN and Daily Mail news websites, together with multi-line human-written summaries. The dataset consists of $287,226$ article-summary training pairs, $13,368$ validation pairs and $11,490$ test pairs.

Besides measuring the degree to which the vocabulary has been tuned, we also use **ROUGE** scores (Lin, 2004) to calculate the degree of similarity between the algorithmically generated summary and a human generated summary in terms of overlap of unigrams (ROUGE-1), bi-grams (ROUGE-2) and longest common subsequence (ROUGE-L).

4.2 Simplified Summary Generation

Our first experiment focuses on simplified summary generation. Simplification aims at rewording given text to make it simpler to understand for an audience. Existing works in simplification (Paetzold and Specia, 2015; Paetzold and Specia, 2016) break down the problem into a pipeline with multiple steps: complex word identification, substitution generation, substitution selection and substitution ranking. The generation of possible substitutions can be done in many ways (Paetzold and Specia, 2015), some of which leverage dictionaries (Yamamoto, 2013), while others leverage learned substitutions from a parallel corpus (Horn et al., 2014). However, Paetzold and Specia (2016) found that using nearest neighbors in word2vec embedding space leads to better performance in substitution generation. The substitution selection part is also responsible for ensuring the contextual appropriateness of the new word. The ranking of words is typically based on the frequency of words in a standard simple corpus. The hypothesis here, is that amongst the words with the same meaning, the ones which are used frequently are simpler.

Following existing works, we set the score $q(w)$ of a word w to be its frequency in the SUBLTEX corpus (Brysbaert and New, 2009) and tune the summary generation. We measure the simplicity of a summary S based on the simplicity score defined as,

$$\text{Simplicity}(S) = \frac{1}{m}\sum_{i=1}^{m}\frac{f(s_i)}{1000}, \tag{10}$$

where $f(s_i)$ is the frequency of the i^{th} word of the summary in the SUBTLEX corpus.

Table 1(a) shows the performance of various methods across different metrics. For CWE and Voting, we tune r to yield a comparable simplicity score and report the other metrics for this setting.The NCP method achieves the highest simplicity score at the cost of the summary quality as shown by low ROUGE scores. A higher number of replacements will decrease the ROUGE scores if the newly introduced replacements are out of context and therefore unlikely to be in the ground truth summary. We observed that NCP replaces 18.429 words per summary (across the 11490 test set) in this experiment where the average summary length is 57.436 words. In contrast, CWE replaces 2.082 words and VoTing replaces

Table 1: Performance of the proposed approach against existing baselines

(a) Simplified Summary

Metric	PGS	NCP	VoTing	CWE
rouge-1 F-score	0.3880	0.2940	0.3790	0.3771
rouge-2 F-score	0.1679	0.0799	0.1563	0.1552
rouge-L F-score	0.3569	0.2706	0.3482	0.3466
Simplicity score	9.67	28.05	12.51	12.35

(b) Readable Summary

Metric	PGS	NCP	VoTing	CWE
rouge-1 F-score	0.3880	0.2724	0.3810	0.3802
rouge-2 F-score	0.1679	0.0693	0.1593	0.1593
rouge-L F-score	0.3569	0.2525	0.3504	0.3498
Reading ease	59.23	80.90	64.15	64.12

2.231 words per summary. Despite VoTing replacing more words (around 2000 more words in total), it manages to score higher on the ROUGE scores suggesting that the new words introduced still keep the summary closer to ground truth while simultaneously increasing the desired vocabulary score (which is the simplicity in this case). Table 2 shows the choices made by our proposed approach towards summary generation using simpler words from the source article.

Table 2: Simplified summaries where our method picks up simpler words, highlighted in boldface, from the source article. Baseline summaries used the words given in parantheses instead

Article: hong kong (cnn) six people were **hurt** after an explosion (...) *Summary:* (...) five out of six people were **hurt** (injured) by broken glass (...)
Article: (cnn) five americans who were monitored for three weeks at an omaha , nebraska , hospital after being exposed to ebola in west africa have been **released**, (...) *Summary:* one of the five had a heart-related issue on saturday and has been **released** (discharged).(...)
Article: (...)"it is shameful that so many states around the **world** are essentially playing with people's lives (...) *Summary:* (...) china is also mentioned , as having used the death penalty as a punitive measure across the **world** (globe).
Article: (...) but corliss was not afraid to puncture hype around **big** movies he found overrated, including "titanic" (...) *Summary:* richard corliss died a week after suffering a **big** (major) stroke. (...)

Table 3(a) shows the summaries generated on one of the articles by these methods. We can see that NCP over-replaces words leading to loss of meaning. For example, it replaces the word *march* (which refers to a month here) by *move* since move is a valid synonym of one of the senses of the replaced word (e.g. *"The army contingent marched towards the fortress."*). VoTing makes fewer replacements which seem to be in context, like replacing *mom* with *ma* and *reversed* with *turned*. CWE replaces *mom* by *grandmother* which leads to factual incorrectness.

Our formulation in VoTing and CWE allows to control the strength of replacement in the algorithm (Eq. 6 and Eq. 9). Higher strength increases the simplicity score but at the cost of reduced ROUGE. To better compare VoTing and CWE, we must look at the quality of summaries for different levels of simplicity desired in the output. We show these in Figure 1(a). It is observed that VoTing is able to achieve higher ROUGE for any given level of simplicity.

4.3 Readable summary generation

In our next experiment, we focus on readable summary generation. To make text more readable, it is advisable to use words with fewer syllables (Kincaid et al., 1975). Kincaid et al. (1975) define the Flesch reading ease to quantify readability. Text which scores high on the Flesch reading ease can be understood more easily by students of lower grade levels (Flesch, 1979). The Flesch reading ease of a summary S is given by,

$$206.835 - 1.015\frac{\text{total words}}{\text{total sentences}} - 84.6\frac{\text{total syllables}}{\text{total words}}$$

To generate more readable summaries, we run VoTing with higher scores given to shorter words, as they are likely to have fewer syllables. Here, $q(w)$ is set to be the inverse of the length of the word w. This encourages the algorithm to use shorter words while generating summaries.

Here again, we tune r for VoTing and CWE to yield a comparable reading ease and report the other metrics for this setting. Table 1(b) shows the performance of different algorithms. Our method achieves comparable ROUGE to CWE, indicating that we achieve the target without compromising on the quality.

Table 3(b) shows some sample outputs for an article. NCP replaces most words with their shortest synonyms leading to complete loss of meaning. CWE makes fewer substitutions which are more appro-

Table 3: Summaries generated by different methods on a sample article. Changed words from the baseline are highlighted in boldface

(a) Simple Summary	(b) Readble Summary
Article: Facebook has admitted it made a mistake when a photo of an Alabama boy who was born without a nose was removed from the social media website because it was deemed to be too controversial. The photo of Timothy Eli Thompson that was removed when a pro-life group posted an ad about the infant's story have since been reinstated. (...)	*Article:* A Paratrooper who braved heavy Taliban fire to rescue a wounded comrade received the Victoria Cross from the Queen yesterday. But in fact the 27-year-old is the second member of his family to receive the highest military decoration for valour a cousin was given the honour 70 years ago (...)
Baseline summary: timothy eli thompson was born without a nose in march in alabama and his mom put his photo on facebook .facebook reversed its decision after public protest and admitted it made a mistake .facebook reversed its decision after public protest .	*Baseline summary:* the 27-year-old is the second member of his family to receive the highest military decoration for valour .it is just the sixth time the queen has given a vc to a living british recipient during the afghanistan campaign but the other two awards were made posthumously .in 2013 he braved heavy gunfire from 20 taliban insurgents in helmand to rush to the aid of a wounded us marine .
VoTing: timothy eli thompson was born without a nose in march in alabama and his **ma** put his photo on facebook . facebook **turned** its decision after public protest and admitted it made a mistake . facebook reversed its decision after public protest .	*VoTing:* the 27-year-old is the second member of his family to **get** the **top** military decoration for valour . it is just the sixth time the queen has given a vc to a living british recipient during the afghanistan campaign but the other two awards were made posthumously . in 2013 he braved heavy gunfire from 20 taliban insurgents in helmand to rush to the aid of a wounded us marine .
CWE: timothy eli thompson was born without a nose in march in alabama and his **grandmother** put his photo on facebook . facebook reversed its decision after public protest and admitted it made a mistake . facebook reversed its decision after public protest .	*CWE:* the 27-year-old is the second member of his family to **get** the highest military decoration for valour . it is just the sixth time the queen has given a vc to a living british recipient during the afghanistan campaign but the other two awards were made posthumously . in 2013 he braved heavy gunfire from 20 taliban insurgents in helmand to rush to the aid of a wounded us marine .
NCP: timothy eli thompson was born **out** a nose in **move** in alabama and his **ma** put his **picture** on facebook . facebook **turned** its **end** after **open question** and **take** it made a **fault** . facebook **turned** its **end** after **open question** .	*NCP:* the 27-year-old is the **twin cut** of his **clan** to **cop** the **top army garnish** for valour . it is just the sixth **go** the **ruler** has **apt** a vc to a **warm** british **heir** during the afghanistan **push** but the other **dos gift** were made posthumously . in 2013 he **firm fat salvo** from 20 taliban **radical** in helmand to **flux** to the aid of a **hurt** us **sea** .

priate like replacing *receive* by *get*. VoTing makes the same replacement and also replaces *highest* by *top* - suggesting that our approach performs more tuning without compromising on the overall quality.

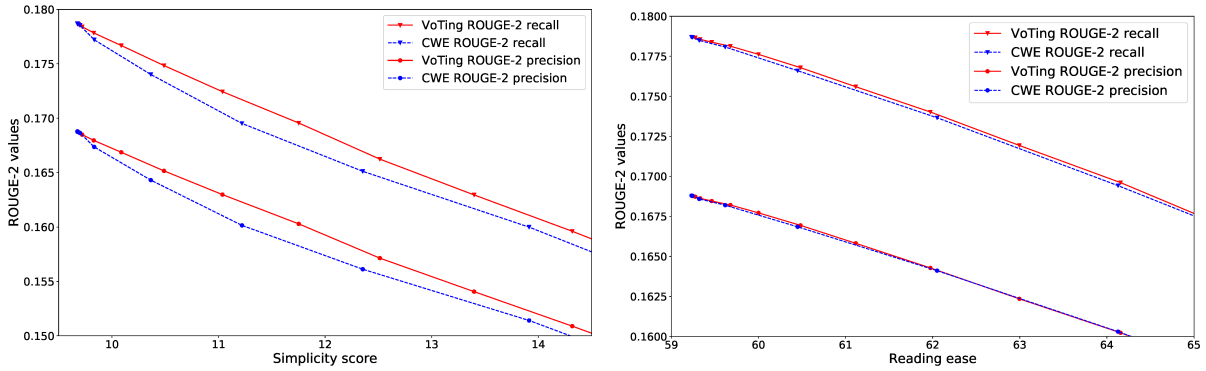
Varying the replacement strength parameter, we find that VoTing again has higher ROUGE-2 scores across different levels of reading ease. This can be seen in Figure 1(b) indicating better contextual tuning by the proposed approach across different reading ease.

4.4 Human evaluation of contextual appropriateness of VoTing

While the level of improvement in the vocabulary tuning achieved in a summary can be measured by using various scores, the contextual appropriateness of the new words added is better judged by humans. We, therefore, conducted a survey, where each annotator was shown the ground truth summary generated by PGS along with the tuned summaries from the three methods - NCP, CWE and VoTing. The annotators were asked to rank the outputs of the three methods according to the extent to which it preserves the meaning of the original summary generated by PGS. The three tuned summaries were shown in random order to remove any positional bias. We used the summaries from 20 randomly chosen articles from the test set for the survey. Each set of summaries was annotated by 4 or 5 different annotators. We had a total of 90 human annotated rankings.

We used the Condorcet fusion (Montague and Aslam, 2002) to aggregate the rankings, which looks at pairwise comparisions between the methods. The results are shown in Table 4, which indicates that VoTing performs the best, beating CWE in 61.11% of responses, and NCP clearly performs the worst. The Krippendorff's alpha (Krippendorff, 2011) for inter-annotator agreement was 0.84 indicating high inter-annotator agreement.

After establishing the comparative superiority of VoTing, we proceeded to objectively analyze the degree to which these three methods preserved the meaning of the original summary. We ran another



(a) Simple Summary

(b) Readable Summary

Figure 1: CWE vs Voting for different simplicity and reading ease levels. ROUGE-2 precision and recall are shown for different levels of tuning achieved.

Table 4: Pairwise comparison of human rankings of different methods. Each row signifies the fraction of times the corresponding method was ranked higher than the method corresponding to the column.

	CWE	**VoTing**	**NCP**
CWE	-	0.3889	0.9667
VoTing	0.6111	-	0.9778
NCP	0.0333	0.0222	-

human evaluation where we showed human raters the summaries from the three methods in random order and asked them to rate the three on a scale of 1 to 5 according to the descriptions given in Table 5, on the extent to which they preserve the meaning of the PGS generated summary. VoTing received an average rating of 3.47 against 3.36 for CWE and 1.83 for NCP, further confirming the contextual appropriateness of the proposed tuning.

Table 5: Description shown to human annotators for ratings on the contextual appropriateness scale

Rating value	**Description**
5	Perfectly captures the original meaning
4	Mostly preserves the meaning
3	Understandably close to the original meaning
2	Changes the meaning by a little bit
1	Completely changes the meaning

5 Conclusions and Future work

We proposed a novel approach to generate summaries of articles while incorporating vocabulary preferences. We showed the application of our algorithm to text simplification and text readability enhancement. We showed that tuning the vocabulary during summary generation leads to fewer out-of-context replacements than post-processing a generated summary. Our findings also suggest that LSTM-based decoders of pointer-generator networks are capable of preserving the local context better than word embeddings trained on vast corpora.

Our current work is limited to replacing words with better synonyms. However, introduction of new words can benefit tuning the generation towards a specific aspect or tone. For example, "Pass me that plate." can be changed to "*Please* pass me that plate." to make it sound more formal. Rephrasing a sequence of words instead of replacing one word at a time or changing the structure of a sentence are other ways to make it suit a target audience's preference. The ability of LSTM based decoders to carry out such transformations is a subject for further explorations.

Reading Comprehension with Graph-based Temporal-Casual Reasoning

Yawei Sun, Gong Cheng, Yuzhong Qu

Abstract

Complex questions in reading comprehension tasks require integrating information from multiple sentences. In this work, to answer such questions involving temporal and causal relations, we generate event graphs from text based on dependencies, and rank answers by aligning event graphs. In particular, the alignments are constrained by graph-based reasoning to ensure temporal and causal agreement. Our focused approach self-adaptively complements existing solutions; it is automatically triggered only when applicable. Experiments on RACE and MCTest show that state-of-the-art methods are notably improved by using our approach as an add-on.

1 Introduction

The task of *reading comprehension* has received wide attention from the research community. A machine's ability to understand natural language is tested by answering multiple-choice questions based on a given passage (Hirschman et al., 1999), as illustrated in Fig. 1. State-of-the-art methods have achieved encouraging results on simple factoid questions, but still, it is a challenge to answer a complex question that requires extracting information from more than one sentence in the passage. Typical examples are those *involving temporal or causal relations* spanning multiple sentences (Sugawara et al., 2017; Trischler et al., 2016), like Questions 1 and 2 in Fig. 1. They constitute a considerable proportion of the questions in popular datasets like MCTest (Richardson et al., 2013) and RACE (Lai et al., 2017).

To integrate multiple sentences for answering a complex question, various techniques have emerged, but many of them ignore the semantic relations between sentences (Wang et al., 2016) or superficially use a sliding window scanning over the words of the passage without sentence breaks (Smith et al., 2015; Trischler et al., 2016). To meet the challenge, we *explicitly model the event structure of the passage by a graph representing temporal and causal relations between events* extracted from the passage. Representing a candidate answer in a similar way, we align the two graphs subject to temporal and causal agreement which is verified by *graph-based reasoning*, and rank candidate answers by their degrees of alignment. Our approach, called Graph-based Temporal-Casual Reasoning (GTCR) which focuses on temporal and casual questions, can be used as *an effective add-on to other methods*.

Our research contribution in this paper is threefold.

- To answer complex questions in reading comprehension tasks, we represent the passage and each candidate answer by an event graph to explicitly model temporal and causal relations, which are crucial to the understanding and integration of multiple sentences for answering questions. We generate event graphs from text based on dependencies produced by an off-the-shelf parser, thereby benefiting from methodological progress and tools on dependency parsing.
- To score a candidate answer, we align it with the passage using their event graphs. In an alignment, event matching is constrained by temporal and causal agreement, for which graph-based event reasoning is performed. The alignment problem is formulated and solved using linear programming.

Proceedings of the 27th International Conference on Computational Linguistics, pages 806–817
Santa Fe, New Mexico, USA, August 20-26, 2018.

Passage: Susan held a birthday party. She made a big cake, and hung up some balloons. Meanwhile, her parents bought chocolate ice creams because she enjoyed it. Soon, her friends showed up. Then, Susan hugged her friends. Each friend had a present for Susan. Therefore, Susan was happy and sent each friend a thank you card. So, her friends were happy, too.

Question 1: What did Susan do before her friends came out?
(A) Susan bought ice cream. (B) Susan hung up balloons. (C) Susan hugged her friends. (D) Susan sent friends thank you cards.

Question 2: Why did Susan send out thank you cards to her friends?
(A) Her friends love her. (B) Her friends brought her gifts at the party. (C) Her friends was happy. (D) Her friends came late.

Figure 1: A passage and two questions for reading comprehension.

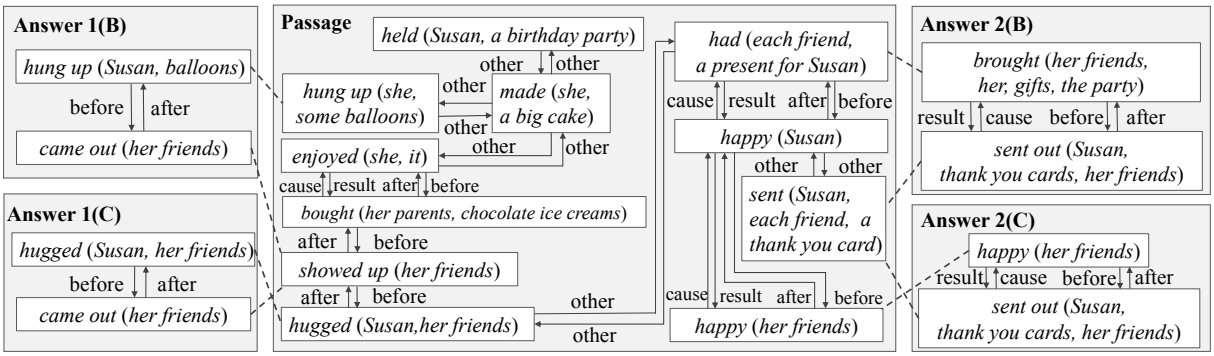

Figure 2: An event graph for the passage and four event graphs for question-answer combinations.

- By automatically detecting question type and determining confidence in scores, our self-adaptive approach is triggered only when appropriate, to enhance existing methods as an add-on. A notable improvement on the state of the art is observed in the experiments on RACE and MCTest.

The paper is structured as follows. Section 2 overviews our approach. Sections 3 and 4 describe event graph generation and alignment, respectively. Section 5 combines our approach with existing methods. Section 6 reports experiments. Section 7 compares related work. Section 8 concludes the paper.

2 Overview of the Approach

Our pipelined GTCR approach is outlined in Fig. 3. The passage is transformed into an event graph called the passage graph. The question and each candidate answer are combined and transformed into an event graph called a QA graph. The two graphs are aligned, and the degree of alignment is assigned as the score of the answer.

2.1 Event Graph Generation

The passage is transformed into an event graph, called the passage graph, representing temporal and causal relations between events extracted from the passage. The transformation firstly recognizes events from each sentence and extracts intra-sentence relations, and then merges the results based on inter-sentence relations. We will define event graph in Section 3.1 and elaborate its generation in Section 3.2.

The question and each candidate answer are combined and transformed in a similar way into an event graph, called a QA graph. We will elaborate this step in Section 3.3.

Example 1 *The passage in Fig. 1 is transformed into the passage graph in Fig. 2. Four out of the eight candidate answers in Fig. 1 are combined with questions and transformed into four QA graphs in Fig. 2.*

2.2 Event Graph Alignment

The passage graph and the QA graph for each candidate answer are aligned. The degree of alignment, which is the maximum sum of the degrees of match between aligned events, is assigned as the score of the answer. Alignment is constrained by the agreement in temporal and causal relations between events, which is verified by graph-based reasoning. We will elaborate this step in Section 4.

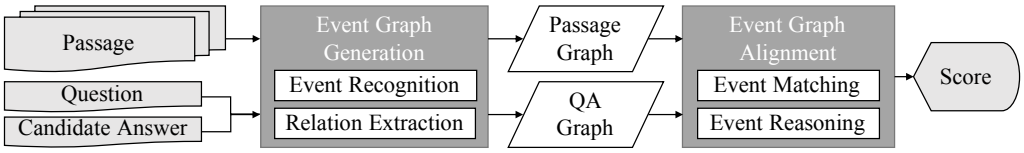

Figure 3: Overview of the GTCR approach.

Example 2 *Dashed lines in Fig. 2 represent exact matches between events, where the alignments for answers 1(C) and 2(C) violate temporal and causal agreement, respectively, thereby being infeasible. The degrees of other (unshown) possible alignments for these answers are not large. Therefore, they are likely to be incorrect answers.*

3 Event Graph Generation

Event graph is a core concept in our approach. In this section we present its definition and detail its generation from the passage. We also describe how to generate an event graph in a similar way from the combination of the question and each candidate answer.

3.1 Event Graph

Definition 1 (Event Graph) *An event graph is a directed multi-graph where vertices represent events which are connected by arcs representing temporal or causal relations between events.*

It is a multi-graph which is permitted to have multiple arcs between two vertices, e.g., both a temporal relation and a causal relation between two events, as illustrated in Fig. 2.

Definition 2 (Event) *An event consists of a predicate and its arguments (Jurafsky and Martin, 2009), and has three attributes (Pustejovsky et al., 2003; Bar-Haim et al., 2015), namely* `aspect` $\in$ $\{$`perfective`, `none`$\}$, `modality` $\in$ $\{$`modal`, `none`$\}$, *and* `polarity` $\in$ $\{$`positive`, `negative`$\}$.

Definition 3 (Relations between Events) *We consider three types of relations.*

Temporal Relation. *An event u can happen* before *another event v, represented by an arc from u to v labeled with* `before`*, and an arc from v to u labeled with* `after`.

Causal Relation. *An event u can* cause *another event v, represented by an arc from u to v labeled with* `result`*, and an arc from v to u labeled with* `cause`.

Other Relation. *We also allow an unspecified relation between two events, represented by a pair of inverted arcs labeled with* `other`.

3.2 Passage Graph Generation

To generate an event graph from the passage, called the *passage graph*, we recognize events from sentences, extract intra-sentence relations to form a local event graph for each sentence, and finally extract inter-sentence relations to merge local event graphs into a global event graph.

3.2.1 Event Recognition

Predicate and Arguments To recognize the predicate and arguments which identify an event, we extend a dependency-based method (Rudinger and Van Durme, 2014). In particular, we consider *embedded events*. Given a dependency relation `ccomp` or `xcomp` whose head is the predicate of an embedding event u and whose dependent is the predicate of an embedded event v, we remove v and assign its predicate and arguments to u's arguments. For example, consider the sentence *Hannah's mother explained that they were moving to Kenya.* The embedded event *moving* is removed; its predicate and arguments, namely *moving* and $\{$*they*, *Kenya*$\}$, become the arguments of the embedding event *explained*.

Attributes To recognize the attributes of an event, we extend a heuristic method (Bar-Haim et al., 2015) which focuses on the attribute `polarity`, and define the following heuristics for recognizing `aspect` and `modality` of an event u based on dependencies.

- Given a dependency relation `aux` whose head is the predicate of u and is POS-tagged with VBN, and whose dependent's lemma is *have*, we have u.`aspect` = `perfective`.
- Given a dependency relation `aux` whose head is the predicate of u and whose dependent is a modal verb (e.g., *will*, *should*), we have u.`modality` = `modal`.

Example 3 *Consider the sentence* Meanwhile, her parents bought chocolate ice creams because she enjoyed it. *As shown in Fig. 2, two events with predicates* bought *and* enjoyed *are recognized. The arguments of* bought *consist of* her parents *and* chocolate ice creams. *The arguments of* enjoyed *consist of* she *and* it. *There is no particular attribute to recognize, so all the three attributes of these events take their default values, i.e.,* `aspect` = `none`, `modality` = `none`, *and* `polarity` = `positive`.

3.2.2 Intra-sentence Relation Extraction

We observe that within a sentence where two or more events are recognized, their relations are usually explicitly indicated by a few syntactic patterns. We define a mapping from dependency patterns to relations as shown in Table 1. Note that some polysemous patterns (e.g., those involving *so*) can give rise to multiple relations. The result is a local event graph generated from each sentence.

Relation	Dependency Pattern
$u \xrightarrow{\texttt{before}} v$ and $u \xleftarrow{\texttt{after}} v$	(i) $u \xrightarrow{\texttt{advcl}} v_{(\texttt{modality=none})} \xrightarrow{\texttt{mark\|advmod}}$ *before|until|till|so|so-that* (ii) $v_{(\texttt{modality=none})} \xrightarrow{\texttt{advcl}} u \xrightarrow{\texttt{mark\|advmod}}$ *after|since|because|for|as* (iii) $v_{(\texttt{modality=none})} \xleftarrow{\texttt{conj}} u \xrightarrow{\texttt{cc}}$ *so*
$u \xrightarrow{\texttt{result}} v$ and $u \xleftarrow{\texttt{cause}} v$	(iv) $u \xrightarrow{\texttt{advcl}} v \xrightarrow{\texttt{mark\|advmod}}$ *so|so-that* (v) $v \xrightarrow{\texttt{advcl}} u \xrightarrow{\texttt{mark\|advmod}}$ *because|for|as* (vi) $v \xleftarrow{\texttt{conj}} u \xrightarrow{\texttt{cc}}$ *so*
$u \xrightarrow{\texttt{other}} v$ and $u \xleftarrow{\texttt{other}} v$	other cases

Table 1: Extraction of intra-sentence relations between two events u and v.

Example 4 *Consider two events* bought *and* enjoyed *recognized in the sentence* Meanwhile, her parents bought chocolate ice creams because she enjoyed it. *Here, two dependency patterns (ii) and (v) in Table 1 are matched, and hence both a temporal relation and a causal relation are extracted, as shown in Fig. 2.*

Example 5 *Consider two events* made *and* hung up *recognized in the sentence* She made a big cake, and hung up some balloons. *An other relation is extracted here, as shown in Fig. 2.*

3.2.3 Inter-sentence Relation Extraction

We extract relations between adjacent sentences, in order to merge local event graphs into a global event graph. For two adjacent sentences, an *exit event* u and an *entrance event* v are selected from the former sentence and the latter sentence, respectively; then relations between u and v are extracted.

Event Selection In the local event graph representing the former sentence, the exit event is one that has `before` or `result` as an incoming arc but never as an outgoing arc. If none of the events in the sentence satisfies this condition, the one that involves the root of the dependency tree (called the *root event*) will be specified as the exit event. Similarly, in the local event graph representing the latter sentence, the entrance event is one that has `before` or `result` as an outgoing arc but never as an incoming arc.

Relation Extraction Having determined the exit event u in the former sentence and the entrance event v in the latter sentence, their relations are extracted in the following way.

- We reuse the set of connective adverbs listed by Lin et al. (2014), and identify two (overlapping) classes: a temporal relation (i.e., $u \xrightarrow{\texttt{before}} v$ and $u \xleftarrow{\texttt{after}} v$) is extracted given *later*, *next*, etc.; or a causal relation (i.e., $u \xrightarrow{\texttt{result}} v$ and $u \xleftarrow{\texttt{cause}} v$) is extracted given *hence*, *therefore*, etc.

- In particular, when $v.\texttt{aspect} = \texttt{perfective}$, a temporal relation in the reverse direction (i.e., $v \xrightarrow{\texttt{before}} u$ and $v \xleftarrow{\texttt{after}} u$) is heuristically extracted.

- In other cases, an other relation (i.e., $u \xrightarrow{\texttt{other}} v$ and $u \xleftarrow{\texttt{other}} v$) is extracted.

Example 6 *Consider two adjacent sentences* Each friend had a present for Susan. Therefore, Susan was happy and sent each friend a thank you card. *The exit event of the former sentence is* had*, and the entrance event of the latter sentence is* happy. *According to the connective adverb* therefore*, both a temporal relation and a causal relation between the two events are extracted, as shown in Fig. 2.*

3.3 QA Graph Generation

We also generate an event graph from the combination of the question q and each candidate answer ans, called a *QA graph*. When q is a fill-in-the-blank question, this QA graph is generated by firstly replacing the blank in q with ans to form a complete text, and then following the method described in Section 3.2 to generate an event graph from this text.

When q is a *wh*-question, we firstly generate an event graph G_q from q using the method described in Section 3.2, and then insert ans into G_q. Here, we differentiate between two types of *wh*-questions.

- For a *why*-question, ans is normally a complete sentence, from which an event graph G_{ans} is generated using the method described in Section 3.2. G_{ans} and G_q are merged by connecting their root events via a causal and a temporal relation, as illustrated by answers 2(B) and 2(C) in Fig. 2.

- For a non-*why*-question, the argument in G_q that contains the interrogative word is replaced by ans. For an exceptional case where ans is a complete sentence and the predicate of the root event in G_q is a general verb like *do* or *happen*, we generate an event graph G_{ans} from ans using the method described in Section 3.2, and then merge G_{ans} and G_q by replacing the event involving the interrogative word in G_q with the root event in G_{ans}, as illustrated by answers 1(B) and 1(C) in Fig. 2.

4 Event Graph Alignment

The degree of alignment between the passage graph G_p and the QA graph G_{qa} for each candidate answer ans is assigned as the score of ans. In this section we formulate and solve the alignment problem, which maximizes event matching and is constrained by graph-based event reasoning.

4.1 Problem Formulation

We define the *degree of alignment* between G_p and G_{qa} as the maximum sum of the degrees of match between aligned events in G_p and G_{qa}, which is formulated as a variant of the maximum weighted bipartite matching problem, which in turn is a special case of a 0-1 linear program.

Specifically, let V_p and V_{qa} be the events in G_p and G_{qa}, respectively. For $u \in V_p$ and $v \in V_{qa}$, let $\texttt{dom}(u, v)$ be the degree of match between u and v, which will be detailed in Section 4.2. The score of ans, i.e., the degree of alignment between G_p and G_{qa}, is given by

$$\begin{aligned} &\text{maximizing} \sum_{u \in V_p, v \in V_{qa}} \texttt{dom}(u, v) x_{uv} \\ &\text{subject to} \sum_{v \in V_{qa}} x_{uv} \leq 1 \text{ for } u \in V_p\,, \quad \sum_{u \in V_p} x_{uv} \leq 1 \text{ for } v \in V_{qa}\,, \\ &\qquad x_{uv} + x_{km} \leq 1 \text{ for } u, k \in V_p,\ v, m \in V_{qa},\ \texttt{conflict}(u, v, k, m) = 1\,, \\ &\qquad x_{uv} \in \{0, 1\} \text{ for } u \in V_p,\ v \in V_{qa}\,, \end{aligned} \tag{1}$$

where $x_{u,v}$ is a binary variable representing the alignment between u and v, taking value 1 if they are aligned, and $\texttt{conflict}(u, v, k, m)$ indicates whether two matches u-v and k-m lead to a conflict in terms of temporal or causal relations between events, which will be detailed in Section 4.3. We further normalize the score of ans by dividing it by the number of events in G_{qa}.

Note that as a special case, we will define the degree of alignment as one minus the above result if the `polarity` of the root event in the question is `negative`.

4.2 Event Matching

The degree of match between two events u and v, denoted by $\texttt{dom}(u, v)$, measures to what extent u and v refer to the same event. For example, each dashed line in Fig. 2 represents an exact match between two coreferential events. Our measure is a combination of element-level matching and word-level matching:

$$\texttt{dom}(u,v) = \begin{cases} \alpha \cdot \texttt{dom}_{\text{elem}}(u,v) + \beta \cdot \texttt{dom}_{\text{word}}(u,v) & \text{if } u.\texttt{polarity} = v.\texttt{polarity}, \\ 0 & \text{if } u.\texttt{polarity} \neq v.\texttt{polarity}, \end{cases} \tag{2}$$

where α, β are weights to be empirically tuned. Note that for two events having opposite values of `polarity`, their degree of match is simply fixed to 0.

Element-level Matching Let $\texttt{Elem}(u)$ be the set of *elements* of event u, consisting of the predicate and arguments of u. For two elements $e_i \in \texttt{Elem}(u)$ and $e_j \in \texttt{Elem}(v)$, we extend the method used by Li and Srikumar (2016) and define 16 features that calculate the similarity between e_i and e_j. Each feature ϕ returns a similarity value in the range of $[0, 1]$. Inspired by Yih et al. (2013), we calculate the overall similarity between e_i and e_j as follows:

$$\texttt{sim}(e_i, e_j) = \max_{\phi} w_\phi \cdot \phi(e_i, e_j)\,, \tag{3}$$

where ϕ is weighted by w_ϕ. The following features and weights are used.

- $w = 1.0$: exact string match, exact string match between roots of dependency trees, existence of trigram overlap, coreference, apposition, sharing synonyms in Wiktionary, sharing synonyms in WordNet, sharing derivations in WordNet, VerbOcean-based similarity;
- $w = 0.5$: Jaccard similarity of words, partial string match, existence of bigram overlap, cosine similarity of Word2vec embeddings, cosine similarity of GloVe embeddings, light-verb-to-verb match;
- $w = 0.1$: existence of unigram overlap.

With `sim` values for all e_i-e_j pairs in $\texttt{Elem}(u) \times \texttt{Elem}(v)$, we find a maximum weighted bipartite matching between $\texttt{Elem}(u)$ and $\texttt{Elem}(v)$, and assign the squared mean weight of this matching to $\texttt{dom}_{\text{elem}}(u, v)$.

Word-level Matching Complementary to element-level matching which relies on dependency-based argument recognition, we measure the degree of word-level match between u and v using a bag-of-words method (Sultan et al., 2016), and assign the result to $\texttt{dom}_{\text{word}}(u, v)$.

4.3 Event Reasoning

For events $u, k \in V_p$ and $v, m \in V_{qa}$, $\texttt{conflict}(u, v, k, m) = 1$ means if two matches u-v and k-m appear in the same alignment, a *conflict* in terms of temporal or causal relations will emerge; such an alignment is not allowed. We consider two types of conflicts by extending the idea in Berant et al. (2014).

Temporal Conflict There is a (directed simple) u-k path in G_p and a v-m path in G_{qa} such that `before` appears in one of them and `after` appears in the other.

Causal Conflict There is a u-k path in G_p and a v-m path in G_{qa} such that `result` appears in one of them and `cause` appears in the other.

For efficiency reasons, our implementation only checks paths that contain not more than 10 arcs.

Example 7 *The alignment represented by the dashed lines between the passage graph and the QA graph for answer 1(C) in Fig. 2 is not feasible due to the temporal conflict induced by the two matches. The alignment for answer 1(B) is feasible. Similarly, the alignment for answer 2(C) is not feasible due to a causal conflict, whereas the alignment for answer 2(B) is feasible.*

5 Combination with Other Methods

Our GTCR approach is specifically developed for temporal and causal questions. Reading comprehension tasks also involve other questions. Therefore, GTCR is to be combined with other methods.

We propose to let GTCR *self-adaptively enhance existing methods as an add-on*. Specifically, GTCR will answer a question only if it accepts the type of the question and is confident in the scores it generates. Otherwise, it will not answer the question, which in turn will be answered by an existing method. In this section we describe how to *automatically* detect question type and determine confidence in scores.

5.1 Question Type

Our current implementation of GTCR can process *wh*-questions and fill-in-the-blank questions. However, it only accepts temporal and causal questions. A temporal question, e.g., Question 1 in Fig. 1, is one that matches dependency patterns (i) or (ii) in Table 1, or in case there are errors in dependency parsing, matches the following POS-level regular expression: .*VB.+(*when*|*after*|*before*|*since*).+VB.*. A causal question, e.g., Question 2 in Fig. 1, is one that begins with *why*, or contains an adverbial clause fronted by *because* (which is common for fill-in-the-blank questions).

5.2 Confidence in Scores

As GTCR relies on the results of dependency parsing, it will not be confident in the scores it generates if it finds errors in the dependency tree of the question. Specifically, inspired by Petrov et al. (2010), our implementation detects five common types of errors in dependency parsing:

- `nsubj`: missing a subject in a question or clause,
- `aux`: placing an auxiliary verb as the root of the dependency tree,
- `dep`: associating `dep` with a subject,
- `acl:relcl`: accompanying `acl:relcl` which indicates a relative clause with a conjunction commonly fronting an adverbial clause (e.g., *when*), and
- `advcl`: missing core arguments (e.g., `nsubj`, `obj`) in an adverbial clause.

When dependency parsing seems correct, GTCR will still reject the question if the score of the answer it selects is below a threshold τ, which will be tuned in the experiments.

6 Experiments

6.1 Datasets

Experiments are performed on two standard datasets for reading comprehension: RACE and MCTest.

RACE (Lai et al., 2017) consists of nearly 28,000 passages and 100,000 questions collected from English exams for middle and high school Chinese students. In particular, 25.8% of these questions require multi-sentence reasoning, though not necessarily temporal or causal reasoning. For our experiments we use middle school data, denoted by RACE-M.

MCTest (Richardson et al., 2013) consists of 660 fictional stories as passages and 2,640 questions that a seven-year-old can understand. It is divided into MC160 where 160 stories have been manually curated for quality, and MC500 where 500 stories may have grammatical or other errors.

6.2 Competing/Collaborating Methods

For RACE we consider two state-of-the-art methods. Stanford Attentive-Reader (Stanford AR) (Chen et al., 2016) is a neural network system based on the Attentive-Reader model. Gated-Attention (GA) Reader (Dhingra et al., 2017) integrates a multi-hop architecture with an attention mechanism.

For MCTest we consider three state-of-the-art methods. Smith et al. (2015) propose a lexical matching method that takes into account multiple context windows, question types, and coreference resolution.

Narasimhan and Barzilay (2015) incorporate discourse information. Trischler et al. (2016) harness simple neural networks arranged in a parallel hierarchy.

Some other methods are not considered in our experiments because their codes or detailed results are not available at the time of experiment so that we could not test the combination of GTCR with them.

6.3 Our Approach

For our implementation of GTCR, we use Stanford CoreNLP (Manning et al., 2014) for dependency parsing and coreference resolution, and use Gurobi (www.gurobi.com) for solving linear programs.

Some parameters are tuned based on the development set in each dataset, which is separate from the test set. Specifically, for Eq. (2) we set $\alpha = \beta = 0.5$ for all the datasets. The confidence threshold τ used for combination with other methods is set to 0.00 for RACE, 0.71 for MC160, and 0.78 for MC500.

Our implementation is open source[1].

6.4 Results

We carry out two experiments. In the first experiment, GTCR *competes* with state-of-the-art methods on complex questions that require temporal or causal reasoning. In the second experiment, GTCR self-adaptively *collaborates* with those methods as an add-on, in order to advance the state of the art.

We measure the accuracy of each method, namely the proportion of correctly answered questions.

Competition On RACE-M, among the 1,436 test questions, 133 are recognized as temporal or causal questions according to question type detection in GTCR. Table 2 shows the accuracy of each method on these questions. Compared with competing methods, GTCR correctly answers 4–10% more of those questions.

On MCTest, among the 240 and 600 test questions in MC160 and MC500, 51 and 99 respectively are recognized as temporal or causal questions. After excluding 10 and 17 questions respectively having dependency errors and those on which GTCR is not confident, Table 3 shows the results on the remaining questions. GTCR notably outperforms competing methods on these questions.

Ablation To evaluate the effectiveness of our event matching and reasoning, we conduct an ablation study. As shown in Tables 2 and 3, the accuracy of our approach decreases by up to 19% and 6% when element-level and word-level event matching are disabled, respectively, showing that the two techniques

[1] http://ws.nju.edu.cn/qa/coling2018

are generally useful; only for one question in MC160, word-level matching has a negative effect. Without performing event reasoning, the accuracy decreases by 2% on RACE-M and by 13% on MC500, showing its usefulness. However, reasoning is not helpful on MC160.

Collaboration By self-adaptively collaborating with existing methods as an add-on, GTCR consistently enhances all the methods and improves the state of the art on both datasets. As shown in Table 4, the overall accuracy is increased by 0.35–0.91% on RACE-M. For MCTest in Table 5, the improvement is in the range of 0.41–0.84% on MC160, and 0.34–0.67% on MC500. On MC160 we do not add GTCR to Trischler et al. (2016) because at the time of experiment we did not obtain its details results.

6.5 Error Analysis and Discussion

In GTCR, errors may occur in event graph generation and event matching. We analyze the 78 questions in Tables 2 and 3 for which GTCR produces incorrect answers.

Event Graph Generation Although GTCR can automatically detect a few common types of errors in dependency parsing, other POS or dependency errors are still observed in the experiments, which lead to imprecise recognition of events and extraction of relations (18%). These errors are propagated along the pipeline framework of GTCR, which has the potential to be significantly improved by benefiting from future advances in dependency parsing.

Another drawback to GTCR is the use of syntactical methods for extracting explicit relations between events. Some temporal and causal relations are implicit, and hence are missing in our generated event graphs (31%). To identify those relations, commonsense knowledge is to be exploited.

Event Matching Event matching is closely related to paraphrasing. Our element-level and word-level matching in GTCR, though utilizing many linguistic resources, still fail to identify some coreferential events that are expressed differently (19%). It inspires us to integrate or develop more effective techniques for paraphrasing and textual entailment in future work.

Another disadvantage of GTCR is its limited expressivity of event alignment. We assume one-to-one event matching between event graphs, but in practice it is sometimes one-to-many (6%).

6.6 Running Time

On an Intel E3-1225v3 (3.2GHz), our approach uses 7.8 seconds, 6.5 seconds, and 7.0 seconds to process a question in RACE-M, MC160, and MC500, respectively, being reasonably fast. Most time is used for: retrieving external resources in element-level event matching, and identifying conflicting event matches in event graph alignment.

7 Related Work

7.1 Reading Comprehension

Many solutions to reading comprehension are learning-based. They either manually define and extract features for learning a model to predict the correct answer (Sachan et al., 2015; Smith et al., 2015; Wang et al., 2015; Sachan and Xing, 2016), or use deep learning with attention mechanisms (Hermann et al., 2015; Trischler et al., 2016; Wang et al., 2016; Chen et al., 2016; Chen et al., 2017; Cui et al., 2017; Dhingra et al., 2017; Samothrakis et al., 2017). These methods have achieved encouraging results on simple factoid questions, but are not optimized for complex questions that require integrating information from multiple sentences. By comparison, our approach is distinguished by the explicit representation and reasoning over temporal and causal relations between events which can span multiple sentences, therefore exactly targeting complex questions and featuring an explainable problem solving process. Due to its unsupervised nature, our approach can be rapidly deployed for a new domain or application.

We are not the first to address complex questions. Sachan and Xing (2016) leverage Abstract Meaning Representation (AMR) to construct graph representations and solve a graph containment problem, but they report that their method suffers from the lack of complex reasoning support (e.g., temporal, causal), which are provided in our approach. Narasimhan and Barzilay (2015) incorporate discourse information

into a discriminative framework with hidden variables that capture relevant sentences and their relations, which is different from our explicit representation of events and their relations extracted from text, and is inferior to our approach in the experiments. Berant et al. (2014) model the relations between events in a biological process using a graph representation, which is similar to our approach. However, to generate a graph, they train dedicated classifiers whereas we use dependencies produced by off-the-shelf parsers. Besides, for question answering, they simply use a few hand-crafted regular expressions over graphs whereas we more thoughtfully formulate and solve a maximum weighted bipartite matching problem.

7.2 Event Extraction

Event extraction has attracted considerable research attention (Pustejovsky et al., 2003; Ahn, 2006; Rudinger and Van Durme, 2014; Mostafazadeh et al., 2016; Mirza and Tonelli, 2016; Judea and Strube, 2016). We extend some of those existing methods (Rudinger and Van Durme, 2014) for event recognition. As to relation extraction, our rule-based method uses dependencies, whereas there are also learning-based solutions (Ahn, 2006; Chambers et al., 2007; Mirza and Tonelli, 2016). Although our focus is on the reading comprehension task, event extraction is at the core of our approach. Advances in this research area will be beneficial to the performance of our approach.

8 Conclusion

To answer complex questions in reading comprehension tasks, we generate event graphs from text for modeling temporal and causal relations spanning multiple sentences. With graph-based reasoning, our self-adaptive GTCR approach helps advance the state of the art on two standard datasets, showing the effectiveness and generalizability of the proposed technical contribution. Furthermore, this graph-based event representation and reasoning complies with human cognition, thereby being capable of not only answering a question but also providing a human-readable explanation. This will expand the scope of application, ranging from explainable question answering to interactive computer-aided education.

Many components of GTCR build upon the results of dependency parsing. Featuring an unsupervised framework, our proposed approach can be conveniently transferred to different domains and applications without the necessity of preparing dedicated training data. Besides, its performance will progress along with the improvement in off-the-shelf dependency parsers. However, as revealed by our post-experiment error analysis, there are still several other directions for improving and extending our approach, to turn it into a more effective add-on to other methods or even a powerful stand-alone solution.

Abstract

Domain adaptation for sentiment analysis is challenging due to the fact that supervised classifiers are very sensitive to changes in domain. The two most prominent approaches to this problem are structural correspondence learning and autoencoders. However, they either require long training times or suffer greatly on highly divergent domains. Inspired by recent advances in cross-lingual sentiment analysis, we provide a novel perspective and cast the domain adaptation problem as an embedding projection task. Our model takes as input two mono-domain embedding spaces and learns to project them to a bi-domain space, which is jointly optimized to (1) project across domains and to (2) predict sentiment. We perform domain adaptation experiments on 20 source-target domain pairs for sentiment classification and report novel state-of-the-art results on 11 domain pairs, including the Amazon domain adaptation datasets and SemEval 2013 and 2016 datasets. Our analysis shows that our model performs comparably to state-of-the-art approaches on domains that are similar, while performing significantly better on highly divergent domains. Our code is available at https://github.com/jbarnesspain/domain_blse

Title and Abstract in Basque

Domeinu-Egokitzapenerako Bektore Proiekzioa:
Domeinu Urrunetarako Sentimenduen Analisiko Eredu Bateratua

Sentimenduen analisirako domeinu-egokitzapena erronka handi bat da oraindik, domeinu arteko ezberdintasunek ondorio esanguratsuak izan baititzakete sailkatzaile gainbegiratuentzat. Arazo honi aurre egiteko bi hurbilpen arrakastatsuenak egiturazko kidetasunaren ikasketa (structural correspondence learning) eta autoencoder-ak dira. Hala ere, denbora asko behar dute sistema entrenatzeko edo, domeinu arteko distantzia handia denean, ez dituzte emaitza onak lortzen. Hizkuntza-arteko sentimenduen analisian egindako azken lanetan oinarrituta, ikuspuntu berri bat eskaintzen dugu, domeinuaren egokitzapen ataza bektore proiekzio ataza gisa planteatuta. Gure sistemaren sarrera domeinu banako bi bektore espazio dira, zeinak sistemak espazio berri batera proiektatzen ikasten duen. Sistema hau optimizatuta dago (1) domeinu batetik besterako proiekzioa egiteko eta (2) esaldi baten sentimendua aurresateko. 20 jatorri-xede domeinu pareetan esperimentuak burutu ditugu eta 11 kasutan artearen egoerako emaitzarik onenak lortzen ditugu Amazon-eko domeinu-egokitzapeneko eta SemEval 2013 eta 2016 datu-multzoetan. Gure analisian ikus daitekeenez, gure hurbilpena artearen egoerako sistemen pareko moldatzen da antzeko domeinuetan, baina emaitza hobeak lortzen ditu oso domeinu ezberdinetan. 1 Introduction

One of the main limitations of current approaches to sentiment analysis is that they are sensitive to differences in domain. This leads to classifiers that, after training, perform poorly on new domains (Pang and Lee, 2008; Deriu et al., 2017). Domain adaptation techniques provide a solution to reduce the discrepancy and enable models to perform well across multiple domains (Blitzer et al., 2007). The two main approaches to domain adaptation for sentiment analysis are *pivot-based methods* (Blitzer et al., 2007; Pan et al., 2010; Yu and Jiang, 2016), which augment the feature space with domain-independent features learned on unsupervised data, and *autoencoder* approaches (Glorot et al., 2011; Chen et al., 2012), which seek to create a good general mapping from a sentence to a latent hidden space. While pivot-based domain adaptation methods are well-motivated, they are often outperformed by autoencoder methods. However, both approaches to domain adaptation effectively lead to a loss of information, as they must reduce the effect of discriminant features which are domain-dependent. We argue in this paper that this leads to a decreased performance especially in cases where the similarity between the domains is low.

Unlike previous approaches, in this paper, we propose a domain adaptation approach based on lessons learned from cross-lingual sentiment analysis (Barnes et al., 2018). This approach maintains the domain-dependent features, while adapting them to the target domain. Following state-of-the-art approaches to create bilingual word embeddings (Mikolov et al., 2013; Artetxe et al., 2016; Artetxe et al., 2017), we learn to project a mapping from a source domain vector space to the target domain space, while jointly training a sentiment classifier for the source domain.

We show that our proposed model (1) performs comparably to state-of-the-art models when domains are similar and (2) outperforms state-of-the-art models significantly on divergent domains. We report novel state-of-the-art results on 11 domain pairs. We also contribute a detailed error analysis and compare the effect of different projection lexicons. Our code is available at `https://github.com/jbarnesspain/domain_blse`.

2 Related Work and Motivation

Domain adaptation is an omnipresent challenge in natural language processing. It has been applied for many tasks, such as part-of-speech tagging (Blitzer et al., 2006; Daume III, 2007), parsing (Blitzer et al., 2006; Finkel and Manning, 2009; McClosky et al., 2010), or named entity recognition (Daume III, 2007; Guo et al., 2009; Yu and Jiang, 2015). In the following, we limit our review to adaptation techniques which have been applied to sentiment analysis.

2.1 Pivot-based Approaches

Blitzer et al. (2006) propose *structural correspondence learning* (SCL), which introduces the concept of *pivots*. These are features that behave in the same way for discriminative learning for both domains, *e. g.*, *good* or *terrible* for sentiment analysis. The intuition is that non-pivot domain-dependent features, *e. g.*, *well-written* for the book domain or *reliable* for electronics, which are highly correlated to a pivot should be treated the same by a sentiment classifier.

Blitzer et al. (2007) extend their SCL approach to sentiment analysis and also create one of the benchmark datasets for domain adaptation in sentiment analysis. They crawl between 4000 and 7000 product reviews for each domain, and create balanced datasets of 1000 positive and 1000 negative reviews for four product types (books, DVD, electronics, and kitchen appliances). The remaining reviews serve as unlabeled training data for the SCL approach. For each pivot, they train a binary classifier to predict the existence of the pivot from non-pivot features. They then use these classifiers to create a domain-independent representation of the data. The concatenation of the original representation and the SCL representation are used to train a classifier.

Pan et al. (2010) also exploit the relationship between pivots and non-pivots to span the domain gap, but use a graph-based approach to cluster non-pivot features and augment the original feature space. Yu and Jiang (2016) learn sentence embeddings that are useful across domains through multi-task learning. They jointly train a convolutional recurrent neural network model to predict the sentiment of source domain sentences while at the same time predicting the presence of pivots. Finally, Ziser and Reichart

(2017) propose neural structural correspondence learning (NSCL), which marries SCL and autoencoder techniques by using a neural network to create a hidden representation of a text, and then using this representation to predict the existence of pivots.

NSCL is currently state of the art, but requires a careful choice of pivot features and extensive hyper-parameter search to achieve the best results.

2.2 Autoencoder Approaches

Glorot et al. (2011) adopt a deep learning approach for domain adaptation. They create lower-dimensional representations for their data through the use of *stacked denoising autoencoders* (SDA), which are trained to reconstruct the original sentence from a corrupted version. They then train a linear SVM on the original feature space augmented with the hidden representations obtained from the autoencoder.

Chen et al. (2012) extend this work by proposing *Marginalized Denoising Autoencoders* (MSDA), which are more scalable thanks to a series of linear transformations which are performed in closed-form, with the non-linearity being applied afterwards. This leads to a significant gain in speed, as well as the ability to include more features from the original representations. Autoencoder models perform better than earlier SCL models (excluding NSCL), but have the disadvantages of being less interpretable, requiring long training times, and only utilizing a small amount of the original feature space.

2.3 Domain Specific Word Representations

A third approach is to create word representations that provide useful features for multiple domains. He et al. (2011) propose a joint sentiment-topic model which uses pivots to change the topic-word Dirichlet priors. Bollegala et al. (2015) create domain-specific embeddings for pivots and non-pivots with the constraint that the pivot representations are similar across domains.

The work that is most similar to ours is that of Bollegala et al. (2014). Their method learns to predict differences in word distributions across domains by learning to project lower-dimensional SVD representations of documents across domains. Unlike our work, however, they learn the projection step separately from the classification. They also only learn to project the features that the two domains have in common, which implies discarding information useful for classification. These approaches, however, perform worse than MSDA and NSCL.

3 Projecting Representations

Our approach is motivated by previous success in learning to project embeddings across languages for cross-lingual sentiment analysis, namely *Bilingual Sentiment Embeddings* (Barnes et al., 2018, BLSE). The inputs for this model are (1) a monolingual embedding space for the source and target language, (2) a translation lexicon, and (3) an annotated sentiment corpus for the source language. It jointly learns to project the source and target vectors into a bilingual space and also to classify the sentiment of the sentences in the source corpus. At test time, the classifier is able to use the projected target words as features because they are optimized such that they resemble the source words.

In this work, we cast domain adaptation for sentiment analysis as a version of this cross-lingual adaptation in which the source and target domains have a large shared vocabulary. However, as is the case in domain adaptation, words do not necessarily have the same semantics across domains. Therefore, we will use the aforementioned projection model to learn a word-level projection from one domain to another, while jointly learning to classify the source domain. In the following, we detail the projection objective, the sentiment objective, and the full objective.

Cross-domain Projection

We assume that we have two precomputed vector spaces $S = \mathbb{R}^{v \times d}$ and $T = \mathbb{R}^{v' \times d'}$ for our source and target domains, where v (v') is the length of the source vocabulary (target vocabulary) and d (d') is the dimensionality of the embeddings. We also assume that we have a projection lexicon L of length n which consists of word-to-word pairs $L = \{(s_1, t_1), (s_2, t_2), \ldots, (s_n, t_n)\}$ which map from source to target domains. In this paper, we assume that the words map to themselves across domains, so that

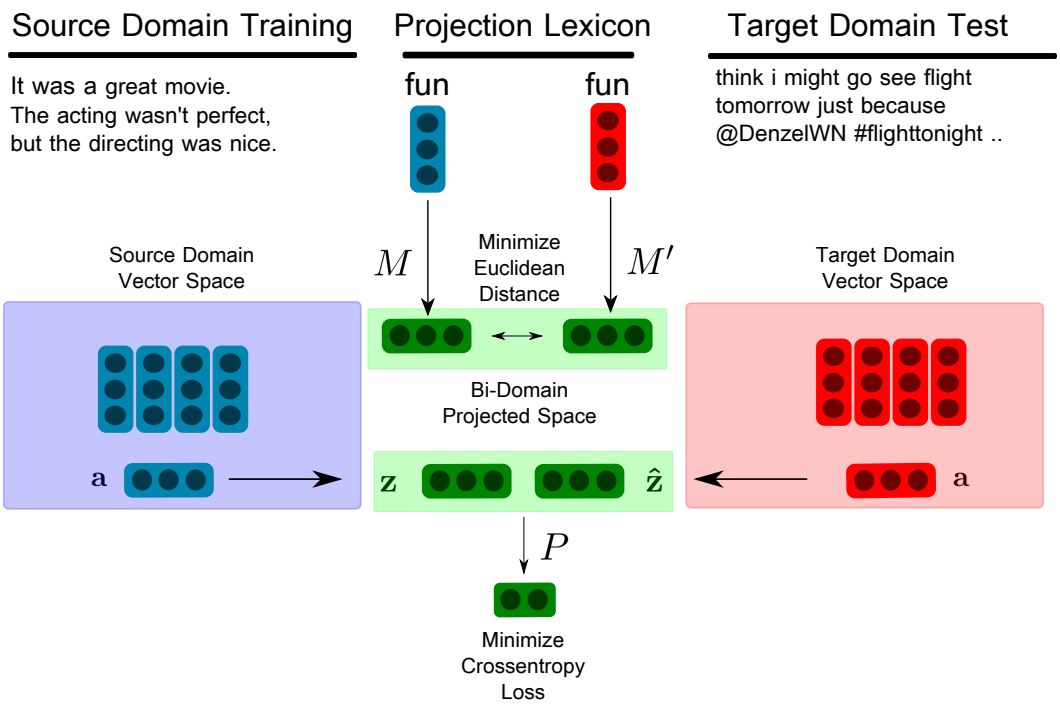

Figure 1: Embedding projection architecture.

$L = \{(s_1, s_1), (s_2, s_2), \ldots, (s_n, s_n)\}$, although other mapping lexicons are possible. One could imagine constructing a lexicon that maps concepts from one domain to those of another, *i. e.* "read" in the books domain and "watch" for movies.

In order to create a mapping from both original vector spaces S and T to shared sentiment-informed bi-domain spaces $\mathbf{z}$ and $\hat{\mathbf{z}}$, we employ two linear projection matrices, M and M'. During training, for each translation pair in L, we first look up their associated vectors, project them through their associated projection matrix and finally minimize the mean squared error of the two projected vectors. This is very similar to the approach taken by Mikolov et al. (2013), but includes an additional target projection matrix.

The projection quality is ensured by minimizing the mean squared error[1]

$$\text{MSE} = \frac{1}{n}\sum_{i=1}^{n}(\mathbf{z_i} - \hat{\mathbf{z}}_\mathbf{i})^2\,, \tag{1}$$

where $\mathbf{z_i} = S_{s_i} \cdot M$ is the dot product of the embedding for source word s_i and the source projection matrix and $\hat{\mathbf{z}}_\mathbf{i} = T_{t_i} \cdot M'$ is the same for the target word t_i and target matrix M'.

The intuition for including this second matrix is that a single projection matrix does not support the transfer of sentiment information from the source domain to the target domain. Although this term is degenerate by itself, when coupled with the sentiment objective, it allows the model to learn to project to a sentiment-aware target language space.

Sentiment Classification

We add a second training objective to optimize the projected source vectors to predict the sentiment of source phrases. This inevitably changes the projection characteristics of the matrix M and consequently M', which encourages M' to learn to predict sentiment without any training examples in the target domain.

To train M to predict sentiment, we require a source-domain corpus $C_{\text{source}} = \{(x_1, y_1), (x_2, y_2), \ldots, (x_i, y_i)\}$ where each sentence x_i is associated with a label y_i.

For classification, we use a multi-layer feed-forward architecture. For a sentence x_i, we take the word embeddings from the source embedding S and average them to $\mathbf{a}_i \in \mathbb{R}^d$. We then project this vector to

[1]We omit parameters in equations for better readability.

Table 1: Statistics for the Amazon corpora (books, DVD, electronics, kitchen), as well as the SemEval 2013 and 2016 message classification tasks (S13 and S16 respectively). * For the Amazon corpora, we test on the entire target domain corpora.

the joint bi-domain space $\mathbf{z}_i = \mathbf{a}_i \cdot M$. Finally, we pass $\mathbf{z}_i$ through a softmax layer P to get our prediction $\hat{y}_i = \text{softmax}(\mathbf{z}_i \cdot P)$.

To train our model to predict sentiment, we minimize the cross-entropy error of our predictions

$$H = -\sum_{i=1}^{n} y_i \log \hat{y}_i - (1 - y_i) \log(1 - \hat{y}_i)\,. \tag{2}$$

Joint Learning

In order to jointly train both the projection component and the sentiment component, we combine the two loss functions to optimize the parameter matrices M, M', and P by

$$J = \sum_{(x,y) \in C_{\text{source}}} \sum_{(s,t) \in L} \alpha H(x, y) + (1 - \alpha) \cdot \text{MSE}(s, t)\,, \tag{3}$$

where α is a hyperparameter that weights sentiment loss vs. projection loss.

Target-domain Classification

For inference, we classify sentences from a target-domain corpus C_{target}. As in the training procedure, for each sentence, we take the word embeddings from the target embeddings T and average them to $\mathbf{a}_i \in \mathbb{R}^d$. We then project this vector to the joint space $\hat{\mathbf{z}}_i = \mathbf{a}_i \cdot M'$. Finally, we pass $\hat{\mathbf{z}}_i$ through a softmax layer P to get our prediction $\hat{y}_i = \text{softmax}(\hat{\mathbf{z}}_i \cdot P)$.

4 Experiments

We compare our method with two adaptive baselines and one non-adaptive version. We describe the six evaluation corpora in Section 4.1 and the baselines in Section 4.3.

4.1 Datasets

4.1.1 Amazon Corpora

In order to evaluate our proposed method, we use the corpus collected by Blitzer et al. (2007), which consists of Amazon product reviews from four domains: books (B), DVD (D), electronics (E), and kitchen (K). Each subcorpus contains a balanced labeled subset, with 1000 positive and 1000 negative reviews, as well as a much larger set of unlabeled reviews. We use the standard split of 1600 reviews from each domain as training data and the remaining 400 reviews as validation data. For testing, we use all of the 2000 reviews from the target domain (Ziser and Reichart, 2017).

We take the unlabeled data from each domain to create the domain embeddings for our method, as well as to train the domain independent representations for the NSCL and MSDA methods. In order to create embeddings for the Amazon corpora, we concatenate all of the unlabeled data from all domains. The statistics for this corpus are given in Table 1.

4.1.2 SemEval Corpora

Sentiment analysis of Twitter data is common nowadays, with several popular shared tasks organized on the topic (Nakov et al., 2013; Villena-Román et al., 2013; Basile et al., 2014; Nakov et al., 2016, *i. a.*). In order to evaluate how well domain adaptation techniques perform on large domain gaps, we also use the message polarity classification corpora provided by the organizers of SemEval 2013 and 2016 (Nakov et al., 2013; Nakov et al., 2016). We will refer to these as S13 and S16, respectively. These contain tweets which have been annotated for positive, negative, and neutral sentiment. We remove neutral tweets, giving us a binary setup which allows compatibility with the Amazon corpora. The statistics for these corpora are given in Table 1.

4.2 Embeddings

For BLSE, we create mono-domain embeddings using the Word2Vec toolkit[2] by training skip-gram embeddings with 300 dimensions, subsampling of 10^{-4}, window of 5, negative sampling of 15 on the concatenation of the unlabeled Amazon corpora. We also create Twitter-specific embeddings by training on nearly 8 million tokens taken from tweets collected using various hashtags. The parameters were the same as those used to create the Amazon embeddings. For out-of-vocabulary words, a vector initialized randomly between -0.25 and 0.25 approximates the variance of the pretrained vectors.

4.3 Baselines and Model

Domain transfer for sentiment analysis has been widely studied on the Amazon sentiment domain corpus. However, we hypothesize that progress previous approaches have made on this particular corpus may not hold when tested on more divergent domains. Therefore, we compare two state-of-the-art approaches on the Amazon corpus with our method, as well as a standard non-adaptive baseline.

NOAD is a non-adaptive approach which uses a bag-of-words representation from each review as features for a linear SVM.

MSDA is the original implementation of marginalized Stacked Denoising Autoencoders (Chen et al., 2012), one of the state-of-the-art domain adaptation methods on the Amazon sentiment domain corpus. The approach learns a latent hidden representation of the data, which is then concatenated to the original feature space. For our experiments, we use the 30000 most common uni- and bi-grams as features and take the top 5000 features as pivots (Chen et al., 2012). We tune the corruption level (0.5, 0.6, 0.7, 0.8, 0.9) and the C-parameter for the SVM classifier on the source domain validation data, but leave the number of layers at 5.

NSCL is an approach that marries both the pivot-based methods and autoencoders. Specifically, we use the original implementation[3] of the Autoencoder SCL with similarity regularization, which we refer to as NSCL. This approach substitutes the reconstruction weights of the autoencoder with a matrix of the pre-trained word embeddings of pivots. This enables the model to generalize beyond boolean features. We set the hyper-parameters for training the autoencoders with stochastic gradient descent to those from the original paper[4] and tune the number of pivots (100, 200, 300, 400, 500), dimensionality of the hidden layer (100, 300, 500), and C-parameter for logistic regression on the source domain validation data (400 reviews).

BLSE is our approach based on cross-domain vector projection. We use the domain-specific word embeddings to initialize our model and following the embedding literature, we take the most common 20,000 words in the concatenated corpora as a projection dictionary (see Section 5.3). We tune the hyper-parameters training epochs, alpha (0.1–0.9), and batch sizes (20–500) on the source domain validation data.

4.4 Results

Tables 2 and 3 present the results of our experiments. In order to compare with previous work, we report accuracy scores for the balanced Amazon corpora. Because the SemEval corpora are highly imbalanced,

we instead present macro F_1 scores. We introduce the notation X→Y, where X is the train corpus and Y is the test corpus, to indicate the domain pairs.

On the Amazon corpora, Table 2, NSCL outperforms the other approaches (3.6 percentage points (pp) in F_1 on average compared to BLSE, 2.5 pp compared to MSDA, and 5.1 pp compared to NOAD). BLSE only performs better than NSCL on three setups (DVD to books, electronics to DVD, and kitchen to DVD) and MSDA on four setups (DVD to books, books to DVD, electronics to DVD, and kitchen to DVD). BLSE performs better on the books and DVD test sets than the electronics and kitchen test sets (an average of 3.23 pp). This can be explained by the fact that the corpora used to train the Amazon embeddings contain many more unlabeled reviews for books and electronics (973,194 / 122,438 respectively) than electronics and kitchen (21,009 / 17,856). Consequently, the vector representations for sentiment words that only appear in the books and DVD subcorpora are of higher quality than those that only appear in the electronics and kitchen subcorpora (see Table 4). BLSE relies entirely on the embeddings as input, and if the quality of the embeddings is lower, the model cannot use these features to correctly classify a review. This suggests that the amount of available unlabeled data in the target domain is important, but not limiting. In this paper, we did not decide to crawl more data for the electronics and kitchen domains, but this would be relatively straightforward.

For the SemEval corpora (see Figures 2 and 3), BLSE significantly outperforms all other models (8.2, 15.5, and 6.4 F_1 better on average compared to NSCL, MSDA, and NOAD, respectively). NSCL is better than MSDA on 7 of the 8 setups, but better than the NOAD baseline on only 4. MSDA performs particularly poorly here and only outperforms the baseline on one setup. We suspect that this may be caused by the substantial differences in the source and target corpora and the way this affects the representation given to the classifier, which we explore in more detail in Sections 5.1 and 5.2.

5 Model Analysis

In this section we examine aspects of our model in an attempt to shed light on its strengths and weaknesses. Specifically, we observe how our model performs on highly divergent datasets, perform an error analysis, motivate our choice of projection lexicon, and motivate the need for M'.

5.1 Domain Divergence and Feature Sparsity

From the initial results, it seems that the BLSE model performs better on more divergent domains when compared to other state-of-the-art models. In order to analyze this further, we test the similarity of our domains using the Jensen-Shannon Divergence, which is a smoothed, symmetric version of the Kullback-Leibler Divergence, $D_{KL}(A||B) = \sum_i^N a_i \log \frac{a_i}{b_i}$. Kullback-Leibler Divergence measures the difference between the probability distributions A and B, but is undefined for any event $a_i \in A$ with zero

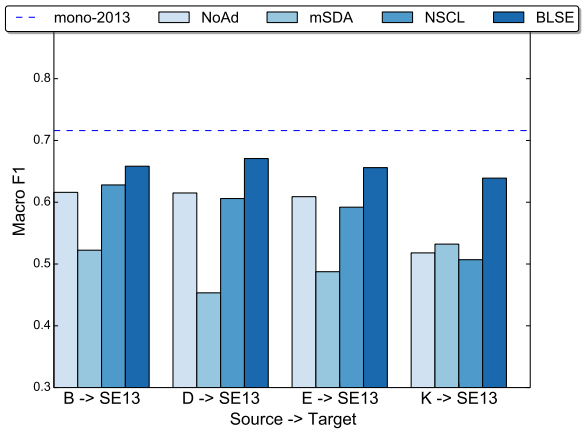

Figure 2: F_1 of approaches trained on the source dataset and tested on the 2013 SemEval corpus.

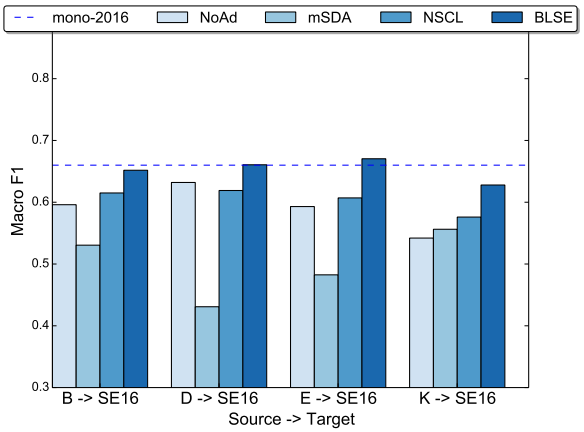

Figure 3: F_1 of approaches trained on the source dataset and tested on the 2016 SemEval corpus.

	unselfish	macgruffen	non-western	setups
	parminder	pretentiously	mindwalk	forgiveable
	well-liked	contrivance	all-too-rare	unweildy

Table 4: Words and their nearest neighbors for important domain-dependent sentiment words. The nearest neighbors for the two example words from the book domain are more coherent than those of the electronics domain.

probability, which is common in term distributions. Jensen-Shannon Divergence is then

$$D_{JS}(A, B) = \frac{1}{2}\Big[D_{KL}(A||B) + D_{KL}(B||A)\Big] .$$

Our similarity features are probability distributions over terms $t \in \mathbb{R}^{|V|}$, where t_i is the probability of the i-th word in the vocabulary V.

For each domain, we create frequency distributions of the most frequent 10,000 unigrams that all domains have in common and measure the divergence with D_{JS}. The results in Table 5 make it clear that the SemEval datasets are more distant from the Amazon datasets than the Amazon datasets are from each other. This is especially true for the distance between the SemEval datasets from the kitchen dataset (D_{JS} = 0.741 and 0.761, respectively). This suggests that NSCL and MSDA give the best results when the difference between domains is relatively small, whereas BLSE performs better on more divergent datasets.

On the SemEval datasets, BLSE also benefits from using dense representations, rather than the sparse unigram and bigram features of NSCL and MSDA. This is particularly important when you have less domain overlap and smaller texts (the average number of features for the Amazon corpora is 76, compared to 17 for SemEval). BLSE is always able to find useful features, even if the tweet is quite short, whereas a bag-of-words representation can be so sparse that it is not helpful.

5.2 Error Analysis

We perform a label-based error analysis of the models on the SemEval 2013 and 2016 datasets by checking the error rate for the positive and negative classes, which we define as

$$\text{Error Rate} = \frac{e_c}{n_c} , \tag{4}$$

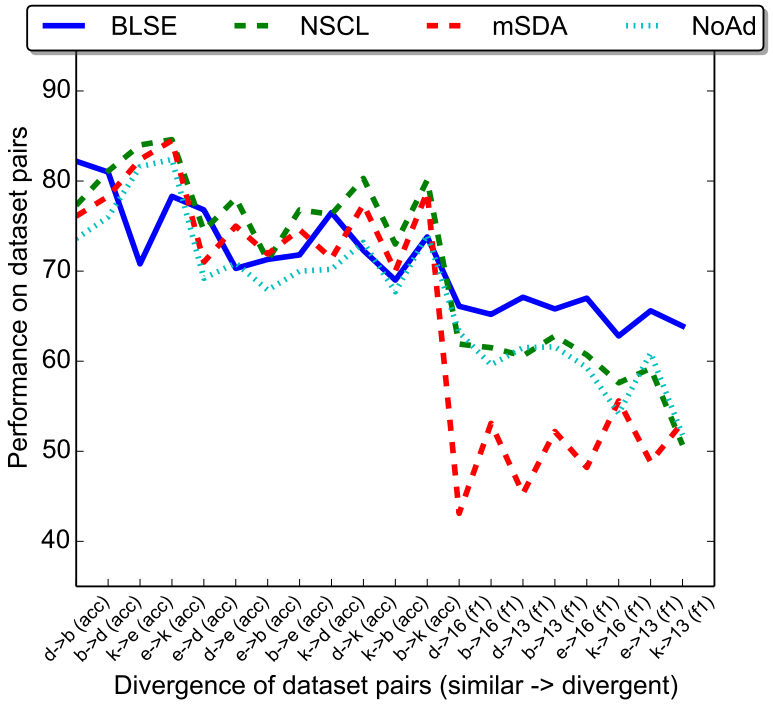

Figure 4: Plot of performance of each model as a function of domain similarity. The x axis plots the rank of similarity from most similar (left) to least similar (right). BLSE maintains its performance as the similarity decreases.

where the number of errors e_c in class c is divided by the total number of examples n_c in the class. We hypothesize that better models will suffer less on minority classes. The results are found in Table 6. In general, BLSE has better overall performance than NSCL or MSDA. In fact, MSDA performs very poorly on the minority negative class, with error rates reaching 98 percent. NSCL almost always favors a single class, with error rates as high as 60.4 on negative and 70.5 on positive.

5.3 Choice of Projection Lexicon

Given that the choice of projection lexicon is one of the key parameters in the BLSE model, we experiment with three approaches to creating a projection lexicon and observe their effect on the books to SemEval 2013 setup.

The **Most Frequent Source Words** are a common source of projection lexicon in the multilingual embedding literature (Faruqui and Dyer, 2014; Lazaridou et al., 2015). For our experiment, we take the 20,000 most frequent tokens from the Brown corpus (Francis and Kučera, 1979). The hypothesis behind using a general corpus is that a large general lexicon will provide more supervision than a smaller task-specific lexicon. This should contribute to learning accurate projection matrices M and M'.

Sentiment Lexicons often contain domain-independent words that convey sentiment. In our model, using a sentiment lexicon as a translation dictionary is equivalent to the use of pivots in other frameworks, as these are usually domain independent words with are good predictors of sentiment. The hypothesis here is that a small task-specific lexicon will help to learn a good projection for the most discriminative words. For our experiment, we take the subset of the sentiment lexicon from Hu and Liu (2004) which is found in the Amazon and SemEval corpora. The final version has 1130 words.

Mutual Information Selected Pivots have been shown to be a good predictor of sentiment across domains (Blitzer et al., 2006; Pan et al., 2010; Ziser and Reichart, 2017). We experiment with using words with the highest mutual information scores as a projection lexicon, although this leads to smaller lexicons.

	book	DVD	electronics	kitchen	SemEval 2013	SemEval 2016
book	1.000	**0.940**	0.870	0.864	0.775	0.802

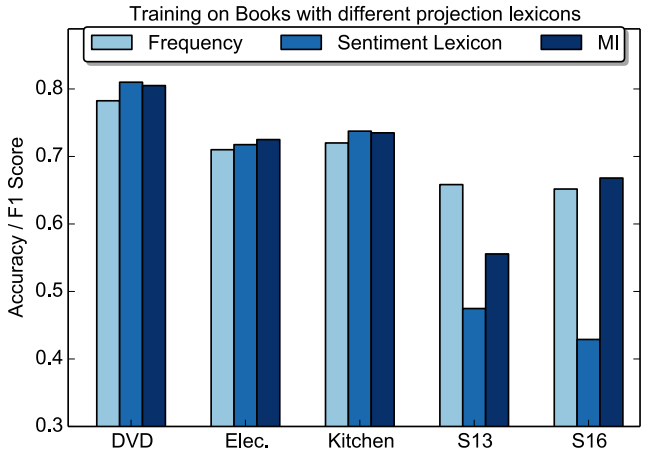

Figure 5: The effect of different projection lexicons for the BLSE method when training on the books domain.

		SemEval 2013		SemEval 2016	
		Pos	Neg	Pos	Neg
books	BLSE	26.9	35.4	31.8	33.0
	NSCL	34.2	43.0	28.9	43.5
	MSDA	1.4	92.7	1.4	89.5
DVD	BLSE	22.8	39.2	28.0	36.5
	NSCL	18.1	60.4	18.7	52.1
	MSDA	0.2	97.8	0.2	98.2
elec.	BLSE	19.1	48.7	27.7	34.6
	NSCL	35.2	41.5	38.9	33.7
	MSDA	1.1	93.7	0.8	91.6
kitchen	BLSE	21.6	49.1	23.3	50.1
	NSCL	63.6	19.3	70.5	13.2
	MSDA	2.4	90.5	2.4	85.8

Table 6: Error rates for positive and negative classes for BLSE, NSCL, and MSDA trained on the Amazon corpora and tested on the SemEval corpora.

Our hypothesis is that specific source-target domain lexicons may provide a better projection between the two specific domains. For each source and target domain pair, we take unigrams and bigrams with high mutual information scores that appear at least 10 times in both domains. The number of pivots differs with each domain pair. The lowest number is 100 (DVD to SemEval 2013) and the highest 955 (books to DVD), with an average of 470 per domain pair.

Figure 5 shows that the frequency-based lexicon gives better results on the more divergent datasets, while the sentiment lexicon performs slightly better on the similar datasets, but poorly on the divergent datasets. The mutual information induced pivot lexicons provide good results on all but the SemEval 2013 dataset. This is likely because the lexicon is too small (103 tokens) to give a good mapping.

5.4 Analysis of M'

The main motivation for using two projection matrices M and M' is to allow the original embeddings to remain stable, while the projection matrices have the flexibility to align translations and separate these into distinct sentiment subspaces. To justify this design decision empirically, we perform an experiment to evaluate the actual need for the target language projection matrix M': We create a simplified version of our model without M', using M to project from the source to target and then P to classify sentiment.

The results of this model are shown in Figure 6. The modified model does learn to predict in the source language, but not in the target language. This confirms that M' is necessary to transfer sentiment in our model.

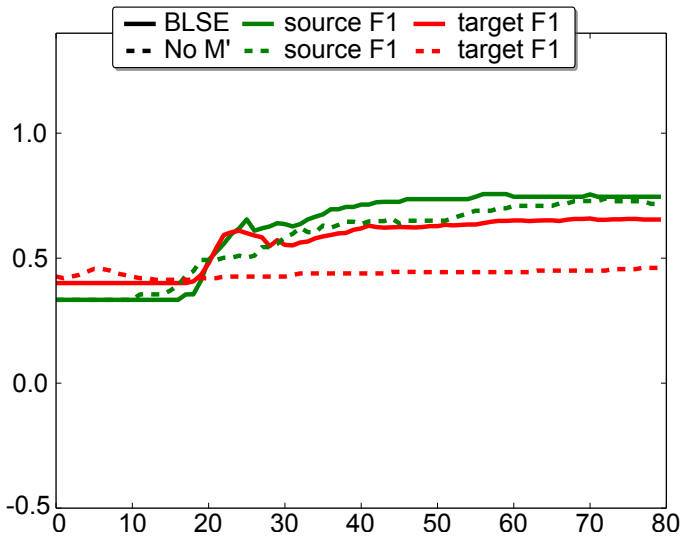

Figure 6: The BLSE model (solid lines) compared to a variant without the target domain projection matrix M' (dashed lines). The red green lines show F_1 on the source books dataset, while the green lines show F_1 on the target SemEval 2013 dataset. The modified model does not learn to predict sentiment on the target dataset (dashed red line).

6 Conclusion and Future Work

We have presented an approach to domain adaptation which learns to project mono-domain embeddings to a bi-domain space and use this bi-domain representation to predict sentiment. We have experimented with 20 domain pairs and shown that for highly divergent domains, our model shows substantial improvement over state-of-the-art methods. Our model constitutes a novel state of the art on 11 of the 20 domain pairs.

One of the main advantages of this approach is that the learned classifier can be used to classify sentiment in either of the two domains without further tuning. In the future, we would like to extend this model to learn multiple domain mappings at a time, effectively permitting zero-shot domain adaptation at a large scale. This would enable a single model to predict sentiment for a number of domains.

Another promising avenue for improvement is to create lexicons that map concepts from the source domain to the target domain, *i. e.*, "read" in the books domain to "watch" in the movies domain. It would be interesting to see if it is possible to use vector algebra (Mikolov et al., 2013) to find similar concepts in different domains, *e. g.*, *read - books + DVD = watch*. It would also be beneficial to map multiword units across domains, *e. g.*, "not particularly exciting" in DVD to "not very reliable" in electronics. This could be particularly helpful for moving beyond a binary view of sentiment at document-level, where domain adaptation would be of particular use, given that the cost of annotation is higher for multi-class, sentence-, or aspect-level classification.

A current disadvantage of our model might be that it uses skip-gram embeddings trained on more than one domain. Therefore, it it would be of interest to investigate if methods which create domain specific embeddings (He et al., 2011; Bollegala et al., 2014; Bollegala et al., 2015) are able to give better results within our framework.

Cross-lingual Argumentation Mining: Machine Translation (and a bit of Projection) is All You Need!

Steffen Eger, Johannes Daxenberger, Christian Stab, and Iryna Gurevych
Ubiquitous Knowledge Processing Lab (UKP-TUDA)
Department of Computer Science, Technische Universität Darmstadt
http://www.ukp.tu-darmstadt.de

Abstract

Argumentation mining (AM) requires the identification of complex discourse structures and has lately been applied with success monolingually. In this work, we show that the existing resources are, however, not adequate for assessing cross-lingual AM, due to their heterogeneity or lack of complexity. We therefore create suitable parallel corpora by (human and machine) translating a popular AM dataset consisting of persuasive student essays into German, French, Spanish, and Chinese. We then compare (i) annotation projection and (ii) bilingual word embeddings based direct transfer strategies for cross-lingual AM, finding that the former performs considerably better and almost eliminates the loss from cross-lingual transfer. Moreover, we find that annotation projection works equally well when using either costly human or cheap machine translations. Our code and data are available at http://github.com/UKPLab/coling2018-xling_argument_mining.

1 Introduction

Argumentation mining (AM) is a fast-growing research field with applications in discourse analysis, summarization, debate modeling, and law, among others (Peldszus and Stede, 2013a). Recent studies have successfully applied computational methods to analyze monological argumentation (Wachsmuth et al., 2017; Eger et al., 2017). Most of these studies view arguments as consisting of (at least) claims and premises—and so do we in this work. Thereby, our focus is on token-level *argument component extraction*, that is, the segmentation and typing of argument components.

AM has thus far almost exclusively been performed *monolingually*, e.g. in English (Mochales-Palau and Moens, 2009), German (Eckle-Kohler et al., 2015), or Chinese (Li et al., 2017). Working only monolingually is problematic, however, because AM is a difficult task even for humans due to its dependence on background knowledge and parsing of complex pragmatic relations (Moens, 2017). As a result, acquiring (high-quality) datasets for new languages comes at a high cost—be it in terms of training and/or hiring expert annotators or querying large crowds in crowd-sourcing experiments. It is thus of utmost importance to train NLP systems in AM that are capable of going cross-language, so that annotation efforts do not have to be multiplied by the number of languages of interest. This is in line with current trends in NLP, which increasingly recognize the possibility and the necessity to work cross-lingually, be it in part-of-speech tagging (Zhang et al., 2016), dependency parsing (Agic et al., 2016), sentiment mining (Chen et al., 2016; Zhou et al., 2016), or other fields.

In this work, we address the problem of cross-lingual (token-level) AM for the first time. We initially experiment with available resources in English, German, and Chinese. We show that the existing datasets for analyzing argumentation are not suitable for assessing cross-lingual component extraction due to their heterogeneity or lack of complexity. Given this scarcity of homogeneously annotated high-quality large-scale datasets across different languages, our first contribution is to (1) provide a fully parallel (en-de), *human-translated* version of one of the most popular current AM datasets, namely, the English dataset of persuasive student essays published by Stab and Gurevych (2017).

Proceedings of the 27th International Conference on Computational Linguistics, pages 831–844
Santa Fe, New Mexico, USA, August 20-26, 2018.

We then (2) *machine translate* the 402 student essays into German, Spanish, French, and Chinese. Both our human and machine translations contain argumentation annotations, in the form of either human annotations or automatically projected annotations. Our experiments indicate that both the translations and the projected annotations are of very high quality, cf. examples in Table 2.

Besides contributing new datasets, (3) we perform the first evaluations of cross-lingual (token-level) AM, based on suitable adaptations of two popular cross-lingual techniques, namely, *direct transfer* (McDonald et al., 2011) and *projection* (Yarowsky et al., 2001). We find that projection works considerably better than direct transfer and almost closes the cross-lingual gap, i.e., cross-lingual performance is almost on par with in-language performance when we use parallel data and project annotations to the target language. This holds both for human (translated, HT) parallel data, which is costly to obtain, and machine translated (MT) parallel data, which is very cheap to obtain for dozens of high-resource languages.

Our findings imply that current neural MT has reached a level where it can act as a substitute for costly (non-expert) HT even for problems that operate on the fine-grained token-level.

2 Related Work

In what follows, we briefly summarize the works that most closely relate to our current research.

Argumentation Mining AM seeks to automatically identify argument structures in text and has received a lot of attention in NLP lately. Existing approaches focus, for instance, on specific subtasks like argument unit segmentation (Ajjour et al., 2017), identifying different types of argument components (Mochales-Palau and Moens, 2009; Habernal and Gurevych, 2017), recognizing argumentative discourse relations (Nguyen and Litman, 2016) or extracting argument components and relations end-to-end (Eger et al., 2017). However, most of these approaches are specifically designed for English and there are only few resources for other languages. For German, a few datasets annotated according to the claim-premise scheme are available (Eckle-Kohler et al., 2015; Liebeck et al., 2016). Furthermore, Peldszus and Stede (2015) annotated a small German dataset with claims and premises and translated it to English subsequently. There are very few works studying AM in other languages, e.g. Basile et al. (2016) for Italian, Li et al. (2017) for Chinese and Sardianos et al. (2015) for Greek. There are also two recent papers addressing some form of cross-linguality: Aker and Zhang (2017) map argumentative sentences from English to Mandarin using machine translation in comparable Wikipedia articles. Sliwa et al. (2018) create corpora in Balkan languages and Arabic by labeling the English side of corresponding parallel corpora on the sentence level and then using the same label for the target sentences. In contrast to these works, we work on the more challenging token-level. Moreover, we actually train classifiers for language transfer rather than only creating annotated data in other languages based on parallel data.

As mentioned, we focus on *cross-lingual component extraction*, that is, the segmentation and typing of argument components in a target language (L2), while having only annotated source language (L1) data. We operate on token-level by labeling each token with a BIO label plus its respective component type. The BIO label marks the start, continuation and end of specific argument components. Examples are given in Tables 2 and 3.

Cross-lingual sequence tagging POS tagging and named-entity recognition (NER) are standard tasks in NLP. In recent years, there is increased interest not only in evaluating POS and NER models within multiple individual languages (Plank et al., 2016), but also cross-lingually (Zhang et al., 2016; Tsai et al., 2016; Mayhew et al., 2017; Yang et al., 2017). Two standard approaches are *projection* (Yarowsky et al., 2001; Das and Petrov, 2011; Täckström et al., 2013) and *direct transfer* (Täckström et al., 2012; Zhang et al., 2016). Projection uses parallel data to project annotations from one language to another. In contrast, in direct transfer, a system is trained in L1 using language independent or shared features and applied without modification to L2.

While these approaches are typically *unsupervised*, i.e., they assume no annotations in L2, there are also *supervised* cross-lingual approaches based on multi-task learning (Cotterell and Heigold, 2017; Yang et al., 2017; Kim et al., 2017). These assume small training sets in L2, and a system trained on them is regularized by a larger amount of training data in L1. In our work, we only consider unsupervised

language adaptation, because it is the most realistic cross-lingual scenario for AM, as it may be costly to even produce small amounts of training data in many different languages.

Most cross-lingual sequence tagging approaches address POS tagging, and only few are devoted to NER (Mayhew et al., 2017; Tsai et al., 2016), aspect-based sentiment classification (Lambert, 2015), or even more challenging problems such as discourse parsing (Braud et al., 2017). While POS tagging and NER are in some sense very similar to AM, namely, insofar as both can be modeled as sequential tagging of tokens, there are also important differences. For example, in POS tagging and NER, the label for a current token usually strongly depends on the token itself plus some local context. This strong association between label, token and local context is largely absent in AM, causing some models that perform well on POS and NER to fail blatantly in AM.[1]

Cross-lingual Word Embeddings are the (modern) basis of the direct transfer method. As with monolingual embeddings, there exists a veritable zoo of different approaches, but they often perform very similarly in applications (Upadhyay et al., 2016) and seemingly very different approaches are oftentimes also equivalent on a theoretical level (Ruder et al., 2017).

3 Data

We chose three freely available datasets: a small parallel German-English dataset, and considerably larger English and Chinese datasets using (almost) the same inventory of argument types, which we therefore assumed to be adequate for cross-lingual experiments. We translated the two last named monolingual datasets in other languages, described below. Statistics for all datasets are given in Table 1.

[1]E.g., we had tried out a word embedding based HMM model (Zhang et al., 2016) in initial experiments but found it to perform below our random baseline. The apparent reason is that an HMM cannot deal with long-range dependencies that abound in AM.

Orig-ZH	几次入住中国大饭店, [**感觉都非常不错**] , [新开的豪华阁酒廊非常棒] , [饮料丰富] , [食物也很好吃] , [服务也非常的棒] , [尤其特别感谢杨雪峰和张东静, 他们非常贴心]

Table 3: Review from CRC corpus as well as English machine translation with projected annotations. Major claims in bold, claims underlined, premises in italics (ZH: regular font).

3.1 Microtexts (MTX)

Peldszus and Stede (2015) annotated 112 German short texts (six or less sentences) written in response to questions typically phrased like "Should one do X". These were annotated according to a version of Freeman's theory of argumentation macro-structure (Peldszus and Stede, 2013b). Each microtext consists of one (central) claim and several premises. As opposed to our other datasets, MTX has no "O" (non-argumentative) tokens and no major claims. The German sentences have been professionally translated to English, making this the first parallel corpus for AM in English and German.

3.2 Chinese Review Corpus (CRC)

Li et al. (2017) created the only large-scale argument mining dataset in Chinese, freely available and with annotations on component level according to the claim-premise scheme (Stab and Gurevych, 2017). We thus chose to include this dataset in our experiments, despite differences in the domain of the annotated texts. Li et al. (2017) used crowdsourcing to annotate Chinese hotel reviews from *tripadvisor.com* with four component types (major claim, claim, premise, premise supporting an implicit claim). We consider only those components with direct overlap with the components used by Stab and Gurevych (2017), thus considering components labeled as "premise supporting an implicit claim" as non-argumentative. We applied the CRF-based Chinese word segmenter by Tseng et al. (2005) to split Chinese character streams into tokens. Furthermore, we only use the "Easy Reviews Corpus" from Li et al. (2017). The remaining part of the corpus are isolated sentences from reviews with low overall inter-annotator agreement, which we ignored. An example from CRC can be found in Table 3.

3.3 A Large-Scale Parallel Dataset of Persuasive Essays (PE)

Stab and Gurevych (2017) created a dataset of persuasive essays written by students on *essaysforum.com*. These are about controversial topics such as "competition or cooperation—which is better?". To obtain a human-translated parallel version of this dataset, we asked seven native speakers of German with an attested strong competence in English (all students or university employees) to translate the 402 student essays in the PE corpus sentence-by-sentence. As only requirement, we asked the translators to retain the argumentative structure in their translations: i.e., the translation of an argument component should be connected and not contain non-argumentative tokens. Since German has a freer word order compared to English, this requirement can in virtually all cases be easily fulfilled without producing awkward sounding German translations. Each essay was translated by exactly one translator. Besides translating the essays, we also asked the translators to annotate argument boundaries so that the original mark-up is preserved in the translations. The translators took about 40min on average to translate one essay and indicate the argument structures. Thus, they required about 270 hours to translate the whole PE corpus into German, and the resulting overall cost was roughly 3,000 USD. The motivations to ask translators to translate argument components contiguously were that (i) all monolingual AM datasets we know of have contiguous components, (ii) transfer would have been naturally hampered had components in the source language been contiguous but not in the target language, at least for methods such as direct transfer.[2]

[2]We note that even professional translations typically differ from original, non-translated texts because they retain traces of the source language (Rabinovich et al., 2017). We thus speculate that our reported results are probably slightly upward biased compared to a situation where the test data consists of original German student essays. This latter situation would have been much more costly to produce, in any way: it would have required retrieval (and, if necessary, creation) of original student essays in German as well as induction of all subsequent annotation mark-up.

To obtain further parallel versions of the PE data, we also *automatically* translated them into German, French, Spanish, and Chinese using Google Translate. Of course, we cannot make any demands on how Google Translate translates text into other languages but noticed that it has a tendency to stay rather close to the original text, but nevertheless has a very high perceived quality of translation. We automatically projected argument structures from the English text to the machine translations using our projection algorithm described in §4. It took few hours to automatically translate the PE corpus into the four languages. Examples of the data as well as the human and machine translations can be found in Table 2. Even though we also provide translations of PE in French, Spanish and Chinese, our primary focus in our experiments below is on the languages for which we have gold (human-created) data, i.e., EN↔DE (for PE and MTX) as well as EN↔ZH.

4 Approaches

In what follows, we describe our adaptations of direct transfer and projection to the AM task. Direct transfer focuses on the source language and trains on human-created L1 data as well as human-created L1 labels. In contrast, during training, projection operates directly on the language of interest, viz., L2. This comes at a cost: the labels in L2 are noisy, because they are projected from L1, which is an error-prone process. The success of projection can therefore be expected to largely depend on the quality of this transfer step. Projection makes stronger assumptions than direct transfer: it requires parallel data.[3] When the parallel data is induced via machine translation, then a second source of noise for projection is the 'unreliable' L2 input training data.

Direct Transfer Here, we directly train a system on bilingual representations, which in our case come in the form of bilingual word embeddings. To retain some freedom over the choice and parameters of our word embeddings, we choose to train them ourselves instead of using pre-trained ones. For EN↔DE we induce bilingual word embeddings by training BIVCD (Vulic and Moens, 2015) and BISKIP models (Luong et al., 2015) on >2 million aligned sentences from the Europarl corpus (Koehn, 2005). BIVCD concatenates bilingually aligned sentences (or documents), randomly shuffles each concatenation and trains a standard monolingual word embedding technique on the result; here, we use the word2vec skip-gram model (Mikolov et al., 2013). BIVCD was shown to be competitive to more challenging approaches in Upadhyay et al. (2016). BISKIP is a variant of the standard skip-gram model which predicts mono- and cross-lingual contexts. It requires word alignments between parallel sentences and we use fast-align for this (Dyer et al., 2013). For EN↔ZH we train the same models on the UN corpus (Ziemski et al., 2016), which comprises >11 million parallel sentences. We train embeddings of sizes 100 and 200.

Projection To implement projection for the problem of token-level AM, we proceed as follows. We take our human-labeled L1 data and align it with its corresponding parallel L2 data using fast-align. Once we have word level alignment information, we consider for each argument component $c(s)$ in L1 of type a (e.g., MajorClaim, Claim, Premise) with consecutive words $s_1, \ldots, s_N$: the word t_1 with smallest index in the corresponding L2 sentence that is aligned to some word in $s_1, \ldots, s_N$, and the analogous word t_{-1} with largest such index. We then label all the words in the L2 sentence between t_1 and t_{-1} with type a, using a correct BIO structure, resulting in $c(t)$. We repeat this process for all the components within a sentence in L1 and for all sentences. In case of collision, e.g., if two components in L2 would overlap according to the above-described strategies, we simply increment the beginning counter of one of the components until they are disjoint. If our above strategy fails, i.e., $c(s)$ cannot be projected, e.g., because the words in an L1 component are not aligned to any words in L2, then we simply ignore the projection of $c(s)$ to the L2 sentence, labeling the corresponding words in L2 as non-argumentative instead. We think of this projection strategy as naive because we do not do much to resolve conflicts and instead trust the quality of the alignments and that the subsequent systems trained on the projected data are capable of gracefully recovering from noise in the projections.

[3]Thus, direct transfer is potentially the cheaper approach, even though it also requires bilingual word embeddings, which themselves are based on some form of bilingual signal, e.g., parallel sentence- or word-level data.

5 Experiments

We perform token-level sequence tagging. Our label space is $\mathcal{Y} = \{\text{B,I}\} \times T \cup \{\text{O}\}$ where T is the set of argument types, comprising "claim", "premise", and (if applicable) "major claim".

5.1 Experimental Setup

To perform token-level sequence tagging, we implement a standard bidirectional LSTM with a CRF layer as output layer in TensorFlow. The CRF layer accounts for dependencies between successive labels. We represent words by their respective embeddings. In addition to this word-based information, we also allow the model to learn a character-based representation (via another LSTM) and concatenate this learned representation to the word embedding. Our model is essentially the same as the ones proposed by Ma and Hovy (2016) and Lample et al. (2016); it is also a state-of-the-art model for monolingual AM (Eger et al., 2017). We name it BLCRF+char, when character information is included, and BLCRF when disabled. For all experiments, we use the same architectural setup: we use two LSTM hidden layers with 100 hidden units each. We train for 50 epochs using a patience of 10. We apply dropout on the embeddings as well as on the LSTM units. On character-level, we also use a bidirectional LSTM with 50 hidden units and learn a representation of size 30. As evaluation measure we choose macro-F1 as implemented in scikit-learn (Pedregosa et al., 2011).

Baseline A simple baseline to test successful learning is to choose the majority label in the test data. However, this performs particularly poorly on token-level and for our chosen evaluation metric. We therefore choose a more sophisticated baseline. We first split our datasets by sentences and then compute a probability distribution of how likely each argument component appears in a sentence. At test time, we again split the test data by sentences and then label each token in the test sentence with a randomly drawn argument component (according to the calculated probability distribution on train/dev sets). We label all the tokens in the sentence with the drawn argument component type, keeping valid BIO structure. We label the last token (which is typically a punctuation symbol) with the "O" label in PE and CRC. In essence, our baseline is a random baseline, but has some basic prior knowledge of the BIO format.

Train/dev/test splits For the PE corpus, we use the same split into training and test data as in Stab and Gurevych (2017). In particular, our test data comprises 80 documents ("essays") with a total of 29,537 tokens (en). We choose 10% of the training data as dev set. Thus, we have 286 essays in the train set with a total of 105,988 tokens (en) and 36 essays in the dev set with a total of 12,657 tokens (en). We report averages over five random initializations of our networks. For the CRC corpus, we perform 5-fold cross-validation on document level. Our train sets consist of roughly 15K tokens, our dev sets of 2K tokens, and our test sets of 4K tokens. For each split, we average over five different random initializations and report the average over these averages. For MTX, we also perform 5-fold cross-validation on document level. Our train sets consist of roughly 6K tokens (en), our dev sets of 500 tokens (en), and our test sets of 1,500 tokens (en). We use the same averaging strategy as for CRC, but average over ten random initializations per fold, to account for the smaller dataset sizes.

5.2 Results

We report results for adapting between datasets in different languages and between parallel versions of one and the same dataset. We only consider cases where one of the involved languages is English. Further, we do not transfer between MTX and the other datasets, because MTX has no "O" units (and no major claims). Unless stated otherwise, we always *evaluate* on `HT` for both direct transfer and projection.

5.2.1 Direct Transfer

For all cross-lingual direct transfer experiments, we train on the union of train and dev (train+dev) sets (randomly drawn for the datasets for which we used cross-validation) of the source language and test either on the whole data (train+dev+test) of L2, or, in case of parallel versions of a dataset (such as PE EN↔DE) on the test set of L2. We do not use `MT` for direct transfer at any stage.

PE_{EN}↔PE_{DE}, results in Table 4: English in-language results do not vary much and are on a level of slightly above 69% macro-F1, largely independent of the embedding types and whether or not character

information is available.[4] German in-language results are 4-5 percentage points (pp) below the English ones. One might suspect the presumed inferior quality (or derivative nature) of the student translations as a cause for this, but we hypothesize that German is simply more complex than English, both in morphology and syntax.

We observe a noticeable drop when moving cross-language. This drop is up to >40% for the direction EN→DE (worst case drop from ∼70% to ∼37%) and slightly less for DE→EN. We explain this drop by the discrepancy between training and test distributions. This discrepancy is present even in bilingual embedding spaces: no test word has the exact same representation as the words in the training data. Further, disabling character information typically has a very positive impact cross-language. For example, EN→DE performance increases from ∼40% F1 to ∼50% when disabling character information. The reason is that a system that extracts a character representation based on English characters may get confused from the diverging German character sequences. Surprisingly, characters do not impede so much in the direction DE→EN. The reason seems to be lexical borrowing in modern German from English. For example, ∼17% of the 'active' vocabulary (i.e., frequency >30) of English in PE_{EN} is also contained in PE_{DE}. In contrast, only 6% of the active vocabulary of German in PE_{DE} occurs also in PE_{EN}.

CRC↔PE_{EN}, results in Table 5 (left): In-language CRC results are lower than in-language PE results (∼46% vs. ∼69% for PE). This is unsurprising since CRC is considerably smaller in size than PE. However, we observe that the cross-language drop is much larger than it is for the PE DE↔EN setting. In fact, performance values always lie below our random baseline. We attribute this huge drop not to the larger language distance between English and Chinese (relative to English and German), but primarily to the domain gap between student essays and hotel reviews. In fact, we observe that, e.g., major claims in PE are almost always preceded by specific discourse markers such as "Therefore, I believe that" or "In the end, I think" (cf. Table 2), while hotel reviews completely lack such discourse connectives (cf. Table 3). Since we expect a system that trains on PE to learn the signaling value of these markers, directly applying this system to text where such markers are absent, fails.

MTX_{EN}↔MTX_{DE}, results in Table 5 (right): Even though the dataset is by far smallest in size it yields the highest F1-scores among all our considered datasets. Moreover, the language drop is comparatively small (between 4 and 7pp). Investigating, we notice that argument components are typically separated by punctuation symbols (mostly "." or ",") in MTX, which is easy to learn even cross-lingually. Moreover, we find that claims can often be separated from premises by simple keywords such as "should", which can, apparently, be reliably spotted cross-lingually via the corresponding bilingual word embeddings.

Model	Embedding Type	EN→EN	EN→DE	DE→DE	DE→EN
BLCRF+Char	BIVCD-100	68.87	41.89	65.22	49.91
	BIVCD-200	**70.51**	39.87	**65.92**	49.52
	BISKIP-100	69.27	37.01	63.33	48.23
BLCRF	BIVCD-100	69.27	49.70	65.90	50.14
	BISKIP-100	69.15	**49.76**	64.92	**50.28**
Baseline		20.	20.	20.	20.

Table 4: Direct transfer results for PE_{EN}↔PE_{DE}. Scores are macro-F1.

Error Analysis and Discussion For PE direct transfer experiments, we find that a major source of errors is incorrect classification of tokens labeled "B-". This means that the system has difficulty finding the exact beginning of an argument span. We find, however, that the reason for the language drop is not that the bilingual embedding spaces are bad: among the top-10 neighbors of English words are roughly five German words, and vice versa. Rather, direct transfer induces a situation very similar to standard monolingual out-of-vocabulary (OOV) scenarios, namely as if all test words had been replaced by synonyms that did not occur in the train data. While systems using embeddings as input are more robust to

[4]Our in-language results are slightly below our previous results reported in Eger et al. (2017) (table 6), where we obtained scores of 72-75% for token-level component extraction, even though the architecture is in principle the same. Reasons may be the different word embeddings used as well as that we reported majority performance over different hyperparameter combinations in the previous work, which typically increased performance scores by a few percentage points.

Model	CRC↔PE_{EN} ZH→ZH	ZH→EN	EN→EN	EN→ZH	MTX_{EN}↔MTX_{DE} EN→EN	EN→DE	DE→DE	DE→EN
BLCRF+Char	**46.31**	14.01	**69.27**	9.50	**73.12**	67.03	**73.41**	**66.62**
BLCRF	44.95	16.52	69.15	12.60	72.15	**69.46**	72.52	63.71
Baseline	18.	**17.**	20.	**17.**	45.	46.	50.	50.

Table 5: Direct transfer results for CRC and MTX. Scores are macro-F1. Embeddings are BISKIP-100.

OOV words, they are still affected by them (Ma and Hovy, 2016; Müller et al., 2013). This "blurring effect" at test time then makes it more difficult to detect exact argument component spans. While this is true in general, it is not true for punctuation symbols, which typically have an identical role across languages and, hence, extremely similar representations. For example, German and English "." have more than 97% cosine similarity in BISKIP-100d, which is much higher than for typical monolingually closely related words. Finally, besides semantic shift direct transfer also faces syntactic shift, because the test words may have different word order compared to the train data (e.g., verb final position in German).

The lessons we learn from our above experiments are that (i) the MTX dataset does not provide a real challenge for cross-lingual techniques because argument components can easily be spotted based on punctuation and component typing appears to be just as easily portable across languages. (ii) Language adaptation between the CRC corpus and PE appears, in contrast, too difficult because argumentation units are very differently realized across the two datasets, and hence, the domain shift appears to be the (much) larger obstacle compared to the language shift.[5] Thus, (iii) we mostly focus on the cross-lingual version of the PE corpus in the sequel, which is a difficult enough dataset for cross-lingual AM, without confounding the problem with issues relating to differences of AM domains. In addition, we only use BISKIP-100d embeddings, because the choice of embeddings seemed to have a negligible effect in our case (certainly, for our main focus, namely, cross-lingual evaluations) and because they showed slightly superior results cross-lingually than BIVCD-100d.

5.2.2 Projection

HT-Projection Table 6 (HT columns) shows results when we project PE_{EN} training data annotations on parallel German HT documents and train and evaluate a system directly on German (and vice versa). As said before, we train in this case directly on the same language as we test on, viz., L2. We observe that this improves cross-language results dramatically. From a best cross-language result of 49.76% for BIVEC-100d in the direct transfer setting, we improve by almost 30% to 63.67%. This is only roughly 1pp below the best in-language result for German which was 64.92%. In the direction DE→EN, we observe the same trend: we improve by over 30% relative to the direct transfer results and achieve a macro-F1 score that is only 1.7pp below the in-language upper-bound.

MT-Projection Next, we investigate what happens when we replace the HT translations with MT translations and perform the same projection steps as before. Results for PE_{EN}↔PE_{DE} are shown in Table 6 (MT columns). We see that EN→DE results get slightly better while DE→EN results get slightly worse. On average, it seems, using machine translations is just as good as using human translations. Moreover, we remain very close to the upper-bound in-language results. The reason why MT results could be better than HT results is that the machine might translate more consistently. It might also be better in certain cases in correcting (the sometimes ungrammatical) English original. Another likely reason is that current MT has reached, if not already surpassed, HT of non-expert (but bilingually fluent) human translators.[6]

Motivated by this finding, we also machine translated the CRC corpus into English, projected annotations and then trained a system on this translation and evaluated on the PE_{EN} corpus. Results improve to 23.15% macro-F1 score relative to the best direct transfer result of 16.52%. This indicates, again, that

[5] This is a similar finding as in Daxenberger et al. (2017).

[6] We conducted a formal test if MT can reliably be distinguished from HT in our setup. We trained a system (an adaptation of InferSent (Conneau et al., 2017)) to predict whether for an English original e and a second input sentence it could determine if the second input is a human or machine translation of e. The system's performance of 54% accuracy (which is only slightly better than random guessing) matched our own intuition and introspection into the quality of the machine translations.

training in L2 is better than training in L1, given the high quality machine translations and a suitable projection algorithm. However, 23.15% is still only slightly better than the random baseline of 17%—and far from the best PE_{EN} in-language result of >69%. In addition, in the direction PE_{EN}→CRC macro-F1 (also) improves to 15.33% relative to a best direct transfer score of 12.60%. However, here the performance is still below the random baseline of 17%. We take this as strong evidence that the domain gap between CRC and PE is too large and it is not possible to train a system in one of these two domains and directly apply it in the other, even when the language gap has been eliminated.

	EN→DE			DE→EN		
	HT	MT	In-Lang.	HT	MT	In-Lang.
BLCRF+Char	63.67	**64.00**	63.33	**67.57**	66.39	69.27
BLCRF	61.18	63.34	64.92	64.87	64.68	69.15

Table 6: Projection on HT/MT translations, evaluated on human-created test data. Scores are macro-F1. Embeddings are BISKIP-100.

Other languages We conducted a final experiment in which we considered our MT translations of PE into French, Spanish, and Chinese. Since we have no human-created test data for these languages we could only evaluate on *machine translations and projected annotations*. For our BLCRF+char model, we obtained performance scores of 62.45%, 65.92%, 59.20% for French, Spanish and Chinese, respectively. To see if these numbers give reliable estimates of the systems when evaluated on HT data, we performed the same test with German and English and got scores of 63.20% and 61.45%, respectively, when trained and evaluated on MT. For CRC, we also trained and evaluated on the English (MT translated and automatically projected) data, obtaining a score of 47.92% with BLCRF+char, which is slightly above the in-language value of 46.31% on the original Chinese data (see Table 5). That all these numbers are close to the original in-language results gives a good indication that the MT evaluations very likely strongly correlate to 'true' performances on HT data.

Error analysis The bottleneck of projection is the quality of the cross-lingual projections (which in turn depend on the quality of the word alignments between bi-text). We can directly assess our projections by comparing them to the human-created annotations. Our algorithmic projections match in 97.24% of the cases (token-level) with the human gold standard for the direction EN→DE. The corresponding macro-F1 score is 89.85%. Inspecting the confusion matrices, we observe that most mismatches occur between the "B" and "I" categories of a given component type and with the "O" category. These numbers and the mismatch types indicate that there are only few projection errors and they typically lead to either (slightly) larger or smaller argument components than given in the human-created data. To illustrate, typical projection errors arise in case of missing articles in one of the two languages involved; cf. Table 2: "luck is [...]" vs. "la chance est [...]". Here, it is likely that the alignment algorithm does not align the French determiner "la" to an English word, and thus, "la" is not included in the argument component. Another case of too short argument components is that of verb final position in German which often gets misaligned and the corresponding final verb omitted from the argument component. These misalignments lead to slightly "shifted" argument components in the L2 train set and are the most prominent source of error for the projection technique. To quantify: the German in-language system classifies 58% of all cases when one of the determiners ("der/die/das") begins an argument component correctly, but the system using projections from the English data only classifies 35% of them correctly. Hence, alignment/projection errors indeed propagate to some degree, but these phenomena are rare and have negligible impact on performance. Note that, by design of our projection algorithm, misalignments of words in the 'center' of an argument component are much less likely to be a problem.

Figure 1 plots individual F1 scores for various systems transferring to English on PE. Here, the cross-lingual systems using HT/MT projection perform roughly as well as the in-language system for "O", "I-C" and "I-P". These are the most frequent classes. For claims and major claims, which have lower frequency, the in-language upper bound tends to perform better. Noteworthy, the in-language system is

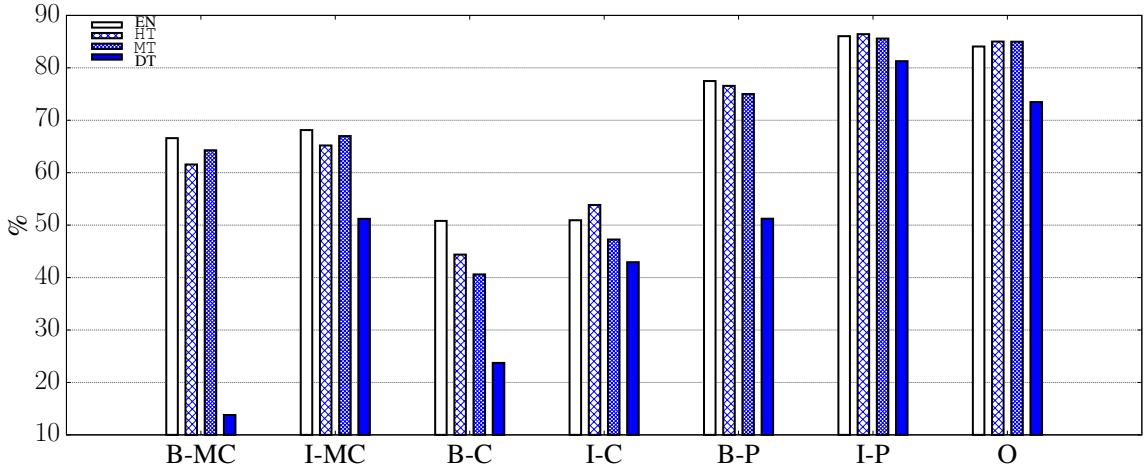

Figure 1: Individual F1-scores for four indicated systems and seven labels. All transfer systems are from PE_{DE} to PE_{EN}; EN is in-language. DT stands for Direct Transfer. HT/MT are projection-based approaches. Embeddings are BISKIP-100. Systems are BLCRF+Char.

always better for the beginnings of an argument component (B-MC,B-C,B-P), which confirms our above analysis. The direct transfer system, in contrast, performs much worse, particularly for major claims and claims, and also for all starts of components, indicating that the blurring ("OOV") effect is here much more severe.

6 Conclusion

Showing that the currently available datasets for AM are not adequate for evaluating cross-lingual AM transfer, we created human and machine translations of one of the most popular current AM datasets, the dataset of persuasive student essays (Stab and Gurevych, 2017). We also machine translated a Chinese corpus of reviews (Li et al., 2017) into English, which provides argumentation structures on hotel reviews. Performing cross-lingual experiments using suitable adaptations of two popular transfer approaches, we have shown that machine translation and (naive) projection work considerably better than direct transfer, even though the former approach contains two sources of noise. Moreover, machine translation in combination with projection almost performs on the level of in-language upper bound results. We think that our findings shed further light on the value—and the huge potential—of current (neural) machine translation systems for cross-lingual transfer. They also cast doubt on current standard use of direct transfer in cross-lingual scenarios. Instead, we propose to simply machine translate the train set, when this is possible, and then project labels to the translated text. This eliminates the (particular) "OOV" and "ordering" problems inherent to direct transfer. Prerequiste to this approach is high quality MT, which, with the advent of neural techniques, appears to be now available.

We hope our new datasets fuel AM research in languages other than English. In this work, we did not consider cross-lingual argumentative relation identification, although relations are available in the newly created parallel PE and CRC datasets. Future work should explore cross-lingual multi-task learning for AM (Schulz et al., 2018) with the source language as main task and small amounts of labeled target language data, as well as adversarial training techniques (Yasunaga et al., 2018), which promise to be beneficial for the particular OOV problem that direct transfer is prone to (though not for the ordering problem). We also want to combine projection with direct transfer by training on the union of projected L2 data as well as the original L1 data using shared representations.

Abstract

Recent years have witnessed a surge of interest on response generation for neural conversation systems. Most existing models are implemented by following the Encoder-Decoder framework and operate sentences of conversations at word-level. The word-level model is suffering from the Unknown Words Issue and the Preference Issue, which seriously impact the quality of generated responses, for example, generated responses may become irrelevant or too general (i.e. safe responses). To address these issues, this paper proposes a hybrid-level Encoder-Decoder model (HL-EncDec), which not only utilizes the word-level features but also character-level features. We conduct several experiments to evaluate HL-EncDec on a Chinese corpus, experimental results show our model significantly outperforms other non-word-level models in automatic metrics and human annotations and is able to generate more informative responses. We also conduct experiments with a small-scale English dataset to show the generalization ability.

1 Introduction

Nowadays, conversation systems have gained a great progress due to the rapid development of big-data and deep learning techniques. A conversation system enables a computer to make human-like conversations with users. Massive conversational datasets can be easily accessed on the Web, which highly promotes both the academia and industry to turn to their attention to develop data-driven conversation systems (Vinyals and Le, 2015; Shang et al., 2015; Chen et al., 2017). A common approach to build a generation-based conversation system is to model it as a response generation task. And a response generation model is often learnt within the Encoder-Decoder framework from large-scale conversational data from the Web.

The Encoder-Decoder is a state-of-the-art framework for SEQ2SEQ (sequence-to-sequence) tasks such as machine translation, abstractive summarization and response generation, etc.. Researchers have proposed several Encoder-Decoder based models, and most of them utilize Recurrent Neural Networks to build an Encoder and an attentional Decoder. Due to the fact that a word is the most basic unit in linguistics, and other larger language elements are built on words, the majority of models operate sentences at word-level. Namely, sentences should be segmented as sequences of words, thus an Encoder-Decoder model could read or generate a sentence with their own vocabularies. Since the computational complexity and the capacity limitation of internal high-speed storage such as GPU VRAM, vocabularies could only record finite words. However, there is an issue that the amount of total words is far more than the volume of vocabularies and the out-of-vocabulary words (denoted as OOVs) may appear in the conversations. Meanwhile, another issue is that words already recorded in the vocabulary have different probabilities to be used in human's dialogues, only a small part of high-frequency words may be learnt well and the remaining low-frequency words may be undertrained. We respectively called the first and

Proceedings of the 27th International Conference on Computational Linguistics, pages 845–856
Santa Fe, New Mexico, USA, August 20-26, 2018.

the second issue as Unknown Words Issue and Preference Issue. Intuitively, both issues seriously impact the generation quality and diversity of a response generation model.

Operating sentences at character-level could address the above issues, for the amount of a language's all characters is fixed and small, for example, the alphabet size of English is 128 (ASCII), which allows a vocabulary to record all characters easily. By representing a word as several characters, two issues could be naturally addressed. (Kim et al., 2016) obtained a word embedding by utilizing a convolutional network with character embeddings of that word instead of directly looking up the word embedding matrix of vocabulary. (Costajussa and Fonollosa, 2016) borrowed this idea and proposed a character-level Encoder, but the entire model does not fully work at character-level. (Lee et al., 2016) proposed a fully character-level Encoder-Decoder model, and initially addressed the previous issues. Letting a model work at subword-level is another choice. The BPE (byte-pair-encoding) algorithm proposed by (Sennrich et al., 2016) is able to mine a specific number of most frequent subword units from the corpora and utilizes them to completely represent sentences. (Chung et al., 2016) utilized BPE to build a decoder.

However, these non-word-level models could sharpen the long-term dependencies issue (Hochreiter and Schmidhuber, 1997) and lost much semantic and syntactic information. And those non-word-level approaches are proposed for the machine translation or language modelling instead of response generation task. To the best of our knowledge, there is no existing work that tries to address Unknown Words Issue and Preference Issue for response generation task. In this work, we focus on addressing these two issues for Encoder-Decoder based response generation model by proposing a model named HL-EncDec. HL-EncDec is an improved Encoder-Decoder based model that operates sentences at hybrid-level, which employs characters and words to represent sentences at the same time. In the source side, HL-EncDec is able to utilize a convolutional network to calculate an equivalent word-level embedding vector from characters of that word. Since characters are fully recorded , we could calculate a well-trained equivalent embedding for any word. Moreover, HL-EncDec could also utilize the original word-level embeddings recorded in the matrix by using the sum of equivalent one and original one, this is the main reason why we claim our model works at hybrid-level. In the target side, we also propose a hybrid-level approach to represent a sentence without the increasing of the complexities.

We compare our HL-EncDec with the most widely used standard Encoder-Decoder implementation and other state-of-the-art non-word-level methods using both automatic metrics and human evaluations. The experimental result shows HL-EncDec delivers more high-quality and informative responses compared to baseline models.

2 Background and Motivation

Inspired by SEQ2SEQ approaches for neural machine translation (Sutskever et al., 2014; Bahdanau et al., 2014; Jean et al., 2015), researchers have started extending these techniques to implement generation-based response generation model and already harvested significant improvements. A standard SEQ2SQ model takes a source sentence $X = (x_1, x_2, \ldots, x_T)$ as an input, and generates another sentence $Y = (y_1, y_2, \ldots, y_L)$ as an output. The word-level RNN Encoder-Decoder (denoted as EncDec) is the most famous and applied framework.

In general, an EncDec model has two components: an Encoder first reads a message from user and summarizes this message into several internal representations, and a Decoder utilizes these internal representations to generate a new sentence as a response to reply user's message.

2.1 Encoder

Formally, given a tokenized source sentence $X = (x_1, x_2, \ldots, x_T)$, Encoder reads each word in order and generates hidden states $\mathbf{H} = (\mathbf{h_1}, \mathbf{h_2}, \ldots, \mathbf{h_T})$ as the internal representation of X with a Recurrent Neural Network (RNN). The hidden state $\mathbf{h_t}$ is considered to have already summarized a slice of words $(x_1, \ldots, x_i)$, which is calculated by:

$$\mathbf{h_t} = f(\mathbf{x_t^w}, \mathbf{h_{t-1}}) \tag{1}$$

where function f is always a long-short term memory unit (LSTM) (Hochreiter and Schmidhuber, 1997) or gate recurrent unit (GRU) (Cho et al., 2014), both of them are able to effectively reduce the impact of

long-term dependencies. In this paper, the LSTM is employed as function f. In addition, suppose that x_t is the i-th word of Encoder's vocabulary , thus the embedding vector $\mathbf{x_t^w}$ of word x_t is obtained by an embedding matrix looking up operation:

$$\mathbf{x_t^w} = lookingup(\mathbf{V^e}, x_t) = \mathbf{V^e}[i] \tag{2}$$

where V^e is Encoder's vocabulary and $\mathbf{V^e} \in \mathbb{R}^{|V^e|*d}$ is the corresponding embedding matrix.

Recently, the biRNN (bi-directional RNN) is a common approach to enhance the Encoder (Chung et al., 2014). A biRNN includes a forward RNN and a backward RNN, the forward RNN reads a sentence in its original order while the backward RNN reads it in the reversed order. Thus, the concatenation $\mathbf{h_t^c}$ of the hidden state $\mathbf{h_t^f}$ generated by forward RNN and the hidden state $\mathbf{h_t^b}$ generated by backward RNN is used to replace the single-directional $\mathbf{h_t}$ in the Equation 1.

2.2 Attentional Decoder

Decoder utilizes the hidden states $\mathbf{H}$, and employs another RNN to predict the conditional probability of the next target word $y_{t'}$ being the k-th word of the vocabulary of Decoder V^d at time $t^{'}$:

$$p(y_{t'} = w_k^d | y_{t'-1}, \ldots, y_1, X) = \frac{exp(z(\mathbf{h_t^{'}}, \mathbf{V^d}[k], \mathbf{c_{t'}}))}{\sum_{i=1}^{|V^d|} exp(z(\mathbf{h_t^{'}}, \mathbf{V^d}[i], \mathbf{c_{t'}}))} \tag{3}$$

Where z is a non-linear is function with activation, and $\mathbf{h_{t'}^{'}}$ is hidden state of Decoder's RNN for time $t^{'}$, which also applies a LSTM or GRU to calculate:

$$\mathbf{h_{t'}^{'}} = f(\mathbf{y_{t'-1}}, \mathbf{h_{t'-1}^{'}}, \mathbf{c_{t'}}) \tag{4}$$

The context vector $\mathbf{c_{t'}}$ is computed as a weighted sum of the hidden states $\mathbf{H} = (\mathbf{h_1}, \mathbf{h_2}, \ldots, \mathbf{h_T})$:

$$\mathbf{c_{t'}} = \sum_{i=1}^{T} \alpha_{t',i} \mathbf{h_i} \tag{5}$$

where weight $\alpha_{t',i}$ is given by:

$$\alpha_{t',i} = \frac{exp(e_{t',i})}{\sum_{j=1}^{T} exp(e_{t',j})} \tag{6}$$

$$e_{t',j} = a(\mathbf{h_{t'-1}^{'}}, \mathbf{h_j}) \tag{7}$$

Where a is an alignment model which is used to score how well the word x_j of the input sentence and the next target word $y_t^{'}$ could be related. (Bahdanau et al., 2014) and (Luong et al., 2015) have proposed two different but effective alignment models, respectively. This paper takes the model of (Luong et al., 2015) as function a, which is computed by employing a bilinear term $\mathbf{W_a}$:

$$a(\mathbf{h_{t'-1}^{'}}, \mathbf{h_j}) = (\mathbf{h_{t'-1}^{'}})^{\mathbf{T}} \mathbf{W_a} \mathbf{h_j} \tag{8}$$

2.3 Training

An Encoder-Decoder model can be trained end-to-end by minimizing the negative conditional log-likelihood of target Y given source X, which is defined as:

$$\pounds = -\frac{1}{N} \sum_{i=1}^{N} \sum_{t'=1}^{|Y^i|} \log(p(y_{t'}^i | y_{t'-1}^i, \ldots, y_1^i, X^i) \tag{9}$$

Where N is the total count of the given corpus D , (X^i, Y^i) is the i-th pair of D, and $y_{t'}^i$ is the $t^{'}$-th word of Y^i. is the $t^{'}$-th word of Y^i.

2.4 Challenges

As described above, a word-level EncDec model operates input messages and output responses at word-level. A word itself could not be utilized by a computer unless it has been converted into the internal representation such as a one-hot vector or an embedding vector. Both of Encoder and Decoder maintain their own vocabulary, such that they are able to understand the meaning or predict the probability of a word by looking up the embedding matrix of their vocabularies.

More or less, due to the complexity of model itself, deep neural network models are suffering from the limited computational power of hardware and the scarce capacity of internal high-speed storages such as the GPU VRAM. An EncDec response generation model is surely not an exception, hence the capacity of a vocabulary of the Encoder or Decoder must be controlled to a finite and relatively small number, for example, 40K. Consequently, a lot of words become out-of-vocabulary words (denoted as OOVs), and an EncDec model could not correctly understand or generate it. It is a common approach to enable an EncDec model to work with OOVs that utilizing a special and universal symbol **unk** to replace all OOVs. In other words, all OOVs share a same embedding vector in the source side and they will never be correctly generated in the target side. Intuitively, the more OOVs a corpus contains, the lower performance an EncDec conversation model has. The challenge of the appearance of OOVs is named **Unknown Words Issue**, for convenience.

If we only consider the words already been recorded in the vocabulary (i.e. known words), another challenge will rise to the surface, which is called **Preference Issue**. All known words could be understood and generated by an EncDec model, but that doesn't mean they have the same chance to appear in the sentences of dialogues. Some words are very potential to appear in our dialogues (for example, what, that, I, etc.) and some words are rare to be adopted while it is not an OOV word. This paper calls the first kind of words as high-frequency words (HF words) and the second kind as low-frequency words (LF words). The embedding vector of HF words would be well learnt but LF words could not, for HF words have more appearance to enable them to be updated by commonly used gradient descent optimizing algorithms. Thus, an EncDec model may not correctly operate LF words, which may sharpen the phenomenon that an EncDec conversation model always generates some too safe, too general but very boring responses (e.g., I think so).

The above two issues have seriously impacted the overall performance of EncDec response generation models, even models to solve other tasks such as neural machine translation and neural abstractive text summarization. In this paper, we propose a novel model HL-EncDec to solve these issues, which has significantly improved the generation quality and diversity.

3 Related Work

In linguistics, a word is the most basic unit, and other larger language elements such as phrases and sentences, etc., are built upon words. Due to this fact, it is natural that most previous works regard a word as the smallest unit in their models, i.e. these models operate at word-level.

The word-level EncDec models have achieved great improvements on neural machine translations (Bahdanau et al., 2014; Jean et al., 2015), which inspired researchers to apply this idea to response generation task to build a generation based neural conversation systems(Vinyals and Le, 2015; Shang et al., 2015; Xing et al., 2016; Chen et al., 2017). This technique enables a conversation system to be end-to-end trained from a large-scale corpus of message-response pairs, but researchers found it tends to generate some general and 'safe' responses(Vinyals and Le, 2015). To address this challenge, (Li et al., 2016) introduced a new objective function with MMI (maximum mutual information) to penalize too general responses. (Shao et al., 2017) presented a novel attentional model to generate long and diverse responses. (Wu et al., 2017) enhanced the quality and diversity of generated responses by constructing a dynamic vocabulary.

In this paper, we focus on two issues discussed in Section 2: Unknown Words Issue and Preference Issue. Actually, many researchers have raised their attention to these two issues, and proposed models operate at non-word-level such as character-level and subword-level. (Kim et al., 2016) solved the representation of unknown words and selection preference for language modelling by utilizing characters

to calculate an equivalent word embedding instead of looking up a word embedding matrix. (Costajussa and Fonollosa, 2016) absorbed this idea and proposed a character-level Encoder for machine translation. Recently, inspired by (Kim et al., 2016; Costajussa and Fonollosa, 2016), (Lee et al., 2016) introduced a fully character-level EncDec model. (Sennrich et al., 2016) mined subword units to represent all words by applying BPE algorithm. (Chung et al., 2016) utilized the BPE to build a subword-level Encoder and proposed a character-level Decoder.

While a character-level model or a subword-level model may address the Unknown Words Issue, but it could sharpen the long-term dependencies issue and lost much semantic and syntactic information due to each word must be decomposed to several characters or subunits. The loss may more than gains, and we consider this is why most models operate sentences at word-level.

In addition, previous models are designed for machine translation task which is actually a different task compared with response generation while they are both SEQ2SEQ tasks. This paper proposes a model HL-EncDec, which utilizes the hybrid-level representation technique to improve the generation quality for response generation task.

In the source side ,for a word x, HL-EncDec not only utilizes the word-level embedding vector $\mathbf{x^w}$ obtained by looking up embedding matrix, but also calculates an equivalent word-level embedding vector $\mathbf{x^c}$ of x. To calculate the $\mathbf{x^c}$, HL-EncDec employs its corresponding character sequence and a Convolutional Neural Network based network. The Encoder of HL-EncDec maintains two vocabularies V_w^e and V_c^e, the first vocabulary V_w^e records a finite number of words and their embedding vectors, the second vocabulary V_c^e records all characters of the language used by current system. In general, the total number of all characters of a language is fixed and small, hence recently GPU devices are very easy to load all characters to its RAM. For example, there are about 128 characters in English alphabet (ASCII). Obviously, the concept of out-vocabulary-character has gone with the wind, and each OOV word could be represented as a sequence of fully known characters.

4 HL-EncDec

4.1 Encoder

HL-EncDec employs CharCNN to calculate the equivalent word-level embedding $\mathbf{x^c}$. CharCNN is initially presented for language modeling by (Kim et al., 2016).

Given a word x , CharCNN first represents x as a sequence of characters $C_x = (c_1, \ldots, c_{N_x}, c_{eos})$ where N_x is the character number of x and c_{eos} is a special symbol to indicate the end of characters. Each character c_i could be represented as an embedding vector $\mathbf{c_i} \in \mathbb{R}^{d_c}$ by looking up the embedding matrix $\mathbf{V_c^e} \in \mathbb{R}^{|V_c^e| * d_c}$. Subsequently, a narrow convolution is applied upon the character embeddings $\mathbf{C_x} = (\mathbf{c_1}, \ldots, \mathbf{c_{N_x}}, \mathbf{c_{eos}}) \in \mathbb{R}^{d_c * (N_x+1)}$. Assuming there is a single convolution filter $\mathbf{f} \in \mathbb{R}^{d_c \times w}$ with a variable width w, and the height of $\mathbf{f}$ is fixed to d_c, thus each character vector could be completely operated. With the padding and convolutional operation, the obtained feature map is denoted as $\mathbf{f^m} \in \mathbb{R}^{N_x+1}$, and the i-th element of $\mathbf{f^m}[i]$ is given by:

$$\mathbf{f^m}[i] = ReLU(\sum \mathbf{C_{x[:,i:i+w-1]}} \otimes \mathbf{f}) \tag{10}$$

Where $\otimes$ denotes element-wise matrix multiplication, $\mathbf{C_{x[:,i:i+w-1]}}$ is the i-to-$(i+w-1)$-th column of $\mathbf{C_x}$, which is corresponding to the i-to-$(i+w-1)$-th characters of x. Finally, we take the max-over-time pooling technique:

$$\mathbf{f^p} = \max(\mathbf{f^m}[i]), i \in [1, N_x + 1] \tag{11}$$

Hence, $\mathbf{f^p}$ is regarded as the feature corresponding to the filter $\mathbf{f}$. Assume there are N_f unique filters in total, then $\mathbf{u} \in \mathbb{R}^{N_f}$ is used to denoted the concatenation of corresponding N_f features. Highway network (Hinton et al., 2012) has been shown to bring significant improvements to many NLP tasks, We apply a 4-layer highway network to $\mathbf{u}$, and a single layer highway network is calculated as:

$$\mathbf{u_h^1} = g \odot ReLU(\mathbf{W_h u} + \mathbf{b_h}) + (1 - g) \odot \mathbf{u} \tag{12}$$

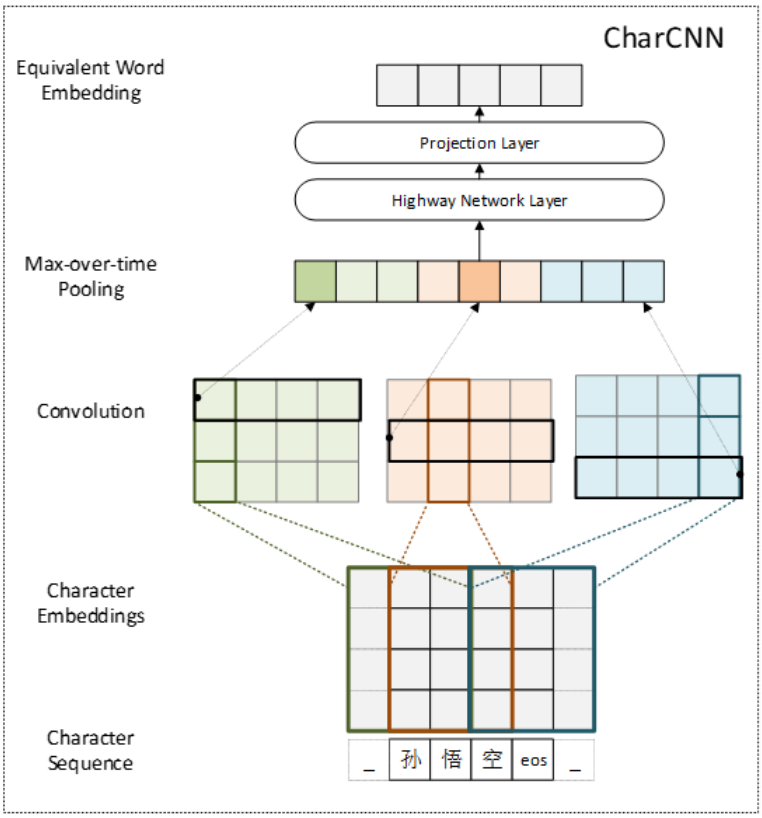

Figure 1: The architecture of CharCNN

where g is called as transform gate, $(1-g)$ is called as carry gate, and $g = sigmod(\mathbf{W_g u} + \mathbf{b_g})$. The equivalent word embedding $\mathbf{x^c}$ is finally worked out by a linear projection:

$$\mathbf{x^c} = \mathbf{u_h^4 W_l} + \mathbf{b_l} \tag{13}$$

Thus, $\mathbf{x^c}$ is the equivalent word embedding calculated by CharCNN, which has the same dimension as $\mathbf{x^w}$ obtained by looking up $\mathbf{V_w^e} \in \mathbb{R}^{|V_w^e| * d_w}$. Then, we calculate the sum of $\mathbf{x^c}$ and $\mathbf{x^w}$:

$$\mathbf{x^h} = \mathbf{x^c} + \mathbf{x^w} \tag{14}$$

Finally, $\mathbf{x^h}$ is the hybrid-level embedding vector for x, and HL-EncDec replaces the word-level $\mathbf{x^w}$ in Equation 2 with $\mathbf{x^h}$. Since $\mathbf{x^c}$ could be generated for any word without the challenge of unknown words and preference, the $\mathbf{x^h}$ could naturally address the Unknown Words Issue and Preference Issue. We also tried to merge $\mathbf{x^w}$ and $\mathbf{x^c}$ with more complex techniques, but this simple summation yield the best result.

4.2 Hybrid-Level Decoder

This paper utilizes a hybrid-level Decoder to avoid the appearance of OOVs and improve the quality and diversity of generated responses. HL-Decoder is able to generate either a word or a character. HL-Decoder has a vocabulary V_d and a corresponding embedding matrix $\mathbf{V_d} \in \mathbb{R}^{|V_d| * d_w}$, which records all characters of the target language, a connector symbol and some HF words. Characters and words are equally recorded in the vocabulary of HL-EncDec, namely HL-Decoder has none explicit operation to judge whether it should generate a character or word, for reducing the complexity of decoding.

While HL-Decoder has another way to segment a sentence into a sequence, HL-Decoder has the same network architecture as the Decoder introduced in Section 2. In the target side of HL-EncDec, a response sentence should be applied a hybrid-level approach to a segment. Assuming there is a tokenized word-level message sequence $Y = (y_1, y_2, \ldots, y_L)$, repeatedly execute the following operation until there is

no OOV word: if y_i is an OOV word, then y_i should be decomposed to several corresponding characters $(c_1, cs, c_2, \ldots, cs, c_{N_y})$, where$(c_1, c_2, \ldots, c_{N_y})$ is the corresponding character sequence of y_i and cs is the connector. Hence, the message sequence could be represented as

$$Y^{'} = (y_1, \ldots, y_{i-1}, c_1, cs, c_2, \ldots, cs, c_{N_y}, y_{i+1}, y_L) \tag{15}$$

Hence, we finally obtain a sequence Y^h without OOVs, and HL-EncDec let the hybrid-level Y^h to replace the word-level Y . Therefore, HL-Decoder is able to generate any word, no matter this word has been recorded in Decoder's vocabulary or not.

5 Experiment

5.1 Model

The widely used word-level model and other famous non-word-level models are selected as baselines:

EncDec: The standard word-level Encoder-Decoder, which has been elaborated in the Section 2. EncDec has a bi-directional LSTM Encoder and a single-directional LSTM Attentional Decoder.

CharEncDec: A character-level EncDec, it has the same network architecture with EncDec, but it fully operates sentences at character-level. Namely, the CharEncDec directly reads or generates a sequence of characters.

BpeEncDec: A subword-level EncDec, and the BPE algorithm is selected to construct the subword units (Sennrich et al., 2016).

CNNEncDec: A fully character-level model proposed by Lee, which employs a character-level convolutional network with max-pooling at Encoder to operate sentence and a character-level Decoder to generate responses (Lee et al., 2016).

For all models, we set the embedding vector dimension as 512, RNN hidden unit size as 256, and batch size as 256. There is an exception in HL-EncDec's source side, the word embedding vector dimension d_w is set to 512 but the character embedding vector dimension d_c is set to 160, for efficiency. The training will be automatically stopped if the perplexity results of dev set are continuously increased in two periods, which is either the end of an epoch or every 10000 global steps. For each model, the beam search with $k = 10$ is applied to infer the responses. All models are implemented by Tensoflow.

5.2 Dataset & Vocabulary

We evaluate HL-EncDec and other models on a Chinese corpus released by Shang, which consists of 4.44 million message-response conversation pairs obtained from Sina Weibo (Shang et al., 2015). Each sentence already been tokenized to words by Stanford Chinese Word Segmenter. After filtering out noisy symbols and duplications, about 3.78 million pairs are finally used. We divide the filtered dataset into 3 sets, there are 20K/20K/3.74M pairs in the test/dev/training sets, respectively.

The vocabulary configurations should be noted here. For character-level models, CharEncDec and CNNEncDec, we keep all characters in vocabularies, and there are 6,690/10,432 characters in the source/target side. For the word-level model EncDec, we individually keep 40,000 most frequent words in the source and target side. For BpeEncDec, we allow BPE algorithm to mine at most (40,000 - 6,454/10,432) subword units in source/target side. For HL-EncDec, we keep 10,432 characters and 29,568 most frequent words in Decoder's vocabulary. In HL-EncDec's source side, we keep 6,690 characters in character vocabulary and keep 38328 words in word vocabulary.

5.3 Metrics

In this paper, we evaluate the performance of models with the following metrics:

BLEU & ROUGE: In previous work, BLEU & ROUGE are already been widely used to evaluate the overall performance of generation quality (Tian et al., 2017; Wu et al., 2017). BLEU is able to configure the max n-gram in the evaluating, hence we configure it from 2 to 4 and respectively denote them as: BLEU-2, BLEU-3 and BLEU-4.

Table 1: Word-level automatic metrics results. A number in bold means the best.

Model	ROUGE	BLEU-2	BLEU-3	BLEU-4	Distinct-1	Distinct-2
EncDec(Dev)	10.75	4.69	3.15	2.44	6.34%	23.48%
EncDec(Test)	10.69	4.60	3.02	2.30	6.28%	23.23%
BpeEncDec(Dev)	**11.45**	5.18	3.40	2.58	6.47%	24.98%
BpeEncDec(Test)	**11.63**	5.15	3.32	2.48	6.37%	24.60%
CNNEncDec(Dev)	9.13	4.00	2.49	1.79	3.85%	16.34%
CNNEncDec(Test)	9.22	3.93	2.39	1.69	3.93%	16.62%
HL-EncDec (Dev)	11.19	**5.28**	**3.55**	**2.74**	**7.08%**	**26.02%**
HL-EncDec (Test)	11.22	**5.26**	**3.53**	**2.74**	**7.03%**	**26.02%**

Table 2: Character-level automatic metrics results. A number in bold means the best.

Model	ROUGE	BLEU-2	BLEU-3	BLEU-4	Distinct-1	Distinct-2
EncDec(Dev)	11.13	6.26	4.42	3.42	1.18%	13.10%
EncDec(Test)	11.09	6.21	4.29	3.24	1.16%	12.87%
CharEncDec(Dev)	11.00	6.18	4.33	3.30	0.86%	12.82%
CharEncDec(Test)	10.83	5.91	4.08	3.07	0.85%	12.69%
BpeEncDec(Dev)	**12.43**	6.68	4.67	3.59	**1.43%**	16.76%
BpeEncDec(Test)	**12.60**	6.69	4.61	3.48	**1.42%**	16.56%
CNNEncDec(Dev)	10.28	5.85	3.83	2.78	0.86%	7.39%
CNNEncDec(Test)	9.22	3.93	2.39	1.69	0.86%	7.39%
HL-EncDec (Dev)	12.37	**6.80**	**4.80**	**3.73**	1.40%	**17.15**%
HL-EncDec (Test)	12.40	**6.83**	**4.77**	**3.68**	1.38%	**17.05**%

DISTINCT-1 & DISTINCT-2: Following (Li et al., 2016; Xing et al., 2016; Wu et al., 2017), we employ the DISTINCT-1/2 to measure how diverse and informative the generated responses are. DISTINCT-1/2 is the ratio of distinct uni-grams/bigrams in generated responses.

Human Evaluation: We employ three native speakers to individually annotate 50 randomly selected groups of responses. Each response may be rated as the following three criteria: +2/Excellent: the response is reasonable, fluent; +1/Acceptable: The response is a little 'safe' or irrelevant or has other small problems; 0/Bad: The response is irrelevant, or ungrammatically or too 'safe'.

5.4 Evaluation Results

Table 1 reports the evaluation results on automatic metrics. The proposed HL-EncDec outperforms baseline models on most metrics. In comparison with the standard EncDec model, HL-EncDec notably outperforms it in all metrics, which demonstrates HL-EncDec is able to generate a more excellent and informative response. Another CNN based model, CNNEncDec, has poor results, we believe the reason behind this is that CNNEncDec could not adapt our Chinese dataset. BPE is one of the state-of-the-art approaches to address the unknown words issue in neural machine translation. Here, BPE keeps this advantage cause BpeEncDec performs better than other baseline models. BpeEncDec only slightly outperforms HL-EncDec in the ROUGE, however, HL-EncDec outperforms BpeEncDec on the other metrics. In the metric BLEU-N, a higher N means it will evaluate the generated responses with more stringent standards. We find that HL-EncDec exceeds BpeEncDec more with the increasement of N, which shows the effectiveness of HL-EncDec from another aspect.

Unlike other languages such as English, etc., a Chinese native speaker always writes or reads a sentence without the explicit segmentation. Considering this fact, we evaluate all models at character-level, namely, we regard each sentence as a character sequence without explicit segmentation. The character-level evaluation results have been reported at Table 2. Clearly, the HL-EncDec still yield the best score on most metrics.

Table 3 reports human evaluation results. HL-EncDec has the highest total score, which means three

Table 3: Human Annotation

Model	EncDec	CharEncDec	BpeEncDec	CNNEncDec	HL-EncDec
0	48.67%	51.33%	32.67%	41.33%	34.00%
1	25.33%	27.33%	30.67%	26.00%	20.00%
2	26.00%	21.33%	36.67%	32.67%	46.00%
Total	38.67	35.00	52.00	45.67	56.00

annotators think our model has the best performance. Similar to the previous results of automatic metrics, although BpeEncDec is behinds HL-EncDec, it still outperforms than other models. EncDec has the lowest score, since EncDec may generate a sentence with unknown words. An unknown word often ruins the whole sentence. In addition, HL-EncDec also has the highest potential to generate a high-quality response, because 46% of responses generated by HL-EncDec are rated as +2/Excellent responses. CNNEncDec beats the EncDec and CharEncDec here, which is different from the automatic metrics results.

Table 4: Case Study

Case	1	2	3
Message	一天两包咖啡已然不够了。	子时已过一小时了，果断睡觉。	晚上吃素，自己动手，啦啦啦。
	It's not enough to drink two packs of coffee a day.	At two in the morning, go to bed	Eat vegetarian at night, DIY， La lala
EncDec	一天一杯，一瓶咖啡。	我还以为是**unk**呢	我也想吃这种蔬菜
	One cup of coffee a day, a bottle of coffee.	I thought it was **unk**	I want to eat this kind of vegetable, too
CharEncDec	一天两包咖啡已然不够了。	子时你过一小时了，果断睡觉。	好可爱啊，好可爱哦
	It's not enough to drink two packs of coffee a day.	At two in the morning, go to bed	It's cute, so cute.
BpeEncDec	一天一天，一天一天	我现在还在睡觉呢。	这就是传说中的胡萝卜?
	Day by day, day by day.	I'm still sleeping now.	This is the legendary carrot?
CNNEncDec	这是什么品种的啊?	时时时刻，果断睡觉	这是什么品种啊？求解
	What kind is this?	Time and time, go to bed	What kind is this?
HL-EncDec	我也想喝一包咖啡。	早睡早起身体健康!	我也想吃。
	I'd like to have a pack of coffee, too.	Early to bed and early to rise makes a man healthy, wealth and wise.	I want to eat, too

We give a qualitative case study in Table 4. By observing, it's easy to find HL-EncDec is able to generate more informative and high-quality responses. In the case 1, sentence generated by EncDec is not fluent, CharEncDec retells the message, BpeEncDec generates a strange response, these three models are unqualified here. In the case 2, EncDec suffers from unknown words, CharEncDec retells message again, CNNEncDec gives an incorrect response. BpeEncDec and HL-EncDec perform well. In the last case, while models except CharEncDec generate acceptable responses, HL-EncDec still gives a most suitable response.

Table 5: Word-level automatic metrics results on Twitter dataset.A number in bold means the best.

Model	ROUGE	BLEU-2	BLEU-3	BLEU-4	Distinct-1	Distinct-2
EncDec	5.84	1.39	0.52	0.23	0.89%	3.19%
BpeEncDec	**6.10**	1.41	0.52	0.23	**1.63%**	**6.06%**
HL-EncDec	5.99	**1.54**	**0.63**	**0.29**	1.34%	4.41%
HL-BPE	5.94	1.25	0.53	0.26	1.53%	5.56%

5.5 Discuss: Generalization

In order to evaluate the generalization ability of HL-EncDec, we take some additional small-scale experiments on an English dataset. The original dataset consists of about 377K message-response pairs from Twitter [1]. We only use 215K pairs with moderate lengths (i.e. 4-20 words). For this dataset, we set the embedding vector dimension as 320, the hidden vector size as 240, and batch size as 64. In HL-EncDec's source side, the character embedding vector dimension d_c is set to 160. The beam search $k = 5$ is applied to infer the responses.

We evaluate four models here, EncDec, BpeEncDec, HL-EncDec, and HL-BPE. HL-BPE is a variant of HL-EncDec, which decomposes an unknown word into a sequence of subword units instead of characters in the target side. An English word generally has more characters than a Chinese word, BPE may help HL-EncDec to reduce the sequence length in the target side. For EncDec, BpeEncDec and the target side of HL-EncDec and HL-BPE, their vocabularies are allowed to record 15,000 items. For the source side of HL-EncDec and HL-BPE, their character vocabularies consist of 617 characters, their word vocabularies consist of 14,383 words.

Table 5 shows the experimental results. EncDec and BpeEncDec have similar BLEU scores, but BpeEncDec has the best ROUGE and Distinct scores. Compared with BpeEncDec, HL-EncDec generates responses with higher qualities (i.e. higher ROUGE+BLEU scores), but less informative(i.e. lower Distinct scores). HL-BPE could be seen as a trade-off between HL-EncDec and BpeEncDec. In brief, these experiments show that HL-EncDec works well with other languages, and HL-EncDec is flexible enough to do some adaptive optimization for a specific language, which is very hard for BpeEncDec.

5.6 Discussion: Why hybrid-level?

Currently, while some previous works could alleviate the Preference Issue for word-level EncDec models in some degree (Weng et al., 2017; Wu et al., 2017), the Unknown Words Issue is still a problem with none effective solution. Employing a vocabulary with fixed words is infeasible since words not only numerous but also being created at any time. A word-level model must take extra actions to alleviate the impact of those unknown OOV words, which may involve more challenges. Character-level approaches could address them, but as what we introduced above and the experimental results, these approaches may decrease the performance.

In the hybrid-level model HL-EncDec, our goal is to keep the advantages of word-level models being reserved as much as possible after we addressed mentioned two issues since a word is a smallest and basic unit in linguistics. Hence, we ingeniously absorb the advantages of characters and propose a hybrid-level Encoder and a hybrid-level decoder.

6 Conclusion and Future work

In this paper, we presented a hybrid-level Encoder-Decoder model, HL-EncDec, for response generation task. This hybrid-level approach absorbs the advantages of both word-level models and character-level models and addressed the Unknown Words Issue and Preference Issue. Experimental results show HL-EncDec could deliver more informative, more relevant responses without the appearance of unknown words. In the future, we will mainly investigate how to improve the techniques in the target side, meanwhile, we will also seek for techniques to enhance our hybrid-level representation technique.

Abstract

Cloze-style reading comprehension has been a popular task for measuring the progress of natural language understanding in recent years. In this paper, we design a novel multi-perspective framework, which can be seen as the joint training of heterogeneous experts and aggregate context information from different perspectives. Each perspective is modeled by a simple aggregation module. The outputs of multiple aggregation modules are fed into a one-timestep pointer network to get the final answer. At the same time, to tackle the problem of insufficient labeled data, we propose an efficient sampling mechanism to automatically generate more training examples by matching the distribution of candidates between labeled and unlabeled data. We conduct our experiments on a recently released cloze-test dataset CLOTH (Xie et al., 2017), which consists of nearly $100k$ questions designed by professional teachers. Results show that our method achieves new state-of-the-art performance over previous strong baselines.

1 Introduction

Reading comprehension is a challenging task which requires the deep understanding of natural language. Cloze test is a particular form of reading comprehension: given a passage with blanks, an examinee is required to fill in the missing word (or phrase) that best fits the context surrounding the blank. Recently, cloze-style reading comprehension has drawn growing interests from NLP research communities, since such a task meets the practical requirements and is relatively easy to design.

The research of cloze-style reading comprehension is first advanced by two large-scale corpora: the CNN/Daily Mail (Hermann et al., 2015) and CBT (Hill et al., 2015) datasets, which are automatically constructed by randomly or periodically deleting a word from original passage. Though the automatically generated datasets usually consist of a large quantity of labeled data and make it possible to train large neural network models, they are in nature far away from real-world language understanding problems and have serious ambiguity issues (Chen et al., 2016). As a result, the state-of-the-art system of cloze test almost reaches the performance ceiling and loses its improvement direction due to the limitation of the corpus (Chen et al., 2016). In such situation, Xie et al. (2017) argues that it is a more reliable means to assess language proficiency with carefully designed questions by professional teachers, and releases a novel corpus CLOTH. The CLOTH dataset brings the new challenge of exploring a comprehensive evaluation of language proficiency and specifically divides the questions into several types including matching, reasoning and grammar etc. Table 1 shows several example questions from CLOTH.

From experiments by Xie et al. (2017), we can see that the *Stanford attention reader* (Chen et al., 2016) of having the near state-of-the-art performance (with an accuracy of about 0.74) on CNN/Daily Mail only gets an accuracy of 0.487 on CLOTH and there exists a huge performance gap between human and popular machine learning models. The main reason is that attention models are mainly good at processing matching questions (e.g., the first example in Table 1 has matching between *"police"* and *"accident"*, *"man died"*), which occupy a less percentage in CLOTH than in CNN/Daily Mail. Xie

question	type
..... As a Senior student, I have to __ many exams. ..... *A: finish* *B: win* ***C: take*** *D: join*	collocation
I am calling from the __ station ..... " There was an accident, and a man died ." ..... *A: post* *B: bus* ***C: police*** *D: railway*	matching
a student reported that I made an error ..... He was __ and after thanking him for his honesty ..... he said angrily . *A: wise* ***B: right*** *C: rigid* *D: angry*	reasoning
..... They are used to __ messages by computers and smart phones. ..... ***A: sending*** *B: send* *C: sent* *D: sends*	grammar

Table 1: Example questions and their corresponding types from the CLOTH dataset. "....." represents some omitted irrelevant sentences.

et al. (2017) also present the word-predicting potential of language models (LM) which can well tackle lexical collocation (e.g., *"take"* and *"exam"* in the second example), given a large volume of unlabeled data and high computation power. Furthermore, Xie et al. (2017) points out that the most difficult questions belong to the long-term-reasoning type (e.g., the third example question), which constitutes approximately 22.4% in CLOTH and needs more semantics to deal with.

To comprehensively consider the progress and questions in CLOTH, we come up with the idea of modeling multiple perspectives to arrive at the correct answer, given limited computation power. Our multi-perspective network consists of several parallel modules, where each module aggregates context information from a unique perspective. We model long-distance matching with attentive readers, global semantics with iterative dilated convolutions and lexical collocation with both n-gram and neural language model(LM). The outputs of aggregation modules are further integrated and fed into a one-timestep pointer network (Vinyals et al., 2015) to get the final answer.

Next, one challenging problem is how to effectively train our multi-perspective network due to the insufficiency of labeled data. To overcome this problem, Xie et al. (2017) present a representativeness-based weighted loss function. Their approach has two drawbacks: first, it requires to train another model for predicting a candidate's representativeness score; second, it is not a sample-efficient way since each word including uninformative stop words becomes a training example. In this paper, we improve on Xie et al. (2017)'s approach and develop a semi-supervised learning method by matching the distribution of candidates between labeled and unlabeled data. The intuition is to make automatically constructed data as similar as possible to existing labeled data. Stop words, named entities and out-of-vocabulary words should be downsampled while meaningful content words should be kept for training.

Our method is simple, straightforward and shows better performance with only a fraction of training examples. Experiments show that our semi-supervised multi-perspective network is able to outperform state-of-the-art results on the CLOTH dataset by 4.2%.

2 Model

Formally, the task of cloze-style reading comprehension requires choosing the correct answer from $|c|$ candidates $\{c_i\}_{i=1}^{|c|}$ given a sequence of words $\{w_i\}_{i=1}^{n}$ as context. Candidate c_i could be a word or a phrase. For the CLOTH dataset, each question has $|c| = 4$ candidates.

2.1 MPNet: Multi-Perspective Context Aggregation Network

The overall architecture of our proposed MPNet is shown in Figure 1. It consists of an input layer, a multi-perspective aggregation layer and an output layer.

Input Layer Given the passage as a variable-length word sequence $\{w_i\}_{i=1}^{n}$, we embed each word into 300-dimensional word embeddings $\{\mathbf{e}_i\}_{i=1}^{n}$ using GloVe vectors. Then, we apply bidirectional GRU(BiGRU) on $\{\mathbf{e}_i\}_{i=1}^{n}$ to get contextualized word representations $\{\mathbf{h}_i\}_{i=1}^{n}$ (McCann et al., 2017)

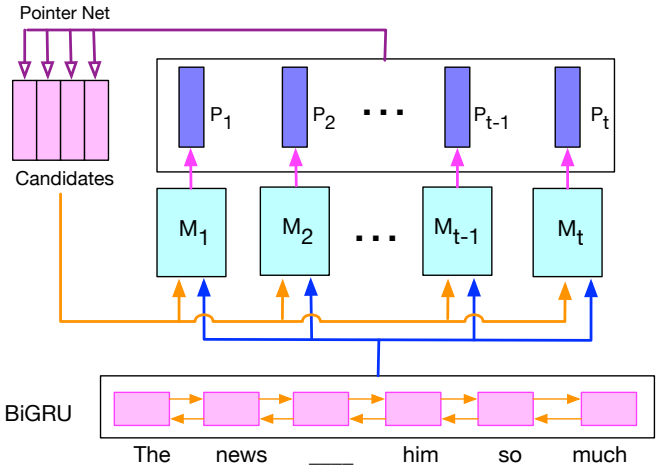

Figure 1: MPNet: **M**ulti-**P**erspective context aggregation network. We only show part of the context *"The news ___ him so much"* and "___" is the blank to fill in.

(Peters et al., 2018), since GRU is computationally more efficient and shows slightly better performance than LSTM.

$$\begin{aligned}\overrightarrow{\mathbf{h}}_i &= \overrightarrow{GRU}(\overrightarrow{\mathbf{h}}_{i-1}, \mathbf{e}_i) \\ \overleftarrow{\mathbf{h}}_i &= \overleftarrow{GRU}(\overleftarrow{\mathbf{h}}_{i+1}, \mathbf{e}_i) \\ \mathbf{h}_i &= [\overrightarrow{\mathbf{h}}_i; \overleftarrow{\mathbf{h}}_i]\end{aligned} \tag{1}$$

We also use another GRU to encode candidates $\{c_i\}_{i=1}^{|c|}$ into fixed-length vectors $\{\mathbf{u}_i\}_{i=1}^{|c|}$, as candidates may be multi-word phrases.

Multi-Perspective Aggregation Layer This layer consists of several independent aggregation modules $\{M_i\}_{i=1}^{t}$. Computation can be easily parallelized since modules are independent. Each module M_i takes contextualized word representations $\{\mathbf{h}_i\}_{i=1}^{n}$ and candidates' encoding $\{\mathbf{u}_i\}_{i=1}^{|c|}$ as input and outputs a vector $\mathbf{p}_i$, which reflects the information from module M_i's perspective. We also assume aggregation modules can have access to $\{w_i\}_{i=1}^{n}$ and $\{c_i\}_{i=1}^{|c|}$. For cloze-style reading comprehension, each module should be able to distill some knowledge which can judge whether a candidate fits a given context from a perspective.

The aggregation modules that we use are listed below:

- **Selective Copying** Assuming the index of the blank is j, this module simply selects the hidden representation of the blank $\mathbf{h}_j$, directly copies it to the output $\mathbf{p}_{sc}$ and ignores everything else. Note that $\mathbf{h}_j$ is the output of BiGRU and already incorporates context information from both forward and backward directions. This resembles a bidirectional language model without softmax output layer. Words near the blank are paid more attention which is consistent with our intuition of filling in the blank.

- **Attentive Reader** A large portion of questions involve matching candidates with related words which may be far away from each other such as the second example in Table 1. *Attentive reader* proposed by Chen et al. (2016) directly attends to the entire context and therefore avoids the difficulty of modeling long-range dependence. Original bilinear attention function (Chen et al., 2016) is slightly modified by introducing $\mathbf{b}_{ar}$ to model attention bias towards the ith word. $\mathbf{u}$ is the vector representation of a candidate, we omit its subscript for simplicity.

$$\begin{aligned}\alpha_i &= \text{softmax}_i(\mathbf{u}^T\mathbf{W}_{ar}\mathbf{h}_i + \mathbf{b}_{ar}^T\mathbf{h}_i), i \in [1, n] \\ \mathbf{p}_{ar} &= \sum_{i=1}^{n} \alpha_i \mathbf{h}_i\end{aligned} \tag{2}$$

- **Iterative Dilated Convolution** Convolutional neural networks have been a successful method for modeling both natural language (Kim, 2014) and images. Multiple layers of CNNs can extract features in a hierarchical way, which shares similarity with the compositional property of natural language. Dilated convolution is a variant of traditional convolution and is more efficient for multi-scale context aggregation (Yu and Koltun, 2015; Strubell et al., 2017). In this work, we use two blocks where each block consists of two dilated convolutions with dilation rate set to 1 and 3 respectively. Max pooling across filters is applied to get the final output $\mathbf{p}_{idc}$.

- **N-gram Statistics** To explicitly incorporate collocation information, we use this module to output logarithmic n-gram counts $\mathbf{p}_{ng}$ from *English Wikipedia* with $n \in [1, 5]$. Logarithmic function avoids the optimization difficulty with extremely large numbers.

Note that the output $\mathbf{p}_{sc}$ from selective copying module and $\mathbf{p}_{idc}$ from iterative dilated convolution module don't depend on the candidates. We therefore get context representation $\mathbf{P}_{ctx} = [\mathbf{p}_{sc}; \mathbf{p}_{idc}]$ by concatenating $\mathbf{p}_{sc}$ and $\mathbf{p}_{idc}$. Similarly, we can get the representation vector $\mathbf{C}_i$ for ith candidate by concatenating the output $\mathbf{p}^i_{ar}$ from attentive reader module, $\mathbf{p}^i_{ng}$ from n-gram statistics and $\mathbf{u}_i$ from the candidate encoder: $\mathbf{C}_i = [\mathbf{u}_i; \mathbf{p}^i_{ar}; \mathbf{p}^i_{ng}], i \in [1, |c|]$.

Output Layer We use a one-timestep pointer network (Vinyals et al., 2015) to choose the correct answer from $|c|$ candidates $\{\mathbf{c}_i\}_{i=1}^{|c|}$. Given context representation $\mathbf{P}_{ctx}$ and candidates representation $\{\mathbf{C}_i\}_{i=1}^{|c|}$, we first refine candidates representation with a gating mechanism:

$$\begin{aligned} \mathbf{g}_i &= \sigma(\mathbf{W}_1\mathbf{P}_{ctx} + \mathbf{W}_2\mathbf{C}_i + \mathbf{b}),\ i \in [1, |c|] \\ \mathbf{C'}_i &= \mathbf{C}_i \odot \mathbf{g}_i,\ i \in [1, |c|] \end{aligned} \tag{3}$$

σ is the sigmoid function and $\odot$ denotes pointwise multiplication. Then we calculate the distribution of being the correct answer over candidates with bilinear function:

$$\hat{y}_i = \mathrm{softmax}_i(\mathbf{C'}_i^T \mathbf{W}_o \mathbf{P}_{ctx} + \mathbf{b}_o^T \mathbf{C'}_i),\ i \in [1, |c|] \tag{4}$$

$\{\hat{y}_i\}_{i=1}^{|c|}$ is a probability distribution and the pointer points to the candidate $\arg\max_i(\hat{y}_i)$.

Model Learning The model is trained by minimizing the standard cross-entropy loss.

Discussion Different aggregation modules summarize context from different perspectives. In order to precisely locate the correct answer, a set of complementary aggregation modules are preferred where one module may only focus on lexical collocation and another module may be sensitive to the global matching. It is worth noting that our MPNet framework can be easily extended by adding other effective aggregation modules.

In addition, the main idea of MPNet is to some extent connected with the mixture of experts (MoE) (Masoudnia and Ebrahimpour, 2014). If each aggregation module can be seen as an expert, then multiple aggregation modules become MoE. One key difference is that aggregation modules in MPNet have heterogeneous network structures while traditional MoE models usually consist of homogeneous experts.

2.2 SemiMPNet: Semi-supervised Learning with Distribution Matching

SemiMPNet is the semi-supervised variant of our proposed MPNet in Section 2.1, with exactly the same network architecture. Though CLOTH consists of nearly $100k$ questions, it is generally not enough to train large neural models. Semi-supervised learning comes to the rescue. We propose to sample from unlabeled text to construct training examples automatically. In order to train effectively, we need to make the automatically generated data similar to labeled data and ensure that candidates should have a similar distribution in original labeled data to that in the generated data. Then, we formulate candidates distribution matching in two datasets as two sampling problems as follows:

How to sample positive candidates? We assume D_u is a collection of unlabeled documents, D_c is the collection of all candidates in the CLOTH dataset and V is the vocabulary which is composed of all the candidates occurring in CLOTH. Each word $w_i \in V$ is associated with an unknown sampling probability $p(w_i)$. To match the distribution of candidates between D_u and D_c, the following constraints about $p(w_i), i \in [1, |V|]$ should be satisfied:

$$\begin{gathered} \frac{p(w_i)\#(w_i, D_u)}{\sum_{j=1}^{|V|} p(w_j)\#(w_j, D_u)} = \frac{\#(w_i, D_c)}{\sum_{j=1}^{|V|} \#(w_j, D_c)},\ i \in [1, |V|] \\ 0 \leq p(w_i) \leq 1, i \in [1, |V|] \\ \max\{p(w_i)|\ i \in [1, |V|]\} = 1 \end{gathered} \tag{5}$$

Function $\#(w_i, D)$ returns the frequency of w_i in corpus D. The second constraint is to make sure $\{p(w_i)\}_{i=1}^{|V|}$ is a valid probability distribution and the third constraint is to make full use of data. There is generally no exact solution to Equation(5) as $\#(w_i, D_u) = 0$ and $\#(w_i, D_c) > 0$ may hold for some i. Instead, we use an approximate solution:

$$p(w_i) = \min(1, \frac{\#(w_i, D_c)}{\#(w_i, D_u)} \times \frac{\gamma \sum_{j=1}^{|V|} \#(w_j, D_u)}{\sum_{j=1}^{|V|} \#(w_j, D_c)}) \tag{6}$$

The coefficient γ can be interpreted as the average probability of sampling a word. We set $\gamma = 0.5$ based on validation data. With this strategy, we sample the positive candidates and use the corresponding passages as their contexts.

How to sample negative candidates? Given a positive candidate w_p, the probability of w_i being sampled as a negative candidate $p(w_i|w_p)$ can be calculated as follows:

$$p(w_i|w_p) = \frac{\lambda}{|V|} + (1 - \lambda)\frac{\#(w_i, w_p)}{\sum_{j=1}^{|V|} \#(w_j, w_p)} \tag{7}$$

$\#(w_i, w_p)$ is the co-occurrence counts of w_i and w_p as candidates in labeled dataset D_c. Intuitively, the co-occurrence probability of w_i and w_p should match between constructed data and labeled data. λ is the probability of randomly selecting a word from the entire vocabulary, similar to the exploration mechanism in reinforcement learning. It makes our model more robust to overfitting and we set $\lambda = 0.1$ throughout the experiments.

In the case that candidates are multi-word phrases, our method is also applicable by simply expanding the vocabulary V to include phrases in D_c.

3 Experiments

3.1 Experimental Setup

Dataset and Evaluation Metrics We use the CLOTH (Xie et al., 2017) dataset for training and evaluation. RACE (Lai et al., 2017) dataset and *English Wikipedia* [1] serve as background text corpora for semi-supervised learning. RACE dataset consists of nearly $28k$ reading comprehension passages from high-school examinations. We delete passages that have a Jaccard similarity over 0.85 with passages in the CLOTH dataset. Furthermore, background text corpora also include training passages from the CLOTH dataset by filling the correct answer back into the corresponding blank.

Accuracy is used as the evaluation metric. To make a fair comparison with Xie et al. (2017), we also report performance on CLOTH-M(middle school questions) and CLOTH-H(high school questions).

Hyperparameters Our model is implemented with Tensorflow (Abadi et al., 2016). Hyperparameters are optimized with random search based on validation data. All our models are run on a single GPU(Tesla P40). NLTK (Bird and Loper, 2004) is used for tokenization. Word embeddings are initialized with

[1] https://dumps.wikimedia.org/enwiki/

300-dimensional GloVe (Pennington et al., 2014) vectors. Only vectors of top 1000 frequent words are fine-tuned during training. Our network is trained with Adam algorithm (Kingma and Ba, 2014). The initial learning rate is set to 10^{-3}. We decrease learning rate to 10^{-4} after $15k$ iterations and further decrease it to 10^{-5} after $50k$ iterations. Both forward and backward GRU have 128 hidden units. For input, we use a context window of 80 words. For 1D dilated convolution, we use 2 blocks, the number of filters is 128 and the convolution width is 3 for all layers. Batch normalization and ReLU are applied on top of convolution. Gradients are clipped to have a maximum L2 norm of 5. Dropout with probability 0.5 is applied to the output of BiGRU.

Model	+ constructed data?	CLOTH	CLOTH-M	CLOTH-H
Random	No	25.0%	25.0%	25.0%
LSTM (Xie et al., 2017)	No	48.4%	51.8%	47.1%
Stanford Attention Reader (Chen et al., 2016)	No	48.7%	52.9%	47.1%
MPNet - ngram	No	**50.1%**	**53.2%**	**49.0%**
Language Model (Xie et al., 2017)	Yes	54.8%	64.6%	50.6%
Representativeness (Xie et al., 2017)	Yes	56.5%	66.5%	52.6%
LSTM + Representativeness (Xie et al., 2017)	Yes	58.3%	67.3%	54.9%
SemiMPNet - ngram	Yes	**60.9%**	**67.6%**	**58.3%**
Human	–	86.0%	89.7%	84.5%

Table 2: Experimental results without using external data. We exclude *n-gram* as *n-gram* is calculated based on external corpus *Wikipedia*. SemiMPNet uses passages from CLOTH for semi-supervised data augmentation. Human performance is from Xie et al. (2017).

3.2 Baselines

LSTM is a baseline model by Xie et al. (2017). First, a BiLSTM layer is applied to context word embeddings. Then it uses the outputs near the blank to calculate the probability of being the correct answer for each candidate.

Stanford Attention Reader is an attention-based neural model for reading comprehension presented by Chen et al. (2016). Experimental results are from Xie et al. (2017).

Language Model To overcome the difficulty of insufficient labeled data. Xie et al. (2017) propose to train a neural language model on passages from the CLOTH dataset. The candidate that results in the highest probability is chosen as the predicted answer. It's fair to say *Language Model* is a simple data augmentation approach that treats every word as a training example with equal weight.

Representativeness is another semi-supervised data augmentation approach by Xie et al. (2017). It assigns different weights to different constructed examples based on *Representativeness score*. *Representativeness* can be interpreted as the probability of a given word being selected as a blank by human. For more technical details, please refer to Xie et al. (2017).

One-billion-word-LM is a state-of-the-art neural language model (Jozefowicz et al., 2016) trained on one-billion-word benchmark (Chelba et al., 2013). It has more than 1 billion parameters and is publicly available[2].

3.3 Main Results

We evaluate our model's performance in two experimental settings: use external data or not. For the setting without external data, we only use passages from CLOTH for training and semi-supervised data augmentation. Though GloVe vectors are trained on external text corpora, it has become a standard practice for NLP to use pretrained embeddings. Therefore, GloVe vectors are used in both settings and so does the work by Xie et al. (2017).

Results w/o External Data Results are shown in Table 2. When trained only on labeled data, both LSTM by Xie et al. (2017) and our proposed MPNet perform poorly, though MPNet slightly outper-

[2] https://github.com/tensorflow/models/tree/master/research/lm_1b

forms LSTM by 1.7% in overall accuracy. The accuracy of middle school questions (CLOTH-M) is consistently higher than high school questions (CLOTH-H) across all of our experiments, since middle school questions are relatively easier.

w	$p(w)$	w	$p(w)$	w	$p(w)$
I	0.04	festivals	0.75	California	0.13
the	0.03	birthday	1.0	thank you	0.26
Frank	0.09	8	0.09	congratulation	1.0

Table 3: Sample probability for some words. $p(w)$ is the probability of sampling w to construct a training example. Stop words, named entities usually have low probability. See Section 2.2 for details.

Table 2 clearly shows that constructed data can significantly boost both models' performance. Xie et al. (2017) explore several different ways for data augmentation: *Language Model* treats every word equally, while *Representativeness* method assigns different weights to different words by training an representativeness prediction network. This mechanism improves the accuracy from 48.4% to 58.3%. Further, our proposed method adopts a new sampling method and requires sampling words with distribution constraints, which makes training more efficient. As shown in Table 3, stop words (e.g., *"I"* and *"the"*), named entities (e.g., *"Frank"* and *"California"*) and common phrases (e.g., *"thank you"*) have low probability of being sampled. Content words such as *"festivals"* and *"birthday"* are more likely to be sampled. One limitation of our sampling method is its inability to handle synonyms. Since synonyms tend to co-occur as candidates in the labeled dataset, this problem is not as severe as it looks like to be. *"SemiMPNet - ngram"* beats all baseline methods and achieves the highest accuracy 60.9%. Human performance is 86.0% which is much higher than *"SemiMPNet - ngram"*. The effectiveness of constructed data indicates that the lack of labeled data has become a bottleneck.

Model	CLOTH	CLOTH-M	CLOTH-H
One-billion-word-LM	70.7%	74.5%	69.3%
MPNet	65.3%	70.0%	63.6%
SemiMPNet	70.4%	75.5%	68.5%
SemiMPNet + One-billion-word-LM	**74.9%**	**79.0%**	**73.3%**
Human	86.0%	89.7%	84.5%

Table 4: Experimental results with external data. SemiMPNet use passages from the RACE dataset for semi-supervised data augmentation.

Results with External Data As shown in Table 4, incorporation of the RACE dataset for semi-supervised learning improves accuracy from 65.3% to 70.4%. However, MPNet and SemiMPNet still underperform a pretrained state-of-the-art neural language model *One-billion-word-LM* (Jozefowicz et al., 2016). It is trained on a large corpus with nearly 1 billion words and achieves an accuracy of 70.7%. In contrast, SemiMPNet is trained on only $\sim$ 10 million words and has a 0.3% gap in accuracy, which is pretty impressive given that the sizes of two corpora differ by two orders of magnitude. Once again it shows the power of transferring knowledge from unlabeled text corpora.

As a further discussion, we'd like to point out that although language model can achieve good results, it is not the most efficient way. Actually, experimental results in Table 2 show that language model underperforms SemiMPNet given the same amount of text. A fair comparison would be training SemiMPNet on the one-billion-word benchmark. Considering the size of the one-billion-word corpus, applying our semi-supervised method directly on the one-billion-word corpus would require a sizable amount of computing power. Here we design an approximate method *"SemiMPNet + One-billion-word-LM"* and combine MPNet and *One-billion-word-LM* by linear interpolation of their output probabilities:

$$p = \beta p_{mp} + (1 - \beta) p_{lm} \tag{8}$$

p_{mp} is the output probability by SmiMPNet and p_{lm} is the normalized probability by *One-billion-word-*

LM[3]. Setting $\beta = 0.5$ yields empirically good results. Hyper-parameter search shows the results are quite robust to a wide range of β values. We can see that our model *"SemiMPNet + One-billion-word-LM"* achieves a new state-of-the-art performance of 74.9%, which improves *One-billion-word-LM* by 4.2%. This also shows the complementarity of SemiMPNet and *One-billion-word-LM*. Two models can learn different aspects of the contexts.

3.4 Ablation Study

Our proposed MPNet consists of four aggregation modules. To examine the effect of each module, we conduct an ablation study. The results are shown in Table 5.

Model	CLOTH
SemiMPNet	**70.4%**
w/o selective copying	69.4% (-1.0)
w/o attentive reader	67.6% (-2.8)
w/o dilated convolution	69.6% (-0.8)
w/o n-gram statistics	63.0% (-7.4)

Table 5: Results for SemiMPNet ablation study. RACE dataset is used for semi-supervised data augmentation.

N-gram statistics turn out to be the single most influential factor. Overall performance decreases by 7.4% without *n-gram statistics*. On one hand, this result further highlights the importance of distilling knowledge from large text corpora. On the other hand, it proves that our background corpus is not large enough for neural models to learn reliable lexical collocation information.

Attentive reader also has a significant impact on overall performance. Attention mechanism is able to locate useful information regardless of its positional distance from the blank. In contrast, RNNs need to preserve such information over a long distance which is nontrivial.

Besides, the results in Table 5 support an important intuition in this paper: different modules capture context information from different perspectives, and removing any one of them would result in decreased performance.

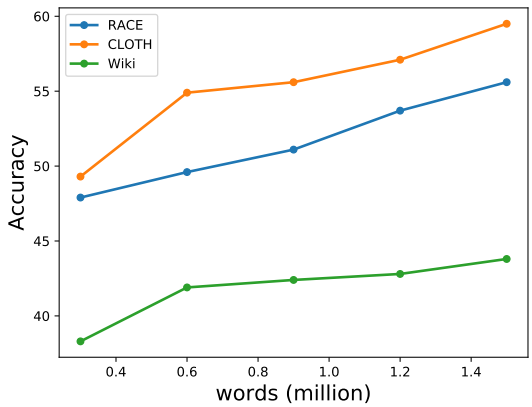

Figure 2: Examining effects of different text corpora. The x-axis is the number of words in background corpus, and the y-axis is the accuracy on test data. To avoid the influence of external data, we report model performance with *"SemiMPNet - ngram"*.

3.5 Examining Effects of Background Corpus

For our semi-supervised learning model SemiMPNet, background corpus is used to construct training examples. The choice of background corpus can make a big difference. In this section, we conduct an

[3]The normalization makes sure the probabilities for all candidates sum to 1.

experiment to examine such effects. Three different corpora are used: passages from the training set of CLOTH, RACE and English Wikipedia.

Results are shown in Figure 2. Unsurprisingly, more data lead to better performance. Moreover, given the same amount of text, CLOTH consistently beats RACE and RACE consistently beats Wikipedia. As we know, CLOTH and RACE consists of passages designed for high school students, while Wikipedia entries are for the general public and therefore have a different word distribution. Thus, how to make use of huge unlabeled data to help training is a key for performance improvement, since training corpora of higher quality are generally smaller in scale.

4 Related Work

Reading Comprension or machine reading is drawing more and more interests among NLP research communities. The CNN/Daily Mail (Hermann et al., 2015) and CBT (Hill et al., 2015) are two automatically generated cloze-style datasets. Though they can be large in scale, the quality of automatically generated questions is generally lower than manually labeled ones. Instead, SQuAD (Rajpurkar et al., 2016) adopts a crowd-sourcing approach to ensure its quality. In SQuAD, each passage accompanies one or more questions and the answer is a text span of the given passage for the convenience of automatic evaluation. Rapid progress has been made with neural network based models (Wang et al., 2016). The performances of state-of-the-art models on SQuAD such as QANet (Yu et al., 2018) and ELMo (Peters et al., 2018) are already very close to human. There are also some datasets focusing on answering questions from real-world scenarios. MS MARCO (Nguyen et al., 2016) and DuReader (He et al., 2017) are two typical examples. Such datasets are usually harder as they require the ability of both comprehension and language generation. BLEU and ROUGE are often used as evaluation metrics. One potential problem is that answers with high BLEU scores may have very different semantic meanings.

Cloze Test is a particular form of reading comprehension task and has been widely adopted as a method for assessing students' language proficiency. Zweig and Burges (2011) presented a challenging dataset for sentence completion but its scale is too small with only 1040 questions. CNN/Daily Mail (Hermann et al., 2015), CBT (Hill et al., 2015), LAMBADA (Paperno et al., 2016) and CLOTH (Xie et al., 2017) are all large-scale cloze-test datasets, with the difference that each question in CLOTH has four candidate options. Recently proposed Story Cloze (Mostafazadeh et al., 2017) is a cloze-test dataset that goes beyond words and phrases, and requires choosing a sentence as the appropriate story ending.

Semi-supervised Methods for reading comprehension are widely studied due to the fact that labeled data is scarce. One major approach is pretraining a model for text representation and reusing the weights during supervised learning. Autoencoders (Hewlett et al., 2017), machine translation (McCann et al., 2017) and language model (Peters et al., 2018) can be used for representation learning. Another approach aims to directly construct training examples from unlabeled text corpora. Weighted loss function (Xie et al., 2017) and reinforcement learning (Yang et al., 2017) can be used to alleviate the discrepancy between human-labeled data and automatically-constructed data.

5 Conclusion

In this paper, we propose a multi-perspective network MPNet for cloze-style reading comprehension. MPNet consists of several parallel context aggregation modules. Each module summarizes the variable-length context and candidates into a fixed-length vector from a unique perspective. We explore four effective implementations of aggregation modules in experiments. The architecture of MPNet is very flexible and can be easily extended by adding more task-specific modules.

To overcome the difficulty of limited labeled data, we turn to semi-supervised learning by automatically constructing training examples from unlabeled text corpora. Experiments on the CLOTH dataset show that our semi-supervised MPNet achieves new state-of-the-art performance. In our future work, we'd like to come up with more effective methods to tackle this challenge.

Abstract

Attention mechanisms have been leveraged for sentiment classification tasks because not all words have the same importance. However, most existing attention models did not take full advantage of sentiment lexicons, which provide rich sentiment information and play a critical role in sentiment analysis. To achieve the above target, in this work, we propose a novel lexicon-based supervised attention model (LBSA), which allows a recurrent neural network to focus on the sentiment content, thus generating sentiment-informative representations. Compared with general attention models, our model has better interpretability and less noise. Experimental results on three large-scale sentiment classification datasets showed that the proposed method outperforms previous methods.

1 Introduction

Sentiment analysis has the goal of analyzing people's sentiments or opinions and has been well explored (Turney, 2002; Tang et al., 2014b; Chen et al., 2016). In order to improve sentiment analysis results, large sentiment lexicons have been built (Wilson et al., 2005; Baccianella et al., 2010; Tang et al., 2014a). A sentiment lexicon is a set of words such as *excellent*, *terrible* and *ordinary*, each of which is assigned a fixed positive or negative score that presents its sentiment polarity and strength (Tang et al., 2014a). Such information can serve as sentiment-informative features and significantly boost the classification performance (Agarwal et al., 2013; Teng et al., 2016; Qian et al., 2016).

In sentiment classification tasks, sentiment words such as *great* and *terrible* tend to play a more critical role than other words in texts (Liu, 2010). One attribute of words annotated in sentiment lexicons is their sentiment strength, which is intuitively associated with a word's contribution to the sentiment representation of a sentence. It is similar to the basic idea of the attention mechanism that not all words have the same importance. However, very few studies have focused on a method that combines an attention mechanism with such sentiment information. Yang et al. (2016) and Chen et al. (2016) proposed a hierarchical RNN model to learn attention weights based on the local context using an unsupervised method. However, their method may induce much noise and suffers from a lack of interpretability because it tends to capture some domain-specific words (Mudinas et al., 2012) instead of real sentiment information. For example, in movie reviews, the name of a movie with a good reputation tends to be regarded as positive words, and is thereby assigned higher weights, which does not work in other domains. Long et al. (2017) incorporated the reading time of human beings into the attention mechanism, but their method also has much noise because during the reading process, people tend to spend more time on intricate contents (Goodman, 1988) than on real sentiment words like *good* and *bad*. Other methods employed external information such as users and products to guide attention weights (Ma et al., 2017; Chen et al., 2016), which can boost the classification performance by a large margin. However, most of the time, we have no access to such external information.

In this paper, we propose a novel Lexicon-Based Supervised Attention model (LBSA) that combines sentiment lexicons and an attention mechanism to better extract sentiment information and form

Proceedings of the 27th International Conference on Computational Linguistics, pages 868–877
Santa Fe, New Mexico, USA, August 20-26, 2018.

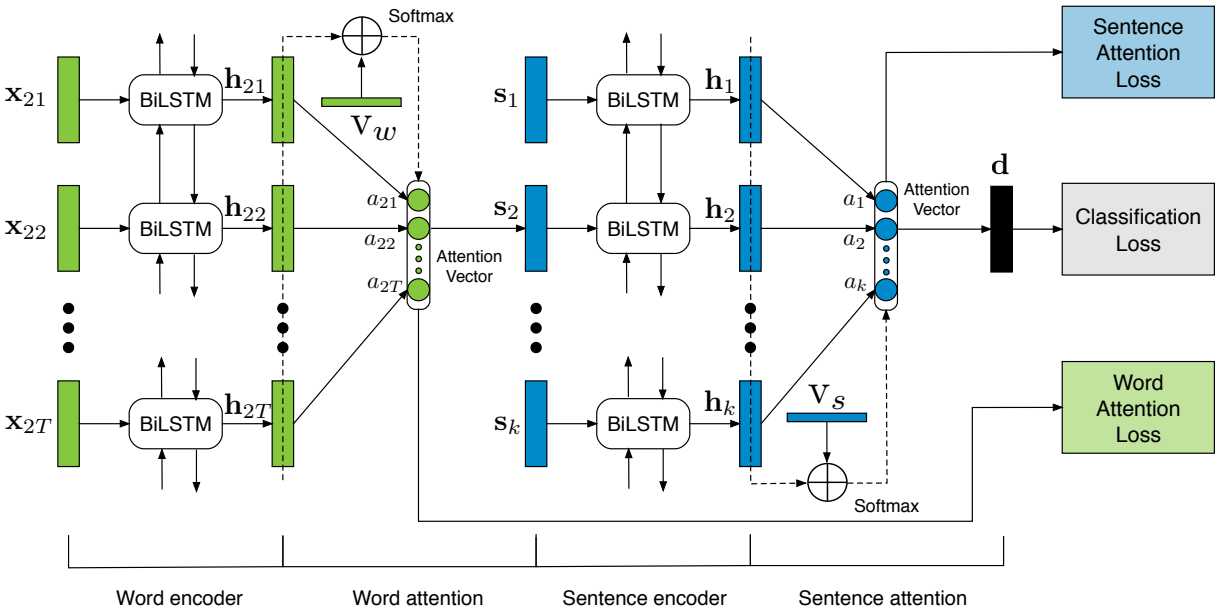

Figure 1: LBSA sentiment classification model.

sentiment-informative representations. We hypothesized that regardless of the polarities, sentiment words should be given more emphasis than other words in texts. For example, in the phrases *great film* and *terrible weather*, we should pay more attention to the sentiment words *great* and *terrible* than the words *film* and *weather*. Moreover, we define the *sentiment degree* to describe the intensity of the word sentiment, which can be attained from existing sentiment lexicons. The sentiment degree can then be used as the criterion for attention weights in a recurrent neural network model. Under the guidance of a supervised mechanism, sentiment words will be assigned higher attention weights, which reduces the influence of domain-specific words and generates sentiment-informative representations. We conducted experiments on three sentiment analysis benchmark datasets (IMDB, Yelp13, Yelp14). The experimental results showed that our model outperformed other state-of-the-art methods.

To summarize, our main contributions are as follows:

- We propose a novel lexicon-based attention model. It combines an attention mechanism with sentiment lexicons based on the *sentiment degree*. As a result, our model can precisely identify the sentiment contents in texts and capture accurate sentiment information.
- Benefiting from the guidance of supervised methods, our attention model has better interpretability and less noise than other attention models. Thus, it is better at summarizing and analyzing the sentiment of texts in an RNN fashion.
- Our model outperforms state-of-the-art methods on three sentiment analysis datasets (IMDB, Yelp13, Yelp14). This work validated the effectiveness of combining the sentiment lexicons and attention mechanism.

2 Approach

The overall architecture of our model is shown in Figure 1. It incorporates a word-level supervised attention layer and sentence-level supervised attention layer into a hierarchical bidirectional LSTM sentiment classification model. Formally, let D be a set of documents, and L be a sentiment lexicon. A document $d_m \in D$ contains k sentences S_1, S_2, ..., S_i, ..., S_k. A sentence S_i is a sequence of words w_{i1} w_{i2}...w_{it}, $t \in [1, T]$, where T denotes the length of S_i. For each word w_{it}, we define $SD^L(w_{it})$ as the *sentiment degree* (see Section 2.2.1) of w_{it} according to lexicon L. The sentiment degree is a positive real number, which can be attained from lexicons and indicates the strength of word sentiment.

As the figure shows, the word w_{it} is represented by its word embedding $\mathbf{x}_{it}$, which is fed into a bidirectional LSTM model (Graves and Schmidhuber, 2005; Graves et al., 2013) to extract sequential information. The word attention layer aggregates the representation of sentiment-informative words to form a sentence representation $\mathbf{s}_i$, with the supervision of the sentiment degree. Similarly, we can obtain the document representation $\mathbf{d}$ through a sentence-level attention layer to finally conduct sentiment classification. The concrete design is introduced in the following subsections.

2.1 Bidirectional LSTM

We adopt a Long Short-Term Memory (LSTM) network (Hochreiter and Schmidhuber, 1997) for the word-level and sentence-level feature extraction. As an example, consider the word-level case. For each word token w_t in a sentence, the model calculates a hidden state vector $\mathbf{h}_t$. The basic LSTM model has five internal vectors for node t. They control the information flow from the history $\mathbf{x}_1$ ...$\mathbf{x}_t$ and $\mathbf{h}_1$ ...$\mathbf{h}_{t-1}$ to the current state $\mathbf{h}_t$. Formally, $\mathbf{h}_t$ is calculated as follows:

$$
\begin{aligned}
\mathbf{i}_t &= \sigma(\mathbf{W_i}\mathbf{x}_t + \mathbf{U_i}\mathbf{h}_{t-1} + \mathbf{V_i}\mathbf{c}_{t-1} + \mathbf{b_i}) \\
\mathbf{f}_t &= \mathbf{1.0} - \mathbf{i}_t \\
\mathbf{c}'_t &= tanh(\mathbf{W_{c'}}\mathbf{x}_t + \mathbf{U_{c'}}\mathbf{h}_{t-1} + \mathbf{b_{c'}}) \\
\mathbf{c}_t &= \mathbf{f}_t \odot \mathbf{c}_{t-1} + \mathbf{i}_t \odot \mathbf{c}'_t \\
\mathbf{o}_t &= \sigma(\mathbf{W_o}\mathbf{x}_t + \mathbf{U_o}\mathbf{h}_{t-1} + \mathbf{V_o}\mathbf{c}_t + \mathbf{b_o}) \\
\mathbf{h}_t &= \mathbf{o}_t \odot tanh(\mathbf{c}_t)
\end{aligned}
$$

Each word is embedded into a low-dimensional semantic space. Namely, each word w_t is mapped to its embedding $\mathbf{x}_t \in \mathbb{R}^n$, where n is the word embedding size. $\odot$ denotes element-wise multiplication, and σ is the sigmoid function. $\mathbf{W_i}$, $\mathbf{U_i}$, $\mathbf{V_i}$, $\mathbf{b_i}$, $\mathbf{W_{c'}}$, $\mathbf{U_{c'}}$, $\mathbf{b_{c'}}$, $\mathbf{W_o}$, $\mathbf{U_o}$, $\mathbf{V_o}$, and $\mathbf{b_o}$ represent LSTM parameters.

We use a bidirectional version of LSTM (BiLSTM) (Graves and Schmidhuber, 2005; Graves et al., 2013) to obtain information from both directions for words. The bidirectional LSTM contains the forward LSTM $\overrightarrow{f}$, which reads the sentence S_i from w_{i1} to w_{it}, and the backward LSTM $\overleftarrow{f}$, which reads from w_{it} to w_{i1}. The BiLSTM model maps each word embedding $\mathbf{x}_{it}$ to a pair of hidden vectors $\overrightarrow{\mathbf{h}_{it}}$ and $\overleftarrow{\mathbf{h}_{it}}$. We use different parameters for the forward LSTM and backward LSTM. These hidden vectors are the composition of sentence embedding $\mathbf{s}_i$, and used as features for calculating attention weights. On the sentence level, we also feed sentence embeddings $[\mathbf{s}_1, \mathbf{s}_2, ..., \mathbf{s}_k]$ into BiLSTM to obtain pairs of hidden vectors in a similar way.

2.2 Lexicon-based Supervised Attention

In this subsection, we introduce supervised attention to explicitly use sentiment lexicon information to aggregate sentiment-informative texts. Our basic idea is simple: sentiment words should be given more attention than others. To achieve this goal, we construct gold attention vectors using the lexicon information. These are employed as criteria to supervise the attention weights.

2.2.1 Gold Attention Vectors

Each word in the sentiment lexicon is annotated or assigned a fixed positive or negative score that reflects its sentiment polarity and strength. We map all of them into the interval $[-1, 1]$ as normalized sentiment scores, where a score in $(0, 1]$ represents various scales of *good* and one close to 1 means *very good*, with negations showing the opposite. Intuitively, a word with a strong positive or negative polarity requires more attention because it contains more sentiment information than a neutral word. In order to quantify the intensity of the sentiment, for each word w_{it} in sentence s_i, we define *sentiment degree* $SD^L(w_{it})$ as follows:

$$SD^L(w_{it}) = |score^L(w_{it})|, \tag{1}$$

where $score^L(w_{it})$ is the normalized sentiment score according to lexicon L. $SD^L(w_{it})$ is the absolute value of $score^L(w_{it})$, which means its range is $[0, 1]$. For words not in the lexicon, their sentiment

degrees are assigned values of 0. For sentence S_i, whose length is T, we compute word-level gold attention vectors $\mathbf{a}_i^\star$ by:

$$a_{it}^\star = \frac{exp(\lambda_w SD^L(w_{it}))}{\sum_{t=1}^{T} exp(\lambda_w SD^L(w_{it}))}. \tag{2}$$

λ_w is a positive hyper-parameter that adjusts the variance of the sentiment degree. A larger λ_w means a sharper distinction between sentiment terms and neutral ones in gold attention vectors. $a_{it}^\star$ denotes the t^{th} dimension of $\mathbf{a}_i^\star$.

We likewise construct sentence-level gold attention vectors. Given a document with k sentences, S_i denotes the i^{th} sentence in it. Empirically, a sentence tends to achieve a higher sentiment degree if it contains a higher proportion of sentiment words. Hence, we calculate the sentiment degree of S_i using a simple averaging method:

$$SD^L(S_i) = \frac{\sum_{t=1}^{T} SD^L(w_{it})}{T}. \tag{3}$$

Let λ_s be the sentence-level hyper-parameter. We then obtain sentence-level gold attention vectors $\mathbf{a}^\star$ in a similar way:

$$a_i^\star = \frac{exp(\lambda_s SD^L(S_i))}{\sum_{i=1}^{k} exp(\lambda_s SD^L(S_i))}. \tag{4}$$

2.2.2 Learned Attention Vectors

As described in the previous subsection, we obtain pairs of hidden states $\overrightarrow{\mathbf{h}_{it}}$ and $\overleftarrow{\mathbf{h}_{it}}$ from the word-level BiLSTM model. They can be employed to calculate a weight value π_{it}, which presents the sentiment strength of word w_{it}. Formally, π_{it} is defined as follows:

$$\pi_{it} = tanh(\mathbf{W}_{wf}\overrightarrow{\mathbf{h}_{it}} + \mathbf{W}_{wb}\overleftarrow{\mathbf{h}_{it}} + \mathbf{b}_w) \cdot \mathbf{v}_w^\top, \tag{5}$$

where $\mathbf{W}_{wf}$ and $\mathbf{W}_{wb}$ denote word-level weight matrices, and $\mathbf{b}_w$ is the bias vector. It is worth noting that $\mathbf{v}_w$ is a weight vector that can record historical sentiment information. It is just like the query vector employed by memory networks (Sukhbaatar et al., 2015). It is jointly learned during the training process. $\mathbf{v}_w^\top$ represents the transpose of $\mathbf{v}_w$.

After calculating the weight value π_{it}, we use a softmax function to generate the attention vector $\mathbf{a}_i$. The t^{th} dimension a_{it} denotes the attention weight of the t^{th} word w_{it} in sentence S_i. Specifically, a_{it} is computed as follows:

$$a_{it} = \frac{exp(\pi_{it})}{\sum_{t=1}^{T} exp(\pi_{it})}. \tag{6}$$

The learned attention vector $\mathbf{a}_i$ contains different weights for the corresponding words in sentence S_i. We then compute the sentence vector $\mathbf{s}_i$ as a weighted sum of the hidden vectors according to the weights, where $\mathbf{h}_{it}$ means a concatenation of $\overrightarrow{\mathbf{h}_{it}}$ and $\overleftarrow{\mathbf{h}_{it}}$:

$$\mathbf{s}_i = \sum_{t=1}^{T} a_{it}\mathbf{h}_{it}. \tag{7}$$

After obtaining sentence vectors $\mathbf{s}_i$, $1 \leq i \leq k$, we feed them into the sentence-level BiLSTM model to output hidden vector pairs. Similarly, with the attention mechanism, the hidden vector pairs $\overrightarrow{\mathbf{h}_i}$ and $\overleftarrow{\mathbf{h}_i}$, and their concatenation $\mathbf{h}_i$, document vector $\mathbf{d}$ can be induced as follows:

$$\pi_i = tanh(\mathbf{W}_{sf}\overrightarrow{\mathbf{h}_i} + \mathbf{W}_{sb}\overleftarrow{\mathbf{h}_i} + \mathbf{b}_s) \cdot \mathbf{v}_s^\top, \tag{8}$$

$$a_i = \frac{exp(\pi_i)}{\sum_{i=1}^{k} exp(\pi_i)}, \tag{9}$$

$$\mathbf{d} = \sum_{i=1}^{k} a_i\mathbf{h}_i. \tag{10}$$

Data	Class	Train Size	Dev. Size	Test Size	Sents/doc	Words/sent
IMDB	10	67,426	8,381	9,112	16.08	24.54
Yelp14	5	183,019	22,745	25,399	11.41	17.26
Yelp13	5	62,522	7,773	8,671	10.89	17.38

Table 1: Statistical information for three datasets. Sents/doc is the average number of sentences in a document, while Words/sent denotes the average length of a sentence.

2.3 Jointly Supervised Classification and Attention

The final document vector $\mathbf{d}$ is used to conduct sentiment classification, which requires the probability of labeling a document with sentiment polarity c, $c \in [1, C]$, where C represents the total number of classes. The probability is computed by a softmax function:

$$\mathbf{p} = softmax(\mathbf{W}_c\mathbf{d} + \mathbf{b}_c). \tag{11}$$

To jointly supervise the classification and attention, we introduce a soft constraint method that is employed by other tasks with supervised attention (Liu et al., 2016). Specifically, it is defined as follows:

$$\mathcal{L} = -\sum_{c=1}^{C} \mathbf{g}_c log(\mathbf{p}_c) + \mu_w \cdot \sum_{i=1}^{T} \triangle(\mathbf{a}_i^\star, \mathbf{a}_i) + \mu_s \cdot \triangle(\mathbf{a}^\star, \mathbf{a}), \tag{12}$$

where the classification loss function is cross entropy. $\mathbf{g}_c \in \mathbb{R}^C$ denotes the ground truth of the sentiment classification, presented by a one-hot vector. $\mathbf{p}_c \in \mathbb{R}^C$ is the predicted probability for each class. $\mathbf{a}_i^\star$ and $\mathbf{a}^\star$ are gold attention vectors for the word and sentence levels, respectively. $\mathbf{a}_i$ and $\mathbf{a}$ are learned attention vectors for the word and sentence levels, respectively. $\triangle$ is a loss function that indicates the disagreement between two vectors. Because the learned attention vector is a distribution, we naturally use cross entropy (CE) as the metric:

$$\triangle(\mathbf{a}^\star, \mathbf{a}) = -\sum_i \mathbf{a}_i^\star log(\mathbf{a}_i). \tag{13}$$

μ_w and μ_s are the coefficients for attention loss functions, which can balance the preference between classification and attention disagreements, to alleviate the overfitting problem.

3 Experimental Settings

In this section, we introduce the experimental settings in detail, including the datasets and lexicons, hyper-parameter settings, and baseline models.

3.1 Datasets and Lexicons

We conduct experiments to evaluate the effectiveness of our method on three document-level review datasets: IMDB, Yelp 2013 and Yelp 2014, which are developed by Tang et al. (2015). We split the datasets into training, development and testing sets in the proportion of 8:1:1, using pre-processing in the same way as Tang et al. (2015). Table 1 summarizes the statistics of the datasets. All of these datasets can be publicly accessed[1].

The sentiment lexicon contains four parts. During the process of constructing our lexicon, we only use the sentiment scores for unigrams. The first part comes from SentimentWordNet3.0 (SWN) (Baccianella et al., 2010). The original scores in SWN are the probabilities of positive, negative, or neutral polarities for words. We take the maximum sum of the positive and negative scores as the sentiment degree for different part-of-speech tags. The second part is extracted from MPQA (Wilson et al., 2005), which tags polarity ratings for sentiment words. To a word whose polarity is positive or negative, we assign 1 as its sentiment degree. Otherwise, the word's sentiment degree is 0. The third part consists of the leaf nodes of the Stanford Sentiment Treebank (SST) dataset (Socher et al., 2013). The sentiment scores of

[1] http://ir.hit.edu.cn/dytang/paper/acl2015/dataset.7z

SST are in the range of [0, 1]. We scale it to [-1, 1] and keep the absolute value as the sentiment degree. The last part is the sentiment lexicon of the Hownet Knowledge Database (HKD)[2], which contains a list of positive or negative words. We conduct the pre-processing in the same way as for MPQA. Finally, we combine the four parts and average the sentiment degree for words appearing in two or more lexicon parts. All of the neutral words in different parts are included in our lexicon because of the ignorance of polarity. Hence, the final lexicon is huge, containing 156,242 tokens and covering 96.8% of the words in three review datasets.

The sentiment lexicon is of great significance in our experiments. A lexicon of high quality ensures the effectiveness of the supervised mechanism. Empirically, if the overlapping of the dataset and lexicon is poor, the performance will be limited. The availability of lexicons is also not a given for any domain or language. In such scenarios, several existing methods can be used to construct or extend sentiment lexicons based on large corpora in a semi-supervised way to cover the dataset (Lu et al., 2011; Hamilton et al., 2016). As the above potential problems are not the main concern of our work, we just briefly touch on this and will explore it in future work.

3.2 Hyper-parameter Settings

Following Tang et al. (2015) and Chen et al. (2016), we set the dimension of the word embeddings to 200. We use the word2vec tool (Mikolov et al., 2013) to pre-train the word embeddings. We set the dimensions of the word-level bidirectional LSTM hidden states to 100. All the weight matrices are initialized by a uniform distribution in [-0.1, 0.1]. The hyper-parameter λ_w and λ_s which adjust the variance of the gold attention vectors, are both set to 3.0. The hyper-parameter μ_w which adjusts the proportion of classification and attention loss, is set to 0.001 while μ_s is set to 0.05. We use Adam (Kingma and Ba, 2014) as the optimizer, which adopts a self-adaptive learning rate to optimize parameters, and its initial learning rate is set to 0.001. The batch size is set to 32 for efficiency. The model achieving best results on the developing set is chosen for the final evaluation of the test set.

3.3 Baseline models

We separate baseline models into four groups. In the first group, all of the methods are recently developed and achieve good performances on three review benchmarks. **SSWE + SVM** (Tang et al., 2014b) first generates sentiment-specific word embeddings to compose document presentations and then trains a SVM classifier. **Paragraph + Vector** (Le and Mikolov, 2014) learns distributed representations of a document for classification. **RNTN + RNN** (Socher et al., 2013) represents sentences with the Recursive Neural Tensor Network (RNTN) and feeds them into a recurrent neural networks (RNN) to obtain document representations. **UPNN** (Tang et al., 2015) uses a text preference matrix and vector for each user and product as extra information to train a CNN sentiment classifier. *UPNN(noUP)* only uses CNN without considering user and product information.

The models in Group 2 are based on sentiment lexicons. **BiLSTM** (Xu et al., 2016) is a bidirectional LSTM baseline with a simple average pooling layer. **AveLex** naively averages sentiment scores of words in the document to measure the overall sentiment polarities according to our sentiment lexicon. **BiLSTM + Lex** (Teng et al., 2016) takes the local context into consideration, which leverages a bidirectional LSTM to capture context information and calculates the weighted sum of the sentiment scores. The two lexicon-based methods only work on the word level because sentences do not have a gold sentiment score. For a fair comparison, **BiLSTM + LBSA** is our model, which removes the hierarchical structure.

The models in Group 3 are based on attention mechanisms. **H-LSTM** (Chen et al., 2016) is a baseline utilizing an average pooling layer at both the word and sentence levels. **H-LSTM + LA** (Chen et al., 2016) uses local context to capture semantic information as an attention mechanism. **H-LSTM + CBA** (Long et al., 2017) adds cognitive information from external reading time materials. For a fair comparison, we simplify our method from bidirectional LSTMs to basic ones, which is denoted as **H-LSTM + LBSA**.

Table 2: Sentiment classification performance on different models. Acc. (Accuracy) and RMSE are the evaluation metrics. The best results are in bold in the last three groups, respectively.

In Group 4, **H-BiLSTM** is a hierarchical bidirectional LSTM model with an average pooling layer. **H-BiLSTM + LA** is a BiLSTM version of the local attention model based on Chen et al. (2016).

4 Results

This section compares our model (LBSA) with other baseline methods. Two common performance evaluation metrics are used, including Accuracy (Acc.) and Root Mean Squared Error (RMSE). They are defined as follows:

$$Accuracy = \frac{T}{N}, \tag{14}$$

$$RMSE = \sqrt{\frac{\sum_{i=1}^{N}(y_i - \hat{y}_i)^2}{N}}. \tag{15}$$

Accuracy is a standard metric to measure the overall sentiment classification performance, where N is the number of overall samples, and T denotes the number of predicted outputs that are identical with gold labels. RMSE measures the divergences between the predicted sentiment classes and ground truth ones, where $\hat{y}_i$ and y_i represent the predicted outputs and gold labels, respectively. Table 2 illustrates the comparison results, which are separated into four groups. Some results of the baseline methods are directly taken from Long et al. (2017) and Xu et al. (2016), because we conducted experiments on the same datasets.

We can observe from Group 2 that the performances are limited without a hierarchical structure because the texts are very long in document-level sentiment classification. **AveLex** is the worst method because it naively averages the sentiment scores of words without considering any textual semantics. Compared with **BiLSTM + Lex**, our method achieves a relatively better result. The main reason is that our method ignores the prior polarity of the sentiment words in lexicons. LBSA is able to lead neural networks to concentrate on sentimental contents and learn a more accurate polarity according to historical information. To illustrate the results more specifically, we investigate the sentiment word *long* in our datasets. *Long* has a sentiment degree of 0.42 in our constructed lexicon, which indicates that it plays a relatively critical role in sentiment classification. The sentiment polarity of *long* in MPQA and SST is negative. A random sentence sample *'The several tables were available, so I didn't understand*

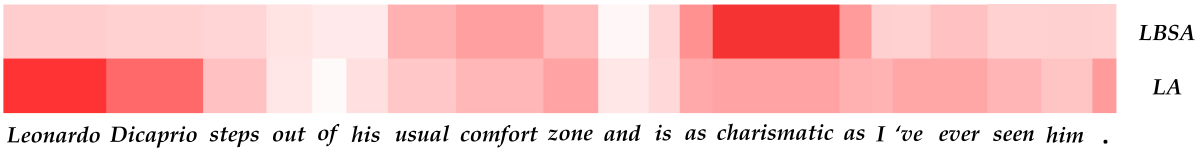

Figure 2: Sentence example from IMDB. Local attention (LA) focuses more on the domain-specific words *Leonardo Dicaprio*, while our model (LBSA) can exactly capture the real sentiment word *charismatic*.

*the **long** wait.'* is taken from a one-star review in Yelp 2013, which meets our expectation. However, in other domains or contexts, *long* is likely to be positive. For instance, the sentence *'Its appeal to me was immediate and **long** lasting.'* is extracted from a 10-star movie review in IMDB. It is obviously a positive sentence, but the prior polarity of *long* in the sentiment lexicon misleads the judgment of general methods that directly use sentiment scores.

In Group 3, we observe that our method significantly outperforms other attention mechanisms with the Yelp 2013 and Yelp 2014 datasets. The evaluation on the RMSE metric is also better than other methods with the IMDB dataset. This demonstrates that LBSA is effective at capturing sentiment information, which can be a crucial factor in sentiment classification. Compared with **H-LSTM + CBA**, our model achieves better results, which means lexicon information is more suitable for attention supervision in sentiment analysis tasks. In the forth group, the bidirectional LSTM improves the basic performance, which indicates that both forward and backward sequences indispensably contribute to information extraction. Compared with local context-based attention, the basic performance of our method is outstanding and has a relatively small improvement when a bidirectional mechanism is added. This indicates that our method lays emphasis on contents containing rich sentiment information, which is robust in a simpler structure. In contrast, local context-based attention relies heavily on contexts in both directions. The characteristic of being dedicated to the contexts may induce domain-specific words and ignore real sentiment information. Here, we use a sentence from a movie review in IMDB as an example: *'Leonardo Dicaprio steps out of his usual comfort zone and is as charismatic as I've ever seen him.'* Figure 2 illustrates the main difference between two attention mechanisms.

The LA model gives higher weights to the name *Leonardo Dicaprio* because it usually appears in a positive movie review. The words are domain-specific and attract attention from real sentiment words. In contrast, our method tends to extract specific sentiment information. As a result, it assigns a very high weight to the word *charismatic*, which indeed plays a decisive role as a positive adjective.

5 Related Work

Sentiment lexicons are widely used in sentiment analysis and opinion mining tasks because they contain rich sentiment information. Turney (2002) employed the sum of the sentiment scores of all the words in the texts that appeared in a sentiment lexicon. This is still the standard practice for specific domains with some carefully constructed domain-specific lexicons. Agarwal et al. (2013) proposed a tree-structured model leveraging non-polarity features such as POS-tags and capitalized words, adding the summation of the prior polarity scores of words, which achieved high performance on the twitter sentiment analysis benchmark. Teng et al. (2016) presented a context-sensitive lexicon-based method that uses a bidirectional LSTM to extract context information. It calculates the weighted sum of the sentiment scores of words to measure the sentiment value of a sentence. Qian et al. (2016) proposed a linguistically regularized LSTM for sentiment analysis. The model combines linguistic resources such as sentiment lexicons, negation words and intensity words with the basic LSTM model. It is able to capture the semantic information and sentiment effects in sentences more accurately. Unlike most previous studies, we incorporate the features of lexicon words into an attention mechanism, which was proven to be effective in our experiments.

Recently, the attention mechanism has been widely studied in sentiment classification. Yang et al. (2016) proposed two attention-based bidirectional GRUs to enforce the neural networks to attend to

the related part of a sentence or document. Apart from local contexts, Chen et al. (2016) incorporated extra information such as users and products in review datasets into a hierarchical attention mechanism. Ma et al. (2017) cascaded multiway of user and product information to enhance the effects of different aspects. Zhou et al. (2016) proposed a LSTM network based on an attention mechanism for cross-lingual sentiment classification at the document level. The model consists of two attention-based hierarchical LSTMs for bilingual representation. Long et al. (2017) took cognition into consideration, leveraging extra resources including the reading time of human beings. They proposed a mutimodel that learns to predict the reading time to construct the cognitive attention. The main difference between our method and others is that we supervise the attention weights using sentiment information. As a result, it is able to capture real sentiment texts and achieves a better result.

6 Conclusion

In this paper, we propose a novel lexicon-based supervised attention model. We combine an attention mechanism and sentiment lexicons to guide the neural network to focus on the sentiment content. It has better interpretability and less noise compared with other attention models. Experiments on three large review datasets validated the effectiveness of our model, showing that it can capture real sentiment information and generate sentiment-informative representations to improve the classification performance.

Open-Domain Event Detection using Distant Supervision

Jun Araki and **Teruko Mitamura**

Pittsburgh, PA 15213, USA
junaraki@cs.cmu.edu teruko@andrew.cmu.edu

Abstract

This paper introduces *open-domain event detection*, a new event detection paradigm to address issues of prior work on restricted domains and event annotation. The goal is to detect all kinds of events regardless of domains. Given the absence of training data, we propose a distant supervision method that is able to generate high-quality training data. Using a manually annotated event corpus as gold standard, our experiments show that despite no direct supervision, the model outperforms supervised models. This result indicates that the distant supervision enables robust event detection in various domains, while obviating the need for human annotation of events.

1 Introduction

Events are a key semantic component integral to natural language understanding. They are a ubiquitous linguistic phenomenon appearing in various domains. For clarification, we use the term 'domain' to refer to a specific genre of text, such as biology, finance, and so forth. Prior studies on automatic event detection traditionally focus on limited types of events, mainly defined by several research initiatives and shared tasks in a few domains:

- Newswire: TIPSTER (Onyshkevych et al., 1993) and MUC (Grishman and Sundheim, 1996)
- Multi-domain: ACE (Doddington et al., 2004) and TAC KBP (Mitamura et al., 2016).
- Biology: PASBio (Wattarujeekrit et al., 2004), GENIA (Kim et al., 2008), BioNLP (Kim et al., 2009) and ProcessBank (Berant et al., 2014).

Although closed-domain event detection might be of practical use in some domain-specific scenarios, it only contributes to partial understanding of events because it only addresses a subset of events by definition. On the other hand, there is an established consensus that in order to advance natural language applications such as open-domain question answering, we need automatic event identification techniques with larger, wider, and more consistent coverage (Saurí et al., 2005; Pradhan et al., 2007).

There are several pieces of prior work on open-domain events, but they have some limitations with respect to coverage of events. Lexical databases such as WordNet (Miller et al., 1990), FrameNet (Baker et al., 1998) and PropBank (Palmer et al., 2005) can be viewed as a superset of events, and their subtaxonomies seem to provide an extensional definition of events. However, these databases have a narrow coverage of events because they are generally expected to cover basic terminology due to their dictionary nature. For instance, none of WordNet, FrameNet and PropBank covers current terminology and proper nouns such as 'Hurricane Katrina'. OntoNotes (Weischedel et al., 2011) is aimed at covering an unrestricted set of events and entities, but its event annotation is limited to a small number of eventive nouns. TimeML (Pustejovsky et al., 2003) annotates events and times in a domain-agnostic manner, focusing on temporal aspects of events, but it does not deal with multi-word and generic events. ECB+ (Cybulska and Vossen, 2014) augments the extended EventCorefBank corpus (Lee et al., 2012) by re-annotating events and event coreference. Our initial analysis shows that it annotates events only in a portion of each document, not all events in the text. Ritter et al. (2012) address open-domain event detection on Twitter. Their annotation follows TimeML and thus is likely to have similar problems to TimeML. Richer

Proceedings of the 27th International Conference on Computational Linguistics, pages 878–891
Santa Fe, New Mexico, USA, August 20-26, 2018.

Event Description (RED) (Palmer et al., 2016) defines events in a general manner, but its annotation was performed only in the clinical domain (O'Gorman et al., 2016).

To address these issues, we introduce a new paradigm of *open-domain event detection*. Our goal is to detect all kinds of events without a specific event type, while not limiting events to particular domains and syntactic types. As compared to the traditional closed-domain event detection described above, our target is more challenging because there is no unified definition of events with wider and more consistent coverage, and there is no training data. Due to the ubiquity and ambiguities of events, human annotation of events in the open domain is substantially expensive, ending up with a small dataset which does not make supervised models generalize well. In this work, we propose a novel approach to circumvent the data sparsity problem in open-domain event detection. At the core of the approach is distant supervision from WordNet (Miller et al., 1990). Our main hypothesis is that the distant supervision allows us to build models detecting events robustly in various domains, while obviating the need for human annotation of events. We verify this hypothesis in both heuristics-based and classifier-based algorithms.

Our contribution is as follows:

1. We introduce **a new paradigm of open-domain event detection**, whose goal is to detect all kinds of events. Specifically, the differences from prior work are events in unrestricted domains and with wider coverage.
2. Our **distant supervision method** is able to generate high-quality training data (see Section 5.1). The method is not bounded to any particular datasets, offering a versatile solution for event detection. Using a manually annotated corpus as gold standard, our experiments show that despite no direct supervision, the distantly supervised model outperforms supervised models in both in-domain and out-domain settings (see Section 5.3).
3. To facilitate future studies on event detection, we **release the new corpus**[1] of human-annotated events in 10 different domains such as geology and economics. The annotated events comprise verbs, nouns, adjectives, and phrases which are continuous or discontinuous (see Section 2.2). Despite this relatively wide and flexible annotation of events, we achieved high inter-annotator agreement (see Section 4).

2 Definition of Events

We give our definition of events from both semantic and syntactic perspective.

2.1 Semantic Perspective: Eventualities

Events are a highly ambiguous notion, and thus there are many ways to define them. In this work, we use the notion of eventualities by Bach (1986) and define the three classes on the basis of durativity and telicity (Moens and Steedman, 1988; Pulman, 1997):

- **states**: notions that are durative and changeless, e.g, want, own, love, resemble
- **processes**: notions that are durative and atelic, e.g., walking, sleeping, raining
- **actions**[2]: notions that are telic or momentaneous happenings, e.g., build, walk to Boston, recognize

We define expressions as events if they denote an eventuality, i.e., a state, a process, or an action.

2.2 Syntactic Perspective: Event Nuggets

From a syntactic perspective, we use the notion of event nugget (Mitamura et al., 2015), which is a semantically meaningful unit that expresses an event. We give several examples below, where we use boldface to highlight event nuggets and underlines to show units of multi-word ones.

(1) He **opened fire** at the teller in the bank.
(2) I **cried** when my grandpa **kicked** the **bucket**.
(3) Tom was **happy** when he **received** a present.
(4) Susan **turned** the TV **on**.
(5) She **responded** his email **dismissively**.

[1] https://bitbucket.org/junaraki/coling2018-event

[2] Bach (1986) uses the term 'events' to refer to this class. In this work, we use 'actions' instead for clarification.

Event nuggets can be either a single word (verb, noun, or adjective) or a phrase which is continuous or discontinuous. For example, 'turned ... on' in (2) is a discontinuous phrasal event nugget, excluding 'the TV'. For more details, we refer readers to our annotation guidelines.[3]

3 Distantly Supervised Event Detection

This section describes our approach for open-domain event detection. Figure 1 shows a high-level overview of the approach. As shown, the algorithm comprises two phases: training data generation and event detection. At the core of the approach is distant supervision from WordNet[4] in the former phase to address ambiguities on eventiveness and generate high-quality training data automatically.

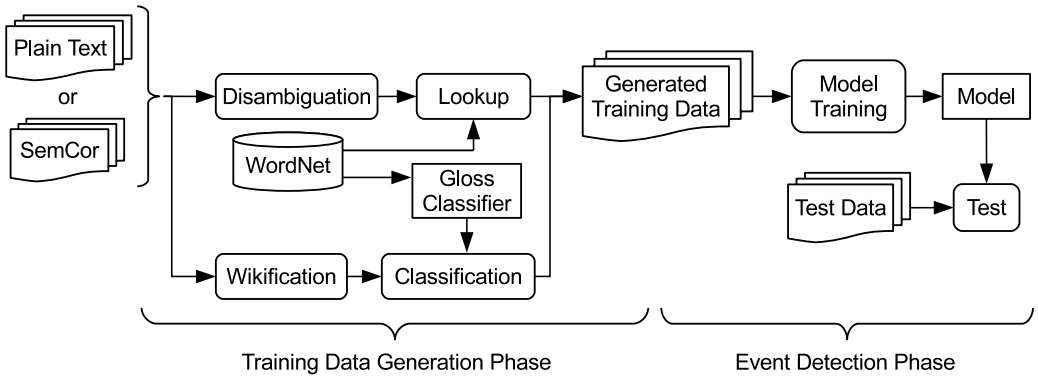

Figure 1: An overview of our distantly-supervised open-domain event detection.

3.1 Training Data Generation

The goal of training data generation is to generate high-quality training data automatically from unannotated text. We first disambiguate text using a WordNet-based word sense disambiguation tool. Given sense-annotated text as input, we implement a rule-based algorithm, which we refer to as **RULE**. It is our basis for generating training data. Looking at our annotation guidelines (see Section 4), we employ several heuristics to identify event nuggets, according to syntactic types:

Verbs. We detect most of main verbs as eventive, excluding be-verbs and auxiliary verbs. However, some exceptions exist. In the examples below, we use italic face to highlight non-eventives.

(6) That is what I **meant**.
(7) 'Enormous' *means* 'very big'.

In (6), 'meant' is eventive because it indicates the action of "intend to say" whereas 'means' in (7) is not because it merely shows equality, playing the almost same role as a be-verb. Thus, we define a set of non-eventive verb senses and filter out verbs if their disambiguated sense is in the set.

Nouns. There are also ambiguous nouns:

(8) His **payment** was late.
(9) His *payment* was $10.
(10) **Force** equals mass times acceleration.

In (8), 'payment' is eventive because it means the action of his paying something while 'payment' in (9) is not because it refers to specific money paid by him, which is $10. These examples also show that eventive nouns cannot be simply approximated by verb nominalizations. 'Force' in (10) can be easily disambiguated to its physical sense, but still deciding its eventiveness is difficult. To address the issue, we make use of distant supervision from WordNet. Let word_n^i denote the i-th sense (synset) of noun word in WordNet. For example, car_n^1 is the first synset of noun 'car'. Looking at textual definitions of synsets called *glosses*, we assume that there is a semantic correspondence between the components of eventualities described in Section 2.1 and the following WordNet synsets:

- state_n^2: the way something is with respect to its main attributes

[3]We release the guidelines at `https://bitbucket.org/junaraki/coling2018-event`.
[4]We access WordNet 3.0 using NLTK (Bird et al., 2009).

- process^{6}_{n}: a sustained phenomenon or one marked by gradual changes through a series of states
- event^{1}_{n}: something that happens at a given place and time

We detect nouns as events if their disambiguated sense is subsumed by the three synsets above through (instance-)hyponym relations.

Adjectives. Adjectives can also be ambiguous:

(11) Mary was **talkative** at the **party**.

(12) Mary is a *talkative* person.

In (11), 'talkative' is eventive because it implies that Mary talked a lot at the party, whereas 'talkative' in (12) is not because it just indicates Mary's personal attribute. As illustrated, major problems with adjectives are to differentiate states from attributes and to figure out if they imply actual occurrences (Palmer et al., 2016). Unlike nouns, no direct supervision is available from WordNet because it does not have hyponym taxonomies for adjectives. Thus, we use simple and conservative heuristics to detect adjectives as events if they are originated from present and past participles of verbs, illustrated as follows:

(13) There is a **man-made** river in the country.

(14) The tower has 20,000 **sparkling** lights.

We convert these adjectives to verbs in the infinitive form using pattern.en (De Smedt and Daelemans, 2012).

Adverbs. We develop heuristics using WordNet. We first convert adverbs to adjectives by looking up pertainyms (relational adjectives) and seeking verbs derivationally related to the adjectives in WordNet. Adverbs connect with their modifying verbs, forming a single event nugget, as illustrated in (5). Thus, we combine eventive adverbs with such verbs to detect resulting verb phrases as events.

Phrases. Following Schneider et al. (2014), we define *phrases* to be lexicalized combinations of two or more words that are exceptional enough to be considered as single units in the lexicon. We assume that this definition is suitable to event detection because the exceptionality of multi-word units in the phrase lexicon translates to the meaningfulness of textual units of (phrasal) event nuggets. From the perspective of open-domain event detection, supervised phrase detection models are likely suboptimal because they might be limited to particular domains or overfitting to small datasets. Therefore, we explore a simple dictionary-lookup approach to detect WordNet phrasal verbs as events, inspired by Yin and Schütze (2015). One enhancement to their approach is that we examine dependencies using Stanford CoreNLP (Manning et al., 2014), illustrated as follows:

(15) Snipers were **picking** them **off**.

(16) He **picked** an apple off the tree.

In (15), 'picking ... off' forms a discontinuous phrasal verb, whereas 'picked' in (16) does not. Dependencies can be of help to resolve these two cases. In the former case, a dependency relation 'picking $\xrightarrow{\texttt{compound:prt}}$ off' is a direct signal of the phrasal verb construction. As for noun phrases, we apply our heuristics for nouns to head words of the phrases.

3.2 Enhancements with Wikipedia

This subsection describes two techniques to enhance our training data generation: heuristics-based enhancement (Section 3.2.1) and classifier-based enhancement (Section 3.2.2). One disadvantage of RULE is the limited coverage of WordNet. As described in Section 1, WordNet does not cover many proper nouns that we generally see in newspaper articles, such as the following:

(17) Property damage by **Hurricane Katrina** around $108 billion.

(18) The **Cultural Revolution** was ...

In order to achieve higher recall, we incorporate Wikipedia to capture proper nouns which are not in WordNet, motivated by the fact that Wikipedia has a much broader coverage of concepts than WordNet synsets.[5] We use the Illinois Wikifier (Ratinov et al., 2011) to extract Wikipedia concepts from text.

[5]WordNet 3.0 has 120K synsets, and English Wikipedia has 5.5M articles as of October 2017, as shown at `https://stats.wikimedia.org/EN/TablesWikipediaEN.htm`.

3.2.1 Heuristics-based Enhancement

For our first enhancement, we make two assumptions: (1) the first sentence of a Wikipedia article provides a high-quality gloss of its corresponding concept, and (2) the syntactic head of a gloss represents a high-level concept carrying significant information to decide eventiveness. The first assumption is supported by Wikipedia's style manual on how to write the first sentence of an article.[6] The manual says "If an article's title is a formal or widely accepted name for the subject, display it ... as early as possible in the first sentence." For instance, the first sentence of entry Electron is:

(19) The electron is a subatomic particle with a negative elementary electric charge.

The gloss of Electron is the underlined text above. Our analysis shows that most Wikipedia articles follow the first-sentence format.

The second assumption is illustrated by the syntactic head of the Electron gloss, which is 'particle'. Based on the assumptions, we develop head-based heuristics, which we call **HeadLookup**. We find the syntactic head of a gloss using dependencies and disambiguate the head using a state-of-the-art word sense disambiguation tool IMS (It Makes Sense) (Zhong and Ng, 2010). We then check if the head's sense is subsumed by the three synsets of state^2_n, $\mathsf{process}^6_n$, and event^1_n. In the case of Electron, the head's sense atom^2_n is not under the synsets. Thus, the model concludes that Electron is non-eventive. Note that HeadLookup itself is a general technique which can be applied to any gloss. Our first enhancement applies it to Wikipedia glosses, and we refer to the enhanced model as **RULE-WP-HL**.

3.2.2 Classifier-based Enhancement

Our second enhancement leverages a binary gloss classifier to decide the eventiveness of proper nouns. We refer to this enhanced model as **RULE-WP-GC**. We use WordNet glosses to train the classifier. Our assumption is that although WordNet and Wikipedia are maintained by different people for different purposes, the classifier trained on WordNet glosses generalizes well against unseen Wikipedia concepts because glosses of the two resources have comparable quality.

Data Collection from WordNet. We collect our gloss datasets automatically from WordNet. The goal of data collection is to create a large amount of dataset $D = D_+ \cup D_-$ where D_+ is a set of eventive (positive) glosses, D_- is a set of non-eventive (negative) ones, and $D_+ \cap D_- = \emptyset$. Since WordNet provides a gloss for each synset, the goal reduces to creating a set of positive synsets S_+ and a set of negative ones S_-. Given root synset s, we collect a subset of synsets S_s (including s) by traversing the WordNet taxonomy under s through hyponym and instance-hyponym relations. Using the three synsets introduced in Section 3.1, we have $S_+ = S_{\mathsf{event}^1_n} \cup S_{\mathsf{state}^2_n} \cup S_{\mathsf{process}^6_n}$. With respect to S_-, we simply take all the WordNet synsets that are not in S_+. Table 1 gives several examples of glosses in D_+ and D_-. As shown, the ambiguous word 'payment' has positive and negative synsets. The sizes of D_+ and D_- are $|D_+| = 13,415$ and $|D_-| = 68,700$.

Synset	Gloss
riding^2_n	travel by being carried on horseback
shower^3_n	a brief period of precipitation
$\mathsf{payment}^2_n$	the act of paying money
pork^1_n	meat from a domestic hog or pig
year^1_n	a period of time containing 365 (or 366) days
$\mathsf{payment}^1_n$	a sum of money paid or a claim discharged

Table 1: Examples of WordNet glosses in D. The examples above and below the dashed line are from D_+ and D_-, respectively.

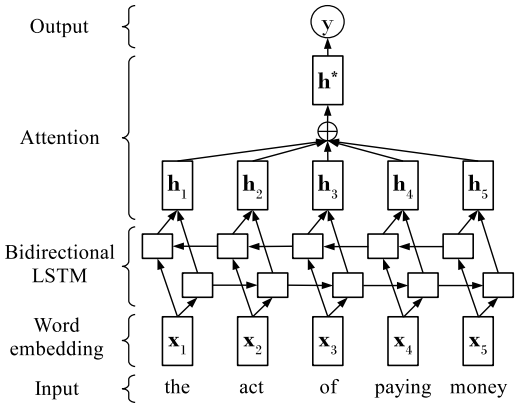

Figure 2: The bidirectional LSTM model with a self-attention mechanism.

[6] https://en.wikipedia.org/wiki/Wikipedia:Manual_of_Style/Lead_section\#First_sentence

Learning. We train the binary classifier on D using a bidirectional long short-term memory (BLSTM) (Graves and Schmidhuber, 2005). We call the classifier **GC-BLSTM**. Given an input vector $\mathbf{x}_t$ at time step t, let us denote the forward hidden state as $\overrightarrow{\mathbf{h}_t}$ and the backward one as $\overleftarrow{\mathbf{h}_t}$. We obtain the hidden state of a BLSTM using concatenation: $\mathbf{h}_t = [\overrightarrow{\mathbf{h}_t}; \overleftarrow{\mathbf{h}_t}]$. We then use a linear projection of $\mathbf{h}_T$ into two classes: $y = 1$ (eventive) and $y = 0$ (non-eventive). Finally, we add a softmax layer on top of the linear projection, and train the model using the binary cross-entropy loss.

Attention. Neural networks with attention mechanisms have achieved great success in a wide variety of natural language tasks. The basic idea is to enable the model to attend to all past hidden vectors and put higher weights on important parts so that the model can encode the sequence information more effectively. This idea intuitively makes sense for gloss classification as well, because syntactic heads are likely more important, as illustrated in Section 3.2.1. As shown in Figure 2, we leverage a self-attention mechanism, following (Zhou et al., 2016; Lin et al., 2017). Let $\mathbf{H} \in \mathbb{R}^{d \times T}$ denote a matrix comprising hidden vectors $[\mathbf{h}_1, \ldots, \mathbf{h}_T]$ where d is the dimensionality of a hidden vector. The self-attention mechanism computes the hidden state as follows:

$$\mathbf{M} = \tanh(\mathbf{H}) \tag{1}$$

$$\alpha = \text{softmax}(\mathbf{w}^T \mathbf{M}) \tag{2}$$

$$\mathbf{r} = \mathbf{H}\alpha^T \tag{3}$$

$$\mathbf{h}^* = \tanh(\mathbf{r}) \tag{4}$$

where a vector $\alpha \in \mathbb{R}^T$ is attention weights and $\mathbf{w} \in \mathbb{R}^d$ is a parameter vector. We refer to the attention-based classifier as **GC-BLSTM-Attn**.

Implementation Details. We randomly sample 1,000 examples from each of D_+ and D_- to create a test set and a validation set, and use the rest of D for a training set. We use the 300-dimensional GloVe vectors[7] from (Pennington et al., 2014) and do not fine-tune them during training. We map all out-of-vocabulary words to a single vector randomly initialized by uniform sampling from $[-0.01, 0.01]$. We use a single hidden layer of 100 dimensions, i.e., $d = 100$. We optimize model parameters using minibatch stochastic gradient descent (SGD) with momentum 0.9. We choose an initial learning rate of $\eta_0 = 1.0\text{e}{-3}$. We use a minibatch of size 1. To mitigate overfitting, we apply the dropout method (Srivastava et al., 2014) to the inputs and outputs of the network. We also employ L2 regularization. We perform a small grid search over combinations of dropout rates $\{0.0, 0.1, 0.2\}$ and L2 regularization penalties $\{0.0, 1.0\text{e}{-3}, 1.0\text{e}{-4}\}$. We use early stopping based on performance on the validation set.

3.3 Learning for Event Detection

After generating training data, we train a supervised event detection model on the synthesized data. As seen in the self-training model by Liao and Grishman (2011), erroneously generated training data worsen system performance. Therefore, we need to generate training data as accurately as possible. On the other hand, our algorithm for generating training data comprises at least three non-trivial (error-prone) submodules: disambiguation, wikification, and gloss classification. To eliminate negative effects of disambiguation errors, we choose the SemCor corpus (Miller et al., 1993) as our base text for training data generation. SemCor has human-annotated WordNet senses on 186 documents in numerous genres. We apply our rule-based event detector to generate training data automatically from SemCor.

We formalize event detection as a sequence labeling problem and employ a BLSTM for sequence modeling. One difference from traditional sequence labeling problems is that our output includes discontinuous phrases. Thus, we leverage an extended version of the standard BIO tagging scheme, inspired by Metke-Jimenez and Karimi (2016). Besides the three tags of B, I and O, we introduce two additional tags: DB and DI. DB means the beginning of a discontinuous concept, and DI the continuation of a discontinuous concept. The BLSTM model computes a hidden representation from each input word and then predicts one of $\{\text{B}, \text{I}, \text{DB}, \text{DI}, \text{O}\}$. For the BLSTM model, we use a fixed concatenation of the GloVe embeddings and 50-dimensional word embeddings from Turian et al. (2010) under the same assumption

[7] https://nlp.stanford.edu/projects/glove/

as (Lee et al., 2017) that different learning objectives of the GloVe and Turian embeddings can provide orthogonal information. We additionally employ 10-dimensional part-of-speech embeddings. We train the model with the objective of minimizing cross-entropy loss. We use early stopping based on the loss on a validation set.

4 Open-Domain Event Corpus

Since our target is unrestricted domains, we need gold standard data to evaluate whether systems work robustly in various domains. However, annotating events manually in all domains would be unrealistic due to annotation cost. To make the corpus creation manageable while retaining the domain diversity, we select 100 articles in Simple English Wikipedia, comprising 10 from each of 10 different domains. The domains are: architecture, chemistry, disasters, diseases, economics, education, geology, history, politics, and transportation. We choose Simple Wikipedia because our annotators are not necessarily experts in these domains, and the simplified sentences could facilitate our annotation of events against text from the wide variety of domains. Three annotators perform annotation independently following our annotation guidelines, and we measure inter-annotator agreement using the pairwise F1 score under two conditions: strict match and partial match. The former checks whether two annotations have exactly the same span. The latter checks whether there is an overlap between annotations, with the restriction that each annotation can only be matched to one annotation by the other annotator. We compute the agreements for all annotator pairs and average them for the overall agreement. As a result, the inter-annotator agreement was 80.7% (strict match) and 90.3% (partial match). Finally, the most experienced annotator finalizes event annotation. We refer to the event corpus as **SW100**.[8]

Table 2(a) shows that event nuggets appear in the 10 domains almost uniformly, ensuring the ubiquity of events. We use Stanford CoreNLP to tokenize text and decide head words of event nuggets with dependencies. Table 2(b) counts multi-word event nuggets by part-of-speech tags of their heads, amounting to 955. 24% of the 955 are discontinuous, and most (97%) of the discontinuous multi-word event nuggets are verb phrases. 'Others' in Table 2(b) include pronouns, demonstrative determiners, and numbers.

Domain	# (%)	Domain	# (%)
Architecture	475 (8.8)	Education	653 (12.1)
Chemistry	576 (10.7)	Geology	483 (8.9)

5 Experimental Results

This section describes our experimental results.

5.1 Results of Gloss Classification

Gloss classification is a binary classification subtask for training data generation, aimed to improve event detection by capturing proper nouns with Wikipedia knowledge. We use two datasets to evaluate our gloss classifiers described in Section 3.2. One is the test set of WordNet glosses described in Section 3.2.2. However, we actually care about the gloss classification performance against unseen Wikipedia concepts. Thus, we create an additional dataset which comprises Wikipedia concepts that do not appear in WordNet. We collect 100 eventive and 100 non-eventive Wikipedia glosses in 10 domains[9], independently of SW100. We measure the performance of gloss classification using accuracy. For comparison, we consider two baselines. **BoW-LR** is a bag-of-words model trained with logistic

[8] https://bitbucket.org/junaraki/coling2018-event

[9] Economics, history, politics, psychology, architecture, earth science, physics, chemistry, biology, and medicine.

regression, and **DAN** is a deep average network proposed by Iyyer et al. (2015). Since DAN can be seen as a neural bag-of-words model, these two models are word-order insensitive baselines. Table 3 shows that GC-BLSTM-Attn performs best and significantly better than GC-BLSTM on both WordNet and Wikipedia datasets. This result verifies our assumptions that the classifier trained on WordNet glosses generalizes well against unseen Wikipedia concepts and that the attention mechanism is effective for gloss classification.

Model	WordNet	Wikipedia
HeadLookup	77.80	73.50
BoW-LR	79.50	73.00
DAN	83.15	64.00
GC-BLSTM	90.10	80.00
GC-BLSTM-Attn	**91.65****	**85.00***

Table 3: Accuracy of gloss classifiers. The stars indicate statistical significance compared to GC-BLSTM (*: $p < 0.05$; **: $p < 0.005$) based on McNemar's test.

Model	Strict			Partial		
	P	R	F1	P	R	F1
VERB (Baseline)	79.5	51.7	62.7	95.4	62.0	75.2
PRED (Baseline)	55.1	62.4	58.5	67.6	76.6	71.8
RULE	80.1	77.0	78.5	89.0	85.5	87.2
RULE-WP-HL	80.5	77.5	79.0	88.6	85.3	86.9
RULE-WP-GC	80.8	77.7	**79.2**	89.1	85.7	**87.3**

Table 4: Performance of the rule-based event detectors on SW100.

5.2 Results of Training Data Generation

We measure the performance of the rule-based event detectors on SW100 using precision (P), recall (R), and F1 with the two matching options described in Section 4. We use IMS (It Makes Sense) for disambiguation. Table 4 shows the results. **VERB** is a simple baseline that detects all single-word main verbs as events, excluding be-verbs and auxiliary verbs. **PRED** is another baseline that detects all predicates as events by running a state-of-the-art semantic role labeler called PathLSTM[10] (Roth and Lapata, 2016). Since PathLSTM is trained on both PropBank and NomBank, it is able to detect both verbal and nominal predicates. However, semantic role labeling has a different focus on predicate-argument structures. More specifically, the combination of PropBank and NomBank has a narrower coverage of events while having non-event predicates. This difference explains PathLSTM's relatively low performance of 58.5 strict F1, even underperforming the VERB baseline. The performance difference between RULE and VERB mostly comes from nouns, indicating that our WordNet-based heuristics is effective. We found that RULE-WP-GC achieves the best F1. This result shows that the proposed enhancements with Wikipedia can contribute to generating higher-quality training data.

We then applied the best-performing RULE-WP-GC to SemCor and found that the generated data contains 59,796 event nuggets in total. We randomly split this data or its subset to 9:1 with respect to the number of documents, creating training and validation data. We train the neural event detector described in Section 3.3 on the training data and measure its performance on SW100. Figure 3 shows how the amount of training data affects the performance of event detection. As shown, a larger amount of training data enables the model to achieve better performance.

5.3 Comparison with Supervised Models

In order to test the robustness of our distant supervision model, in this experiment we divide SW100 into in-domain and out-domain datasets by randomly sampling 5 domains for each. We further split the in-domain dataset into training (60%), validation (20%) and test subsets (20%) with respect to the number of documents, and then train the BLSTM event detection model described in Section 3.3. We repeat this procedure three times and measure the average of F1 scores with strict match (Table 5). We refer to the model trained on the in-domain data as **BLSTM** and the model trained on the data generated from SemCor as **DS-BLSTM**. In all the three runs, DS-BLSTM outperforms BLSTM in both in-domain and out-domain settings. The performance difference in the out-domain setting is statistical significant at $p < 0.05$ based on a two-tailed t-test. BLSTM ends up overfitting to the training data, and its weak generalization power is more evident in the out-domain setting. In contrast, DS-BLSTM performs robustly in both settings. Table 6 shows more detailed performance of DS-BLSTM.

(b) With respect to syntactic types.

Table 6: Detailed performance of DS-BLSTM.

6 Error Analysis and Discussion

This section discusses our error analysis.

Analysis of Gloss Classification. One error pattern is that the gloss of an eventive example is partially or completely overlapped with that of non-eventive one, confusing the classifier:

- broadcast^2_n: a radio or television show
- laugh_track^1_n: prerecorded laughter added to the soundtrack of a radio or television show

The former is eventive and the latter is not. Beside such errors, we found possible inconsistencies in WordNet entries in terms of eventiveness:

- sufficiency^1_n: sufficient resources to provide comfort and meet obligations
- unanimity^1_n: everyone being of one mind
- minority^3_n: any age prior to the legal age

The first three synsets are in the state^2_n taxonomy, but the ways of defining them, especially the syntactic heads of glosses (underlined above) sound like non-eventive entities rather than events.

#	Submodule	Description	Examples
(1)	Phrase detection	A phrase is missing or incorrectly detected.	amount to, stay clear, take one's toll
(2)	Wikification	A proper name is not identified or disambiguated into an incorrect entry in Wikipedia.	Polish Revolution, Battle of The Little Horn
(3)	Wikipedia gloss extraction	A corresponding Wikipedia article does not provide a gloss of an expected form.	Spanish flu, Exxon Valdez oil spill
(4)	Gloss classification	A disambiguated gloss is misclassified.	Anglican parson, Archbishop

Table 7: Noticeable errors of our training data generation.

Analysis of Training Data Generation. Besides gloss classification, our training data generation is subject to errors from the rule-based event detection and wikification. Table 7 shows noticeable errors in training data generation. The cause of error (1) is small coverage of WordNet phrases, particularly verb phrases. Error (2) and (4) can be reduced by more sophisticated wikification and gloss classification, respectively. An example of error (3) is that Wikipedia entry Spanish_flu is empty because it is redirected

to 1918_flu_pandemic. A simple remedy of partial help to error (3) is to resolve such empty concepts using Wikipedia redirect relations.

Analysis of Event Detection. Two major error sources of the DS-BLSTM model are nouns and phrases. Our training data generated from SemCor is 11 times larger than SW100 with respect to the number of event nuggets. Still, many nouns and phrases do not appear in the training data, making correct predictions difficult. As shown in Table 5(a), the most difficult domain is 'Disease' where numerous domain-specific terms, such as migraine and bubonic plague, can appear even in simplified text of Simple Wikipedia, but not in SemCor at all.

7 Related Work

Most prior work has addressed event detection using supervised models based on symbolic features. Some studies employ token-level classifiers (Ahn, 2006; Ji and Grishman, 2008; Liao and Grishman, 2010b; Hong et al., 2011; Berant et al., 2014), while others cast event detection as a sequence labeling problem and apply structured prediction models (McClosky et al., 2011; Lu and Roth, 2012; Li et al., 2013; Li et al., 2014; Araki and Mitamura, 2015; Yang and Mitchell, 2016). Recent work has explored neural network models with distributional features (Ghaeini et al., 2016; Nguyen et al., 2016; Chen et al., 2015; Nguyen and Grishman, 2015; Feng et al., 2016). These models are typically trained on a small amount of human-annotated data in closed domains and thus subject to overfitting.

Semi-supervised and unsupervised approaches are less studied than supervised ones in event detection. Several studies leverage bootstrapping methods to find new patterns for similar events (Liao and Grishman, 2010a; Liu and Strzalkowski, 2012; Huang and Riloff, 2012; Huang and Riloff, 2013). Others explore self-training (Liao and Grishman, 2011), event vector representation (Peng et al., 2016), tensor-based composition (Huang et al., 2016), and distant supervision (Chen et al., 2017). However, their models focus on predicate-argument structures and are validated in a few domains, mostly in ACE. It is unclear how well they scale to the open domain, particularly to phrases and proper nouns.

Several lines of recent work refine the definition of events. Rich ERE (LDC, 2015) defines events under a particular event ontology mainly from the syntactic perspective, without clarifying what semantically constitutes events. The ISO-TimeML specification (Pustejovsky et al., 2010) defines events as "something that can be said to obtain or hold true, to happen or to occur." This definition is consistent with Bach's eventualities and the closest to ours. The studies described above have narrower coverage of events than our work in terms of domains, syntactic types, or multi-word expressions.

8 Conclusion and Future Work

We have introduced open-domain event detection, a new event detection paradigm whose goal is to detect all kinds of events regardless of domains. Due to the ubiquity and ambiguities of events, human annotation of events in the open domain is substantially expensive. We presented a distant supervision method that is able to generate high-quality training data automatically, obviating the need for human annotation. Our distantly supervised model is not bounded to any particular datasets and offers a versatile solution for event detection. Our experiment shows that the model outperforms supervised models in both in-domain and out-domain settings.

There are numerous avenues for future work. One could conduct experiments on normal English text, such as newspaper articles, in various domains. We plan on event coreference resolution to detect eventive pronouns and demonstrative determiners. We recognize that event types and epistemic status are key features for event coreference resolution, and thus extracting them is an important problem.

Abstract

Semantic parsers critically rely on accurate and high-coverage lexicons. However, traditional semantic parsers usually utilize annotated logical forms to learn the lexicon, which often suffer from the lexicon coverage problem. In this paper, we propose a graph-based semi-supervised learning framework that makes use of large text corpora and lexical resources. This framework first constructs a graph with a phrase similarity model learned by utilizing many text corpora and lexical resources. Next, graph propagation algorithm identifies the label distribution of unlabeled phrases from labeled ones. We evaluate our approach on two benchmarks: WEBQUESTIONS and FREE917. The results show that, in both datasets, our method achieves substantial improvement when comparing to the base system that does not utilize the learned lexicon, and gains competitive results when comparing to state-of-the-art systems.

Title and Abstract in Chinese

基于半监督词典学习的语义解析技术研究

语义解析器的性能往往依赖于词典的准确度和覆盖度。传统语义解析器利用标注好的句子-逻辑表达式对来学习词典，这通常会面临词典覆盖度不足的问题。本文提出了一种基于图的半监督学习框架，该框架能够充分利用容易获取的大量文本语料和词典资源来进行词典扩充学习。该词典扩充学习方法首先利用大量文本语料和词典资源来学习词语与词语之间的相似度，并构建用于图传播的图；接着使用图传播算法从少量标注的词汇中学习新的词汇。本文在两个公开数据集上进行了实验，实验结果表明：本文系统相比未使用新词汇的基准系统取得了显著提升，相比当前最好的系统，也取得了具有竞争力的结果。

1 Introduction

Semantic parsing aims to map natural language sentences into formal meaning representations, e.g., Figure 1 shows an example of semantic parsing. Semantic parsing plays an important role in natural language understanding, and has attracted increasing attention in recent years (Zelle and Mooney, 1996; Wong and Mooney, 2007; Lu et al., 2008; Liang et al., 2011; Kwiatkowski et al., 2011; Artzi and Zettlemoyer, 2013; Krishnamurthy and Mitchell, 2014; Li et al., 2015; Chen et al., 2016; Xiao et al., 2016; Jia and Liang, 2016; Reddy et al., 2016; Liang et al., 2017).

The performance of semantic parsers critically depends on the quality of lexicon, including accuracy and coverage. Specifically, in order to construct the logical form from a sentence, we first need to learn a lexicon,[1] which contains the mappings from natural language phrases (e.g., "*born*") to logical predicates (e.g., `PlaceOfBirth`). From the example in Figure 1, we can see that lexicon is the foundation of parsing, and lexicon learning plays an important role in semantic parsing.

Traditional semantic parsers are usually domain-specific, which only contains a limited number of logical predicates (Zettlemoyer and Collins, 2005; Kwiatkowksi et al., 2010; Artzi et al., 2014). In this

[1]We follow the lexicon style defined in Berant et al. (2013).

Proceedings of the 27th International Conference on Computational Linguistics, pages 892–904
Santa Fe, New Mexico, USA, August 20-26, 2018.

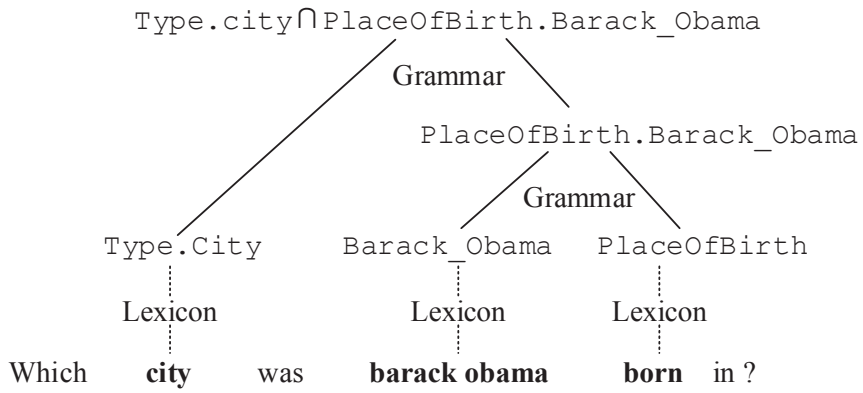

Figure 1: An example of semantic parsing, which uses lexicons to map phrases to predicates, and applies grammars to construct the logical form.

case, the mappings for each predicate can be learned relatively easily from training corpus. Recently, a growing body of research has scaled up semantic parsers to open domain (Cai and Yates, 2013a; Cai and Yates, 2013b; Berant et al., 2013; Krishnamurthy and Mitchell, 2012; Kwiatkowski et al., 2013) , where the number of predicates has increased substantially, making it hard to learn a lexicon with high coverage.

To resolve the lexicon coverage problem, there have been several papers on lexicon learning for semantic parsing. Cai and Yates (2013a) learns lexicons by pattern matching. Berant et al. (2013) learns lexicons by aligning Freebase [2] predicates with relations from ClueWeb [3], and then the alignments are used as lexicons. However, the lexicon coverage of these alignment-based methods highly depends on entity co-occurrences, and they mostly can only learn predicates which indicating relations between entities. It is still hard to cover all expressions and all predicates using alignment-based methods.

In this paper, we propose a semi-supervised lexicon learning algorithm for semantic parsing, which can increase the lexicon coverage by exploiting easily obtained text corpora and lexical resources. [4] The intuition behind our approach is that similar phrases should map to similar predicates, thus the phrase similarity can be used to propagate known predicate mappings to unknown mappings. For example, assuming we have a seed mapping: "*currency*" :: `currency`, and we know "*money*" is strongly related to "*currency*", we then can predict "*money*" should also map to `currency`. To achieve the above goal,we employ a graph-based semi-supervised learning framework, which learns lexicons not only used the alignments between Freebase and text, but also the semantic relatedness between phrases in the text side. Specifically, we use the abundant lexical resources for high coverage lexicon learning (Figure 2 shows the difference). There are three main tasks in this process. (1) we need a seed lexicon; (2) we need to measure the similarity between words; (3) we need to smooth the mappings to unlabeled words. For the similarity measure between words, we learn them from large text resources. This similarity plays two roles in our lexicon learning: (1) it is used for label propagation; (2) the similarity is used as a constraint on smoothing. That is, since we assume similar words will map to similar labels, the similarity can then strengthen the correct mapping and weaken the wrong mapping. Once we have seed lexicons and similarities between words, we smooth the lexicon by using a graph-based semi-supervised learning framework.

[2]https://en.wikipedia.org/wiki/Freebase

[3]https://www.lemurproject.org/clueweb12.php/

[4]We use *text corpora* to refer text resources from web, e.g., Wikipedia and WikiAnswers, and *lexical resources* to refer organized resources related to lexical items, e.g., WordNet and PPDB.

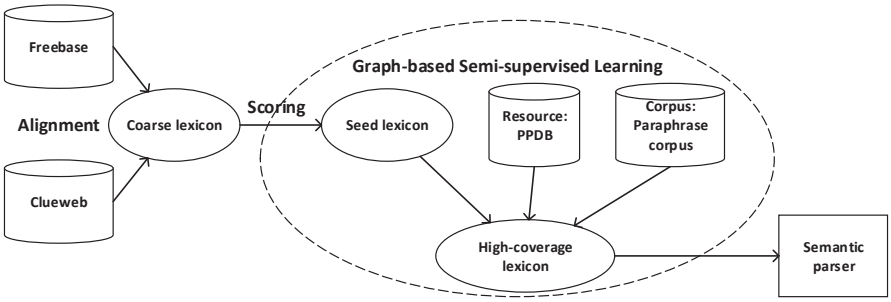

Figure 3: The framework of lexicon learning for semantic parsing in this paper. We can utilize large amount of text corpora and lexical resources to extend the lexicon for wide-open semantic parsing.

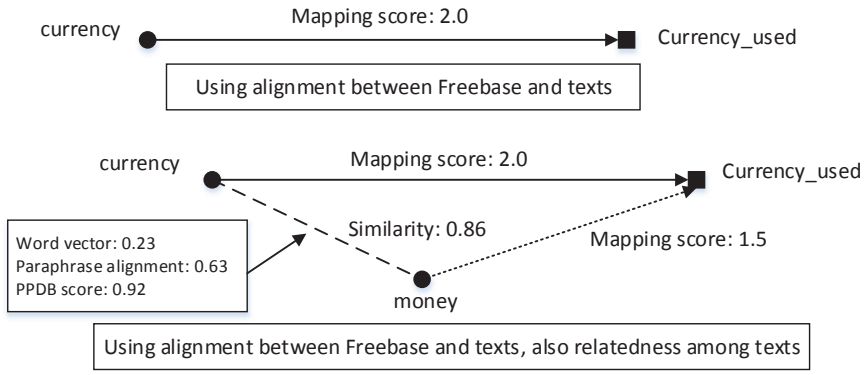

Figure 2: Example of our approach (the below one) and the previous approach (the above one). The previous approach only utilizes the alignments between text corpora and Freebase. By contrast, our approach further makes use of alignments between text and text. In this way, we can learn wide-coverage lexicon from several labeled lexicon.

The framework of our approach is shown in Figure 3. First, we make use of Freebase and ClueWeb to gain a coarse lexicon, and then we score these lexicons to gain the seed lexicon for following smooth. Next, we utilize easily obtained text corpora and text resources to learn the wide-coverage lexicon in a graph-based semi-supervised learning framework. Finally, we use the extended lexicon in the semantic parser to evaluate our approach.

We evaluate our lexicon learning algorithm on two benchmark datasets: WEBQUESTIONS and FREE917. The results show that our method can learn lexicon with higher coverage, and enhance the performance of semantic parsing system, especially its recall.

The contributions of this paper can be summarized as follows:

1. We propose a new semi-supervised learning framework for wide-coverage lexicon learning. Different to previous work, our approach can improve the lexicon coverage by further exploiting the easily obtained text corpora and lexical resources.

2. We design a graph-based learning algorithm to learn a wide-coverage lexicon from a seed lexicon.

3. We evaluate our approach on two benchmark datasets. Our system outperforms baseline systems significantly, and achieves competitive results with state-of-the-art systems.

2 Related Work

Lexicon learning is fundamental for semantic parsing. Traditional semantic parsers usually utilize annotated logical forms to learn the lexicon (Zettlemoyer and Collins, 2005; Kwiatkowksi et al., 2010; Kwiatkowski et al., 2011; Krishnamurthy and Mitchell, 2012; Berant et al., 2013; Krishnamurthy, 2016). Zettlemoyer and Collins (2005) utilizes the alignment between phrases in sentences and predicates in

annotated logical forms, and then assigned a confidence score to each lexical entry. Obviously, these approaches are limited by the annotated data.

Recently, many researchers begin to scale up semantic parsers to open domain. Learning high coverage lexicon in open domain requires large amount of annotated data, which is quite expensive even they only use question-answer pairs for supervision. There are several papers that focus on extending the lexicon for open-domain semantic parsing.

Cai and Yates (2013a) first extend the semantic parser to open domains. They utilize pattern matching to extend the lexicon. Specifically, they define knowledge patterns from knowledge bases, and text patterns from a search engine. Then they learn the lexicon based on the assumption that the phrase between two entities may map to the predicate if these two entities are also found under the predicate in knowledge bases. Berant et al. (2013) learn the lexicon by similar idea, but they use annotated ClueWeb corpus as the text side. Besides, they propose what they call a bridge operation, which is in fact a type-shifting which can bring in a predicate using minimum information. Compared to these approaches, our approach not only utilizes the alignments between knowledge bases and text corpora, but also makes use of text corpora and text resources to get the phrase similarity and phrase co-occurrence. In this way, we can learn more lexicon from little seed lexicon. Krishnamurthy (2016) also learned a lexicon for semantic parsing. However, they aim to extend the predicate side as they think the predicates have limited coverage for new sentences. Our aim is to extend the phrase that can trigger the predicates.

Graph-based semi-supervised learning algorithm has been used to resolve the OOV problem in machine translation (Razmara et al., 2013; Saluja et al., 2014; Zhao et al., 2015; Mehdizadeh Seraj et al., 2015). frame semantic parsing (Das and Smith, 2011), sentiment lexicon induction (Hamilton et al., 2016), and morph-syntactic lexicon induction (Faruqui et al., 2016).

3 Graph-based Lexicon Induction

Lexicon learning aims to learn the mapping from natural language phrases to predicates in knowledge base. There are three types of lexicons, including entity lexicon (e.g., "*city*" :: `Type.City`), unary lexicon (e.g., "*barack obama*" :: `Barack_Obama`) and binary lexicon (e.g., "*born*" :: `PlaceOfBirth`). In most cases entity lexicons are learned using entity linking techniques, therefore we usually only consider unary and binary lexicons in lexicon learning.

In open-domain semantic parsing, it is hard to learn high-coverage lexicon from annotated data for lexicon learning. In this paper, we use the (phrase, predicate) mappings as seeds, then learn new (phrase, predicate) mappings by propagating mapping information through similarities between phrases. Specifically, we propose a graph-based semi-supervised approach to resolve this problem. Our approach makes use of easily obtained text corpora and lexical resources to learn a similarity between words,[5] and then use a graph-based semi-supervised learning framework to smooth the lexicon graph. In this way, we can learn a new lexicon from labeled ones. Our method consists of three main steps:

1. Construct seed lexicon using alignments between Freebase and text corpora.
2. Learn similarities between words using both text corpora and text resources.
3. Learn new lexicon using label propagation.

3.1 Seed Lexicon Construction

We propagate information from seed lexicon to unknown ones. However, as we do not have enough annotated logical forms to learn the lexicon, and the number of predicates is too large, It is impossible to hand-make the lexicon, To obtain high-quality phrases mappings for each predicate, we construct the seed lexicon in two steps.

First, we gain a coarse lexicon by aligning Freebase with text corpora, using the lexicon learning methods as the same as Berant et al. (2013), with a slight difference that we only use unigram. We do this for two reasons: one is that a word (e.g., `born`) in a phrase (e.g., `born in`) can trigger a

[5]We use *phrase* and *word* alternately in this paper, since we use unigram for the lexicon and a *phrase* contains a single word.

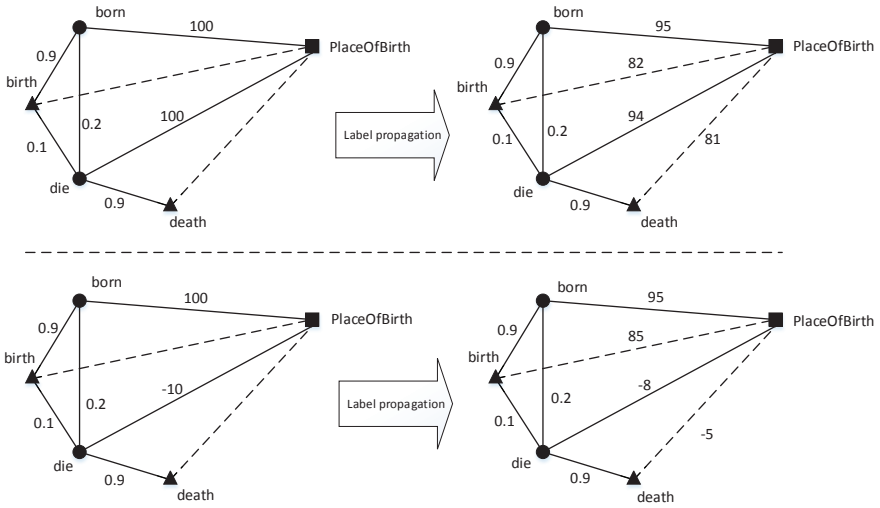

Figure 4: An example of propagation. This example shows that we need to score the seed lexicon first. Otherwise, the label propagation will bring more noise to lexicon learning.

predicate (e.g., *PlaceOfBirth*) if the phrase triggers the predicate. The other is that it is easy to compute the similarity between unigrams. Although this technique will raise more ambiguity, we use an extra feature template to handle this.

Next, we select high quality lexicons by scoring each lexical entry. Specifically, we use the lexicon gained in first step to train a semantic parser, and define several features to measure the quality of each lexical entry. After training, we can compute the score for each lexical entry. Since the higher the score of a lexical entry, the better its quality. We pick top K (K=5) lexical entries for each predicates as our seed lexicon. It is important to assign score to each lexical entry in the seed lexicon. As Figure 4 shows if we don't assign score, as there are many incorrect lexical entries in the seed lexicon, and these lexical entries will bring more noise to the lexicon when doing graph propagation.

3.2 Graph Construction

We construct a graph over all phrases in the seed lexicons and words which occur in the whole data. Besides, we also consider bridge words, which are both near to labeled node and unlabeled node. There are three types of nodes in the graph (As Figure 5 shows): Labeled nodes represent words in the seed lexicon; unlabeled nodes represent words in the whole data; bridge nodes represent the shared nearest neighbor nodes for the labeled nodes and unlabeled nodes.

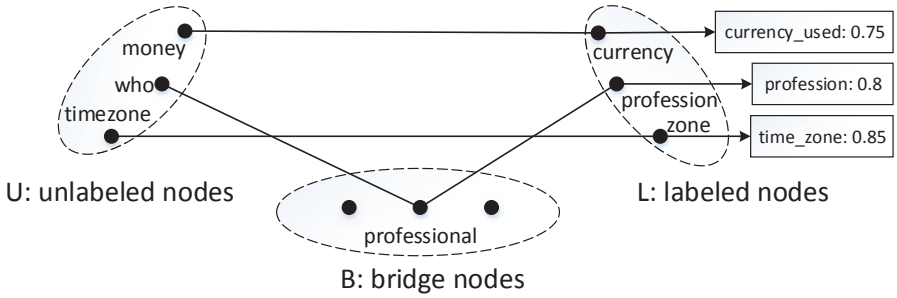

Figure 5: The graph between labeled nodes, unlabeled nodes and bridge nodes. Mapping can propagate either directly from labeled nodes to unlabeled nodes or indirectly via bridge nodes.

We use three resources to compute similarity for graph construction.

First, we use distributional representations for phrases to compute the similarity. Recently, a fair amount of research has showed that the word vector is quite useful for natural language process, especially for tasks related to similarity. Our purpose is to find similar words for the labeled ones, and label

neighbor words	scores
guilder	3.05
coin	3.03
taxa	3.00
les	2.89
exchange	2.85
monetary	2.76
money	2.63

Table 1: Nearest neighbor words for "*currency*" from PPDB-2.0.

them with the same labels. We use the published word vector (Huang et al., 2012) directly, and use cosine distance for similarity.

The second resource we used is paraphrase tables. In this part, we want to utilize paraphrase pairs, like "*money*" and "*currency*". We construct these pairs using the Paralex corpus (Fader et al., 2013). Paralex is a large question paraphrases corpus from WikiAnswers,[6] and each clique questions were tagged as expressing the same meaning by users. Paraphrase pairs in Paralex are word-aligned using standard machine translation methods. We use the word alignments to construct a word table by applying the consistent word pair heuristic to only unigram. This paraphrase tables is suitable for our needs since it focuses on question paraphrases.

The third resource we used is PPDB. Specifically, we use PPDB-2.0 (Pavlick et al., 2015) to calculate the similarity between two phrases by utilizing their scores, which consider many aspects. As we argued before, we only consider single word. So we use the lexical part of PPDB-2.0. Moreover, we pre-process the PPDB dataset by lemming the words. Table 1 shows several nearest neighbor words for the word "*currency*" from PPDB-2.0.

In fact, we can also use lexicon resources like synset from WordNet,[7] and Allen (2014) has used the VerbNet for learning a lexicon for broad-coverage semantic parsing. However, we find that the synsets for words are almost covered by the resources mentioned before. So we don't use these resources here.

In order to limit the graph size, we consider the top 10 nearest labeled nodes and top 5 nearest bridge nodes for each unlabeled one; for the each bridge node, we consider the top 5 nearest labeled nodes. Moreover, we also consider edges between labeled nodes and labeled nodes.

Finally, the overall similarity score between two given phrases w_1 and w_2 is computed as follow:

$$sim(w_1, w_2) = \alpha sim_1(w_1, w_2) + \beta sim_2(w_1, w_2) + (1 - \alpha - \beta) sim_3(w_1, w_2) \quad (1)$$

Before the final computing, we normalize each similarity score which are obtained using three resources separately. The hyperparameters are turned by development training.

3.3 Graph Propagation

Graph propagation is used to propagate the labels from labeled nodes to unlabeled ones by following the graph's structure. This approach is based on the smoothness assumption: similar nodes in the graph have similar labels. This paper utilizes the modified Adsorption algorithm (Talukdar and Crammer, 2009).

$$\min_{\widehat{Y}} \quad \mu_1 \sum_{v \in V_L} p_1 \, ||Y_v - \widehat{Y}_v||_2^2 \; + \mu_2 \sum_{v,u} p_2 \, W_{v,u} \, ||\widehat{Y}_v - \widehat{Y}_u||_2^2 \; + \mu_3 \sum_{v} p_3 \, ||\widehat{Y}_v - R_u||_2^2 \quad (2)$$

There are three parts in Formula (2), the first part enforces the labels of the seed nodes to keep unchanged. The second part enforces the smoothness, making similar nodes have similar labels. The third part enforces an uniform distribution for the unlabeled nodes. We use the Junto label propagation toolkit[8] for label propagation.

[7] https://wordnet.princeton.edu/

[8] https://github.com/parthatalukdar/junto

4 Semantic Parsing with Extended Lexicon

After graph propagation, each unlabeled phrase is labeled with a distribution over the set of predicates. We use SEMPRE (Berant et al., 2013; Berant and Liang, 2015) as our base semantic parser. In order to use the learned lexicon, we add a feature which indicates the final score for each lexical entry. The semantic parser will train on the training data with the learned lexicon as its initial lexicon. Following Berant and Liang (2015), we also use the feature template that conjoins predicates and content lemmas, and this feature template has been proved very helpful in Berant and Liang (2015).

5 Experiments

We evaluate our method on two benchmark datasets: WEBQUESTIONS and FREE917.

Dataset: WEBQUESTIONS dataset (Berant et al., 2013) contains 5,810 question-answer pairs. These questions are collected by crawling the Google Suggest API, and the answers are obtained using Amazon Mechanical Turk. This dataset covers several popular topics and its questions are commonly asked on the web. In our experiments, we use the standard train-test split (Berant et al., 2013), i.e., 3,778 questions (65%) for training and 2,032 questions (35%) for testing.

The FREE917 dataset (Cai and Yates, 2013a) contains 917 questions, annotated with logical forms. This dataset covers a wide range of domains. One example is "*what fuel does an internal combustion engine use*". Following Cai and Yates (2013a), we use the original split of the questions into 70% questions (641) to train and 30% questions (276) to test.

Setup: In our experiments, we use the Freebase Search API for entity lookup in WEBQUESTIONS dataset, and build a Lucene index over the 41M Freebase entities to map entities in FREE917 dataset. We load Freebase using Virtuoso, and execute logical forms by converting them to SPARQL and querying using Virtuoso. We learn the parameters of our system by making several passes (3 for WEBQUESTIONS and 6 for FREE917) over the training dataset, with the beam size (200 in WEBQUESTIONS and 500 for FREE917).

For the similarity computation, we set $\alpha = 0.05$, $\beta = 0.85$. For the parameters in Junto, we set $\mu_1 = 0.55$, $\mu_2 = 0.44$, $\mu_3 = 0.01$, $\beta = 2$.

Comparing systems: To evaluate our method, we mainly compare our system (Base + lexicon) to the base system (Base) which does not use the learned wide-coverage lexicon, also to system (Base + bridge) which utilize bridge operator to serve as lexicon (Berant et al., 2013). We also compare to several nearly published systems, including semantic parsing based system (Kwiatkowski et al., 2013; Berant and Liang, 2015), information extraction based systems (Yao and Van Durme, 2014; Yao, 2015), machine translation based systems (Bao et al., 2014), embedding based systems (Bordes et al., 2014; Yang et al., 2014), and QA based system (Bast and Haussmann, 2015).

5.1 Experimental Results

Table 2 and Table 3 provide the performances of all baselines[9] and our method in WEBQUESTIONS and FREE917. From Table 2 and Table 3, we can see that:

1. Our method achieves competitive performance: Our system outperforms base system (Base) greatly and gets a better performance when comparing to the base system with a bridge operator (Base + bridge).

2. The learned lexicon has wider coverage than the seed one: Our system obtains higher recall than the Base. By utilizing large amount of text corpora and lexical resources, the extended lexicon improves the semantic parsing system. For FREE917, our system gains the highest recall. This indicates that our lexicon really has wider coverage, especially for dataset with more domains like FREE917.

3. The bridge operation from Berant and Liang (2015) is quite powerful. It can resolve the problem of lexicon coverage to some degree. And our approach, which learns the lexicon directly, can gain a better performance.

[9]We collect the results of other systems from https://nlp.stanford.edu/software/sempre/.

Our approach	71.5	67.9	69.6

Table 3: The results of our system and recently published systems on FREE917.

4. Compared to all baselines, our system gets a competitive recall. This result indicates that our parser can parse more sentences when the lexicon has wider coverage. Interestingly, for WEBQUESTIONS, both the two systems with the highest recall (Bast and Haussmann, 2015; Yih et al., 2015) rely on extra-techniques such as entity linking and relation matching.

In Section 3.1, we normalize the seed lexicon using the unigram for the lexeme. By this way, the final graph for label propagation will not be too large, and it is convenient to compute the similarity between word and word using text corpora and lexical resources. We design some experiments to evaluate the new seed lexicon (unigram for lexeme). Table 4 and Table 5 shows the results. We can see that the system using the new seed lexicon has similar performance to the system using the original seed lexicon.

System	Prec.	Rec.	F1 (avg)
Original seed	40.6	47.5	**40.6**
New seed	**51.0**	**47.6**	40.5

Table 4: The results of using different seed lexicons on WEBQUESTIONS dataset.

System	Prec.	Rec.	F1 (avg)
Original seed	69.8	59.0	63.9
New seed	**71.2**	**59.5**	**64.8**

Table 5: The results of using different seed lexicons on FREE917 dataset.

System	Prec.	Rec.	F1 (avg)
Only word vector	41.8	45.9	39.7
Only paraphrase table	50.0	46.3	39.4
Only PPDB-2.0	51.2	58.7	50.6
All	**51.6**	**59.7**	**51.2**

Table 6: The results of using different resources for measuring similarities on WEBQUESTIONS dataset.

To evaluate the text corpora and lexical resources we used, we also conduct several experiments on WEBQUESTIONS. Table 6 shows the results. We can see that:

1. Only using word vector for similarity computation, the final result is not ideal. We think that the word vector consider many aspects in similarity, and in lexicon learning, what we expect for similarity is paraphrasing.

2. The paraphrase table pairs help a little. We think that is due to we use simple alignment for scoring.

3. The PPDB-2.0 serves quite well, even only use PPDB-2.0 score for similarity computation. We think that the PPDB-2.0 was extracted from paraphrase corpus, so the similar lexicon are almost paraphrase to each other.

4. Using word vector, paraphrase align table pairs and PPDB-2.0 score together achieves the best performance.

5.2 Analysis

Our aim is to learn a wide-coverage lexicon for semantic parsing. Our approach utilizes text corpora and lexical resources to extend seed lexicon. Table 7 shows several learned new mappings with the final score from the semantic parser. We can find that after label propagation, we can obtain new lexical entries which can improve the coverage of semantic parser. The results proved our intuition, i.e., the unlabeled phrase maps to the same predicate of its nearest labeled phrases.

Predicate	Seed phrase	Learned phrase	score
`Currency`	*currency*	*money*	4.91
`Education`	*education*	*school*	4.75
`Religion`	*religion*	*believe*	2.30
`Profession`	*professional*	*who*	2.30

Table 7: Several learned lexical entries with un-normalized scores on WEBQUESTIONS dataset.

The learned new lexicon has wide coverage, however, this means the accuracy for the lexicon will be influenced. Berant and Liang (2015) added new lexicalized features (lemmaAndBinary) that connect natural language phrases to binary predicates. For example, given the utterance "*What countries have german as the official language?*", the predicate for phrase "*language*" can be `Language-spoken` and `Offical-language`. The added feature will conjoin binaries with all content word lemmas. After observing enough examples, the phrase "*language*" will map to `Offical-language` when has "*official*" as its content, because the feature, which corresponds to "*offical*" and `Offical-language`, will be up-weighted. Berant and Liang (2015) have proved this feature is really helpful. In our experiments, we also use this feature. Table 8 shows the ablation test results. We can see that, this feature improves our system greatly, especially for precision. We think that as we only use the unigram as our lexeme for lexical entry, the lexicon has more noise. And the alignments between predicates with content words will help the parser to choose the right lexicon during parsing.

System	Prec.	Rec.	F1 (avg)
Our system - feature	48.0	48.9	41.8
Our system	**51.6**	**59.7**	**51.2**

Table 8: The results of ablation test for the lemmaAndBinary feature.

Manual error analysis To better understand our system, we manually inspected the errors our system made. We found that many errors are due to mistakes in labeling. The rest of the errors are mainly complicate cases, like N-ary predicate (event in Freebase), superlative, temporal clause etc. We argue that more attention should be given to these complicated cases.

6 Conclusion

In this paper, we make use of low-cost, easily obtained text corpora and lexical resources in a graph-based semi-supervised learning framework to learn lexicon for semantic parsing. Experiments demonstrate that our method improves the semantic parsing system, especially, when the lexicon is not covered in the training data. Our method can learn wide-coverage lexicon for open-domain semantic parsing.

Traditionally, a semantic parser needs a lexicon first, and then parses the sentence in a bottom-up way. For these parsers, the lexicon is extremely important, and it is hard to learn lexicon with high coverage. Currently, some semantic parsers use the knowledge base in advance, and utilize entity linking and relation matching during parsing, and these methods parse the sentence like a top-down way. As the knowledge base is huge, the searching space is usually quite large. In future work, We want to design parsing algorithm which can take advantages from both sides.

Abstract

We present a new summary evaluation approach that does not require human model summaries. Our approach exploits the compositional capabilities of corpus-based and lexical resource-based word embeddings to develop the features reflecting coverage, diversity, informativeness, and coherence of summaries. The features are then used to train a learning model for predicting the summary content quality in the absence of gold models. We evaluate the proposed metric in replicating the human assigned scores for summarization systems and summaries on data from query-focused and update summarization tasks in TAC 2008 and 2009. The results show that our feature combination provides reliable estimates of summary content quality when model summaries are not available.

1 Introduction

Quantifying the quality of summaries is an important and necessary task in the field of automatic text summarization. Current summary evaluation methods like manual and automated pyramid (Passonneau et al., 2005; Passonneau et al., 2013) and well-established ROUGE scores (Lin, 2004) heavily rely on multiple human-generated model summaries to assess the quality of system-generated summaries. This evaluation paradigm falls short on non-standard test sets where model summaries are not available. According to the quantitative analysis by Louis and Nenkova (2009a); Singh and Jin (2016), evaluating summaries by their comparison with the input obtains good correlations with manual evaluations. Therefore, identifying a suitable input-summary similarity metric will provide a means for model-free evaluation of summaries.

We hypothesize that comparing semantic representations of the input and summary content will lead to more accurate input-summary evaluation. Hence, we explore the effectiveness of compositionality of word embeddings in developing a model-free automatic metric to evaluate summary content quality. In particular, our approach incorporates the word embedding models trained on the Google News corpus and the WordNet lexical resource to compare centroid vectors of the input and summary. To demonstrate the effectiveness of our approach, we have conducted a set of experiments on data from query-focused and update summarization tasks in TAC[1] 2008 and 2009. The reliability of our metric is also studied conducting an error analysis. The experiment results show that quantifying the indicators of content quality by taking advantage of compositional properties of the word and sense embeddings produces summary scores which accurately replicate human assessments. It is noteworthy that our approach complements but is not intended to replace existing model-based evaluation approaches, since their reliability and strength are important for high confidence evaluations.

2 Related Work

Proposals for developing automatic summary evaluation methods (Ellouze et al., 2013; Ng and Abrecht, 2015; ShafieiBavani et al., 2017) have been put forward in the past. However, these methods are not

[1] http://www.nist.gov/tac/

Proceedings of the 27th International Conference on Computational Linguistics, pages 905–914
Santa Fe, New Mexico, USA, August 20-26, 2018.

applicable on non-standard test sets where model summaries are not available. Herein, we try to briefly review the most significant approaches that have addressed this issue. Donaway et al. (2000) proposed an alternative to model-based evaluation where a comparison of the input text with a summary can clarify how good the summary is. A summary that has higher similarity with the input text can be considered better than one with lower similarity. Radev et al. (2003) performed an automated ranking of the test documents using a search engine scenario. Their approach was motivated by the assumption that the distribution of terms in a good summary is similar to the distribution of terms in the input document.

With the same intuition, Louis and Nenkova (2009a; 2013) introduced an evaluation system (SIMetrix) that comprises multiple features to determine the quality of a summary. Their focus was on computing divergences between the probability distributions of words in the input and summary. Jensen Shannon divergence and feature regression turned out to be their best metrics. Louis and Nenkova (2009b) also presented a similar evaluation approach utilizing a collection of large number of system summaries in place of model summaries. Saggion et al. (2010); Cabrera-Diego and Torres-Moreno (2017) proposed follow-up works to SIMetrix to assess the usefulness of divergences for multilingual summarization evaluation, and the applicability of multiple divergences for evaluating summaries.

Alternatively, we assume that the way of representing the input and summary is a key factor in high performance prediction of manual metrics. To this end, we exploit the compositional capabilities of word embeddings to design our features of content quality based on the continuous vector representation of words and senses. We then present a quantitative analysis of our features for characterizing the relation between the input and summary content in the absence of model summaries. We have finally evaluated our approach through two levels of granularity on two years data in TAC for query-focused and update summarization tasks. We have also compared our approach with model-based ROUGE, and model-free SIMetrix as an input-summary evaluation metric. The results demonstrate that the Support Vector Regression (SVR) of our features achieves the best correlation with manual judgments.

3 Data and Evaluation Metrics

We carry out our experiments on the query-focused and update summarization tasks from TAC 2009 with 44 inputs as our test set, and from TAC 2008 with 48 inputs as the development set. These datasets consist of two sets of 10 news documents for each input: (i) set *A* for initial summaries; (ii) set *B* for update summaries. Both *A* and *B* are on the same general topic but *B* contains documents published later than those in *A*. The update summary of set *B* is created assuming that the user is aware of what exists in set *A*. There are also four human-crafted model summaries for each input in each document set. A maximum of 100 words summary that addresses the information required by the given query statement (consisting of a title and narrative) has been produced by each of the 53 and 58 automatic summarizers participated in TAC 2009 and 2008, respectively. An example query statement is shown here:

Title: Barack Obama
Narrative: Track the increase in Barack Obama's popularity, visibility, support, and activities.

Content and linguistic quality are two conventional factors in evaluation of summary quality. Herein, we focus on the problem of automatic evaluation of content quality. Hence, we assess the performance of our metrics in replicating manual correlations of pyramid and responsiveness. It is noteworthy that responsiveness incorporates at least some aspects of linguistic quality.

Pyramid: This evaluation method (Passonneau et al., 2005) is a content assessment measure which compares content units in a system summary to weighted content units in a set of model summaries. It uses multiple human models from which annotators identify semantically defined Summary Content Units (SCU). Each SCU is assigned a weight equal to the number of human model summaries that express that SCU. An ideal maximally informative summary would express a subset of the most highly weighted SCUs, with multiple maximally informative summaries being possible. The pyramid score for a system summary is equal to the ratio between the sum of weights of SCUs expressed in a summary (again identified manually) and the sum of weights of an ideal summary with the same number of SCUs.

Four human summaries provided by NIST for each input and task were used for the pyramid evaluation at TAC.

Responsiveness: This is a measure of overall quality combining both content and linguistic quality. Summaries must present useful content in a structured fashion in order to better satisfy the user's need. Assessors directly assigned scores on a scale of 1 (poor) to 5 (very good) to each summary. These assessments are done without reference to any model summaries.

Linguistic Quality: This measure ranks summaries in a 5-point scale indicating how well a summary satisfied the factors of linguistic quality (i.e., grammaticality, non-redundancy, referential clarity, focus, structure and coherence). In our work, we do not evaluate linguistic quality.

4 Features for Summary Evaluation

We propose five classes of features to assess the quality of summary content in the absence of model summaries: (i) *Distributional Semantic Similarity*; (ii) *Topical Relevance*; (iii) *Query Relevance*; (iv) *Coherence*; and (v) *Novelty*. Before computing the features, all words in input documents, summaries, and queries are converted to lower case and stop-word filtered. We experiment with two variants of word embeddings as the basic building block to design our features:

Corpus-based Word Embeddings: We utilize the 300-dimensional embeddings for 3M words and phrases trained on Google News[2], a corpus of $\sim 10^{11}$ tokens, using word2vec CBOW (Mikolov et al., 2013). Word2vec learns a vector representation for each word using a neural network language model. It also allows to learn complex semantic relationships using simple vectorial operators, such as $vec(king) - vec(man) + vec(woman) \approx vec(queen)$. Stemming is not performed to make the word embeddings discover the linguistic regularities of words with the same root.

Lexical Resource-based Word Embeddings: We use WordNet (Fellbaum, 1998) to measure the lexico-semantic similarity between the input and its summary. Since the constraints of WordNet lexical resource can be formalized as constraints on embeddings, we can use embeddings of non-word data types (i.e., senses). Specifically, we compute the embedding of a word by averaging the embeddings of its senses in WordNet. For example, the vector of the word *suit* is modeled as the average of a vector representing *lawsuit* and a vector representing *business suit*.

We obtain the sense embeddings using the pre-trained model by Rothe and Schütze (2015), that lives in the same vector space as the pre-trained word2vec by Mikolov et al. (2013). Their model is an autoencoder neural-network that takes word embeddings and learns sense embeddings based on the following intuitions: (i) a word's embedding is the sum of the embeddings of its senses; and (ii) the senses related by WordNet relations (e.g., hypernymy, antonymy, similarity) have similar embeddings. Considering WordNet relations also helps to compute embeddings for senses in WordNet which are not in the word2vec vocabulary.

We further assume that the probability of a word sense is in proportion to its frequency in WordNet. Hence, the probability that a sense $\mathcal{S}_{ij}$ is the meaning of the word w_i, is the ratio of the frequency of that sense $freq(\mathcal{S}_{ij})$ to the total frequency of the word. If the frequency of a word sense is 0 in WordNet, we set it to 1. Finally, the embedding of word w_i is computed[3] as a weighted average of its senses $\mathcal{S}_{ij}, 1 \leq j \leq n$, where the weights represent the probability of senses:

$$\vec{w_i} = \frac{\sum_{\mathcal{S}_{ij} \in \mathcal{S}yn(w_i)} freq(\mathcal{S}_{ij}) \times \vec{\mathcal{S}_{ij}}}{n \sum_{\mathcal{S}_{ij} \in \mathcal{S}yn(w_i)} freq(\mathcal{S}_{ij})} \quad (1)$$

4.1 Distributional Semantic Similarity

A good summary must satisfy both *coverage* and *diversity* properties. For clarity, summary sentences should cover a sufficient non-redundant amount of information from the original input text. Diversity

[2]https://code.google.com/p/word2vec/

[3]Words were stemmed before inferring their embeddings.

property is also fundamental especially for multi-document summarization. Moreover, one would expect good summaries to be characterized by low distance between probability distributions of words in the input and summary, and by high similarity with the input. Hence, we design this feature based on the geometric meaning of the centroid vector of a document using the compositional properties of the word embeddings (Mikolov et al., 2013). The main idea is to give a distributed representation of words/senses in the input and its summary, and compare their centroid vectors to realize how much the summary content works as a pseudo-input and condenses the meaningful information of the input.

The centroid embedding $\vec{T}$ of a text $T = \{t_1, t_2, ..., t_n\}$, is the sum of the embeddings of tokens of T divided by the number of tokens n. Based on the problem, we can also assign a weight $\mathcal{W}$ to each token in T (Figure 1). Accordingly, the centroid embedding for each summary sentence $\vec{s_j}$ is computed by averaging the embeddings of all words comprising the sentence (Radev et al., 2004). Similarly, we construct a centroid vector for each document, $\vec{d_i}$, in the input document set. To better assess the *informativeness* of the summary content, we assign higher weights to specialized words in a document by considering the Inverse Document Frequency (IDF) scores of words:

$$\vec{d_i} = \frac{\sum_{w_j \in d_i} \vec{w_j} \times TF(w_j, d_i) \times IDF(w_j)}{n \sum_{w_j \in d_i} TF(w_j, d_i) \times IDF(w_j)} \tag{2}$$

where n is the number of words in document d_i, and $\vec{w_j}$ is the embedding of word w_j. $TF(w_j, d_i)$ stands for the term frequency of w_j in d_i. The IDF scores are computed on the whole document set.

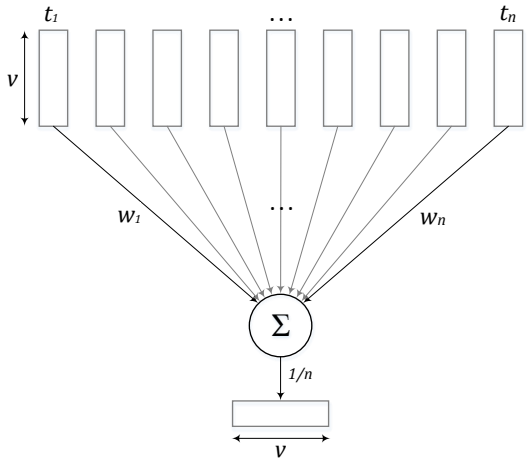

Figure 1: The weighted centroid embedding of text $T = \{t_1, t_2, ..., t_n\}$

Finally, we compare summary sentences and the input documents using the Word Mover's Distance (WMD) algorithm (Kusner et al., 2015). WMD measures the total distance the centroid embeddings of summary sentences and the input documents have to travel to become identical. Accordingly, we measure the dissimilarity degree between two sets of embedding vectors, $D = \{\vec{d_1}, ..., \vec{d_n}\}$ and $S = \{\vec{s}_1, ..., \vec{s}_m\}$, by calculating the minimum amount of summing up individual distances (travel costs) that centroid embeddings of the documents in D need to travel to reach the embeddings of sentences in S:

$$WMD(D, S) = \min_{F \geq 0} \sum_{\vec{d_i} \in D} \sum_{\vec{s_j} \in S} F_{\vec{d_i}\vec{s_j}} \times dist(\vec{d_i}, \vec{s_j}) \tag{3}$$

subject to,

$$\sum_{\vec{d_i} \in D} F_{\vec{d_i}\vec{s_j}} = \frac{1}{|S|}, \forall \vec{s_j} \in S, \sum_{\vec{s_j} \in S} F_{\vec{d_i}\vec{s_j}} = \frac{1}{|D|}, \forall \vec{d_i} \in D$$

where $F \in \mathbb{R}^{V \times V}$ with V as the vocabulary size, is a flow matrix which indicates how much probability mass should flow (or travel) from document centroid embedding $\vec{d_i}$ in set D to sentence embedding $\vec{s_j}$

in set S, and vice versa. $dist(\vec{d_i}, \vec{s_j})$ denotes the individual distance (or travel cost) between $\vec{d_i}$ and $\vec{s_j}$: $dist(\vec{d_i}, \vec{s_j}) = \|\vec{d_i} - \vec{s_j}\|_2$.

4.2 Topical Relevance

Topic features serve as a basis for evaluating topical relevance of a summary to the input documents. Herein, we aim to find the distribution of the most probable topics embodied in the input document set, and their relevance to the summary sentences. To this end, we use Latent Dirichlet Allocation (LDA) algorithm (Blei et al., 2003; Arora and Ravindran, 2008) to determine the topics that characterize every document set. LDA is a generative model for documents to determine topic compositions of words and document mixtures of topics (represented by a probability distribution over topics), by assigning words to topics within documents. Hence, in the context of text modeling, the topic distribution provides an underlying semantic representation of the documents and can be useful in evaluating the summaries. Using weighted topic compositions, we measure the similarity of summary sentences with the most important topics identified in the document set.

We use Gibbs sampling (Griffiths, 2002) for inference in the topic model with concentration parameters $\alpha = 0.1$ and $\beta = 0.01$. We also set the number of topics $K = 10$ for each document set. Formally, each topic is defined as $\mathcal{T}_i = \{p_1, p_2, ..., p_n\}$, where p_j is the probability distribution of word w_j. We consider top $m = 30$ words and their probabilities to build a centroid as the representative of each topic. The embedding vector for word w_j is then multiplied with its normalized probability $\mathcal{P}_j$, and the weighted vectors are averaged to build a topic centroid representation:

$$\vec{\mathcal{T}_i} = \frac{1}{m} \sum_{j=1}^{m} \mathcal{P}_j \vec{w_j}, \quad where\ \mathcal{P}_j = \frac{p_j}{\sum_{i=1}^{m} p_i} \tag{4}$$

Finally, we use WMD to measure the dissimilarity degree between the centroid embeddings of summary sentences and those of the topics for evaluating topical relevance of the summary content.

4.3 Query Relevance

To measure the relevance degree of the summary content to the given query, we calculate the query embedding vector $\vec{Q}$ by averaging the embeddings of all words in the query narrative. Similarly, the centroid embedding vector for each summary $\vec{S}$ is also constructed. We further measure the cosine similarity between these vectors to formulate query relevance:

$$sim(\vec{S}, \vec{Q}) = \frac{\vec{S} \cdot \vec{Q}}{\| \vec{S} \| \| \vec{Q} \|} \tag{5}$$

4.4 Coherence

Coherence measures the degree to which a sequence of summary sentences represents a logical flow of thought. We compute the similarity between embeddings of adjacent summary sentences using cosine similarity. It results in $n-1$ comparisons for a summary of n sentences. While similarity between sentences is beneficial for coherence, very high similarity reflects redundancy in the summary. Given that, we combine the *mean* and *standard deviation* of the cosine similarity scores by training a simple linear regression model on our development set. In this way, we measure the trade-off between continuity and redundancy as the coherence feature.

4.5 Novelty

We would like our evaluation model to move beyond assessing initial summaries by giving a simple feature of Novelty to better evaluate update summaries. This feature rewards the update summary consisting novel words that do not exist in initial document set D_A, but are semantically related to update document set D_B. The relevancy of these words in update summary S_j, to the documents in set *B*, is measured using the cosine similarity between the embeddings of novel words and the centroid embedding of the

whole document set *B*. We use the bag-of-words representation of the summary and the document sets while defining novel words. We finally measure the degree of novelty ($\mathcal{N}$) as:

$$\mathcal{N}(S_j) = \frac{1}{|S_j|} \sum_{w_i \in S_j | w_i \notin D_A} sim(\vec{w_i}, \vec{D_B}) \tag{6}$$

where $|S_j|$ is the total number of unique words in the update summary S_j. For S_j without any novel words, $\mathcal{N}(S_j) = 0$.

5 Feature Combination with SVR

We combine all the above features using a Support Vector Regression (SVR) model to predict the summary quality. We first transform the proposed features into a standard vector notation. Each summary S_i is represented by a feature vector $X = \{x_1, x_2, ..., x_n\}$ where n is the number of features. SVR model aims to learn a function $f : \mathbb{R}^n \mapsto \mathbb{R}$, which will be used to predict the content evaluation score for each summary $y \in \mathbb{R}$ given a feature vector $X \in \mathbb{R}^n$. In particular, given l training instances $(X_1, y_1), ..., (X_l, y_l)$, the SVR model is learnt by solving the following optimization problem (Vapnik, 1999); W is a vector of feature weights; ϕ is a function that maps feature vectors to a new vector space of higher dimensionality to allow non-linear functions to be learnt in the original space; $C > 0$ and $\epsilon > 0$ are given.

$$\min_{W,b,\xi,\xi^*} \frac{1}{2}\|W\|^2 + C\sum_{i=1}^{l} \xi_i + C\sum_{i=1}^{l} \xi^* \tag{7}$$

subject to (for $i = 1, ..., l$):

$$\begin{aligned} W^T \cdot \phi(X_i) + w_0 - y_i &\leq \epsilon + \xi_i \\ y_i - W^T \cdot \phi(X_i) - w_0 &\leq \epsilon + \xi^* \\ \xi_i &\geq 0 \\ \xi^* &\geq 0 \end{aligned}$$

The goal is to learn a linear (in the new space) function, whose prediction (value) $W^T \cdot \phi(X_i) + w_0$ for each training instance X_i will not to be farther than ϵ from the target (correct) value y_i. Since this is not always feasible, two slack variables ξ_i and ξ_i^* are used to measure the prediction's error above or below the target y_i. The objective (7) jointly minimizes the total prediction error and $\|W\|$, to avoid overfitting. The utilized SVR is implemented in Scikit-learn (Pedregosa et al., 2011). We use the default parameter settings, (*kernel='rbf', degree=3, gamma='auto', coef0=0.0, tol=0.001, C=1.0, epsilon=0.1, shrinking=True, cache_size=200, verbose=False, max_iter=-1*) without further optimization.

6 Experiments and Results

Reporting correlations with manual evaluation metrics is the norm for validating automatic metrics. We use Spearman correlation metric to study the predictive power of our automatic features in replicating manual correlations of pyramid and responsiveness. Hence, we compare the rankings of systems against the human scores assigned to systems. The correlations[4] of our metrics are reported at two levels of granularity:

System Level (MACRO): The average score for a system is computed over the entire set of test inputs using both manual and automatic evaluations. The correlations between ranks assigned to systems by these average scores are indicative of the strength of our features to predict overall system rankings on the test set.

Analyzing the macro level results on TAC 2008 (Table 1), we find that the variants of distributional similarity and the topical relevance features produce system rankings very similar to those produced by

[4]Significance values for the correlations are produced using the AS 89 algorithm (Best and Roberts, 1975).

Table 1: Input-summary evaluation on the query focused and update summarization tasks from TAC 2008 data: MACRO level Spearman correlations, all results are significant ($p < 0.05$); MICRO level percentage of inputs with significant correlations ($p < 0.05$).

human. Other features, on the other hand, are less predictive of content quality. Distributional similarities also outperform SIMetrix, which proves the importance of semantic representation of the input and summary for comparison purposes in summary content evaluation. Overall, our feature regression obtains the best correlations with both types of manual scores, and even outperforms ROUGE-1 regarding pyramid for query-focused task. The usefulness of novelty feature is also reflected in high SVR correlation results for the update summarization task.

Overall ROUGE correlation is evidence that the model summaries provide information that is unlikely to ever be approximated by exploring the input alone. However, our features can provide reliable estimates of system quality when averaged over a set of test inputs. We also observe that corpus-based models mostly outperform their corresponding lexical resource-based models. A possible reason is the higher coverage of Google News word2vec model comparing to the WordNet-based sense embedding model. For example, some words like proper nouns (e.g., *'Barak Obama'*) are not covered in WordNet. However, replacing a word's embedding by the sum of the embeddings of its senses could generally improve the quality of embeddings (Rothe and Schütze, 2015). That is why our SVR performs well by leveraging WordNet senses for more precise word embeddings, and involving Google News to complement the WordNet coverage.

Input Level (MICRO): For each individual input, we compare the rankings for the system summaries using manual and automatic evaluations. Micro-level analysis highlights the ability of an evaluation metric to assess the quality of system summaries produced for a specific input. This task is bound to be harder than system level predictions. For clarity, even with wrong prediction of rankings on a few inputs, the average scores (macro-level) for a system might not be affected.

To be in line with SIMetrix, we report the percentage of inputs for which significant correlations were obtained (Table 1). We observe that feature combination with SVR gives the best results overall, similar to our findings for the macro level. The implication is that no single feature can reliably predict good content for a particular input. Moreover, our feature regression outperforms SIMetrix. This is because our approach depends not merely on the distribution of terms in the input, and therefore provides better representation for a set of documents each describing different opinion on a given issue. For example, our topical relevance feature gives a representative vector for every important aspect of the document set. However, superiority of ROUGE performance to the rest of measures shows that model summaries generated for specific input would still give better indication of important information in the input.

6.1 Error Analysis:

In this study, we aim to assess the reliability of our metric for evaluation in the absence of human model summaries, where ROUGE cannot be used. It is noteworthy that we do not intend to directly compare the performance of ROUGE with our metric. Thereupon, we provide an error analysis to understand if our SVR and ROUGE are making errors in ordering the same systems or whether their errors are different. Since at the macro level, the correlations between our regression and pyramid scores is close to those of ROUGE-2, we further analyze their errors. We considered pairs of systems and identified the better system in each pair according to the pyramid scores. Afterwards, we recorded how often ROUGE-2 and the SVR provided the correct judgment for the pairs as indicated by the pyramid evaluation. Table 2 provides the results for all 1,653 pairs of systems at the macro level.

	SVR correct	**SVR incorrect**
ROUGE-2 correct	1,355(82.0%)	97(5.9%)
ROUGE-2 incorrect	100(6.0%)	101(6.1%)

Table 2: Error analysis: Overlap between ROUGE-2 and SVR predictions for the best system in a pair (TAC 2008, 1,653 pairs). The gold-standard judgment for a better system is computed using pyramid.

A large majority (82%) of the same pairs are correctly predicted by both ROUGE and the SVR. Another 6% of the pairs are such that both metrics do not provide the correct judgment. Therefore, ROUGE and our SVR appear to agree on a large majority of the system pairs. There is a small percentage (12%) that is correctly predicted by only one of the metrics.

6.2 Evaluation on the Test Set:

Our SVR was trained on the TAC 2008 data with pyramid scores as the target. Herein, we evaluate this metric using the TAC 2009 data (Table 3). We report the correlations obtained by ROUGE-SU4 as the official baseline measure at TAC 2009 for comparison of automatic evaluation metrics. The results indicate that the correlations are lower than on our development set. This might be caused by the different characteristics of inputs in two year's data (Louis and Nenkova, 2013). However, the SVR is consistently predictive across two years, and outperforms SIMetrix.

	QUERY - MACRO		**QUERY - MICRO**		**UPDATE - MACRO**		**UPDATE - MICRO**	
Metric	**Pyr.**	**Resp.**	**Pyr.**	**Resp.**	**Pyr.**	**Resp.**	**Pyr.**	**Resp.**
Support Vector Regression	0.80	0.75	87.5	77.1	0.77	0.65	79.2	75.0
SIMetrix JS divergence	-0.74	-0.71	84.1	75.0	-0.72	-0.61	77.3	72.7
SIMetrix Regression	0.77	0.67	81.8	65.9	0.71	0.54	75.0	52.3
ROUGE-SU4 (4 models)	0.92	0.79	95.5	81.8	0.85	0.69	100	86.4

Table 3: Input-summary evaluation on the query focused and update summarization tasks from TAC 2009 data: MACRO level Spearman correlations, all results are significant ($p < 0.05$); MICRO level percentage of inputs with significant correlations ($p < 0.05$).

Overall results also show that correlations with pyramid scores are higher than those with responsiveness. The reason is that our features mainly evaluate summary content. Responsiveness judgments, on the other hand, are based on both content and linguistic quality. Nevertheless, our SVR performs better than SIMetrix in replicating responsiveness scores. This might be advantaged by considering coherence as a linguistic quality feature. Hence, a natural extension of our work would be considering more linguistic quality features along with content evaluations.

7 Conclusion and Future Work

We have presented an effective model-free summary content evaluation approach that exploits the compositional properties of word and sense embeddings to develop a variety of features for input-summary comparisons. The results show that the strength of different features varies considerably, and their combination provides reliable estimates of summary content quality when model summaries are not available. This lends further support to our proposal to use semantic representation of the input and summary contents for the model-free summary content evaluation.

Our ongoing work includes considering distributional and relational semantics together (Fried and Duh, 2014; Verga and McCallum, 2016; Rossiello, 2016) for different sentence representations, and using more complex neural language models (Le and Mikolov, 2014; Zhang and LeCun, 2015; Jozefowicz et al., 2016) for the comparison.

Abstract

The availability of corpora annotated with negation information is essential to develop negation processing systems in any language. However, there is a lack of these corpora even for languages like English, and when there are corpora available they are small and the annotations are not always compatible across corpora. In this paper we review the existing corpora annotated with negation in Spanish with the purpose of first, gathering the information to make it available for other researchers and, second, analyzing how compatible are the corpora and how has the linguistic phenomenon of negation been addressed. Our final aim is to develop a supervised negation processing system for Spanish, for which we need training and test data. Our analysis shows that it will not be possible to merge the small corpora existing for Spanish due to lack of compatibility in the annotations.

Title and Abstract in Spanish

Revisión de los corpus españoles anotados con negación

La disponibilidad de corpus anotados con información sobre la negación es esencial para cualquier idioma, ya que son necesarios para poder desarrollar sistemas capaces de procesar este fenómeno lingüístico. Sin embargo, hay una escasez de corpus anotados con negación, incluso para idiomas como el inglés, y cuando hay corpus disponibles, en la mayoría de los casos son pequeños y las anotaciones no siempre son compatibles entre ellos. En este trabajo revisamos los corpus anotados con información sobre la negación en español con el propósito, en primer lugar, de recopilar la información para que esté disponible para otros investigadores y, en segundo lugar, de analizar la compatibilidad de los corpus y las estructuras de negación que se han anotado. Nuestro objetivo final es desarrollar un sistema automático para el procesamiento de la negación en español. Nuestro análisis muestra que no será posible unir los pequeños corpus existentes actualmente en español debido a la falta de compatibilidad en las anotaciones.

1 Introduction

Nowadays, there is a vast amount of information on the Internet. The large number of sources and the high volume of texts make it difficult for users to select information of interest. In order to extract fine-grained information, automatic systems need to be able to process a diversity of linguistic phenomena such as negation, irony or sarcasm that are used to add extra-propositional meaning. In this study, we focus on negation.

Negation is a very relevant linguistic phenomenon for most of Natural Language Procesing (NLP) tasks, such as information extraction, question answering and sentiment analysis, since negation cues act as operators that can change the meaning of the words that are within their scope by changing the truth value of propositions (Horn, 1989). Negation is a main linguistic phenomenon whose computational

Proceedings of the 27th International Conference on Computational Linguistics, pages 915–924
Santa Fe, New Mexico, USA, August 20-26, 2018.

treatment has not been solved yet, not even for English, due to its complexity and the multiple forms in which it can appear (syntactic, lexical and morphological). Because of the low frequency of negations as compared to other phenomena, the impact in the performance of applications is low from a quantitative perspective, but high from a qualitative view, for example, when processing clinical records. Moreover, some systems we use regularly do not treat this phenomenon effectively. Not even Google deals properly with negation in Spanish. The search "películas que no sean de aventuras", returns adventure movies, whereas it should return non adventure movies.

The standard two phases of a negation processing system are: identifying the presence of negation markers and determining their scope. As in NLP tasks, the availability of corpora annotated with information about negation is essential to train algorithms. However, it is not easy to find corpora annotated with negation, especially in languages other than English. In addition, it is not only necessary that corpora exist, but also that corpora are publicly available for the community to use them, that they are well documented, and that they contain annotations of quality. Ideally, they should also be large enough to allow training robust machine learning systems.

There are different catalogs and platforms that provide information about resources and/or access to them, such as LDC catalog[1], ELRA catalog[2], LRE Map[3], META-SHARE[4] and ReTeLe[5] catalog. If we make a query[6] in these repositories for Spanish corpora annotated with negation, we only find 1 resource in ReTeLe catalog, the SFU Review$_{SP}$-NEG corpus (Jiménez-Zafra et al., 2018). Therefore, we decided to perform an exhaustive search of resources. In this way, we facilitate the task for researchers interested in working on this topic by providing a description of the corpora as well as the direct links to get the data when possible.

In this work, we review the existing Spanish corpora annotated with negation. We focus on Spanish because i) there are no negation processing systems available, ii) it is the second language with most native speakers, and iii) it is the third language most used on the Internet. Our final goal is to develop a supervised negation processing system, for which we need to use annotated corpora. The main purposes of our review are to analyze how compatible are the Spanish corpora annotated with negation and to find out whether the annotations account for the complexity of negation in Spanish.

The rest of the paper is organized as follows: in Section 2 we describe the main features of negation in Spanish, in Section 3 we present the corpora annotated with negation, in Section 4 we analyzed them, in Section 5 we propose a solution to the problems found and, finally, we put forward conclusions in Section 6.

2 Negation in Spanish

Processing negation is not as easy as using a list of negation markers and applying look-up methods. They can be used to find out potential negation cues but they are not adequate because the presence of a cue does not imply that it acts as a negation. In the sentence "You bought the car to use it, didn't you?" the cue "not" is not used as a negation but it is used to reinforce the first part of the sentence. Moreover, it is also necessary to identify the scope or part of the sentence affected by the negation and its focus, the part more prominently negated. If we want to advance in the study of this phenomenon, as for most of NLP tasks, the availability of annotated corpora is essential to train algorithms. According to existing resources for English, annotating negation involves the annotation of the following aspects:

- *Negation cue*: lexical item(s) that modify the truth value of the propositions that are within its scope. There are different types of negation according to the type of the negation cue used:

[1] https://catalog.ldc.upenn.edu/

[2] http://catalog.elra.info/en-us/

[3] http://lremap.elra.info/

[5] ReTeLe is a network of resources for language technologies that has as goal the compilation and documentation of linguistic resources created in Spain. ReTele catalog contains metadata describing resources in RDF format. ReteLe catalog: http://linguistic.linkeddata.es/retele-share/sparql-editor/

[6] Query performed on March 6th 2018

  - Syntactic negation, if a syntactically independent negation marker is used to express negation (i.e. *no ['no/not']*, *nunca ['never']*).
  - Lexical negation, if a word is used whose meaning has a negative component (i.e. *negar ['deny']*, *desistir ['desist']*).
  - Morphological negation, if a morpheme is used to express the negation (i.e. *i-* in *ilegal ['illegal']*, *in* in *incoherente ['incoherent']*). It is also known as affixal negation.

- *Scope*: the part of the sentence affected by the negation cue (Vincze et al., 2008). The scope can be continuous or discontinuous.

- *Focus*: the part of the scope that is most prominently or explicitly negated (Blanco and Moldovan, 2011).

- *Negated event*: the event that is directly negated by the negation cue, usually a verb, a noun or an adjective (Kim et al., 2008).

This is just a list of the main aspects that have been annotated for negation. However, each language has specific linguistic resources to express negation and specific negation structures, which should also be reflected in the information annotated in corpora. As we will show in Section 4, most existing annotation schemes for Spanish do not account for the complexity of the linguistic structures used to express negation that are present in texts. This happens mainly because of two reasons: first, annotation of negation started with the annotation of clinical reports in English (Chapman et al., 2001; Goldin and Chapman, 2003; Mutalik et al., 2001a), where there is not too much variation of negation structures. Second, corpora have been created for specific purposes, such as extracting negated clinical events, and not with the intention of accounting for all the linguistic complexity of the negation phenomenon.

An exception to this is the SFU Review$_{SP}$-NEG corpus (Jiménez-Zafra et al., 2018; Martí et al., 2016). The guidelines specify a great variety of negation patterns at the syntactic level that we summarize below. Additionally, the guidelines also specify expressions that involve a negation cue but do not express negation.

On the one hand, patterns that express negation can be divided into three categories:

1. *Simple negation markers*, if they are composed of only one single negation marker (i.e. *no ['no/not']*, *nunca ['never']*).
2. *Complex negation markers*, if negation is expressed using two or more negation markers that can be continuous (i.e. *casi no ['almost not']*, *casi nunca ['hardly ever']*) or discontinuous (i.e. *no ... en absoluto ['not ... at all']*, *no ... mucho ['not ... a lot']*). Complex negation markers are usually used to reinforce negation or to modulate the value of negation (increase or diminish the degree of negation).
3. *Expressions that do not contain any negation marker*: lexicalized complex constructions that express negation in specific contexts even though they do not contain any negation marker (i.e. *en mi vida ['in my life']*).

On the other hand, patterns that not express negation can be categorized as follows:

1. *Rhetorical negation markers*, if a negation marker is used with an emphatic or expletive value, that is, if it is used to make a sentence more full, intense or harmonious, although it is not necessary to understand the meaning of the sentence (i.e. *Viniste a verlo, ¿no? ['You came to see him, didn't you?']*).
2. *Idioms containing negation markers*, if an idiom (i.e. *ni corta ni perezosa ['without thinking twice']*) or a lexicalised cue (i.e. *hasta que no ['until']*) contain a negation marker that does not express negation.

3. *Negation markers in contrastive constructions*, if negation markers are used to counterpose different ideas, to correct something, to introduce new information or to express obligation, rather than to express negation (i.e. *No hay más solución que comprar una lavadora ['There is no other solution than to buy a washing machine']*).
4. *Negation markers in comparative constructions*, if negation markers are used to compare some property with something, that is, negation is used to place an entity below or above another entity on a scale (i.e. *No es tan grande como me lo imaginaba ['It is not as big as I imagined']*).

3 Corpora annotated with negation

In this section, the Spanish corpora annotated with negation are presented[7]. To the best of our knowledge, five corpora exist from different domains, although the clinical domain is the predominant one.

3.1 UAM Spanish Treebank

The first Spanish corpus annotated with negation that we are aware of is the UAM Spanish Treebank (Moreno et al., 2003), which was enriched with the annotation of negation cues and their scopes (Sandoval and Salazar, 2013).

The initial UAM Spanish Treebank consisted of 1,500 sentences extracted from newspaper articles (*El País Digital* and *Compra Maestra*) that were annotated syntactically. Trees were encoded in a nested structure, including syntactic category, syntactic and semantic features, and constituent nodes, following the Penn Treebank model. Later, this version of the corpus was extended with the annotation of negation and 10.67% of the sentences were found to contain negations (160 sentences).

In this corpus, syntactic negation was annotated but not lexical nor morphological negation. It was annotated by two experts in corpus linguistics who followed similar guidelines to those of Bioscope corpus (Szarvas et al., 2008; Vincze, 2010). They included negation cues within the scope as in Bioscope and NegDDI-DrugBank (Bokharaeian et al., 2014). All the arguments of the negated events were also included in the scope of negation, including the subject, which was excluded from the scope in active sentences in Bioscope. There is no information about inter-annotator agreement.

The UAM Spanish Treebank corpus is freely available at `http://www.lllf.uam.es/ESP/Treebank.html`. It is in XML format, negation cues are tagged with the label *Type="NEG"* and the scope of negation is tagged with the label *Neg="YES"* in the syntactic constituent on which negation acts.

3.2 IxaMed-GS

The IxaMed-GS corpus (Oronoz et al., 2015) is composed of 75 real electronic health records from the outpatient consultations of the Galdakao-Usansolo Hospital in Biscay (Spain). It was annotated by two experts in pharmacology and pharmacovigilance with entities related to diseases and drugs, and with the relationships between entities indicating adverse drug reaction events. They defined their own annotation guidelines taken into consideration the issues that should be considered for the design of a corpus according to Ananiadou and McNaught (2006).

The objective of this corpus was not the annotation of negation but the identification of entities and events in clinical reports. However, negation and speculation were taken into account in the annotation process. In the corpus, four entity types were annotated: diseases, allergies, drugs and procedures. For diseases and allergies, they distinguished between negated entity, speculated entity and entity (for non-speculative and non-negated entities). 2,362 diseases were annotated, out of which 490 (20.75%) were tagged as negated diseases and 40 (1.69%) as speculated diseases. 404 allergy entities were identified, of which 273 (67.57%) were negated and 13 (3.22%), speculated. The quality of the annotation process was assessed by measuring the inter-annotator agreement, which was 90.53% for entities and 82.86% for events.

The corpus might be acquired via the EXTRECM project[8] by agreeing to some conditions that include a confidentiality agreement.

[8] `http://ixa.si.ehu.eus/extrecm`

3.3 SFU Review$_{SP}$-NEG

The SFU Review$_{SP}$-NEG[9] (Jiménez-Zafra et al., 2018) is the first Spanish corpus that includes the event in the annotation of negation and that takes into account discontinuous negation markers. Moreover, it is the first corpus where the effect of the negation on the words that are within its scope is annotated, that is, whether there is a change in the polarity or an increment or reduction of its value. It is an extension of the Spanish part of the SFU Review corpus (Taboada et al., 2006) and it could be considered as the counterpart of the SFU Review Corpus with negation and speculation annotations[10] (Konstantinova et al., 2012).

The Spanish SFU Review corpus consists of 400 reviews extracted from the website *Ciao.es* that belong to 8 different domains: cars, hotels, washing machines, books, cell phones, music, computers, and movies. For each domain there are 50 positive and 50 negative reviews, defined as positive or negative based on the number of stars given by the reviewer (1-2=negative; 4-5=positive; 3-star review were not included). Later, it was extended to the SFU Review$_{SP}$-NEG corpus in which each review was automatically annotated at the token level with POS-tags and lemmas, and manually annotated at the sentence level with negation cues and their corresponding scopes and events. It is composed of 9,455 sentences, out of which 3,022 sentences (31.97%) contain at least one negation marker.

In this corpus, syntactic negation was annotated but not lexical nor morphological negation, as in the UAM Spanish Treebank corpus. Unlike this one, annotations on the event and on how negation affects the polarity of the words within its scope were included. The annotations were performed by two senior researchers with in-depth experience in corpus annotation who supervised the whole process and two trained annotators who carried out the annotation task. The Kappa coefficient for inter-annotator agreement was of 0.97 for negation cues, 0.95 for negated events and 0.94 for scopes.[11] A detailed discussion of the main sources of disagreements can be found in (Jiménez-Zafra et al., 2016).

The guidelines of the Bioscope corpus were taken into account but after a thorough analysis of negation in Spanish, a typology of Spanish negation patterns was defined (Martí et al., 2016). As in Bioscope, NegDDI-DrugBank and UAM Spanish Treebank, negation markers were included within the scope. Moreover, the subject was also included within the scope when the word directly affected by negation is the verb of the sentence, as in ConanDoyle-neg corpus (Morante and Daelemans, 2012). The event was also included in the scope of negation as in ConanDoyle-neg corpus.

The SFU Review$_{SP}$-NEG is publicly available and can be downloaded at `http://sinai.ujaen.es/sfu-review-sp-neg-2/`.

3.4 UHU-HUVR

The UHU-HUVR (Cruz Díaz et al., 2017) is the first Spanish corpus in which affixal negation is annotated. It is composed of 604 clinical reports from the Virgen del Rocío Hospital in Seville (Spain). 276 of this clinical documents correspond to radiology reports and 328 to the personal history of anamnesis reports written in free text.

In this corpus, all types of negation were annotated, syntactic, morphological (affixal negation), and lexical. It was annotated with negation markers and the negated events by two domain expert annotators following closely the Thyme corpus guidelines (Styler IV et al., 2014) with some adaptations. In the anamnesis reports, 1,079 sentences (35.20%) were found to contain negations out of 3,065 sentences. On the other hand, 1,219 sentences (22.80%) out of 5,347 sentences were annotated with negations in the radiology reports. The Dice coefficient for inter-annotator agreement was higher than 0.94 for negation markers and higher than 0.72 for negated events. Most of the disagreements were the result of a human error, i.e., the annotators missed a word or included a word that did not belong either to the event or to the marker. However, other cases of disagreement can be explained by the difficulty of the task and the lack of clear guidance. They encountered the same type of disagreements as Jiménez-Zafra et al. (2016) when annotating the SFU Review$_{SP}$-NEG corpus.

[9]First Online: 22 May 2017 `https://doi.org/10.1007/s10579-017-9391-x`

[10]`https://www.sfu.ca/~mtaboada/SFU_Review_Corpus.html`

[11]The inter-annotator agreement values have been corrected with respect to those published in (Jiménez-Zafra et al., 2018) due to the detection of an error in the calculation thereof.

Authors say that the annotated corpus will be made publicly available, but it is not currently available probably because of legal and ethical issues.

3.5 IULA Spanish Clinical Record

The IULA Spanish Clinical Record corpus (Marimon et al., 2017) contains 300 anonymized clinical records from several services of one of the main hospitals in Barcelona (Spain) that was annotated with negation markers and their scopes. It contains 3,194 sentences, out of which 1,093 (34.22%) were annotated with negation cues.

In this corpus, syntactic negation and lexical negation were annotated but not morphological negation. It was annotated with negation cues and their scopes by three computational linguists annotators advised by a clinician. The inter-annotator agreement Kappa rates were 0.85 between annotators 1 and 2, and annotators 1 and 3; and 0.88 between annotators 2 and 3. The authors defined their own annotation guidelines taking into account the currently existing guidelines for corpora in English (Mutalik et al., 2001b; Szarvas et al., 2008; Morante and Daelemans, 2012). Differently from previous work, they did not include the negation cue nor the subject in the scope (except when the subject is located after the verb).

The corpus is publicly available with a CC-BY-SA 3.0 license and it can be downloaded at `http://eines.iula.upf.edu/brat//#/NegationOnCR_IULA/`.

4 Analysis

In order to take an informed decision about which (combination of) corpus can we use to develop a system, we have performed a detailed analysis. An overview of the information annotated can be found in Tables 1 and 2.

Table 1 presents a summary of the negation aspects annotated in each corpus, the domain of the documents, the size in number of sentences and the inter-annotator measure used to estimate the agreement. Table 2 contains the type of negation cues that have been annotated in each corpus and negation types that have been taken into account.

	UAM Spanish Treebank	IxaMed-GS	SFU Review$_{SP}$-NEG	UHU-HUVR	IULA Spanish Clinical Record

Scope	✓	-	✓	-	✓
Event	-	✓	✓	✓	-
Focus	-	-	-	-	-
IAA measure	NA	%	Kappa	Dice	Kappa

Table 1: Spanish corpora annotated with negation (NA: Non-Available, -: Absent, ✓:Present).

The years of publication of the corpora show the novelty of the task. The first corpus annotated with negation in Spanish appeared in 2013, while the others have been compiled in the last two years. Important aspects of the corpora to be analyzed are the type of documents included, the size, the guidelines applied, the annotation schemes and the inter-annotator agreement.

Three of the five corpora focus on the clinical domain, which reflects the demands for the treatment of negation in this domain. Processing negation in clinical documents is crucial because the health of a patient is at stake, it is not the same to say that *a patient has* or *does not have a disease* or that *he is* or *is not allergic to a compound*. Moreover, we observe that there are other domains of interest, such as product reviews and news. The rating of a film will be totally different if a viewer says *"I liked the*

	UAM Spanish Treebank	SFU Review$_{SP}$-NEG	UHU-HUVR	IULA Spanish Clinical Record
Syntactic	✓	✓	✓	✓

movie" or if he says *"I did not like the movie"*. In the case of news, the impact would be totally different if it is said *"A plane crashed"* or if it is said *"Finally the plane did not crash"*.

As for the size, the available corpora are not very large and, although negation is an important phenomenon for NLP tasks, it is relatively unfrequent. In newspaper articles, only 10.73% of the sentences contain negation and, in the case of product reviews and clinical reports this value amounts to 31.97% and 29.22%[12], respectively. These percentages show the need of continuing working on the annotation of negation and its study. Training supervised systems usually relies on the existence of annotated corpora and, consequently, corpus generation is an important part for the development and testing of NLP techniques.

In relation to the guidelines used, it is noteworthy that there is no uniformity. In the first place, there are divergences in the negation aspects being annotated (negation cue, scope, event, focus). None of the corpora contain annotations of the four elements and the focus has been annotated in none of them. Only the SFU Review$_{SP}$-NEG corpus contains annotations of three elements (negation cue, scope and event). The UAM Spanish Treebank and the IULA Spanish Clinical Record corpora have focused on annotating negation cues and their scopes, and the UHU-UVR on the annotation of negation cues and their events. In the second place, these elements have not been annotated in the same way:

- *Negation cue*. As it has been described in Section 2, negation in Spanish is a complex phenomenon. Depending on the negation cue used, it can be syntactic, lexical or morphological. Moreover there are different types of negation patterns that express negation (simple negation markers, complex negation markers and expressions not containing any negation marker) and that do not express negation (rhetorical negation markers, idioms containing negation markers, negation markers in contrastive constructions and negation markers in comparative constructions). Only the UHU-UVR corpus contains annotations about the three types of negation cues (syntactic, lexical and morphological). The UAM Spanish Treebank and the SFU Review$_{SP}$-NEG corpora take only into account syntactic negation, and the IULA Spanish Clinical Record corpus also considered it along with lexical negation. However, in general, it is not specified whether the complexity of negation has been taken into account during the annotation process. An exception to this is the SFU Review$_{SP}$-NEG corpus. The guidelines specify that the different types of negation patterns according to the semantic interpretation have been considered for the annotation of negation at the syntactic level. This

[12]For clinical reports, it has been considered the average corresponding to the sentences annotated in UHU-HUVR and IULA Spanish Clinical Record corpora.

information has been summarized in Table 2.

- *Scope*. In the UAM Spanish Treebank and the SFU Review$_{SP}$-NEG corpora negation cues were included within the scope of negation as in Bioscope (Vincze et al., 2008), but in the IULA Spanish Clinical Record corpus they were not included. On the other hand, in the UAM Spanish Treebank all the arguments of the negated events, including the subject, were included within the scope of negation. However, in the SFU Review$_{SP}$-NEG corpora, the subject was included within the scope of negation when the word directly affected by negation is the verb of the sentence, as in ConanDoyle-neg corpus (Morante and Daelemans, 2012). In the IULA Spanish Clinical Record corpus it was not included, except when the subject is located after the verb.

- *Focus*. This element has not been annotated in the existing corpora.

- *Negated event*. In the SFU Review$_{SP}$-NEG corpus the event is always included within the scope of negation, as in Conan Doyle-neg corpus, and it is usually the head of the phrase in which the negation appears. In the UHU-UVR corpus negated events are annotated if they are clinically relevant, so not all negated events are annotated.

As for the annotation schemes, there is no a standard one. Each project devices the own scheme according to the needs of the project, which has consequences in the compatibility of the annotations across corpora. It is not possible to combine the corpora for machine learning purposes in order to obtain more training data.

Furthermore, the annotated corpora do not use the same coefficient to measure the inter-annotator agreement and there is even a corpus for which this measure is not provided. Providing this measure is very important because it allows to show the reliability of the annotation and the difficulty of the task.

The main purposes of our review was to analyse how compatible are the Spanish corpora annotated with negation and to find out whether the annotations account for the complexity of negation in Spanish. We have found that the existing corpora are not compatible, they have not been annotated with the same purpose and they do not contain annotations for the same negation aspects. Even in those corpora that contain annotations for the same negation aspect, the annotations have been made based on different guidelines. In relation to the complexity of negation, only the SFU Review$_{SP}$-NEG guidelines specify how different negation structures should be annotated. The guidelines of the other corpora do not contain information about the linguistic structures that have been taken into account.

5 A solution

The result of this analysis opens some questions. The existing annotation schemes are not compatible because of differences in genre, annotation guidelines, and the aspects of negation that have been annotated (negation cue, scope, event, focus). Therefore, it would be desirable to define a new scheme that integrates the contents of existing schemes. The scheme should be domain independent and all negation elements should be annotated in the same way. We are currently working on this. We have proposed a workshop (NEGES - Workshop on Negation in Spanish[13]) to advance in the study of this phenomenon and one of the tasks[14] has as goal to reach an agreement on the guidelines to follow. In order to participate in the task, researchers must analyze the existing guidelines and send a document indicating which aspects of the guidelines they agree with and which they do not, all duly justified. This information will be used to discuss the aspects of interest and to try to reach a consensus.

Additionally, we will conduct a study on the feasibility of an automatic conversion of the corpora. It is a pity that after all the work done and the time invested in the annotation of these corpora, it is not possible to merge them. We will explore semi-automatic approaches to re-annotate the most corpora possible.

[14] Task 1 - Annotation guidelines

6 Conclusions

Processing negation is a very important task in NLP because negation can change the truth value of a proposition. Detecting this is crucial in some tasks such as sentiment analysis or question answering. Most existing work on the treatment of negation has been carried out for English, but it is necessary to focus on other languages such as Chinese, Spanish or Arabic.

In this paper, we have presented the existing Spanish corpora annotated with negation information and we have described the main features of each one. Three of them are centered on the clinical domain probably because it is one of the areas where the treatment of negation is crucial in order not to extract false information about clinical conditions. It is worth noting that the first corpus annotated with negation appeared in 2013, whereas the rest have been compiled in the last two years, which shows the novelty of the task.

Our analysis shows that it would not be possible to merge the existing corpora in order to obtain a bigger one to train a machine learning system because of differences in genre, annotation guidelines, and the aspects of negation that have been annotated. The corpora have not been annotated with the same purpose and they do not contain annotations for the same negation aspects. Despite the fact that there have been already several annotation efforts, the community lacks a standard to annotate negation, contrary to what happens with other phenomena such as semantic roles.

As future work we plan to develop annotation standards to annotate negation in Spanish, in such a way that they are applicable to different genres and domains, and to analyze the feasibility of an automatic conversion of the corpora to a common annotation scheme.

Abstract

Document-level multi-aspect sentiment classification aims to predict user's sentiment polarities for different aspects of a product in a review. Existing approaches mainly focus on text information. However, the authors (i.e. users) and overall ratings of reviews are ignored, both of which are proved to be significant on interpreting the sentiments of different aspects in this paper. Therefore, we propose a model called Hierarchical User Aspect Rating Network (HUARN) to consider user preference and overall ratings jointly. Specifically, HUARN adopts a hierarchical architecture to encode word, sentence, and document level information. Then, user attention and aspect attention are introduced into building sentence and document level representation. The document representation is combined with user and overall rating information to predict aspect ratings of a review. Diverse aspects are treated differently and a multi-task framework is adopted. Empirical results on two real-world datasets show that HUARN achieves state-of-the-art performances.

1 Introduction

The ever-increasing popularity of online consumer review platforms, such as Tripadvisor[1] and Yelp[2], has led to large amounts of online reviews that are often too numerous for users to analyze. Consequently, there is a growing need for systems analyzing reviews automatically. Lots of approaches (Xia et al., 2011; Socher et al., 2013; Tang et al., 2015a; Yang et al., 2016) usually focus on determining the overall sentiment rating of a review. Actually, not only does a review express the general attitude of reviewer, but it also conveys fine-grained sentiments towards different aspects of corresponding products. Figure 1 shows an example where *Bob* posts a review about a hotel and gives scores on overall attitude, *location*, *room*, and *service* respectively. The analysis of these aspect ratings could not only benefit mining interested aspects for users, but also help companies better understand the major pros and cons of the product. However, compared with the overall rating, users are less motivated to give aspect ratings. The reviews without aspect ratings are rampant, which are more than 46% in a simple corpus-based statistics[3]. Accordingly, it is really useful to perform document-level multi-aspect sentiment classification, whose goal is to predict ratings for different aspects in a review (Yin et al., 2017).

Multi-task learning (Caruana, 1997; Collobert et al., 2011; Luong et al., 2016) is a straightforward approach for document-level multi-aspect sentiment classification, which shares the input and hidden layers to obtain a document representation as the input of different aspect-specific classifiers. However, the representation fails to capture the differences between aspects. In fact, when we predict the sentiment rating of *service*, the first two sentences in Figure 1 are most helpful and other sentences are auxiliary or even unnecessary for classifying *service*. Therefore, aspect-specific document representation is vital for this task. To this end, Yin et al. (2017) use iterative attention module to mine aspect-specific words and sentences based on a list of aspect keywords and obtain state-of-the-art results.

[3] The result is computed on 387,805 reviews crawled from https://www.tripadvisor.com/.

Proceedings of the 27th International Conference on Computational Linguistics, pages 925–936
Santa Fe, New Mexico, USA, August 20-26, 2018.

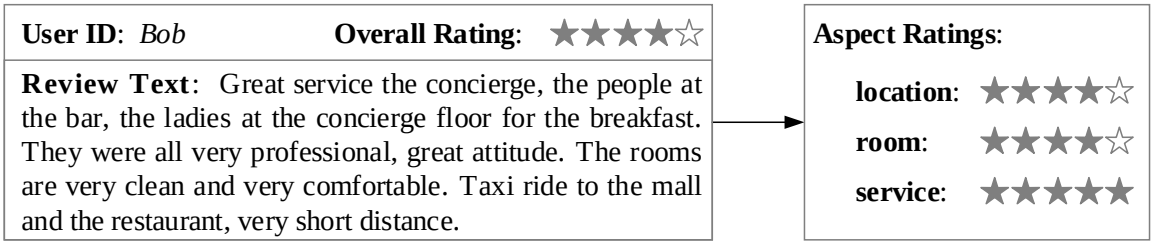

Figure 1: An example of a review. The left part is the review content, the upper right part is the reviewer *Bob* and overall rating of the review and bottom right part is different aspect ratings of the review. We focus on incorporating user preference and overall rating into review content to infer aspect ratings.

Despite the success of methods mentioned above, they typically only use text information. Two kinds of important information are ignored: users and overall ratings of reviews. The results of our statistical analysis are convincing that the two factors have strong correlations with aspect ratings (Section 2). As for users, different users may care about different aspects. When scoring aspects of a hotel, a business traveler may be critical to *service* but lenient with *price* or *room*. Such preference obviously affects the aspect ratings. Actually, many studies (Tang et al., 2015b; Chen et al., 2016; Dou, 2017) have shown that user preference can boost the performance of a related task, document-level sentiment classification that predicts an overall polarity instead of multi-aspect ratings. For our multi-aspect sentiment classification, the overall rating is given, and it can provide prior information to aspect ratings. Usually, the two types of rating are positive correlation. For example in Figure 1, the overall rating is 4 stars and the aspect ratings are all not less than 4 stars.

Inspired by the above analysis, we propose a model called Hierarchical User Aspect Rating Network (HUARN) to consider user preference and overall rating jointly for document-level multi-aspect sentiment classification. Specifically, HUARN utilizes a hierarchical structure to encode word, sentence, to document level information. Then, user and aspect information are embedded as attentions over word-level and sentence-level representation to construct a user-aspect-specific document representation. Based on the document representation, users and overall ratings are combined to express their influences on predicting aspect ratings. Finally, we adopt a multi-task framework to mutually enhance aspect rating prediction between different aspects.

In summary, our main contributions are as follows:

- For document-level multi-aspect sentiment classification, we validate the influences of users and overall ratings in terms of aspect ratings on massive Tripadvisor reviews.
- To the best of our knowledge, this is the first work to incorporate user preference and overall rating into a unified model (HUARN) in this task.
- We conduct experiments on two real-world datasets to verify the effectiveness of HUARN. The experimental results show that HUARN outperforms state-of-the-art methods significantly. The code and data for this paper are available at https://github.com/Junjieli0704/HUARN.

2 Data and Observations

In this section, we first introduce real-world datasets used in our work and present some explorations about the impacts of user preference and overall ratings on aspect ratings.

2.1 Data

We evaluate HUARN on two datasets: TripDMS and TripOUR. They are both crawled from Tripadvisor website and contain seven aspects (*value*, *room*, *location*, *cleanliness*, *check in*, *service*, and *business service*) which are provided by Tripadvisor website. The first dataset is built by Yin et al. (2017). However, there is no available user information in this dataset, thus we create the second one. Statistics

Datasets	#docs	#users	#docs/user	#words/sen	#words/doc
TripOUR	58,632	1,702	34.44	17.80	181.03
TripDMS	29,391	N/A	N/A	18.0	251.7

Table 1: Statistics of our datasets. The rating scale of TripOUR and TripDMS are 1-5.

Datasets	*value*	*room*	*location*	*cleanliness*	*check in*	*service*	*business service*
TripOUR	43,258	41,295	42,354	42,601	1,283	58,449	801
TripDMS	28,778	29,140	23,401	29,184	23,373	28,322	15,939

Table 2: The absolute number of rating of different aspects in TripOUR and TripDMS.

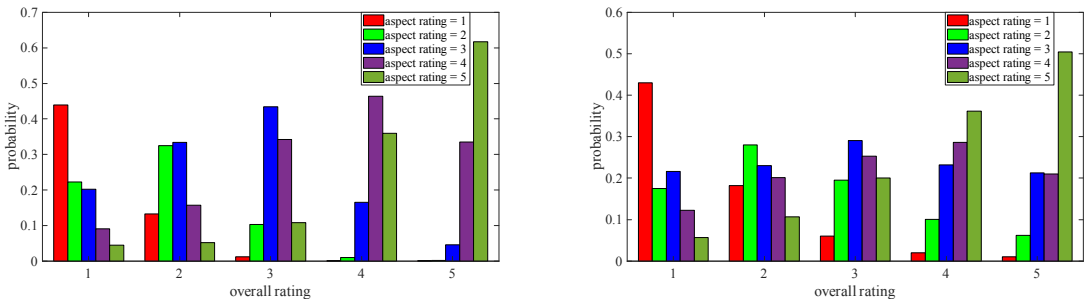
of our datasets are summarized in Table 1. Table 2 presents the absolute number of ratings of these aspects in our datasets.

2.2 Observations

Effects of user preference. Inspired by Tang et al. (2015b), we argue that the influences of users include the following two aspects: (1) *user-rating consistency*: different users have different characteristics in scoring aspects, and aspect ratings from the same user are more consistent than those from different users. (2) *user-text consistency*: different users have different word-using habits to express opinions and texts from the same user are more consistent than those from different users. To verify these consistencies, we conduct hypothesis testing as follows:

First, we construct three vectors $\mathbf{v}_s$, $\mathbf{v}_r$ and $\mathbf{v}_a$ with equal number (l) of elements. $\mathbf{v}_{s_i}$ is obtained by calculating a measurement between two reviews (d_i and d_i^+) posted by the same user, $\mathbf{v}_{r_i}$ is obtained by calculating a measurement between d_i and another random review and $\mathbf{v}_{a_i}$ is a random aspect (such as *service*), where $i \in \{1, 2, ..., l\}$.

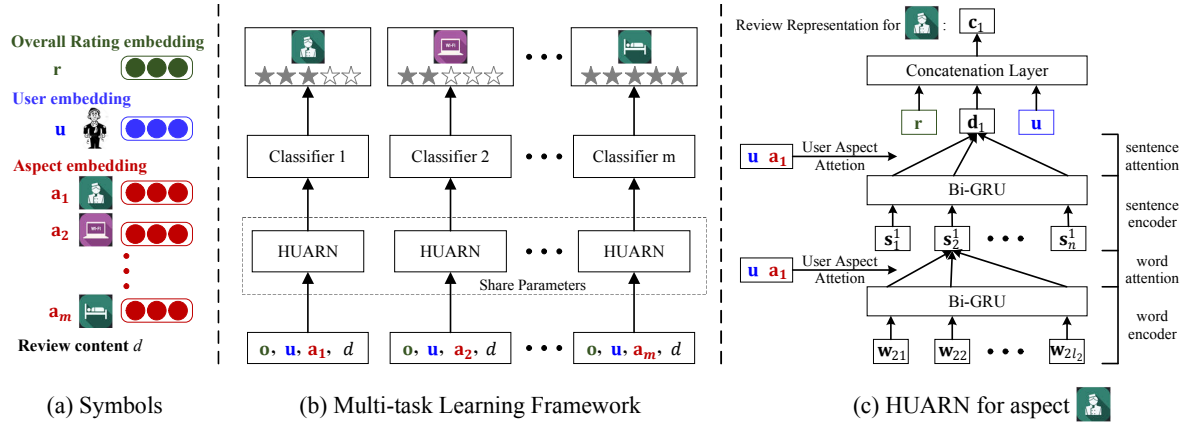
For *user-rating consistency*, the measurement is calculated by $||y - y^+||$ for $\mathbf{v}_s$ or $||y - y^-||$ for $\mathbf{v}_r$, where y, y^+, y^- is aspect rating of review d, d^+, d^- with aspect $\mathbf{v}_{a_i}$ respectively. For *user-text consistency*, the measurement is calculated by the cosine similarity between bag-of-words representation of two reviews. We perform a two-sample t-test on $\mathbf{v}_s$ and $\mathbf{v}_r$. The null hypothesis is that there is no difference between the two vectors, $H_0 : \mathbf{v}_s = \mathbf{v}_r$; the alternative hypothesis is that the difference between reviews with same user is less than with two random reviews , $H_1 : \mathbf{v}_s < \mathbf{v}_r$. The t-test results, p-values, show that there is strong evidence (with the significance level $\alpha = 0.01$) to reject the null hypothesis in *user-rating consistency* test and *user-text consistency* test on TripOUR. In other words, we observe the existence of *user-rating consistency* and *user-text consistency* in TripOUR.



(a) TripOUR (b) TripDMS

Figure 2: Aspect rating distributions for different overall ratings in TripOUR and TripDMS.

Effects of overall ratings. When scoring a product, users may consider multiple aspects of the product. If these aspects could meet the users' requirement, they can give a high overall rating, otherwise, they could give low scores. Therefore, overall rating can partly reflect the user's attitudes to aspects, which



(a) Symbols (b) Multi-task Learning Framework (c) HUARN for aspect

Figure 3: The architecture of HUARN. Left: some embedding symbols used in the figure. Example aspects are *service*, *business service*, and *room*. Middle: Multi-task learning framework for document-level multi-aspect sentiment classification. Right: the architecture of HUARN for aspect *service*.

is called *overall rating prior*. To investigate effects of overall ratings, we compute the aspect rating distributions for different overall ratings from our two datasets and the distributions are shown in Figure 2. We can conclude that high/low overall ratings often result in high/low aspect ratings. For example, when the overall rating is 5 stars, more than 70% aspect ratings are not less than 4 stars in our datasets.

3 Methods

The analysis proves users and overall ratings are significant on interpreting the sentiments of different aspects. Therefore, we introduce these two kinds of information into HUARN and detail the model here. First, we give the formalizations of document-level multi-aspect sentiment classification (Figure 3(a)). Afterwards, we discuss the multi-task learning framework for this task (Figure 3(b)) and how to obtain document semantic representation via Hierarchical Bidirectional Gated Recurrent Unit network. At last, we present user and aspect attention mechanism to construct user-aspect-specific representation and add a concatenating layer to combine user, overall rating and document representation together (Figure 3(c)). The enhanced document representation is used as features for predicting aspect ratings.

3.1 Formalizations

Suppose we have a corpus D about a specific domain (such as "hotel") and m aspects $\{a_1, a_2, ..., a_m\}$ (such as *service* and *room*). Review d is a sample of D with n sentences $\{s_1, s_2, ..., s_n\}$. Sentence s_i consists of l_i words as $\{w_{i1}, w_{i2}, ..., w_{il_i}\}$. The overall rating of review d is r and its author is user u. Document-level multi-aspect sentiment classification aims to predict aspect ratings for these reviews.

3.2 Multi-task Learning Framework

It is natural to model document-level multi-aspect sentiment classification as a multi-task learning. First, we can treat each aspect rating as a classification task. Then, we share document encoder network to obtain document representation and exploits different softmax classifiers to predict ratings of different aspects. The main benefit of the multi-task framework is that it can mutually enhance aspect rating prediction between different aspects.

3.3 Hierarchical Bidirectional Gated Recurrent Network

Since a document is composed of multiple sentences, and a sentence is composed of multiple words, we model the semantics of a document through a hierarchical structure from word-level, sentence-level to document-level. To model the semantic representation of a sentence, we adopt bidirectional GRU (Bi-GRU). Similarly, we also use Bi-GRU to learn document representations.

Given sentence s_i, we embed each word w_{ij} to vector $\mathbf{w}_{ij}$. Then, we use a Bi-GRU to encode contextual information of word w_{ij} into its hidden representation $\mathbf{h}_{ij}$. Hidden states $\{\mathbf{h}_{i1}, \mathbf{h}_{i2}, ...\mathbf{h}_{il_i}\}$ are feed

into an average pooling layer to obtain the sentence representation $\mathbf{s}_i$. In sentence level, we also feed the sentence vectors $\{\mathbf{s}_1, \mathbf{s}_2, ..., \mathbf{s}_n\}$ into Bi-GRU and then obtain the document representation $\mathbf{d}$ similarly.

3.4 Encoding user, aspect, and overall rating

It is obvious that not all words (sentences) contribute equally to the sentence (document) meaning. To consider *user-text consistency* and build an aspect-specific representation, we introduce user attention and aspect attention. Specifically, we employ word (sentence) level user aspect attention to generate sentence (document) representation.

Word-level Attention. We first embed user u and aspect $\{a_k|k \in 1, 2, ..., m\}$ as continuous and real-valued vector $\mathbf{u}$ and $\mathbf{a}_k$. Then, instead of feeding word-level hidden states ($\mathbf{h}_{ij}$) to an average pooling layer, we adopt a user aspect attention mechanism to extract user-aspect-specific words and obtain the sentence representation as follows:

$$\mathbf{m}_{ij} = \tanh(\mathbf{W}_{wh}\mathbf{h}_{ij} + \mathbf{W}_u\mathbf{u} + \mathbf{W}_a\mathbf{a}_k + \mathbf{b}_w) \tag{1}$$

$$\alpha_{ij} = \frac{\exp(\mathbf{v}_w^T\mathbf{m}_{ij})}{\sum_j \exp(\mathbf{v}_w^T\mathbf{m}_{ij})} \tag{2}$$

$$\mathbf{s}_i^k = \sum_j \alpha_{ij}\mathbf{h}_{ij} \tag{3}$$

where $\mathbf{W}_{wh}, \mathbf{W}_{wu}, \mathbf{W}_{wa}$ and $\mathbf{b}_w$ are parameters in the attention layer. α_{ij} measures the importance of the j-th word for user u and aspect a_k and $\mathbf{s}_i^k$ is the representation of sentence s_i for aspect a_k.

Sentence-level Encoder and Attention. After obtaining sentence representation $\mathbf{s}_i^k$ for aspect a_k, we also use a Bi-GRU to encode the sentences and get hidden representation $\mathbf{h}_i^k$ for $\mathbf{s}_i^k$.

When classifying document based on different aspects, different sentences may have different influences. Different users may also pay attention to different sentences. Therefore, in sentence level, we also apply an attention mechanism with user vector $\mathbf{u}$ and aspect vector $\mathbf{a}_k$ in sentence level to select informative sentences to compose user-aspect-specific document representation. The document representation $\mathbf{d}_k$ for aspect a_k is obtained via:

$$\mathbf{t}_i = \tanh(\mathbf{W}_{sh}\mathbf{h}_i^k + \mathbf{W}_{su}\mathbf{u} + \mathbf{W}_{sa}\mathbf{a}_k + \mathbf{b}_s) \tag{4}$$

$$\beta_i = \frac{\exp(\mathbf{v}_s^T\mathbf{t}_i)}{\sum_i \exp(\mathbf{v}_s^T\mathbf{t}_i)} \tag{5}$$

$$\mathbf{d}_k = \sum_i \beta_i\mathbf{h}_i^k \tag{6}$$

where β_i measures the importance of the i-th sentences for user u and aspect a_k.

Concatenation Layer. To explicitly encode *user-rating consistency* and *overall rating prior*, we add a concatenation layer. First, we embed overall rating r as continuous and real-valued vector $\mathbf{r}$ with g_r dimensions. Then, we generate review content representation $\mathbf{c}_k$ by concatenating user embedding $\mathbf{u}$, rating embedding $\mathbf{r}$ and document vector $\mathbf{d}_k$:

$$\mathbf{c}_k = \mathbf{u} \oplus \mathbf{r} \oplus \mathbf{d}_k \tag{7}$$

3.5 Document-level Multi-aspect Sentiment Classification

For each aspect, we obtain review representation $\{\mathbf{c}_k|k \in 1, 2, ..., m\}$. All these representations are high-level representations of the combination of user, aspect, overall rating and document information. It can be used as features for predicting aspect ratings. For aspect a_k, we can use a softmax layer to project $\mathbf{c}_k$ into sentiment distribution $\mathbf{p}(d, k)$ over L classes:

$$\mathbf{p}(d, k) = \text{softmax}(\mathbf{W}_{lk}\mathbf{c}_k + \mathbf{b}_k) \tag{8}$$

where $p_l(d,k)$ is used to represent the predicted probability of sentiment class l for d based on a_k and $\mathbf{W}_{lk}, \mathbf{b}_k$ are parameters of softmax layer for classifying review $\mathbf{c}_k$. Then we define the cross-entropy error between gold sentiment distribution and our model's sentiment distribution as our loss function :

$$L = -\sum_{d \in D} \sum_{k \in \{1,2,\ldots,m\}} \sum_{l=1}^{L} \mathbb{1}\{g_{d,k} = l\} \cdot \log(p_l(d,k)) \tag{9}$$

where $\mathbb{1}\{\cdot\}$ is the indicator function and $g_{d,k}$ represents the ground truth label for review d for aspect a_k.

4 Experiments

In this section, we present data preprocessing and implementation details, all the comparison methods and the empirical results on the task of document-level multi-aspect sentiment classification.

4.1 Data Preprocessing and Implementation Details

We preprocess our datasets as follows: For TripDMS, we use the same splitting method as (Yin et al., 2017). For TripOUR, we tokenize the dataset, split sentences by Stanford CoreNLP (Manning et al., 2014) and randomly split them into training, development, and testing sets with 80/10/10%.

The model hyper-parameters are tuned based on the development sets. For word embeddings, we use the pre-trained word embeddings provided by (Yin et al., 2017), whose embedding size is 200. For user and overall rating embeddings, we initialize them randomly and set their dimensions to 200. For aspect embeddings, we first get aspect keywords[4] from (Yin et al., 2017) and initial aspect embedding by averaging word embeddings of these keywords belong to the aspect. The dimensions of all hidden vectors are set to 150. To avoid model over-fitting, we use dropout with rate of 0.2. All the parameters are trained using Adam (Kingma and Ba, 2014) with a learning rate of 0.001.

4.2 Comparison Methods

We compare HUARN with the following baselines:

Majority is a heuristic baseline method, which assigns the majority sentiment category in the training set to aspect rating in the test dataset.

OverallRatingSame is also a heuristic baseline method, which assigns the overall rating of a review to its aspect ratings.

MajOverallRating splits the training instances into five clusters (per overall rating) and assigns the most frequent rating for the seven aspects per cluster in the test dataset.

SVM and **NBoW** are SVM classifiers with different features. One with unigrams, bigrams as features and another with the mean of word embeddings in a document as features.

CNN (Kim, 2014) performs a convolution operation over a sentence to extract words neighboring features, then gets a fixed-sized representation by a pooling layer.

HAN (Yang et al., 2016) models review in a hierarchical structure and utilizes an attention mechanism to capture important words and sentences, which is only based on text information and achieves state-of-the-art result in predicting overall rating of document.

MHCNN is an extended model of **CNN** with hierarchical architecture and multi-task framework.

MHAN is an extended model of **HAN** with multi-task framework.

DMSCMC (Yin et al., 2017) use iterative attention modules to build up aspect-specific representation for review, and obtain state-of-the-art results in document-level multi-aspect sentiment classification.

HGRUN is the basic form of **HUARN** without user, aspect and overall rating.

HARN is a variant of **HUARN**, which abandons user information from **HUARN**.

4.3 Results

We use Accuracy and Mean Squared Error (MSE) as the evaluation metrics, and the results are shown in Table 3. For heuristic methods, we can see that **Majority** performs very poor because it does not

[4]Sample keywords for *service* are service, food, breakfast, and buffet.

Models	TripOUR		TripDMS	
	Accuracy↑	MSE↓	Accuracy↑	MSE↓
Majority	0.3850	0.954	0.2389†	2.549†
OverallRatingSame	0.3074	1.705	0.2012	3.446
MajOverallRating	0.3487	1.536	0.2414	3.273
SVM	0.4635	1.025	0.3526†	1.963†
NBoW	0.4865	0.912	0.3909†	1.808†
CNN	0.5054	0.752	0.4335†	1.456†
HAN	0.5123	0.705	0.4468†	1.301†
MHCNN	0.5108	0.712	0.4379†	1.398†
MHAN	0.5419	0.629	0.4494†	1.210†
HGRUN	0.5392	0.635	0.4435	1.303
DMSCMC	0.5549	0.583	0.4656†	1.083†
HARN	0.5815*	0.528	**0.4821***	**0.923**
HUARN	**0.6070***	**0.514**	N/A	N/A

Table 3: Document-level multi-aspect sentiment classification on our datasets. Our full model is HUARN. The best performances in **bold**. "†" indicates that the result is reported from (Yin et al., 2017). "*" indicates that the model significantly outperforms DMSCMC. Statistical significance testing has been performed using paired t-test with $p < 0.05$.

capture any text information. **OverallRatingSame** and **MajOverallRating** are also very poor, even though overall rating has strong correction with aspect ratings, it is not enough to decide aspect ratings only based on it.

Compared with **SVM**, **NBoW** achieves higher accuracy by at least 2.3% in both datasets, which shows that embedding features are more effective than unigram and bigram features on these two datasets. When applying more complex neural networks (such as **CNN** and **HAN**), the model can achieve higher accuracy by at least 1.5% in both datasets compared with **NBoW**. Additionally, we observe that the multi-task learning and hierarchical architecture are beneficial for neural networks. Performance on **MHAN** and **MHCNN** are slightly better than **HAN** and **CNN**. Beyond that, we also find attention mechanism is useful. The only difference between **MHAN** and **HGRUN** is that **MHAN** uses attention mechanism to obtain sentence and document representations while **HGRUN** utilizes an average pooling layer, which results in the performance of **MHAN** is better than **HGRUN**. After obtaining aspect-aware representation for the document, **DMSCMC** achieves best results and outperforms other baselines.

Compared to **DMSCMC**, **HARN** achieves improvements of 2.7% and 1.7% on TripOUR and TripDMS respectively, which shows that the incorporation of overall rating and aspect attention helps build up more discriminative representation. Moreover, when incorporating user information, our full model (**HUARN**) can achieve improvements of 5.3% compared with **DMSCMC** on TripOUR[5], which shows user preference can benefit the document-level multi-aspect sentiment classification task.

5 Discussions

In this section, we first give some discussions about the effects of users, aspects and overall ratings on predicting aspect ratings, and then show case study for attention results and visualize user embeddings.

5.1 Effects of Users, Overall Ratings and Aspects

Users, overall ratings and aspects are three kinds of information in HUARN. We present the effects of users, overall ratings, and aspects on document-level multi-aspect sentiment classification in Table 4. From the table, we can observe that: (1) Compared with user-agnostic models (line 1-4), user-aware models (line 5-8) can achieve improvements of 2.2%, 2.5%, 1.2% and 2.5% in TripOUR, which shows

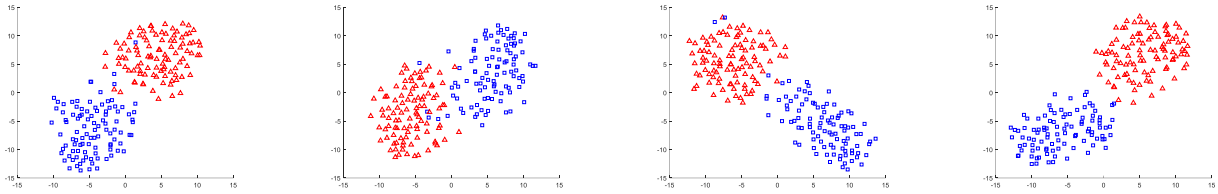
[5]Since there is no user information in TripDMS, we can only compare **DMSCMC** with **HARN**.

No.	Different information			TripOUR		TripDMS	
	User	**OverallRating**	**Aspect**	Accuracy↑	MSE↓	Accuracy↑	MSE↓
1	–	–	–	0.5392	0.635	0.4435	1.303
2	–	–	✓	0.5514	0.599	0.4566	1.256
3	–	✓	–	0.5719	0.555	0.4740	1.093
4	–	✓	✓	0.5815	0.528	0.4821	0.923
5	✓	–	–	0.5640	0.619	N/A	N/A
6	✓	–	✓	0.5764	0.581	N/A	N/A
7	✓	✓	–	0.5839	0.560	N/A	N/A
8	✓	✓	✓	0.6070	0.514	N/A	N/A

Table 4: Effects of user, overall rating and aspect on document-level multi-aspect sentiment classification. Each line represents a variant of HUARN, where "✓" denotes the variant considers the specific information, while "–" denotes not. For example, model in line 1 means HUARN abandons these three kinds of information and degenerates into HGRUN.

that model encoding user information can obtain user-aware document representation and is more suitable for document-level multi-aspect sentiment classification. (2) Compared with models without overall rating information (line 1, 2, 5 and 6), models considering overall ratings (line 3, 4, 7, 8) can obtain 3.2% (3.1%), 3.0% (2.6%), 1.9% (N/A) and 3.1% (N/A) improvements in accuracy in both datasets, which indicates overall rating information is useful for building more discriminative document representation and helpful for predicting aspect ratings. (3) Compared with models without aspect information (line 1, 3, 5 and 7), aspect-based models (line 2, 4, 6, 8) can obtain 1.2% (1.3%), 1.0% (0.8%), 1.2% (N/A) and 2.4% (N/A) improvements in accuracy in both datasets. It shows that aspect information is useful for building aspect-aware document representation and helpful for predicting aspect ratings. (4) After users, overall ratings, and aspects being considered jointly, our model obtains the best performance.

5.2 Visualization of User Embeddings



(a) Service (b) Value (c) Cleanliness (d) Location

Figure 4: t-SNE visualization of user embeddings for different aspects in TripOUR. Blue square and red triangle represent users are "High Score" users and "Low Score" users, respectively.

As different users have different aspect rating preferences and HUARN imports user embedding to consider users, we identify whether such personalized information are encoded in user embedding. To this end, we first rank all users according to their average score in the training set for each aspect. Then the top 100 users are labeled as "High Score" users and bottom 100 users are labeled as "Low Score" users. Due to space limit, here we only show embeddings of users in four aspects (*service*, *value*, *cleanliness*, *location*), which are top frequently scored by all users, in Figure 4. We find "High Score" users and "Low Score" users are separated apparently. The visualization shows that user embedding learned by HUARN can encode personalized traits in scoring different aspects.

5.3 Case Study for Attention Results

To show the ability that HUARN captures user preference and aspect semantic meanings, we take one sentence from TripOUR as example. The content of the sentence is "The food is **good**, but the price is

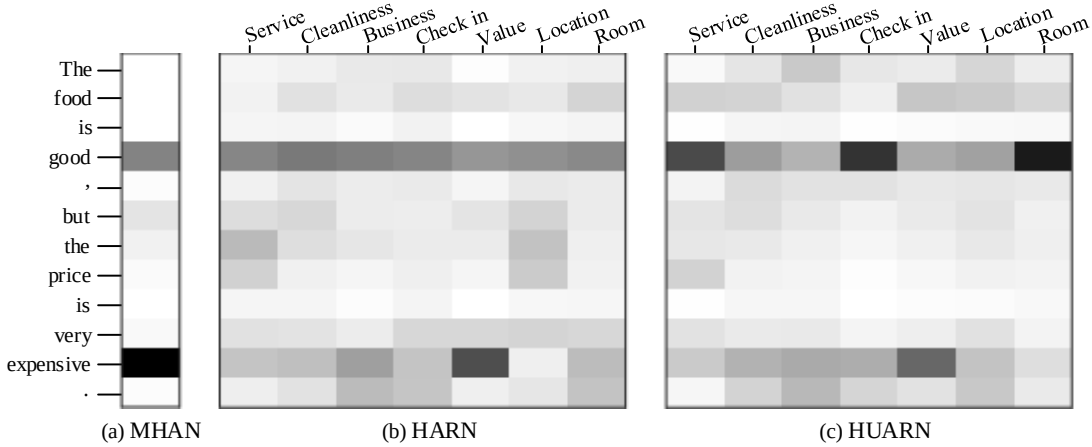


Figure 5: The attention visualization of words. Dark color means higher weight. (a), (b) and (c) show word-level attention weights of **MHAN**, **HARN** and **HUARN**.

very **expensive**", in which "good" is a general sentiment word and can be used to describe many aspects (such as *service*, *room* and so on), while "expensive" is a aspect-specific sentiment word which only applies to describe *value*. We visualize attention weights of the sentence in Figure 5.

From Figure 5(a), we can find that considering word-level attention, **MHAN** distinguishes sentiment words and non-sentiment words, however it is hard to identify the sentiment word is a general one or an aspect-specific one. After adding aspect attention over word-level representations, **HARN** can distinguish these two kinds of sentiment words (Figure 5(b)). The attention weights of "good" for different aspects are very close, while the attention weights of "expensive" for different aspects are different, and the maximum is *value*. When adding user information into word-level attention, **HUARN** can also treat "good" differently. From figure 5(c), we can find attention weights of "good" are different for different aspects, where weights for *service*, *check in* and *room* are higher than weights for other aspects. we check all reviews of the sample review's author and find that he/she often (more than 80%) use "good" to describe *service*, *check in* and *room*.

5.4 Error Analysis

Figure 6: Examples of error cases. GT means ground trouth and P means prediction result of HUARN. Sentences in review text with darker color means higher attention weight for the sentence.

We analyze error cases in the experiments. Some examples of error cases are shown in Figure 6. We can find that HUARN is hard to select important sentences for aspects. For example, sentence "the rooms are large and the bed comfy." and sentence "however the carpet should have been replaced long time." in the first sample in Figure 6 are all important to decide the rating of aspect *room*. However, HUARN pays more attention to the former sentence when predicting rating of *room* and obtains the wrong result.

Based on the literature study, we find that Yin et al. (2017) uses iterative attention models to build up aspect-specific representation for review. It may alleviate this problem. We leave how to encode user and overall rating information into DMSCMC as our future work.

6 Related Work

Multi-aspect sentiment classification is an extensively studied task in sentiment analysis (Pang and Lee, 2008; Liu, 2012). Lu et al. (2011) propose Segmented Topic Model to model document and extract features, then exploit support vector regression to predict aspect ratings based on these features. McAuley et al. (2012) add a dependency term in final multi-class SVM objective to consider the correction between aspects. Many other studies (Titov and McDonald, 2008; Wang et al., 2010; Wang et al., 2011; Diao et al., 2014; Pappas and Popescu-Belis, 2014; Pontiki et al., 2016; Toh and Su, 2016) solve multi-aspect sentiment classification as a subproblem by utilizing heuristic based methods or topic models. However, these approaches often rely on strict assumptions about words and sentences, for example, word syntax has been used to distinguish aspect word or sentiment word, or appending an specific aspect to a sentence. Another related problem is called aspect-level sentiment classification (Pontiki et al., 2014; Dong et al., 2014; Wang et al., 2016; Tang et al., 2016; Schouten and Frasincar, 2016). Wang et al. (2016) and Tang et al. (2016) employ attention-based LSTM and deep memory network for aspect-level sentiment classification, respectively. However, the task is sentence level. Document-level sentiment classification (Li and Zong, 2008; Li et al., 2010; Li et al., 2013; Xia et al., 2015; Yang et al., 2016) is also a related research field because we can treat single aspect sentiment classification as an individual document classification task. However, they did not consider multiple aspects in a document.

In addition to these methods, the work of Yin et al. (2017) is the most related to ours, which focuses on using iterative attention mechanism to build discriminative aspect-aware representation to perform document-level multi-aspect sentiment classification. However, it ignores the influences of users and overall ratings on aspect ratings. Actually, many studies (Tang et al., 2015b; Tang et al., 2015c; Chen et al., 2016; Li et al., 2016; Dou, 2017) have shown considering user preference can boost the performance of Document-level Sentiment Classification. Partially inspired by these approaches, we propose HUARN to consider users, overall ratings and aspects jointly into document-level multi-aspect sentiment classification. Compared with these user-aware approaches, HUARN has some differences: (1) They do not consider aspects. (2) Although Chen et al. (2016) and Dou (2017) embedding user to consider user-text consistency to perform sentiment classification, they ignore user-rating consistency. (3) Tang et al. (2015b; 2015c) embed user in a matrix and build user-specific representation by a convolutional neural network structure. However, it is hard to train with limited reviews for user matrix. Our motivation is that (1) Aspect information is very useful for selecting informative words and sentences and building up aspect-specific representation for document-level multi-aspect sentiment classification, therefore, we add aspect attention into our model. (2) Compared with user-text consistency, user-rating consistency describes the correlation between users and ratings more directly. (3) Embedding user in a vector and using attention mechanism to build user-specific representation is an effective way to consider users. User embedding is enough to encode the relation between user and rating in The most important is that it is easy to train.

7 Conclusion and Future work

In this paper, we present Hierarchical User Aspect Rating Network (HUARN) to incorporate user preference and overall rating into document-level multi-aspect sentiment classification. HUARN encodes different kinds of information (word, sentence and document) into a hierarchical structure. To consider user preference and overall rating, HUARN introduces user information as attention over word-level representation and sentence-level representation, and then generates review representation by combining user, overall rating and document information. Extensive experiments show that our model outperforms state-of-the-art methods significantly. In the future, we will study how to encode user and overall rating information into DMSCMC.

Leveraging Meta-Embeddings for Bilingual Lexicon Extraction from Specialized Comparable Corpora

Amir Hazem **Emmanuel Morin**

LS2N - UMR CNRS 6004, Université de Nantes, France
{amir.hazem,emmanuel.morin}@univ-nantes.fr

Abstract

Recent evaluations on bilingual lexicon extraction from specialized comparable corpora have shown contrasted performance while using word embedding models. This can be partially explained by the lack of large specialized comparable corpora to build efficient representations. Within this context, we try to answer the following questions: First, (i) among the state-of-the-art embedding models, whether trained on specialized corpora or pre-trained on large general data sets, which one is the most appropriate model for bilingual terminology extraction? Second (ii) is it worth it to combine multiple embeddings trained on different data sets? For that purpose, we propose the first systematic evaluation of different word embedding models for bilingual terminology extraction from specialized comparable corpora. We emphasize how the character-based embedding model outperforms other models on the quality of the extracted bilingual lexicons. Further more, we propose a new efficient way to combine different embedding models learned from specialized and general-domain data sets. Our approach leads to higher performance than the best individual embedding model.

1 Introduction

Bilingual lexicons are fundamental resources in multilingual natural language processing tasks such as machine translation (Och and Ney, 2003), cross-language information retrieval (Nie, 2010) or computer-assisted translation (Delpech, 2014). Because a manual compilation of bilingual lexicons requires substantial human efforts, bilingual lexicons are automatically extracted from bilingual corpora. These corpora can be parallel or comparable data sets. Despite good results obtained when compiling bilingual lexicons from parallel corpora, the latter are scarce resources, especially for specialized and technical domains and for language pairs not involving English. In this context, comparable corpora are an interesting and practical alternative to the use of parallel corpora.

Comparable corpora, which gather texts sharing common features such as domain, topic, discourse, etc. without having a parallel source text-target text relationship, allow access to the original vocabulary without falling under the influence of the human translation. Compiling a large comparable corpus is easier, especially for general language (Talvensaari et al., 2007). In contrast, specialized comparable corpora are traditionally of modest size due to the difficulty to obtain many specialized documents in a language other than English. Specialized comparable corpora have a size of around one million words whereas general-domain comparable corpora can gather several million words (Morin and Hazem, 2014).

One way to overcome the small size of specialized comparable corpora is to associate external resources. These resources may be close specialized corpora (e.g. a breast cancer corpus may benefit from contexts derived from a more general oncology corpus), corpora of different types of discourse and gender (e.g. a corpus of popular science discourse supplementing a corpus of scientific discourse), corpora of general language or out-of-domain data. The main challenge is to know how to associate such resources with a comparable specialized corpus.

Proceedings of the 27th International Conference on Computational Linguistics, pages 937–949
Santa Fe, New Mexico, USA, August 20-26, 2018.

According to Jakubina and Langlais (2017), word embeddings are more effective on large comparable corpora than on small comparable corpora. This statement lend support the idea that enriching small specialized comparable corpora may be beneficial to bilingual terminology extraction task. The combination of external resources such as a general-domain comparable corpus with a specialized comparable corpus can be performed using word embedding models. We recently conducted a first attempt in Hazem and Morin (2017) and have shown under which conditions external resources introduced in the form of Skip-gram and CBOW models can be jointly used to improve the performance of bilingual terms extraction. However, our approach was not able to compete with the historical count-based projection approach (Fung and McKeown, 1997; Rapp, 1999). Our current work pursues this direction by contrasting different neural embedding models and by showing how to take advantage of their combination. More specifically, we show that the character-based Skip-gram and CBOW models (Bojanowski et al., 2016) drastically outperform other models including Skip-gram and CBOW. We also propose a new approach based on Ensemble models which combines specialized and general domain embeddings to obtain a unified Meta-Embedding model. Our approach shows significant improvements and obtains the best results on two specialized English/French comparable corpora.

2 Related Work

According to Hermann and Blunsom (2014), methods dealing with bilingual lexicon extraction from comparable corpora can be classified as distributional-based or distributed-based approaches. In the former, words are represented by their context vectors using a distributional count-based approach also known as the standard approach (Fung, 1998; Rapp, 1999). While in the latter, words are embedded into a low-dimensional vector space using neural network models (Bengio et al., 2003; Mikolov et al., 2013b).

The historical standard approach builds a context vector for each word of the source and the target languages, translates the source context vectors to the target language using a bilingual seed lexicon, and compares the translated context vectors to each target context vector using a similarity measure. Different contributions have been proposed in the past few years to improve each step of the standard approach (Gaussier et al., 2004; Gamallo, 2007; Ismail and Manandhar, 2010; Prochasson and Fung, 2011; Hazem and Morin, 2012; Bouamor et al., 2013, among others).

With the advent of neural network techniques, Mikolov et al. (2013a) were the first to propose a method to learn a linear transformation from the source language into the target language to improve the task of lexicon extraction from bilingual corpora. Faruqui and Dyer (2014) introduced canonical correlation analysis (CCA) to project the embeddings in both languages to a shared vector space. More recently, Artetxe et al. (2016) presented an approach for learning bilingual mappings of word embeddings that preserves monolingual invariance using several meaningful and intuitive constraints related to other proposed methods (Faruqui and Dyer, 2014; Xing et al., 2015).

Jakubina and Langlais (2017) made a careful comparison of the approaches of Mikolov et al. (2013a) and Faruqui and Dyer (2014) with the standard approach. They have clearly shown that the two previous approaches outperform the standard approach for very frequent terms to be translated (the number of occurrences is at least 250 from an English-Spanish comparable corpus obtained from the 6th workshop on statistical machine translation gathering 2.55 giga words). On the other hand, when the terms are less frequent (the number of occurrences is less than 25 from a French/English comparable corpora built from the Wikipedia dumps gathering 1.53 giga words), the standard approach slightly outperforms the two previous embedding approaches. More recently, we have shown under which conditions Skip-gram and CBOW models can be jointly used to improve the performance of bilingual terms extraction from specialized comparable corpora without exceeding the results of the standard approach (Hazem and Morin, 2017).

Other works performed bilingual word representation without word-to-word alignments of comparable corpora. Chandar et al. (2014) and Gouws et al. (2014) for instance used multilingual word embeddings based on sentence-aligned parallel data whereas Vulić and Moens (2015) and Vulić and Moens (2016) used document-aligned non-parallel data to produce bilingual word embeddings. Theses works are based

on sentence- or document-aligned of general-domain comparable corpora and are outside the scope of this study. It is unlikely to find this type of alignments in a specialized comparable corpus.

3 Embedding Models

In this section, we briefly recall the main and recent word embedding models that we will investigate in this study.

CBOW and Skip-gram are two distributed representations introduced by Mikolov et al. (2013b) that capture linguistic regularities, namely the Continuous Bag-of-Words (CBOW) model and the Skip-gram model. The principle of the CBOW model is to combine the representations of surrounding words to predict the word in the middle, while the training objective of the Skip-gram model is to learn how to predict the surrounding words based on the representations of the middle word. If these models exhibit similar architectures, CBOW is faster and more suitable for large data sets while Skip-gram gives better word representations when monolingual data is small (Mikolov et al., 2013a).

Glove takes advantage of the main benefits of count data while simultaneously capturing the meaningful linear substructures prevalent in prediction-based methods such as word2vec. It is a global log-linear regression model that makes use of a global factorization model and local context window methods to represent words in a global vector space model (Pennington et al., 2014). This model directly captures the global statistics from the corpus based on co-occurrence word probabilities. Its training objective is to learn word vectors such that their dot product equals the log-probability of word's co-occurrence. Glove has shown good results in word analogy, word similarity, and named entity recognition tasks.

Structured Embeddings are two adaptations of CBOW and Skip-gram models that include ordering information[1] (Ling et al., 2015). While word2vec is insensitive to word order, the structured embedding model includes position information in the context representation of words. Given the embedding of the center word w, the Skip-gram model for instance uses a single output matrix to predict every contextual word. In contrast, the structured Skip-gram adapts the model to the positioning of the surrounding words. It defines an output for each relative position to the center word. The adaptation of CBOW is the continuous window model where the input is the concatenation of the embeddings of context words. While in the standard CBOW, the input model is the sum of the embeddings of the context words.

Character n-gram Embeddings is an enhanced variant of the Skip-gram and CBOW models that enrich word vectors with subwords information. It takes into account the internal structure of words which can be very useful for morphologically rich languages. It also incorporates character n-gram embeddings where each word is represented by a bag-of character n-gram (Bojanowski et al., 2016). More precisely, it uses character embedding and word embedding models jointly performing the vector sum of both to form the final embedding representation of words. We refer to the character Skip-gram model by CharSG and the character CBOW model by CharCBOW.

Other models such as the dependency-based model (Levy and Goldberg, 2014) and generalized-based model (Li et al., 2017) were assessed but not presented in this paper for sake of clarity and because of the very low results obtained on the specialized domains when compared to the above presented models.

Several pre-trained embedding models are publicly available such as CBOW and Skip-gram models (Mikolov et al., 2013b), global word representation-based models (Pennington et al., 2014), character skip-gram-based models (Bojanowski et al., 2016), etc. If it is interesting to study the impact of pre-trained embeddings on bilingual terminology extraction from comparable corpora. The major part of the above cited pre-trained embedding models exist solely in English. We only use the character skip-gram (CharSG) model (Bojanowski et al., 2016) which is available in both French and English.

[1] Word order in context word representation.

4 Approach

The task of bilingual terminology extraction from specialized comparable corpora consists of acquiring for each term of the source language its translation in the target language. The basic idea using embedding models is to first (1) build word embeddings of the source and the target languages, then, (2) to build a mapping matrix (Artetxe et al., 2016) that allows to obtain for each source term, its representation in the target language and finally, (3) to measure the similarity between the target representation of the source term and all the word candidates of the target language to extract the most similar term as the correct translation (Mikolov et al., 2013a; Artetxe et al., 2016). Our approach follows these three steps (Mikolov et al., 2013a) while acting at the word embedding level representation. Our idea is to enrich the word embedding representation of the source and target languages in order to improve the mapping matrix and so, bilingual terminology extraction from specialized comparable corpora. To do so, we present several ways to take advantage of word embedding models and ensemble approaches.

The principle of ensemble approaches is to combine different models in order to capture the strengths of each individual model. The main combination techniques that have shown their effectiveness so far are vectors addition (Garten et al., 2015) and vectors concatenation (Garten et al., 2015; Yin and Schütze, 2016). For vectors addition, given two embedding models, the procedure consists in applying a simple dimension-wise vectors addition[2]. For vectors concatenation, given two embedding models of dimensions $dim1$ and $dim2$, the resulting concatenated embedding vector will be of size $dim1+dim2$. The vectors have to be normalized before concatenation. Usually L2 norm is applied[3]. Yin and Schütze (2016) performed a weighted concatenation of five embedding models. They also experienced the SVD (Singular Value Decomposition) on top of weighted concatenation vectors of dimension 950. This resulted in a reduced model of 200 dimensions.

In the line of the above cited approaches, we first explore the ensemble modeling (additive and concatenation) on a large scale over the multiple word embedding models presented in Section 3. This is done exclusively on the small specialized comparable corpora. We then explore different ways to supply each specialized comparable corpus with external resources based on ensemble approaches. We show new ways to take advantage of external data and embedding models in order to efficiently extract bilingual lexicons from specialized comparable corpora. Our methodology is two-fold. In the subsection 4.1 we first describe ensemble approaches and their application on one type of corpora (here the specialized comparable corpora), then in subsection 4.2, we introduce the adaptation of ensemble approaches while combining the specialized corpus with external resources.

4.1 Specialized Meta-Embeddings

While each embedding model captures some specific context word information, it is natural and straightforward to seek for their complementarity. The specialized meta-embeddings approach consists in combining different embedding models learned from the specialized corpus. We basically use an ensemble approach to represent each word, which means that each word has its own meta-embedding. This is illustrated in the following equation:

$$Ensemble(w) = f(v_w^1, v_w^2, ..., v_w^n) \quad (1)$$

with $Ensemble(w)$ the meta-embedding representation of a given word w and f the ensemble approach used to combine the different embedding models. f can be the additive or the concatenation technique. Finally, v_w^n represents a given embedding model of the word w and n the number of used embedding models. For instance, given the Glove, the CBOW and the Skip-gram models trained on a specialized corpus, the ensemble model of a given word w would be the concatenation (or addition) of its three embedding representations ($f(v_w^{Glove}, v_w^{CBOW}, v_w^{Skip-gram}$).

[2]This technique can not be applied when embeddings are not of the same dimension size (unless using padding).

[3]L2 norm can be applied either at dimension level (as suggested by Glove authors) or at vector length level.

4.2 Mixed Meta-Embeddings

While specialized comparable corpora suffer from the lack of data, one good alternative is to enrich them with external resources. The remaining question is how to take advantage of out-of-domain data to increase specialized corpus size without degrading its specific properties. A basic way to combine word embeddings from two different data sets (here the specialized and the external corpora) is to apply an ensemble approach while fixing the type of the embedding model. For instance, using the CBOW model, each word can be jointly represented by its embedding vector issued from the specialized corpus (noted v_w^s) and its embedding model issued from the general domain corpus (noted v_w^g). This is illustrated in the following equation:

$$Ensemble(w) = f(v_w^s, v_w^g) \tag{2}$$

The Mixed Meta-Embedding representation can be generalized over several embedding models as follows:

$$Ensemble(w) = f'(f(v_w^{s^1}, v_w^{g^1}), f(v_w^{s^2}, v_w^{g^2}), ..., f(v_w^{s^n}, v_w^{g^n})) \tag{3}$$

where f and f' represent the ensemble functions (concatenation or addition). n represents the number of embedding models. One condition while combining embeddings built from different corpora is to ensure that a given word w is present in all the combined corpora. If not, we can choose to discard this word or to replace the missing vector by zeros (padding).

5 Data and Resources

In this section, we describe the different textual resources used for our experiments: the comparable corpora, the bilingual dictionary and the terminology reference lists.

5.1 Comparable Corpora

The specialized comparable corpora were selected in terms of bilingual terminology access in technical domains. For our experiments, we used two specialized comparable corpora:

Breast cancer corpus (BC) is composed of documents collected from scientific and medical portals such as the ScienceDirect[4]. The documents were taken from the medical domain within the sub-domain of "breast cancer". We have selected the documents published between 2001 and 2015 where the title or the keywords contain the term *breast cancer* in English and its translation in French.

Wind energy corpus (WE) has been released in the TTC project[5]. This corpus has been crawled from the Web using *Babouk* crawler (Groc, 2011) based on several keywords such as *wind*, *energy*, *rotor* in English and its translation in French.

In addition, we use three corpora of general language as external resources:

JRC acquis corpus (JRC) is a collection of legislative texts of the European Union[6]. We used the French-English version at OPUS which is based on the paragraph-aligned corpus provided by JRC (Tiedemann, 2012).

Common crawl corpus (CC) is an open repository of data collected over 7 years of web crawling sets of raw web page data and text extracts[7].

[4] www.sciencedirect.com/
[5] www.ttc-project.eu/index.php/releases-publications
[6] opus.lingfil.uu.se/JRC-Acquis.php
[7] commoncrawl.org

Wikipedia corpus (Wiki) The English wikipedia corpus[8] is a dump which was released on 03-Feb-2018 and the French wikipedia corpus [9] was released on 02-Feb-2018.

Even if JRC, CC are parallel corpora, we didn't explicitly exploit their parallel relationship. We considered these external data sets as if they were comparable corpora. The documents were normalized through tokenisation, part-of-speech tagging, and lemmatisation using the TTC TermSuite[10]. Finally, the function words were removed and the hapax were discarded. Table 1 shows the number of documents (# doc.) and the number of content words (# words) for each corpus.

Corpus	# content words		# distinct words

Table 1: Characteristics of the corpora.

5.2 Bilingual Dictionary

The bilingual dictionary used in our experiments is the French/English dictionary ELRA-M0033 (243,539 entries) available from the ELRA catalogue[11]. This resource is a general language dictionary which contains only a few terms related to the medical and wind energy domains.

5.3 Gold Standard

To evaluate the quality of bilingual terminology extraction from specialized comparable corpora, a bilingual terminology reference list is required. In the general domain, the reference list is randomly composed of a sub-part of the bilingual dictionary (Gaussier et al., 2004; Jakubina and Langlais, 2017). In the specialized domain, this list is usually composed of few words that reflect the terminology of the specialized comparable corpus. For instance, Chiao and Zweigenbaum (2002) used a list composed of 95 single words, Morin et al. (2007) used 100 single words and Bouamor et al. (2013) used 125 and 79 single words. For breast cancer, the lists are derived from the UMLS[12] meta-thesaurus. Concerning wind energy, the lists are provided with the corpora (see footnote 5). Each word composing a pair of terms of a reference list appears at least 5 times in the comparable corpus. The bilingual terminology reference list is composed of 248 French/English single words for the Breast cancer corpus and 150 French/English single words for the Wind energy corpus.

6 Experiments and Results

We conducted two sets of experiments. The first one aims at providing insights into the behaviour of each state-of-the-art embedding model on the specialized comparable corpora. The second one aims at studying the contribution of ensemble models.

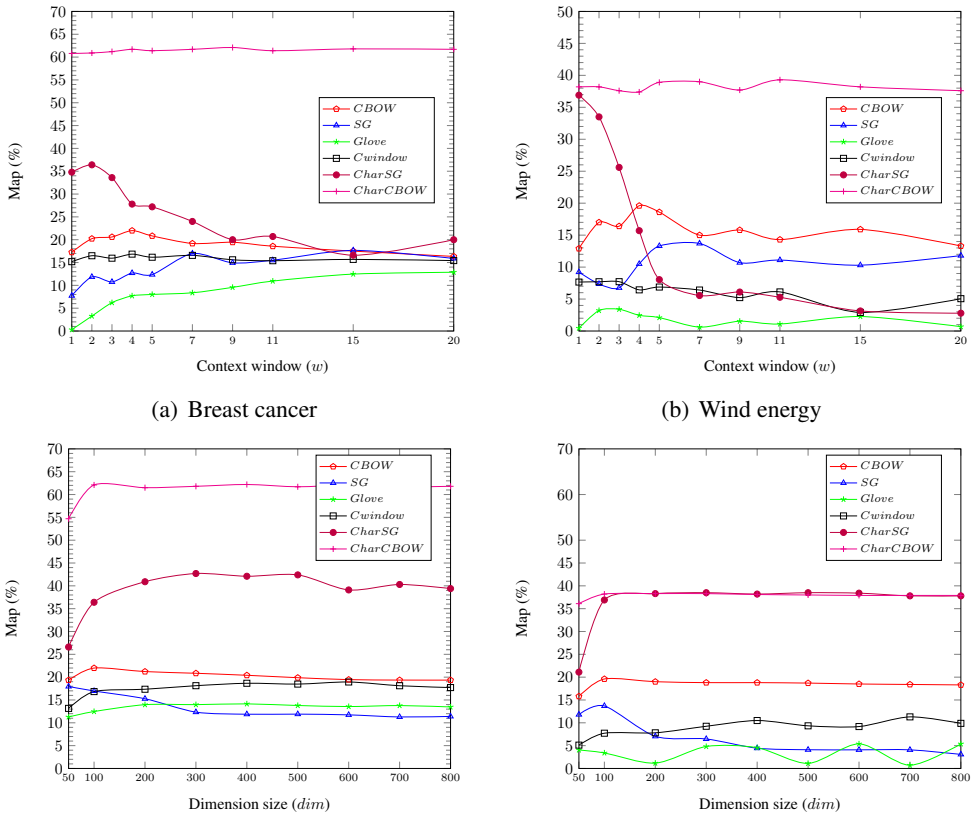
We present the results obtained for the terms belonging to the reference list for English to French direction measured in terms of the Mean Average Precision (MAP) (Manning et al., 2008) as follows:

$$MAP(Ref) = \frac{1}{|Ref|} \sum_{i=1}^{|Ref|} \frac{1}{r_i} \quad (4)$$

[8] dumps.wikimedia.org/enwiki/latest/enwiki-latest-pages-articles.xml.bz2
[9] dumps.wikimedia.org/frwiki/latest/frwiki-latest-pages-articles.xml.bz2
[10] code.google.com/p/ttc-project
[11] www.elra.info/
[12] www.nlm.nih.gov/research/umls

where $|Ref|$ is the number of terms of the reference list and r_i the rank of the correct candidate translation i.

Figure 1 shows the results of each embedding model for the task of bilingual terminology extraction from the two specialized comparable corpora. We report the results of the continuous bag-of-word model ($CBOW$), the Skip-gram model (SG), the glove model ($Glove$), the structured continuous window model ($Cwindow$) and the two character n-gram models, namely the character skip-gram model ($CharSG$) and the character CBOW model ($CharCBOW$)[13]. For each specialized comparable corpus, we varied the context window size (w) (see sub-figures 1(a) and 1(b)) and the embeddings dimension size (dim) (see sub-figures 1(c) and 1(d)).



(a) Breast cancer (b) Wind energy

(c) Breast cancer (d) Wind energy

Figure 1: Contrasting several embedding representations on the breast cancer and wind energy corpora.

The first remarkable point is the performance of the character n-gram embedding models which far outperform other models. This is an important finding since to our knowledge, no previous evaluation of character n-gram-based models have been conducted so far for bilingual terminology extraction from specialized corpora. The first competitive model which is $CharCBOW$, is not sensitive to the context window size as well as the embeddings dimension size. The second competitive model which is $CharSG$, is also not sensitive to the embeddings dimension size but sensitive to the context window size. $CBOW$ which is the third competitive model, turned out to be the best word-based model. Nevertheless, its performance is far below the character-based models. $CBOW$ is also not very sensitive to the context window and the embeddings dimension sizes.

Tables 2 and 3 show a comparison of several combinations of word embedding models for the two specialized comparable corpora. Each combination is based on L2 normalization at vector length level (len) or at vector dimension level (dim). We chose the three embedding models that have shown the best performance individually (according to the Figure 1: $CharSG$, $CharCBOW$ and $CBOW$) and

[13]We don't report the results of dependency-based and structured-based models due to the low performance of these approaches.

we combine them with all the models. For each Table, the first line is a quick reminder of the three embedding models and their performance in terms of MAP scores shown between brackets. The following two lines also remind the embedding models used for combination and their MAP scores when used individually. The following four lines present the results of the combination of these models by addition or concatenation for both normalizations. For instance in Table 2, the $CharSG$ and $CBOW$ embedding models used individually have respectively 36.4% and 21.9% of MAP and the combination of the two models gives 22.9% of MAP by addition and 34.9% of MAP by concatenation with L2 normalization at vector length level. Combining embedding models is very effective when using concatenation in most cases. The best combination model is obtained by the concatenation of $CharSG$ and $CharCBOW$ using length L2 Norm (70.3% of MAP in Table 2) and by the concatenation of $CharCBOW$ and $CBOW$ (49.5% of MAP in Table 3) followed by the same model using dimension L2 Norm for breast cancer corpus (68.1% of MAP in Table 2) and using $CharSG$ with SG concatenation for wind energy corpus (45.4% of MAP in Table 3). We observe that both types of L2 normalization are in general useful for concatenation with a better performance when using length normalization.

CharSG	36.4	41.1	61.6	58.8	61.8	65.2	76.5	69.2	70.3
(Bojanowski et al., 2016)	-	-	-	**72.4**	-	-	-	-	-
Model	WE	JRC	CC	WIKI	ALL	WE + JRC	WE + CC	WE + WIKI	ALL
CharCBOW	**38.2**	42.8	60.1	67.8	70.1	43.8	65.9	71.3	71.4
CharSG	36.9	49.9	61.9	71.0	**70.8**	55.1	65.7	72.2	**72.4**
(Bojanowski et al., 2016)	-	-	-	68.2		-	-	-	-

Table 4: Results (MAP %) of different embedding models on the specialize corpora as well as several out-of-domain corpora and their combinations ((Bojanowski et al., 2016) is the pre-trained CharSG model).

Table 4 shows the results of different combinations[14] of specialized corpora with external resources.

[14]Combination means that we first merge different data sets in one single corpus and then, we learn an embedding model

We represent in the 1^{st} column the results for the specialized corpora taken individually (BC and WE) and then, from the 2^{nd} to the 4^{th} column we show the results of the external resources taken individually and their combination represented in the 5^{th} column (ALL). Finally, from the 6^{th} to the 8^{th} column we combine the specialized corpora with each external data and then their entire combination[15] (All).

Overall, we see that combining different resources gives significant improvements over the two specialized corpora. We also notice the usefulness of external data used individually which performs better than small specialized corpora, except for CharCBOW which shows the strength of this model and its usefulness over other types of embedding models. Also, using the pre-trained embedding model of Bojanowski et al. (2016) obtained good results (72.4% for BC and 68.2% for WE) but if we compare it to the same model (CharSG) learned while combining specialized and external data sets, we observe better performance (76.5% for BC and 72.4% for WE) which shows that using jointly specialized and external data is more efficient than the use of external data only. This statement is confirmed by the results obtained by individual external data sets which are always lower than their combination with specialized corpora.

	Individual corpus			Corpus combination (GSA)	
Models	BC	JRC	CC	BC + JRC	BC + CC
SA	27.0	**52.0**	**75.5**	61.7	**80.2**
CBOW	17.1	40.3	60.9	49.9	67.7
SG	12.8	40.5	56.0	46.5	63.2
CharCBOW	**60.8**	35.3	57.4	52.9	73.9
CharSG	36.4	41.1	61.6	**65.2**	76.5
				Vector concatenation	
SCBOW	-	-	-	53.7	70.7
SSG	-	-	-	36.3	40.2
SCBOW+SSG	-	-	-	56.1	70.9
SSA	-	-	-	66.6	**82.3**
Our approaches					
SCharCBOW	-	-	-	64.9	74.9
SCharSG	-	-	-	73.0	77.4
SCharCBOW+SCharSG	-	-	-	67.0	**80.7**
Meta-Emb (Best)	-	-	-	**74.8**	**83.1**

Table 5: Results (MAP %) of the *Standard Approach* (SA), the *Global Standard Approach* (GSA) and the *Selective Standard Approach* (SSA) and our approaches using CharCBOW and CharSG and their combinations (SCharCBOW, SCharSG and Meta-Emb) for the breast cancer corpus (BC) using the different external data (the improvements indicate a significance at the 0.05 level using the Student t-test).

In Table 5, we report the results obtained in Hazem and Morin (2017) (SA, CBOW, SG, SCBOW, SSG ,SCBOW+SSG and SSA) and our results using combination and meta-embeddings of character n-gram models (SCharCBOW, SCharSG, SCharCBOW+SCharSG and Meta-Emb (Best)[16]). The main conclusion in Hazem and Morin (2017) is that the best embedding combination (SCBOW+SSG) couldn't outperform the selective standard approach (SSA). According to our results, character n-gram models and their combination obtained better results than the best CBOW and Skip-gram combination (SCBOW+SSG) and also outperformed the selective standard approach (SSA obtained 66.6% using BC + JRC and 82.3% using BC + CC while our best model obtained **74.8%** and **83.1%** on the same corpora). The results of Table 5 provide strong support for data combination and meta-embeddings using character n-gram models. Also, we highlight the fact that character ngram models and their combination is much faster than CBOW and Skip-gram models. In addition, the dimension size of embedding models

on the merged corpus.

[15] ALL in the 5^{th} column means that we combine JRC, CC and WIKI, while ALL in the 9^{th} column means that we combine JRC, CC and WIKI and the specialized corpora BC or WE.

[16] Meta-Emb (best) stands for the combination of SCharSG on specialized corpus with SCharCBOW+SCharSG on external data.

is very low (around 300) while in the standard approach it corresponds to the vocabulary size which leads to sparse vectors and high computational cost.

7 Discussion

The first important finding of this work is the efficiency of the character n-gram models (CharCBOW and CharSG) which drastically outperform other models, whether on specialized or general domain data sets. Their better performance can be explained by the fact that both models are based on characters to build the embedding models. While CBOW and Skip-gram suffer from the lack of data to build efficient models over specialized corpora, the character-based approaches benefit of much more training examples as they use characters for their models. The second important finding is the performance of external data when applied for extracting bilingual terms. This is not surprising as external data sets such as wikipedia or common crawl for instance, contain several scientific and specialized documents. In addition, we could observe the complementarity of external resources with the specialized domain data sets. More precisely, concatenating embeddings of specialized and external resources significantly improves the results. This can be explained by the nature of the captured information which can be resumed in the concatenated embedding vectors. If a single generic embedding model is difficult to obtain, character n-gram and word-based embedding models can be efficiently combined to improve bilingual terminology extraction from comparable corpora.

We also conducted an error analysis of the different proposed models and we couldn't find a strong relation between the embedding models and the non captured terms. However, we observed that the CharCBOW model with the meta-embedding combination using BC with CC corpora improves overall the rank of the translations obtained for each individual corpus. By looking at the 115 translations of BC and the 80 of BC+CC not found in the first rank, we found 58 terms in common including 44 terms with a better rank with BC+CC corpora. In the same way, from the 75 translations of CC and the 80 of BC+CC not found in the first rank, we found 62 terms in common including 46 terms with a better rank with BC+CC corpora. It might seem surprising that we found more terms outside the first rank with CC corpus than BC+CC (80 versus 75) since the MAP is lower with CC than BC+CC (57.4 versus 73.9). In fact, the CharCBOW model with BC+CC improves overall the rank of all the translations of CC and more particularly the rank of the first hundred translations taken into account in the calculation of the MAP. We also observed that the more frequent terms are the best translated for SA and SSA approaches. For the embedding approaches, this observation is not relevant. For instance, the translations of frequent terms such as *cancer* and *breast* are found in the first ranks and the translations of infrequent terms such as *lumpectomy* and *fibroadenoma* are found in the last ranks with SA and SSA approaches. With embedding approaches, *cancer* and *fibroadenoma* are found in the first ranks and *breast* and *lumpectomy* in the last ranks. We have not been able to better characterize terms in the last ranks with embedding approaches. This is strongly dependent on embedding parameters and also context size and embedding dimensions. Our best system, however obtained 90% of precision on top 5, in the perspective of providing first translation terms for translation aided systems, our proposed approach is certainly more appropriate than the standard approach whether in terms of computational cost or in terms of accuracy.

8 Conclusion

In this paper we have explored a variety of embedding models and there impact on the task of bilingual terminology extraction from specialized comparable corpora. We have also proposed meta-embedding representations and have shown under which conditions they can be jointly used for better performance. If further investigations are probably needed, our findings strengthens the idea that using meta-embeddings based on specialized and general domain data sets improves the performance of mining bilingual specialized lexicons.

Learning Emotion-enriched Word Representations

Ameeta Agrawal, Aijun An and **Manos Papagelis**

York University, Toronto, Canada
{ameeta,aan,papaggel}@eecs.yorku.ca

Abstract

Most word representation learning methods are based on the distributional hypothesis in linguistics, according to which words that are used and occur in the same contexts tend to possess similar meanings. As a consequence, emotionally dissimilar words, such as "*happy*" and "*sad*" occurring in similar contexts would purport more similar meaning than emotionally similar words, such as "*happy*" and "*joy*". This complication leads to rather undesirable outcome in predictive tasks that relate to affect (emotional state), such as emotion classification and emotion similarity. In order to address this limitation, we propose a novel method of obtaining emotion-enriched word representations, which projects emotionally similar words into neighboring spaces and emotionally dissimilar ones far apart. The proposed approach leverages distant supervision to automatically obtain a large training dataset of text documents and two recurrent neural network architectures for learning the emotion-enriched representations. Through extensive evaluation on two tasks, including emotion classification and emotion similarity, we demonstrate that the proposed representations outperform several competitive general-purpose and affective word representations.

1 Introduction

Emotion detection from text is the task of identifying emotions from natural language data such as reviews, blogs, news articles, and so on (Alm et al., 2005; Aman and Szpakowicz, 2007). While numerous taxonomies of emotions have been proposed (Ekman, 1992; Plutchik, 1980; Parrott, 2001), most psychologists agree that an emotion is a feeling that characterizes the state of mind such as *happiness*, *sadness*, *anger*, among others. The ability to detect emotions in text is critical for a number of applications and services in diverse domains, including market research, customer relations, gaming, and intelligent tutoring systems, to name a few (Mohammad and Turney, 2013).

Despite its potentially wide-spread use, the automatic detection of emotions remains a challenging multi-class, sometimes multi-label, classification problem due to a number of reasons, including: (i) different emotion models consist of different number and types of emotion categories; (ii) emotions are not only subjective but also fuzzy, with more than one emotion occurring at the same time. As a result, development of emotion related resources, such as training data, has been limited to a few manually annotated datasets or lexicons, a process that requires much time and effort, and is expensive.

To solve the limited training data problem, the recent success of word embeddings has garnered increased attention in the design of emotion classification systems (Bravo-Marquez et al., 2016; Pool and Nissim, 2016; Mohammad and Bravo-Marquez, 2017). Word embeddings are distributed word representations (Collobert et al., 2011; Turian et al., 2010), where each word w in the vocabulary $\mathcal{V}$ is mapped into a dense, low-dimensional, continuous-valued vector $x \in \mathbb{R}^d$, $d \ll |\mathcal{V}|$. The underlying idea is that words that frequently occur together in same contexts get mapped to similar regions of the vector space.

Most embeddings (Mikolov et al., 2013b; Pennington et al., 2014) are typically modeled using the syntactic context of words following the distributional hypothesis, i.e., words which occur in similar

(cry, weep) ↑	0.605	0.574
(cry, laugh) ↓	0.657	0.403

Table 1: Cosine similarity between emotionally similar (↑) and emotionally dissimilar (↓) word pairs

contexts tend to be semantically similar. While the property of semantic similarity is beneficial in a number of tasks, modeling emotionally *dissimilar* words with similar contexts into neighboring spaces becomes counterproductive in affective tasks such as emotion classification. To further motivate this limitation, Table 1 presents the cosine similarity between the word vectors of a few word pairs obtained from popular pre-trained word embeddings such as GloVe (Pennington et al., 2014) and CBOW (Mikolov et al., 2013b). According to the similarity scores, both GloVe and CBOW rate the word pair (*happy*, *sad*) as more similar than (*happy*, *joy*).

The effectiveness of word embeddings has been shown to be task-dependent (Labutov and Lipson, 2013; Bansal et al., 2014) and while there is some work on generating task-specific embeddings (Kalchbrenner et al., 2014; Tang et al., 2014; Chen and Manning, 2014; Qu et al., 2015), there is little work specifically exploring the role of task-specific *emotion-enriched* embeddings.

In this paper, we propose learning emotion-enriched word representations[1], which we call Emotion Word Embeddings (EWE), in order to project emotionally similar words into neighboring spaces. Towards that end, first, a method of distant supervision is employed to automatically create a large training dataset with a rich spectrum of emotions. Then, two recurrent neural network architectures are employed to learn emotion-aware word representations by leveraging noisy, but large training data. Specifically, we use Long Short-Term Memory (LSTM) networks (Hochreiter and Schmidhuber, 1997) to capture the *semantic* information between the words of the text document as well as the *emotion* information provided in the form of the target label obtained through distant supervision. Experimental evaluation demonstrates the effectiveness of learned emotion embeddings in the two tasks of emotion classification and emotion similarity.

The major contributions of this work include: (i) a novel distant supervision method for automatically labeling a large corpus of training data with fine-grained emotions; (ii) two LSTM model architectures for learning emotion-enriched word embeddings from text documents (a single-label model and a multi-label model); (iii) and, an extensive evaluation of the learned word vectors on two tasks: emotion classification over four domains of text (blogs, fairy tales, personal experiences, and tweets) and emotion similarity.

The rest of this paper is organized as follows. Section 2 introduces the related work. Section 3 describes the proposed model, followed by the experimental setup and results in Section 4. Section 5 presents the qualitative analysis and finally, Section 6 concludes the paper.

2 Related Work

There exists a large body of work discussing representation learning. Generic word vector models use unannotated text to learn the embedding vector of each term as a fixed length continuous representation by predicting adjacent terms in the document (Bengio et al., 2003; Collobert and Weston, 2008; Collobert et al., 2011; Mikolov et al., 2013b; Mikolov et al., 2013a; Pennington et al., 2014). Incorporating distributed word embeddings as features has proven effective in a variety of natural language processing tasks, including parsing (Socher et al., 2013), language modeling (Bengio et al., 2003; Mnih and Hinton, 2008) and sentiment analysis (Socher et al., 2011; Labutov and Lipson, 2013; Tang et al., 2014; Tang et al., 2016). However, the effectiveness of generic word embeddings has been shown to be heavily task-dependent (Labutov and Lipson, 2013; Bansal et al., 2014).

[1]Available for download: `https://www.dropbox.com/s/5egqnbktbfxp2im/ewe_uni.txt.zip?dl=0`

To increase the effectiveness of generic word embeddings, therefore, there have been some lines of work in using neural networks for inducing task-specific *affective* embeddings. Socher et al. (2011) learned vector space representations for multi-word phrases using recursive autoencoders for the task of sentiment analysis. Labutov and Lipson (2013) produced task-specific embeddings from existing word embeddings for sentiment analysis. Kalchbrenner et al. (2014) trained their models on a large dataset of tweets, where a tweet was automatically labeled as positive or negative depending on the emoticon that occurs in it. Tang et al. (2014; 2016) also induced embeddings from scratch for sentiment analysis using a dataset of 10M tweets obtained through distant supervision labeled with positive and negative emoticons. More recently, affective word representations have been obtained using a corpus of almost 1B tweets weakly labeled with a set of 64 emojis (Felbo et al., 2017). An alternative to learning task-specific embeddings from scratch or updating existing embeddings using neural networks is post-processing (or fine-tuning) existing embeddings with respect to some external knowledge source such as a lexicon (Faruqui et al., 2015).

All the above-mentioned approaches of learning task-specific affective embeddings (Tang et al., 2014; Tang et al., 2016; Felbo et al., 2017) rely on tweets data obtained from Twitter, automatically labeled using emoticons. However, tweets data do not generalize well to texts from other domains such as blogs, narratives, etc. Instead, we explore a novel domain of text (product reviews) to present a more generalizable approach to obtaining large-scale training data using distant supervision. In addition, while previous embeddings were trained on corpora of sizes ranging from 10M to 1B tweets, our models are able to learn rich representations from a much smaller dataset of about 200K reviews. Furthermore, although a binary spectrum of positive and negative sentiment (Tang et al., 2014) or a large axis of 64 emojis (Felbo et al., 2017) has been previously used to generate representations, we align our embeddings along an emotion model firmly grounded in psychology which remains unexplored yet. Lastly, while the previous approaches used only a single-label setting (i.e., only one affect label per document), we propose modeling a more natural multi-label setting where a document can be associated with more than one emotion label.

3 Emotion-enriched Word Representations

In this section, we first describe two neural network models and their components for learning Emotion Word Embeddings (EWE). Then, we describe the process of automatically obtaining a large training dataset of text documents labeled with emotions through distant supervision.

3.1 Training Word Embeddings using LSTM

Let $\mathcal{V} = \left\{w_1, ..., w_{|\mathcal{V}|}\right\}$ be the vocabulary of word tokens in the annotated dataset. Each word w_i is represented as a n-dimensional continuous vector $\mathbf{x}_i \in \mathbb{R}^n$ and the full embedding matrix is $E \in \mathbb{R}^{n \times |\mathcal{V}|}$. Starting from original embeddings $\mathbf{x}_i^o$ of word w_i (initialized either randomly or through some pre-trained word embeddings), the goal is to learn emotion-enriched embeddings $\mathbf{x}_i^e$ for w_i.

The LSTM (Long Short-Term Memory) model finds a dense low dimensional representation of words by sequentially and recurrently processing each word in a document. Specifically, the inputs of the LSTM are preprocessed text documents that consist of a sequence of words and their corresponding target variable. Let $\mathcal{D} = \{(d_1, y_1), ..., (d_D, y_D)\}$ denote an annotated dataset of documents, where $d = \{w_1, w_2, ..., w_N\}$ denotes a text document consisting of a sequence of N words and y_i is the corresponding emotion label distribution for document d_i. The words of the text document are, first, converted into vector representations, which are then sequentially fed into the LSTM model left-to-right. Then, through back-propagation, the original word vectors get updated during training, producing emotion-enriched embeddings $\mathbf{x}_i^e$ for all $w_i \in \mathcal{V}$.

In this work, we consider two model architectures to capture the *context* information by modeling the long-range dependencies between the words of a text document and *emotion* information provided through the target label to map each word into an affective embedding space. Model 1 (EWE_{UNI}) considers a single emotion label for each document, whereas Model 2 ($\text{EWE}_{\text{MULTI}}$) allows multiple labels for a document. Figure 1 presents an overview of the proposed framework. First, we create a cor-

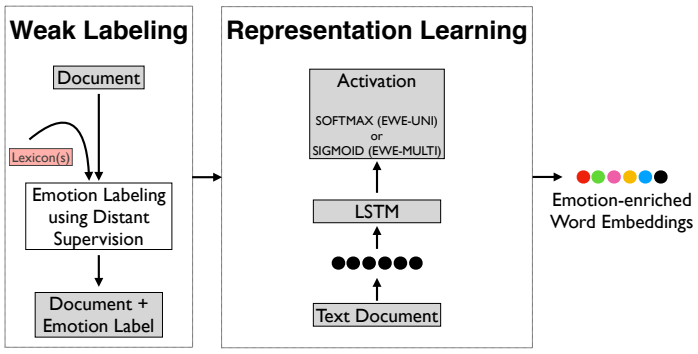

Figure 1: Overview of the framework for obtaining emotion-aware word representations

pus of emotion-labeled documents using emotion lexicons through a distant supervision process (to be described in Section 3.2). Then this corpus is used as training data to learn emotion-enriched word representations using LSTM. In other words, while document-level (entire examples) labeling is used to create the training set, the embeddings get updated at individual word level.

3.1.1 Model 1: EWE_{UNI}

Most words evoke only one emotion depending on the context. As an example, consider two benchmark emotion datasets (Alm et al., 2005; Aman and Szpakowicz, 2007) where each sentence is annotated with a single emotion label. Guided by this intuition, we propose EWE_{UNI} which follows a multi-class setting, where there exists only one valid mutually exclusive emotion label l_i for a text document d_i, and $l_i \in \mathcal{L}$, where $\mathcal{L} = \{l_1, ..., l_k\}$ denotes a discrete, finite set of k emotions.

Given an annotated document with its associated emotion label, the target value y is a one-hot vector, where the values of all the indices but one are 0. For example, if d is labeled with emotion l_i, then it holds that:

$$y_j = \begin{cases} 1, & \text{if } y_j = l_i \\ 0, & \text{otherwise} \end{cases} \tag{1}$$

The neural network consists of one hidden layer, with the embedding matrix E added to the input layer. To predict the emotion label of the input text, an output layer with a softmax activation function which gives a probability distribution over the k classes is added on top of the hidden layer for modeling multi-class probabilities. The softmax function converts the classification result into label probabilities, i.e. $y' \in [0, 1]^k$.

The final training objective is to minimize the multinomial cross-entropy loss of the predicted and true distributions, where the error over a batch of n documents is calculated as:

$$\xi = -\frac{1}{n} \sum_{i=1}^{n} \sum_{j=1}^{k} y_{ij} \log \left(y'_{ij} \right) \tag{2}$$

where i denotes the ith training sample, j denotes the jth class, y is the true distribution (one-hot representation of the emotion label), and y' is the predicted probability distribution, $y'_{ij} \in [0, 1]$ and $\sum_j y'_{ij} = 1$.

3.1.2 Model 2: $\text{EWE}_{\text{MULTI}}$

Although modeling emotion classification as a multi-class problem captures the basic emotion connotation of many words, in reality, most words can be associated with more than one emotion. For instance, during the process of creating the NRC EmoLex emotion lexicon (Mohammad and Turney, 2013), it was found that *anger* words tend to be associated with *disgust*, *joy* terms tend to be related with *trust*, and *surprise* terms are largely also associated with *joy*.

In order to capture a word's association with more than one emotion, the $\text{EWE}_{\text{MULTI}}$ models multi-label classification setup where each document can belong to multiple emotion classes at the same time.

Assuming k emotion classes, and more than one valid emotion label for each document, the target variable y is binary represented. In other words, $y_j = 1$ indicates presence of an emotion class, and $y_j = 0$ otherwise. For example, if document d is labeled with a subset of emotion classes, $s_i \subseteq \mathcal{L}$, then:

$$y_j = \begin{cases} 1, & \text{if } y_j \in s_i \\ 0, & \text{otherwise} \end{cases} \tag{3}$$

To predict the emotion label of the input text, an output layer with a sigmoid activation function, which squashes the inputs into a probability range of $[0, 1]$ for every class, is added to the last layer for modeling the probability of each class independently from the other classes.

The loss objective in this case is binomial cross-entropy, computed as follows:

$$\xi = -\frac{1}{n}\sum_{i=1}^{n}\left[y_i \log\left(y_i'\right) + (1 - y_i)\log\left(1 - y_i'\right)\right] \tag{4}$$

where i denotes the ith training sample, y is the binary representation of true emotion label, and y' is the predicted probability.

3.1.3 Implementation

We use pre-trained word embeddings (GloVe $|\mathcal{V}| = 1.9\text{M}$, $d = 300$ (Pennington et al., 2014)) to initialize E and use random initialization sampled from a zero mean Gaussian distribution: $x \sim \mathcal{N}\left(0, \sigma^2\right)$ for words not found in the pre-trained embeddings. Optimization of the loss function is carried out with the Adam optimizer (Kingma and Ba, 2014), which is known for yielding quicker convergence, with learning rate of 0.001, and mini-batch size set to 1024.

3.2 Labeling Training Data using Distant Supervision

To learn the emotion embeddings, we require a large dataset of text with corresponding emotion labels. Due to the challenges involved in creating large-scale emotion resources (Mohammad and Turney, 2013), however, most existing manually-annotated emotion datasets contain a very limited number of instances and words. For example, two popular emotion datasets created by Alm (2008) and Aman and Szpakowicz (2007) contain around 1200 sentences each and only about 5000 unique words each. At the same time, in order for learned word representation models to be useful, they need to generalize well to diverse domains and applications by including a much larger number of words. For instance, the vocabulary size of most existing word representations is orders of magnitude larger (e.g., 400K to 1.9M words in GloVe (Pennington et al., 2014), 3M words in word2vec (Mikolov et al., 2013a), and so on).

As it is quite challenging to create a large manually annotated emotion dataset due to human time and effort required, we leverage distant supervision (Go et al., 2009) to create a weakly labeled training dataset automatically in order to obtain emotion-enriched word representations for a much larger vocabulary. Distant supervision is the process of labeling instances based on some heuristics or rules, with some of the instances being assigned noisy or imprecise labels.

3.2.1 Distant Supervision for EWE_{UNI}

Let $\mathcal{D} = \{d_1, d_2, ..., d_D\}$ be the set of unlabeled documents. The goal is to generate an annotated dataset $\mathcal{D} = \{(d_1, l_1), ..., (d_D, l_D)\}$, where $l_i \in \mathcal{L}$ is the corresponding emotion label for document d_i and $\mathcal{L} = \{l_1, ..., l_k\}$ is a known finite set of emotion labels.

Let $d = \left\{w_1, w_2, ..., w_{|d|}\right\}$ denote the sequence of words in a document, $w_i \in d$. For each word w_i, we compute an emotion vector $\mathbf{a}(w) = \langle a_1, a_2, ..., a_k\rangle$, where a_j indicates the word-emotion association as derived from a lexicon. Although technically, while any emotion taxonomy can be followed for deriving the word-emotion vector $\mathbf{a}(w)$, in this work, we adopt Ekman's (1992) model of six emotions (*anger*, *disgust*, *fear*, *happiness*, *sadness* and *surprise*), whose origins are firmly grounded and extensively verified in psychology. To this end, we select **WordNetAffect (WNA)** (Strapparava and Valitutti, 2004), which was developed by manually labeling the emotions of a few seed words and extending it to all their WordNet synonyms, and **NRC EmoLex (NRC)** (Mohammad and Turney, 2010; Mohammad

and Turney, 2013), which was created through crowdsourcing by annotating unigrams with one or more of Plutchik's (1980) eight emotions, which in turn is a superset of Ekman's (1992) model. In WNA, each word is associated with only one emotion, therefore $a_j = 1$ if w is associated with that emotion, and $a_j = 0$ otherwise. On the other hand, in NRC, a word can be binary associated with more than one emotion, with 1 indicating an association and 0 denoting no association. For a given word w, we extract its binary association scores corresponding to the six categories of Ekman's model.

The emotion vector $\mathbf{a}(d)$ for document d is then, the sum of the emotion vectors of all its words, $\mathbf{a}(d) = \sum_{i \in d} \mathbf{a}(w_i)$. If the document has an association with at least one emotion, i.e., $\exists j, a_j(d) > 0$, then, $S = \text{argmax}_i\ \mathbf{a}(d)$, where $S \subseteq \mathcal{L}$. In other words, documents assigned zero emotion score are not considered. Finally, in case multiple emotion labels have the maximum value, i.e., $|S| > 1$, we sample uniformly at random one emotion label $l \in S$.

We investigate two strategies of computing the affective knowledge: (i) **one lexicon** - where any one lexicon is used to guide the labeling process; and, (ii) **two or more lexicons** - whereby two or more lexicons are used in order to mitigate some effects of noisy labeling. This variant assigns an emotion label to a document only if the labels output by both the lexicons match.

3.2.2 Distant Supervision for $\text{EWE}_{\text{MULTI}}$

Some words evoke more than one emotion at the same time. For example, out of the 14,000 words annotated with emotions in the NRC lexicon, almost 8,000 words (57%) are associated with more than one emotion. Therefore, we relax the labeling scheme followed in EWE_{UNI} and design $\text{EWE}_{\text{MULTI}}$ to take into consideration a multi-class, multi-label setting, where a document can have more than one emotion label.

Unlike EWE_{UNI}, in $\text{EWE}_{\text{MULTI}}$ the set of all emotions with $a_j(d) > 0$ for document d is used as final emotion labels for d. Thus, the multi-label annotated dataset $\mathcal{D}$ is $\{(d_1, S_1), ..., (d_n, S_n)\}$, where each document d_i is assigned a set of emotion labels, $S_i \subseteq \mathcal{L}$

3.2.3 Training Data

Our large corpus of unlabeled documents is extracted from the Amazon reviews dataset (McAuley et al., 2015) consisting of product reviews, spanning May 1996 - July 2014. Each review (considered as a document) is preprocessed by converting it to lowercase, tokenizing it with the NLTK toolkit (punctuation is preserved as tokens), and filtering out reviews that are too short (less than 5 words). Note that, as the proposed weak labeling is not dependent on any domain-specific indicators of affect such as emoticons or hashtags, it can be easily generalized to any type of text documents.

4 Experiments

4.1 Emotion Classification

The first task validates the effectiveness of the emotion embeddings under the supervised framework of emotion classification, where the learned word vectors are fed as features into classification models for predicting the emotion labels. We train two classifiers: (i) L2-regularized multi-class logistic regression (LR) and (ii) support vector machine (SVM) based on LIBSVM (Chang and Lin, 2011), to predict the fine-grained emotion label at the sentence level. The results of 10-fold cross validation are reported in terms of macro F_1 score, which is the average F_1 score over all the emotion classes. F_1 score is the harmonic mean of precision (p) and recall (r), $F_1 = 2\frac{p \cdot r}{p+r}$.

For the emotion lexicons, we generate a feature vector consisting of the total number of words in the sentence associated with each emotion category. For the word embedding models, we compute the average of the word vectors of all the words in the sentence along each dimension to obtain the sentence representation as the input to the classification algorithm.

4.1.1 Emotion Datasets

The following four benchmark emotion datasets from various genres of text are considered for emotion classification. The statistics of the datasets are summarized in Table 2.

dataset	domain	# emotions	total
Alm	fairy tales	5	1207
Aman	blogs	6	1290
ISEAR	experiences	5	5412
EmoTweet-top8	tweets	8	4664

Table 2: Statistics of emotion datasets

Methods		Alm	Aman	ISEAR
Lexicons	WNA	0.459	0.405	0.384
	NRC	0.387	0.370	0.378
	WNA+NRC	0.521	0.474	0.465
EWE_{UNI}	WNA	0.635	0.604	0.674
	NRC	0.604	0.582	0.666
	WNA+NRC	**0.661**	**0.623**	**0.679**
EWE_{MULTI}	NRC	0.630	0.602	0.666

Table 3: Comparison of using lexicons directly versus using lexicons to guide representation learning.

Alm: Emotions are particularly significant in the literary genre of fairy tales and this dataset contains sentences marked with one of five emotion categories: *angry-disgusted, fearful, happy, sad* and *surprised* (Alm, 2008).
Aman: Consisting of highly informal blog data, this dataset includes sentences annotated with one of six emotions: *anger, disgust, fear, joy, sadness* and *surprise* (Aman and Szpakowicz, 2007).
ISEAR: Developed for studying the relationships among cultures and emotions, this dataset contains personal experiences evoking seven emotions (Wallbott and Scherer, 1986). We use a subset of this dataset marked with one of the five emotions: *anger*, *disgust*, *fear*, *joy* and *sadness*.
EmoTweet-28: While the other annotated datasets are modeled after existing emotion taxonomies, this corpus was created by inductively identifying a set of emotion categories that characterize the emotions expressed in tweets (Liew et al., 2016). For our experiments, we extract a subset (**EmoTweet-top8**) of the eight most frequent emotions in the dataset.

4.1.2 Lexicons versus Representations

As the quality of the emotion embeddings depends on the underlying emotion lexicons adopted to create the training data, we analyze the results of using the source emotion lexicons directly versus using them to initialize EWE in Table 3.

We observe that the configurations using both the lexicons (WNA+NRC) yield better results than using any one lexicon alone. Morevover, all the EWE embeddings demonstrate significant improvements over using the lexicons directly, indicating that the affective word representation model learns useful information in addition to the knowledge available in the base lexicons adopted during distant supervision to guide the representation learning process.

4.1.3 Comparison Against State-of-the-art Representations

Next, we analyze the performance of EWE against state-of-the-art *generic embeddings* and *task-specific affective embeddings* described below, and summarized in Table 4.
Generic Embeddings: **(i) GloVe**: Global vectors[2] for word representations (Pennington et al., 2014) trained on aggregated global word-word co-occurrence statistics from a corpus capture linear substructures of the word vector space. We use the vectors that were trained on: **GloVe 6B**: 6 billion words, uncased, from Wikipedia 2014 and Gigaword v5, of dimension $d = 300$; **GloVe 42B**: 42 billion words,

[2]http://www-nlp.stanford.edu/projects/ glove/

embeddings	corpus	size	$\|\mathcal{V}\|$
GloVe 6B	Wiki + Gigaword	6B tokens	400K
GloVe 42B	Common Crawl	42B tokens	1.9M

Table 5: Comparison against state-of-the-art word representations (*generic embeddings* in the top half; *affective embeddings* in the bottom half) on emotion classification. The best results are shown in **bold**, and the second best results are <u>underlined</u>. Paired t-tests using the results on all four datasets indicate EWE is significantly better than all the other methods with p-values < 0.02.

uncased, from Common Crawl, of dimension $d = 300$. **(ii) `word2vec`**: These word representations[3] were learned with a continuous bag-of-words model (CBOW) (Mikolov et al., 2013a), where a target word is predicted given its surrounding context words. We use the vectors that were trained on 100 billion words of Google news dataset and are of $d = 300$.

Affective Embeddings: **(i) Sentiment-specific word embeddings (SSWE)**: These embeddings, obtained using a corpus of 10 million tweets, encode the sentiment information (derived using a set of positive and negative emoticons) of the text in the continuous representation of words[4] (Tang et al., 2014). We use embeddings that were trained with the unified model (SSWE_u). **(ii) DeepMoji**: These word representations were obtained from a corpus of almost 1 billion tweets weakly labeled using a set of 64 emojis (Felbo et al., 2017). **(iii) Retrofitting**: Instead of directly training task-specific affective embeddings such as SSWE and DeepMoji, Retrofitting (Faruqui et al., 2015) is a post-processing technique of tuning existing embeddings according to a task-specific lexicon. Using WNA as the source emotion lexicon, where words with same emotions are clustered together, we apply Retrofitting to the generic word vectors (GloVe and word2vec).

The results of the emotion classification are presented in Table 5, with the generic embeddings model in the top half and affective embeddings in the bottom half. In general, we observe that GloVe 42B yields the second best results overall, and in line with other recent studies (Pool and Nissim, 2016), Retroffiting did not improve over any original word embeddings suggesting that post-processing word embeddings with respect to emotion knowledge requires additional considerations.

Secondly, although SSWE and DeepMoji were both trained on tweets data, they perform very differently to each other, most likely due to their extremely different choices of affect spectrum (SSWE was

Table 6: Accuracy of emotion similarity tested on emotion lexicon DepecheMood

modeled along binary polarities, whereas DeepMoji used an axis of 64 categories), thus highlighting the importance of the emotion model adopted for creating the training dataset. In addition, and rather surprisingly, all the generic embeddings (GloVe and word2vec) outperform all the affective embeddings (SSWE and DeepMoji) on all the four datasets. One possible reason for this could be due to the more generalizable sources of data that were used to induce the generic embeddings, while the affective embeddings were trained on tweets data, thus showing the significance of the choice of the underlying text used to derive the representations.

Lastly, $\text{EWE}_{\text{UNI(WNA+NRC)}}$ statistically significantly outperforms all the other baselines across all the four datasets, indicating the effectiveness of the proposed method.

4.2 Emotion Similarity

The second task measures the *emotion similarity* of the word vectors by comparing against the emotion similarity obtained from an emotion lexicon. In this experiment, the test affective information is derived from **DepecheMood (DM)** (Staiano and Guerini, 2014), an emotion lexicon consisting of 37,000 words and their emotion scores across eight affective dimensions. We consider the emotion label of a word as the emotion category with the maximum affective weight.

Following previous experimental setup for measuring affective consistency (Tang et al., 2014), we compute the accuracy of emotion similarity consistency between each emotion word and its top n nearest neighboring words as follows:

$$Accuracy = \frac{\sum_{i=1}^{m}\sum_{j=1}^{n}\alpha\left(w_i, c_{ij}\right)}{m \times n} \tag{5}$$

where m is the number of words in the emotion lexicon, w_i is the ith word in the lexicon, c_{ij} is the jth closest word to w_i in terms of their cosine similarity, $\alpha\left(w_i, c_{ij}\right)$ is an indicator function, where $\alpha = 1$ if w_i and c_{ij} belong to the same emotion category and $\alpha = 0$ otherwise. The higher the accuracy, the better the clustering of emotionally similar words in the embedding space.

Table 6 presents the results of various embeddings for $n = \{10, 20, 30\}$, where n is the number of nearest neighboring words. For fair comparison, for each word embeddings, only the words that appear in both the vocabularies (i.e., DM and word embeddings) have been used. Again, we observe that generic embeddings such as GloVe and word2vec outperform affective embeddings such as SSWE. The best results are obtained from EWE which have been specifically trained to capture emotion similarity.

5 Qualitative and Error Analysis

To further analyze the learned emotion embedding space, we use t-SNE (van der Maaten and Hinton, 2008) to visualize the word representations of a small subset of words in Figure 2. The plots show that compared to other models, EWE is effective in clustering emotionally similar words into neighboring vector spaces. Figure 3 shows confusion matrix plots providing an overview for some error analysis. In general, for imbalanced datasets such as Alm and Aman, it is observed that most misclassified instances are incorrectly labeled as *happy* class, likely because the *happy* class contains a disproportionately large number of training instances. Moreover, instances belonging to the *surprise* class are more often misclassified than correctly predicted, likely because the *surprise* class is highly underrepresented. Balancing

the datasets might prove helpful. In ISEAR, *anger* and *disgust* classes are found to be confused with each other and *sadness* seems to be challenging.

6 Conclusions

In this paper, we described a novel method of learning emotion-enriched word representations by leveraging distant supervision and neural networks. Significant improvements over baseline representations in two tasks including emotion classification and emotion similarity is obtained. In addition, we presented a qualitative analysis of the learned word vectors. As future work, we plan on considering alternate taxonomies of emotions such as Plutchik's (1980), obtaining emotion-enriched representations at phrase level and exploring sentence compositionality.

Abstract

We present an evaluation of PASS, a data-to-text system that generates Dutch soccer reports from match statistics which are automatically tailored towards fans of one club or the other. The evaluation in this paper consists of two studies. An intrinsic human-based evaluation of the system's output is described in the first study. In this study it was found that compared to human-written texts, computer-generated texts were rated slightly lower on style-related text components (fluency and clarity) and slightly higher in terms of the correctness of given information. Furthermore, results from the first study showed that tailoring was accurately recognized in most cases, and that participants struggled with correctly identifying whether a text was written by a human or computer. The second study investigated if tailoring affects perceived text quality, for which no results were garnered. This lack of results might be due to negative preconceptions about computer-generated texts which were found in the first study.

1 Introduction

Evaluation of end-to-end Natural Language Generation (NLG) systems is important to assess whether the system has properly expressed certain properties (e.g. quality, speed), or whether the designed properties work as intended (Gkatzia and Mahamood, 2015). Traditional NLG evaluation approaches can typically be assigned to one of two categories: intrinsic or extrinsic (Belz and Reiter, 2006). Intrinsic approaches seek to evaluate properties of the system itself. This can be done using automatic measures such as BLEU, NIST, ROUGE, etc. or by asking human participants to rate the systems output with e.g. Likert or rating scales. Extrinsic approaches aim to assess the impact of the system, by measuring if the system can fulfill its purpose or what the user gains from the systems output.

While scholars have been positive about the effort the NLG community has put into their evaluations (Gatt and Belz, 2010, for instance), it is often the case that an extensive evaluation does not take much priority after a system is built. The usage of automatic measures is gaining traction due to its quickness and low costs, but they are still considered controversial by many (Reiter and Belz, 2009; Novikova et al., 2017, for instance). Furthermore, the intrinsic approaches with human ratings are often limited in scope, using a relatively small sample of participants, using relatively short questionnaires that only shine light on a small aspect of text quality, and/or comparing the computer-generated texts against non-representative human texts. Similarly, the amount of extrinsic evaluations that have been performed up until now is low. While they are considered the most useful type of evaluation by some (Reiter and Belz, 2009), they are not carried out as often as other types of evaluation.

In many cases, an extrinsic evaluation is also difficult because of the system's set-up. A system that is designed to produce texts that stay close to the facts and which purpose is to merely inform readers, should mainly be evaluated on the factual correctness of its output, which is covered by doing an intrinsic evaluation. A different kind of system was chosen as the object of evaluation in the current study: the Personalized Automated Soccer texts System (hereafter: PASS). This system generates summaries of soccer matches based on match statistics (van der Lee et al., 2017). A unique feature of PASS is that

Proceedings of the 27th International Conference on Computational Linguistics, pages 962–972
Santa Fe, New Mexico, USA, August 20-26, 2018.

the system produces texts tailored towards fans of one club or the other. Previously, scholars have emphasized that one of the potential strengths of data-to-text systems is their potential to produce multiple variants of texts based on the same data (Gatt and Krahmer, 2018). This tailoring has been suggested to improve attitudinal and behavioral outcomes in the context of human-written persuasive texts (Noar et al., 2007), but if these positive outcomes can also be found for computer-generated texts and/or texts with aims other than persuasion warrants further research.

PASS is relatively unique in the NLG landscape, because of its aim to not only inform but also to produce a text that is 'enjoyable' to read by its target audience, which it tries to accomplish by tailoring texts towards the wishes of an audience. These goals make a brief check for readability of its texts inadequate, and make a more extensive evaluation project necessary. The current study examined whether the PASS system succeeds in the aim to produce texts of significant linguistic quality and if the tailoring component plays a role in this aim, similar to how tailoring improves attitudinal and behavioral responses for human-written persuasive texts. To examine this, the goals of this paper were twofold. The first goal was to assess how the quality of PASS-generated texts fares against similar human texts, and the second goal was to assess whether the intended tailoring was clear and if it had effects on attitude towards the text. Besides these two main points, differences in preconceptions about human-written and computer-generated texts were also investigated, because these preconceptions could moderate the effectiveness of tailoring.

2 Background

2.1 Evaluation in NLG

Evaluation has become an increasingly important topic within the NLP domain as a whole, but also within the NLG domain more specifically. While the NLG domain has a strong evaluation tradition (Gatt and Belz, 2010), there is an ongoing discussion regarding the type of evaluation that should be used. One popular evaluation method is the use of metrics that can be computed automatically, such as BLEU (Papineni et al., 2002), METEOR (Banerjee and Lavie, 2005), and NIST (Doddington, 2002). However, previous literature suggests that the use of such metrics should be done with caution. These metrics are attractive because they are quick, fast and repeatable (Reiter and Belz, 2009), and have in some cases been found to correlate with human judgments (Gkatzia and Mahamood, 2015). However, most if not all of the current automated metrics that are used in the NLG domain are based on overlap with a certain reference text. Therefore, it can be derived that such metrics are only useful if an aligned NLG output-reference text corpus can be constructed and if it can be assumed that qualitatively good output has a strong overlap with this standard. This will not be the case in many situations. Furthermore, these metrics also rely on the assumption that the reference text is a good representation of the 'best case scenario, which it often is not (Reiter and Sripada, 2002). Finally, it has been argued that such metrics do not provide a good assessment of many linguistic properties such as content selection, information structure, appropriateness, etcetera (Scott and Moore, 2007).

While use of automatic metrics is increasing (Gkatzia and Mahamood, 2015), the above concerns might contribute to the fact that evaluation using human input is still the most popular evaluation method in the NLG domain. Most of these evaluations have been quantitative (Sambaraju et al., 2011), but there can be sizable differences between these quantitative evaluations. A main distinction can be made between intrinsic and extrinsic methods (Hastie and Belz, 2014). Intrinsic methods evaluate the output of the system itself, for example by having humans read and rate text output of the NLG system and comparing these ratings against human written texts on metrics such as fluency, correctness, understandability, etcetera. Extrinsic measures aim to evaluate the impact of the system, for instance by measuring whether a system can fulfill the purpose it was built for (Hastie and Belz, 2014). A corpus analysis by Gkatzia and Mahamood (2015) shows that intrinsic human-based measures are used to a much greater degree compared to extrinsic human-based evaluations, although increasingly more effort regarding the latter evaluation can be observed in the past few years (Gkatzia et al., 2017; Goldstein et al., 2017; Ramos-Soto et al., 2017, for instance)

These extrinsic task-focused evaluations have traditionally been regarded as the type of evaluation

that provides the most meaningful results. However, it can be an expensive and timely undertaking to execute such an evaluation (Reiter and Belz, 2009). Another reason why extrinsic evaluations are not used as often is because in many cases, the purpose of the system itself makes such an evaluation unfit to use. An intrinsic evaluation measuring correctness and grammaticality would often be sufficient for systems that are designed to provide a general audience information in a straightforward manner. However, one of the strengths of data-to-text systems is the fact that they can tailor texts towards specific audiences relatively effortlessly. A notable example of this is the BabyTalk project (Gatt et al., 2009), where separate reports about babies in a Neonatal Intensive Care Unit (NICU) are generated for physicians, nurses and the baby's family based on data in the baby's electronic medical record. Recently, an increasing trend might also be observed in methods that can produce a text without too much human input (e.g. sequence-to-sequence models), which would make the development of systems with this feature much easier. Implementation of a tailoring feature, however, also means that the purpose of the system extends beyond merely informing a general audience. Tailoring is often implemented to increase behavior or attitude (Noar et al., 2007, for an overview), which would warrant a more extensive evaluation to measure the outcomes of the computer-generated texts. Furthermore, the effects of tailoring have mainly been investigated using human-written texts. It might be possible that people respond differently to computer-generated texts, for instance because they have different expectations of texts written by computers compared to human-written texts (Graefe et al., 2016).

2.2 PASS and 'Affective' Natural Language Generation

While an increase in NLG systems with a tailoring component might be expected, one of the few systems in this category is PASS (van der Lee et al., 2017). PASS generates soccer match summaries aimed at fans of one of the teams that participated in the match. Thus, the system can be seen as part of the 'Affective' NLG (ANLG) tradition, which aims to produce texts tailored towards the emotional aspects of the intended reader (Mahamood and Reiter, 2011; Ghosh et al., 2017, for instance). The input data is scraped from Goal.com and contains various types of data related to a soccer match (e.g. date played, goals scored, information about the players). Based on this data, a short Dutch match summary of about 50 to 150 words is produced, which is inspired by the reports of the GoalGetter system (Theune et al., 2001). However, although inspired by previous work, texts by PASS are novel in the sense that the templates have been directly derived from sentences in the MeMo FC corpus (Braun et al., 2016). This corpus contains match reports directly taken from the clubs that participated in the match. This often means that the tone of voice in these reports is emotional, while still maintaining a relatively professional style. Using these reports makes it possible to produce tailored match reports with PASS. This means that the tone of a generated report should appear to be more disappointed or frustrated in case the team of the target audience lost, and more upbeat in case of a win for the team of the target audience (van der Lee et al., 2017, for examples).

Empirical evaluation of ANLG systems is considered challenging (Belz and others, 2003; Mahamood and Reiter, 2011) and very few ANLG systems have been tested properly at this point in time. PASS is no exception to that. The lack of extensive empirical testing of that system makes it difficult to determine how well the system performs in terms of text quality and the effectiveness and importance of its 'emotional' tailoring component. Therefore, a more extensive evaluation is necessary in order to assess the perception of the generated texts and the consequences of tailoring.

2.3 Current challenges

Part of what makes evaluation of ANLG systems challenging is finding the right material to compare the output to. One way to compare the output quality of PASS to human texts would be to use texts in the MeMo FC corpus about the same soccer matches, written for the same target audience as reference texts. However, questions arise whether the texts in the MeMo FC corpus are a suitable equivalent for the texts produced by PASS. The texts in the MeMo FC corpus are usually match reports written by people that watched the full soccer match. Thus, it can be assumed that the writers of MeMo FC corpus texts had much more input data to base their reports on. Furthermore, there are no standard guidelines (e.g. text length, text structure) that all writers for soccer team websites adhere to, meaning that the style and

quality of texts in the MeMo FC corpus can be vastly different depending on the writer and the website it was written for.

The use of automated metrics was also deemed to be a non-viable option for the current study if texts from the MeMo FC corpus serve as reference texts, since sentences from the MeMo FC corpus are used as the basis for the templates in PASS. This would make it likely that much overlap occurs between the generated texts and the reference texts, resulting in high scores on metrics such as BLEU and METEOR. However, these scores would say little about how well these templates blend together to form an enjoyable and coherent text that displays the information in a sensible way (Scott and Moore, 2007).

Finding the right reference texts is not the only challenge when evaluating ANLG systems. The effects of tailoring the generated text towards the emotional needs of the intended audience has not received a lot of attention yet. Most research has focused on the effects of tailoring in the context of persuasive messages. A meta-analysis by Noar et al. (2007) shows that tailoring can improve the attitude towards a message and behavioral outcomes, although a relatively small mean effect size for tailoring interventions was found. In the context of texts that aim to achieve other goals rather than persuade, much less is known about the effects of tailoring. Especially in the NLG domain. One of the notable studies in this domain that attempts to study the effects of tailoring is by Reiter et al. (2003) who studied the effects on smoking behavior that tailored smoking cessation letters had. They did not find significant behavioral differences between people that received a tailored vs. non-tailored letter. However, it might be argued that such behavioral changes are difficult to achieve with only a letter. Furthermore, the tailoring aspect was elaborated by tailoring the arguments to the specific challenges that the reader said to face, which is a different kind of tailoring compared to the tailoring of PASS where the style and diction was tailored to fit with the emotions that the reader experiences. This difference in tailoring could also result in different effects.

A study similar to the current study is that of Wann and Branscombe (1992), who investigated mood changes after reading a (human-written) tailored basketball summary. They found that if participants identified strongly with a team involved in the match and if the text was tailored towards fans of that team, the emotions were the most extreme: participants reported the most positive mood if the team won and the most negative if the team lost. Tailoring did not have a significant effect on mood if the participants did not identify strongly with the team. Mahamood and Reiter (2011) found that affective texts were also preferred to non-affective texts and that emotional appropriateness of texts also correlated with understanding ratings when investigating generated BabyTalk texts. These results support the basic premise of PASS that tailoring of sports reports results in behavioral and attitudinal outcomes that non-tailored texts do not achieve. The current study investigated this more deeply, while also investigating the overall perceived text quality of the system. Furthermore, possible moderators of the effectiveness of computer-generated texts on attitudinal and behavioral responses were investigated by looking into possible differences in preconceptions between human-written and computer-generated texts.

3 Evaluation

As previously noted, the aim of the current paper was to study several components of PASS via two evaluation studies. The first study was a human evaluation of the systems output compared to human-written texts. The second study assessed the impact of PASSs tailoring feature. Both evaluation methods will be described more thoroughly in this section.

3.1 Evaluation of text-related attributes and preconceived notions

In this study, texts generated by PASS were compared to human-written texts regarding the perceived text quality, the evidentness of tailoring, and whether participants can accurately identify the writer to be a human or a computer. Furthermore, preconceived notions about human-written and computer-generated texts were investigated.

3.1.1 Participants

A total of 60 people participated in the study (35 women). All these participants were native Dutch college students and had an average age of 21 years and 9 months.

3.1.2 Design

Participants were asked to rate a total of 5 text-pairs (5 human texts and 5 texts generated by PASS). The human texts were written by 14 journalism and communication students, that together, wrote a total of 22 texts. These writers were given the same match statistics as PASS uses to generate a text and they were instructed to write a soccer match summary of a similar size as PASSs reports based on this data. Furthermore, the writers were asked to imagine that they were writing the reports for the club website of one of the two teams that participated in the match, thus writing one soccer report per match. No writers were involved in the rating task. All these instructions were implemented to get the foundation of the human-written text to be fairly equal to the PASS-generated text. The written soccer matches were about soccer matches played in the Dutch second league in the 2015/2016 season. The teams in this division are generally more obscure teams, which would minimize the chance that people's ratings are affected by their love or hatred for one of the teams involved in the match. Furthermore, the computer-generated texts were about the same Dutch second division matches from 2015/2016 and written for the same target audience as the human-written texts. The participants were randomly assigned to one of two versions where each version contained 5 different text-pairs. Counterbalancing was also applied to reduce order bias: so half of the participants in each version received the text-pairs in opposite order from the other half.

Not only were participants provided with a match report, they were also given the match data so that they were able to rate the completeness and accurateness of the information discussed in the report.

3.1.3 Procedure

The study was conducted using *Qualtrics*: an online platform to design surveys. The procedure for all participants was the same. The experiment started with a written instruction and consent form, after which the experiment started. On every page the participants were provided with match statistics and an accompanied text written by either a human or by PASS. The match data was shown so that participants were able to rate the correctness of the information discussed in the report.

After viewing the match data and reading these match reports, participants were asked to indicate whether they thought the text was written for fans of the home team or the away team, whether they thought the text was written by a human or generated by a computer, and why they thought the text was written by a human or generated by a computer. This last question asked for free-text comments to obtain information about preconceived notions participants have in regards to differences between human-written and computer-generated texts. Previous research has shown that these free-text comments often provide valuable insights about generated texts (Reiter and Belz, 2009). These comments were structured based on the text components of (Callaway and Lester, 2002): style (comments on the overall writing style), grammaticality (comments on the syntactic quality of the text), flow (comments on the fluency of the sentences), diction (comments on word choices), readability (comments on how easy to read the text is), logicality (comments on the aptness of the text structure and if information is correctly represented), detail (comments on the amount of detail in the text), and other (uncategorized comments). Furthermore positive, negative, and preconceptions with unclear valence were distinguished for every category.

The participants judged the quality of each text using seven-point Likert-scales on clarity: how clear and understandable the report is ('While reading, I immediately understood the text), fluency: how fluent and easy to read the report is ('This text is written in proper Dutch, 'This text is easily readable), and correctness: how well the information the report is based on is represented in the report itself ('This report does not include extraneous or incorrect information, 'This report does not omit important information).

3.2 Evaluation of tailoring effects

In this study, the effects of tailoring in a soccer match report on perceived text quality was investigated.

3.2.1 Participants

Native Dutch fans of the three most popular and successful soccer teams in the Netherlands: *Ajax*, *Feyenoord*, and *PSV*, were recruited via *Crowdflower*, these clubs were chosen because previous research has found that success increases fan identification (Wann et al., 1994). This resulted in a total of 171 participants (118 male, average age of 29 years and six months). Most of them were Ajax-fans (99), followed by PSV (55) and Feyenoord (47). Supporters of all three teams identified themselves with the club to a similar degree ($F(2, 168) = 1.77$, $p = .17$). Participants also had different educational backgrounds (72 participants college or university; 99 lower education level).

3.2.2 Design

Participants in this study were asked to read and rate a total of four match reports generated by PASS. The match reports that were presented to the participants was based on the club that they supported. The team they supported was involved in all four instances. A between-subjects design with two conditions was used (text tailored towards the team the participant identifies with, or text tailored towards the team the participant does not identify with).

Participants in all conditions got to see similar match summaries. The reports were based on actual matches played by Ajax, Feyenoord and PSV in the 2015-2016 season. By presenting matches based on actual matches, the aim was to present summaries that are realistic to the participants, but not recent enough for participants to remember the match. Perspective was manipulated by generating two reports with PASS, tailored towards fans of each respective team that participated in the match. The matches shown to participants were chosen randomly from the matches that Ajax, Feyenoord and PSV played in the 2015-2016 season, with the exception of any matches that the team they identified with played against rivaled teams, since these matches could result in more extreme ratings (Cialdini et al., 1995). Similarly, no matches of clubs that have been relegated since the 2015-2016 season were shown to avoid that participants view these matches as unrealistic.

3.2.3 Procedure

Participation of this study was done via an online *Qualtrics* survey. After receiving instructions and filling out a consent form, the participants were asked via multiple choice to indicate whether they had a preference for Ajax, Feyenoord, or PSV. After indicating their preference, fans were asked to read and rate four texts. The texts they received were based on their team preference: all match reports shown involved the preferred team.

After reading a match report, participants were asked to rate the text on 10 7-point semantic differentials based on Maes et al. (1996). Five differentials covered an aesthetic judgment on the text ('uninteresting/interesting', 'detached/appealing', 'distant/inviting', 'boring/engaging', 'impersonal/personal', 'monotonous/varied') and five covered clarity ('difficult/easy', 'complicated/simple', 'unclear/clear', 'complex/clear', 'illogically structured/logically structured', 'cumbrous/concise').

4 Results

4.1 Evaluation of text-related attributes and preconceived notions

4.1.1 Text quality

A two-way repeated-measures ANOVA was executed to investigate an effect of computer-generated vs. human-written texts on perceptions of clarity, fluency and correctness. The results showed main effects for all three text quality components (clarity: $F(1, 59) = 9.448$, $p = .003$; fluency: $F(1, 59) = 8.656$, $p = .005$; correctness: $F(1, 59) = 8.302$, $p = .006$). The participants rated the human-written texts as more clear and fluent compared to its computer-generated counterparts. Conversely, the computer-generated counterparts gave a more precise overview of the information it is trying to convey although scores in both categories were low. These low scores might be due to the fact that most human-written as well as most computer-generated texts did not express all the match data that was shown to raters. While the differences were significant, it should also be noted that the differences were relatively small: for all

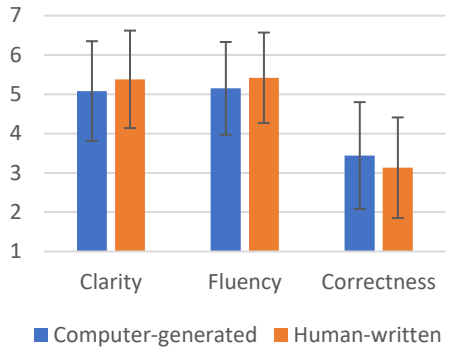

Figure 1: Average scores on clarity, fluency and correctness for the human-written and computer-generated texts on a 7-point Likert-scale. Error bars represent standard deviations.

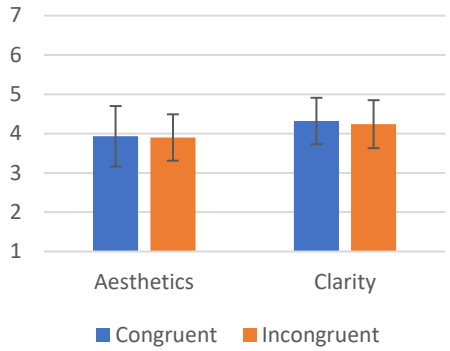

Figure 2: Average scores on aesthetics and clarity for the texts congruent and incongruent with team preference of participants on a 7-point Likert scale. Error bars represent standard deviations.

three text components, the difference between the computer-generated and human-written text was only around 0.3 on a 7-point scale; cf. Figure 1. This would suggest that PASS-generated texts are not that far off the text quality of human texts.

Text type	Correct perception	Incorrect perception
Computer	246	55
Human	228	72

Table 1: Cross-tab comparing the participants' correct and incorrect tailoring perceptions for computer-generated and human-written texts

Text type	Computer (perceived)	Human (perceived)
Computer	121	180
Human	94	206

Table 2: Cross-tab comparing the participants' perceived type of text versus the actual text type (computer-generated or human-written)

4.1.2 Perceived tailoring

In general, participants were able to correctly identify the target audience the text was tailored to. In almost 79% of all cases, the participants' perceived target audience was congruent with the intended target audience. An additional chi-square test did not show a significant difference in the evidentness of tailoring between the computer-generated and human-written texts ($\chi^2(1) = 2.96$, $p = .09$). The tailoring was similarly clear for computer-generated texts as for human-written texts; cf. Table 1.

4.1.3 Perceived text type

Results of a chi-square test showed a correlation between the perceived type of writer and the actual type of writer ($\chi^2(1) = 5.14$, $p = .02$). The origin of human-written texts were more often perceived as human and less often as computer compared to computer-generated texts. However, subsequent analysis made it clear that participants had trouble with this task. Mostly for the computer-generated texts: in less than half of the cases were people able to correctly identify the computer-generated text as such (in 40% of cases). Similar to 4.1.1, these results suggest that the texts generated by PASS contains human-like qualities, which was also further investigated in 4.1.4; cf. Table 2.

4.1.4 Free text comments

The free text comments - structured using the aforementioned categories based on (Callaway and Lester, 2002) - revealed clear differences in preconceived notions, most evidently between human-written and computer-generated texts. This was corroborated by a chi-square test for positive and negative notions ($\chi^2(1) = 391.09$, $p < .001$): participants generally had a much more positive stance towards human-written texts compared to computer-generated texts for nearly every text component. People tend to think of human-written texts as more emotional, dynamic, and well-written and computer-generated texts as more static, boring and poorly-written. This was expressed in the style, flow, and readability category. Interestingly, these judgments were not always justified, as 3 and 4 show. Human-written texts

		Positive	Negative	Unclear	Total
	Style	47	0	5	52
	Grammaticality	9	3	2	14
	Flow	8	0	0	8

	Other	0	0	3	3
	Total	8	116	17	141

Table 4: Frequency of the type of comments in support of participants' correctly perceived text type

were often misjudged as computer-generated, with substantiations such as *less personal*, *boring* and *no emotion*. Similarly, computer-generated texts were mistaken for human-written because they were *vividly written*, *enthusiastically written* and contained *emotions*. Thus, the intended design of PASS, which was to produce texts that are similar to human in style seems to be successful according by these comments.

Further support for this was found in the comments on diction. Participants expected human texts to contain more varied, figurative language and more adjectives (e.g. *use of proverbs*, *lots of variation in word choice*, *use of adjectives*), while computer-generated language was expected to be factual, simple, and sometimes illogical (e.g. *contains lots of numbers*, *illogical word choices*, *simple language use*). Examples of these comments were also found in correct and incorrect attributions of the text type, further suggesting that the computer-generated texts used in this study had similar qualities as human-written texts.

Participants also expected computers to be wrong more often in terms of syntax and information presented. Examples like *contains many errors*, and *grammatically incorrect* were used to explain why the text was perceived as a computer-generated text. These results are especially interesting, because these preconceptions contradict the findings in 4.1.1 where correctness for computer-generated texts was rated (slightly) higher compared to human-written texts.

4.2 Evaluation of tailoring effects

An independent-samples MANOVA was performed on the average scores of the four rated texts. A distinction between aesthetics and clarity was made in the test. For both these components, the MANOVA did not show a significant effect of tailoring congruity (aesthetics: $F(1, 167) = 0.11$, $p = .74$; clarity: $F(1, 167) = 0.61$, $p = .45$). Participants did not find the text to be aesthetically different if the tailoring was congruent with their preference or if it was not. Similarly, participants did not perceive the text as more clear if they were part of the audience tailored to or if they were not; cf. Figure 2. Thus, while the tailoring component was clear, no effects of tailoring were found on attitude towards the text.

5 Discussion

Various aspects of PASS, a data-to-text system that converts soccer match data into a textual soccer match summary, have been evaluated in this paper (van der Lee et al., 2017). PASS is relatively unique in the NLG landscape in the sense that it tailors texts towards specific subgroups. In the case of PASS: supporters of one team or the other involved in a soccer match. This tailoring component is enabled by using texts from the MeMo FC corpus, which contains soccer reports for club websites written in a more emotional tone-of-voice compared to the more neutral newspaper reports. By incorporating a tailoring component, it can be argued that the purpose of PASS is not to merely inform readers of a soccer match, but also to entertain, which required further investigation. Tailoring has been found to increase behavioral and attitudinal outcomes (Noar et al., 2007), and tailored sports reports have been

found to increase emotions for people who identify with a participating team (Wann and Branscombe, 1992). However, if tailoring-related effects could be found for computer-generated texts and if tailoring also affects perceived text quality warranted further investigation. In sum, the aim of the paper was to perform a more extensive evaluation of PASS by comparing its output to similar human-written texts, and to investigate if the attempted tailoring was clear and if it had any attitudinal effects. Furthermore, differences in preconceived notions between human-written and computer-generated texts - a possible moderating factor in the effectiveness of tailoring - was explored. These aims were investigated using two evaluation studies.

The first evaluation study showed differences in perceived quality between human-written and computer-generated soccer match summaries from PASS. The results showed that the language use of the human-written texts was found to be more fluent and easy to read, as well as more clear and understandable. However, the computer-generated texts gave a better overview of the match-data it was based on. The differences in perceived text quality between the human-written and computer-generated texts might be due to the fact that PASS texts are inspired by texts from GoalGetter - a data-to-text system that attempted to produce a neutral and factual match summary (Theune et al., 2001) - in terms of its text structure and the types of data that are incorporated into a text. Perhaps, if the aim of PASS is to entertain rather than inform, it might be fruitful to stray further away from the structure and data use of GoalGetter texts. Interesting, however, was the fact that despite differences in information representation and language use, participants had trouble identifying the computer-generated texts as such: these texts were incorrectly marked as a human text in 60% of cases, which does suggest that the current state of PASS-generated texts is of good quality. Another reason to think that the PASS-generated texts are effective in their goal is the fact that the intended tailoring was correctly identified by participants during evaluations, to a similar degree as the tailoring in human-texts.

However, the second study did not show any effects of tailoring on perceived text quality. Texts that were tailored towards the preferences of the participant were neither seen as more aesthetically pleasing nor as more understandable. Thus, no support was found for tailoring to have an effect on the attitude towards the text. A reason for this might be the findings in the free text comments of the first study. These comments showed that people have negative preconceived notions about computer-generated texts. They are generally expected to be written with boring and unemotional language in a predictable and static style. Knowing that the reports were computer-generated might have biased the participants in the second study to think that the reports were lacking emotions, thus making it harder to achieve tailoring effects. However, it should be noted that this lack of result in the second study does not necessarily mean that there is no effect of tailoring in PASS texts. Previous research has shown that tailored human-written texts about sports matches did increase emotional experiences for participants the texts were tailored towards (Wann and Branscombe, 1992), which could suggest that the PASS texts affect emotional experiences rather than opinions on the text itself. Furthermore, (Mahamood and Reiter, 2011) found that 'emotional appropriateness' correlated with understandability and that 'tailored' texts scored higher on all aspects of text quality compared to 'neutral' texts, which are aspects that are still worth investigating in the context of PASS. There is also a lack of research looking into the relationship between extrinsic evaluation and intrinsic evaluation (Gatt and Belz, 2010), which could be an interesting avenue for further research. Furthermore, the current quantitative human-based approaches could be combined with a qualitative analysis of the output texts similar to McKinlay et al. (2010) and Sambaraju et al. (2011) in order to get a better sense which components of PASS should be improved and how they should be improved.

With the study described in this article, a more extensive evaluation of a data-to-text system was executed than is conventional in the NLG domain, with a few notable exceptions (Reiter and Belz, 2009; Reiter et al., 2003, for instance). We feel that similar evaluations and further research into evaluation methods should be greatly encouraged. Over the last few years, interest in NLG systems has been increasing in domains outside academia as well, such as the journalism domain, and many people expect that computer-generated texts will become more visible in everyday life. In light of these developments, increasing the quality and quantity of evaluations is necessary for a better understanding of the state of these NLG-systems and the role they should play alongside human writers.

Acknowledgements

We received support from RAAK-PRO SIA (2014-01-51PRO) and The Netherlands Organization for Scientific Research (NWO 360-89-050), which is gratefully acknowledged. Thanks are due to Martijn Goudbeek for help in setting up in the experiments, Nadine Braun for providing us with the corpus, Monique Hamers for helping us find young journalists and the three reviewers for their comments.

Answerable or Not: Devising a Dataset for Extending Machine Reading Comprehension

Abstract

Machine reading comprehension (MRC) has recently attracted attention in the fields of natural language processing and machine learning. One of the problematic presumptions with current MRC technologies is that each question is assumed to be answerable by looking at a given text passage. However, to realize human-like language comprehension ability, a machine should also be able to distinguish not-answerable questions (NAQs) from answerable questions. To develop this functionality, a dataset incorporating hard-to-detect NAQs is vital; however, its manual construction would be expensive. This paper proposes a dataset creation method that alters an existing MRC dataset, the Stanford Question Answering Dataset, and describes the resulting dataset. The value of this dataset is likely to increase if each NAQ in the dataset is properly classified with the difficulty of identifying it as an NAQ. This difficulty level would allow researchers to evaluate a machine's NAQ detection performance more precisely. Therefore, we propose a method for automatically assigning difficulty level labels, which basically measures the similarity between a question and the target text passage. Our NAQ detection experiments demonstrate that the resulting dataset, having difficulty level annotations, is valid and potentially useful in the development of advanced MRC models.

1 Introduction

Language understanding is one of the ultimate goals of artificial intelligence. Because the machine understanding of human language is hard to define, one often presumes that if a machine can answer a set of questions under given circumstances, then it understands language. Machine reading comprehension (MRC) developed along this direction and has recently attracted a great deal of attention in natural language processing (NLP) and machine learning.

The tasks of MRC are defined in various ways (Richardson et al., 2013; Mostafazadeh et al., 2017; Weston et al., 2015; Chen et al., 2016; Rajpurkar et al., 2016). Some tasks (Chen et al., 2016; Hill et al., 2016) provide a set of fill-in-the-blank style questions. The most prominent tasks (Rajpurkar et al., 2016), however, allow a machine to locate an answer span in given text passages. It is a highly efficient scheme, because the task can be formulated by the recognition of the start and end positions of the passage. This model facilitates the development of machine learning approaches and the automatic evaluation of performances. However, as criticized by (Jia and Liang, 2017), a machine can succeed in a task of this kind by remembering and recalling linguistic patterns that are prominent in a target dataset. This means that machine comprehension of this type would be an insufficient measure for assessing the degree of machine understanding of language.

To tackle this issue, Jia and Liang (2017) developed a dataset, in which passages were altered to include adversarial sentences that could lead to wrong answers. Contrary to their approach, which modified text passages, this paper proposes to extend MRC by incorporating questions for which relevant answers cannot be found in the given text passages. These questions are called *not-answerable questions (NAQs)*.

Proceedings of the 27th International Conference on Computational Linguistics, pages 973–983
Santa Fe, New Mexico, USA, August 20-26, 2018.

This partly meets our expectation, which can be stated as, "a good MRC system, given text passages, should properly detect and reject NAQs."

To develop an appropriate functionality, a dataset that accommodates NAQs and answerable questions is mandatory. Furthermore, each NAQ in the dataset should not be easily detected. However, the manual construction of such a dataset would be very costly. Therefore, this paper proposes an automatic dataset creation method for incorporating NAQs by making use of an existing MRC dataset. We created such a dataset by modifying a popular MRC dataset, the Stanford Question Answer Dataset (SQuAD) (Rajpurkar et al., 2016).

The value of such a dataset would increase if each NAQ in the dataset were to be graded according to the difficulty level used to determine question as not-answerable. These difficulty level annotations would allow us to choose a subset where the difficulty levels of NAQs could be adjusted as required. Therefore, we propose a method for automatically assigning difficulty level labels to NAQs. The proposed method employs a set of similarity features that are highly effective in determining the not-answerability of a question. NAQ detection experiments, employing an answerable/not-answerable binary classifier and a "null-answer detector" are conducted, showing that the resulting dataset with its respective difficulty level labels can be effectively used in the study of the genuine machine understanding of a language.

2 Related Work

Recently, several MRC datasets have been developed. The characteristics of each MRC dataset varies, depending on the purpose. For example, the Childrens Book Test dataset (Hill et al., 2016) was built from books for children, where the 21st sentence that follows the preceeding 20 sentences is employed as a "question." Additionally, the CNN/Daily dataset (Chen et al., 2016) collects news articles with bullet-pointed summaries, in which each summary is converted into a question. Among the many MRC datasets, this section introduces two datasets, WIKIQA (Yang et al., 2015) and SQuAD (Rajpurkar et al., 2016). Of these, the latter is used in this work. Additionally, we address potential problems with SQuAD.

2.1 Related MRC Datasets

WIKIQA: WIKIQA is one of the few MRC datasets that contains questions without answers, which is a main concern of this paper. WIKIQA was created to capture the characteristics of natural queries asked by people in the real world. Each question in this dataset was taken from a search engine's actual query log, and the corresponding Wikipedia summary paragraph is employed as a text passage, where each of the contained sentences is treated as an answer candidate. This means that a machine is only required to infer the positive or negative status of each sentence. This problem can be often solved by only looking at the questions; the ability of reading comprehension is not necessarily required. WIKIQA maintains 3,047 questions, of which about two thirds are NAQs, as they never have a positive sentence in the corresponding paragraphs. Moreover, 20.3% of the answers share no content words with the questions, contributing to the elevated difficulty level of the dataset. Unfortunately, this dataset is relatively small, and the amount of training data is inevitably limited.

SQuAD: SQuAD is an MRC dataset accommodating 107,785 question-and-answer (QA) pairs on 536 Wikipedia articles. A passage is associated with, at most, five QA pairs, and each question has the corresponding answer, forming a span in the associated passage. The evaluation metrics are exact match (EM) and F1. An EM score measures the percentage of predictions that match any one of the ground truth answers exactly. An F1 score is a metric that measures the average overlap between the prediction and the ground truth answer. Figure 1, adopted from (Rajpurkar et al., 2016), exemplifies three QA pairs taken from a paragraph in a Wikipedia article, whose topic is precipitation. Note that each of the three questions refers to the same passage, and the corresponding answer can be found as a span within the passage. As detailed in the next section, we create an MRC dataset with NAQs by modifying an existing dataset. If a good source dataset is properly chosen, this strategy could prevent the shortage of QAs and enjoy the advantages of the existing dataset. Among the many MRC datasets, we choose SQuAD as the source, because it is a rather large-scaled dataset of the answer-in-the-text style, which functions as a good starting point to pursue the study of genuine machine understanding of a language.

In meteorology, precipitation is any product of the condensation of atmospheric water vapor that falls under gravity. The main forms of precipitation include drizzle, rain, sleet, snow, graupel and hail... Precipitation forms as smaller droplets coalesce via collision with other rain drops or ice crystals within a cloud. Short, intense periods of rain in scattered locations are called "showers".

What causes precipitation to fall?
gravity

What is another main form of precipitation besides drizzle, rain, snow, sleet and hail?
graupel

Where do water droplets collide with ice crystals to form precipitation?
within a cloud

Figure 1: Example of QA pairs on a text passage in SQuAD.

2.2 Potential Problems with SQuAD

Jia and Liang (2017) make a point that the extent to which MRC systems truly understand language remains unclear. To reward systems that have real language understanding abilities, they proposed an adversarial evaluation method for SQuAD. Their method challenges the MRC system by altering the passages to include adversarial sentences that could lead to wrong answers. The results of their experiments proved that current MRC systems are easily affected by inserted adversarial sentences, concluding that the machines need to understand language more precisely. Their approach can be contrasted with ours, in that they modify text passages, whereas we propose to incorporate NAQs. However, both share the same objective of extending the conventional MRC framework.

Sugawara et al. (2017) evaluated a published MRC dataset for ascertaining its quality. They adopted two metrics: prerequisite skills and readability. Prerequisite skills include abilities, such as object tracking, coreference resolution, and logical reasoning. Readability was evaluated based on NLP metrics, such as average sentence length in words and adverb variation. Their evaluation analyses revealed that the prerequisite skills correlated more with dataset quality than readability. They concluded that SQuAD passages were not very readable, whereas the questions were relatively easy to answer. Although this insight does not have any direct connection with the present work, it should be noted, because it provided considerable analyses of SQuAD.

3 Dataset Creation

We propose an automatic method for creating a dataset that is useful in the development of an NAQ detection mechanism. The proposed method modifies an existing popular MRC dataset (i.e., SQuAD), which avoids the manual construction of a dataset from scratch. This section first describes the dataset creation method and then proposes a method for grading the difficulty level of an NAQ. Here the "difficulty level" signifies how difficult a question is for a machine to identify as an NAQ[1]. The description of the resulting dataset concludes this section.

[1] A set of Python scripts for creating an NAQ dataset from SQuAD is available at `https://github.com/nknsh0000/createNAQs`.

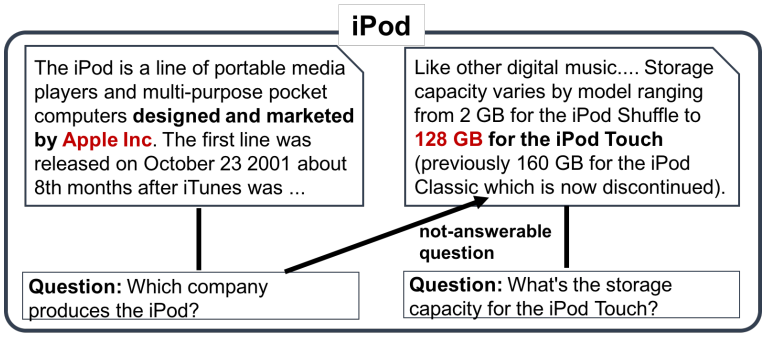

Figure 2: Creation of NAQ with our proposed creation strategy.

3.1 Devising NAQs

3.1.1 The Strategy

The priority in the creation of an applicable dataset is to incorporate hard-to-detect NAQs. It seems rather easy to devise an NAQ. Randomly selected or generated questions can cater to the most fundamental requirements. However, the questions gathered by this manner could be easily detected by a machine. Thus, they are an inadequate device for assessing the degree of machine language comprehension.

The similarity between a question and the corresponding text passage plays a key role in the creation of NAQs. More specifically, an NAQ is created by simply taking a question that was originally associated with another text passage that is highly similar to the text passage of the current target. This practical method can be applied to any MRC datasets, where the answer to a question is restricted to a span in the corresponding text passage.

3.1.2 Creation of NAQs using SQuAD

Adjacent text passages in SQuAD are taken from Wikipedia articles, meaning that these passages are very likely to share a topic and thus be similar. This pattern allows us to simply select an adjacent passage as the target text passage of an NAQ. Figure 2 illustrates the procedure for NAQ creation from two pairs of a text passage and a question. The question, "which company produces the iPod?," originally associated with the left passage, is taken as an NAQ of the right passage. Notice here that the entity, "iPod," resides in the passage, potentially confusing a machine. Questions that accidentally have the corresponding answers in a shifted passage are thus removed[2].

3.2 Grading NAQ Difficulties

Although the difficulty levels of created NAQs may vary, their proper annotations can be effectively utilized. We can extract a subset of the entire dataset by choosing the difficulty levels and by enabling more detailed evaluation of a machine's NAQ detection performance. Difficulty levels should be automatically determined by referring to mechanically-extractable features, rather than relying on human assessments.

3.2.1 Feature Detection

The selection of a feature to well-estimate the difficulty level of an NAQ is not trivial. To accomplish this sub-task, we first collect potentially useful features and train an answerable/not-answerable binary classifier. We then conduct ablation tests to find the most effective feature among the candidates.

Potentially useful features can be divided into two feature groups: Individual features and Similarity features.

Individual features: To represent a passage and a question individually, an averaged word embedding vector and its TF-IDF weighted version are respectively computed for each of the passages and

[2]We removed 1,825 questions.

each of the questions. We employed pre-trained 100-dimensional GloVe (Pennington et al., 2014) word embedding vectors[3].

Similarity features: A largely irrelevant NAQ that is easy-to-detect is expected to have lower similarity to the given passage. We thus compute five types of similarity features as listed below.

- (a) max_word_sim: the maximum similarity between a word in the question $q = (\boldsymbol{w_1^q}, \ldots, \boldsymbol{w_m^q}, \ldots, \boldsymbol{w_M^q})$ and a word in the passage $p = (\boldsymbol{w_1^p}, \ldots, \boldsymbol{w_n^p}, \ldots, \boldsymbol{w_N^p})$. Thus, this similarity feature is formulated as: $max\_word\_sim = \max_{m,n} \cos(\boldsymbol{v_m^q}, \boldsymbol{v_n^p})$;
- (b) ave_word_sim: the averaged similarity between a word in the query and its most similar word in the passage: $ave\_word\_sim = \frac{1}{M} \sum_{m=1}^{M} \max_n \cos(\boldsymbol{v_m^q}, \boldsymbol{v_n^p})$;
- (c) the BLEU score (Papineni et al., 2002);
- (d) t_{cos}: the cosine similarity between each of the TF-IDF bag-of-words vectors; and
- (e) gt_{cos}: the cosine similarity between the averaged TF-IDF weighted word embedding vectors.

In the calculation of all features, we treat all out-of-vocabulary words as "unknown", which means that these words are simply skipped.

Binary classification: We conducted answerable/not-answerable binary classification experiments by employing the above-mentioned feature groups. In the experiments, we compared four classification algorithms (i.e., random forest (RF), linear regression (LR), support vector machine (SVM), and AdaBoost). Each were trained with 45,000 NAQs and the same number of answerable questions, randomly chosen from the created dataset. A 10-fold cross validation was applied in each run. As Table 1 clearly shows, similarity features could be utilized as a relatively good indicator.

Classifier	RF	LR	SVM	AdaBoost
Individual Features	0.597	0.563	0.565	0.554
Similarity Features	0.847	**0.852**	0.851	**0.852**

Table 1: Accuracy results of the binary classification.

Ablation tests: Based on the experimental results, we employed similarity features with the LR classifier. We then conducted ablation tests, where each similarity feature was ablated under the same experimental settings. Table 2 summarizes the results. As indicated by the greatest degradation, the feature of average similarity between words in the question and the passage, ave_word_sim, contributed the most. Given these results, we simply exploited the ave_word_sim feature as the indicator of difficulty level.

Ablated feature	max_word_sim	ave_word_sim	BLEU	t_{cos}	gt_{cos}
Accuracy	0.851	**0.812**	0.830	0.852	0.851

Table 2: Accuracy results from the ablation tests (comparing accuracy: 0.852).

3.3 Created Dataset

We finally completed our dataset by integrating the created NAQs with the original answerable questions from SQuAD. Table3 measures the number of questions in the created dataset.

Furthermore, we assigned a difficulty level label to each NAQ in the dataset by using the similarity feature, ave_word_sim, with the following criteria. Table 4 classifies the distribution of assigned difficulty levels. Note that the NAQs creation and the difficulty level assignment were individually conducted for train set and dev set.

[3] `http://nlp.stanford.edu/data/glove.6B.zip`

	Train		Dev	
	#passages	#questions	#passages	#questions
Answerable questions	18,896	87,599	2,067	10,570
NAQs	17,071	75,155	2,065	9,762

Table 3: The number of questions in the created dataset.

- LEVEL1 (easy): $0.0 \leq ave\_word\_sim < 0.5$
- LEVEL2 (moderate): $0.5 \leq ave\_word\_sim < 0.7$
- LEVEL3 (difficult): $0.7 \leq ave\_word\_sim \leq 1.0$

	Ranges of ave_word_sim	Train	Dev
ALL	$0.0 \leq ave\_word\_sim \leq 1.0$	75,155	9,762
LEVEL1	$0.0 \leq ave\_word\_sim < 0.5$	9,686	823
LEVEL2	$0.5 \leq ave\_word\_sim < 0.7$	57,730	4,636
LEVEL3	$0.7 \leq ave\_word\_sim \leq 1.0$	7,739	4,303

Table 4: Distribution of NAQ difficulty levels.

For reference, Figure 3 and Figure 4 respectively exemplify a LEVEL3 (difficult) and a LEVEL1 (easy) questions.

Passage:
On September 6 2006 Sony announced that PAL region PlayStation 3 launch would be delayed until March 2007 because of a shortage of materials used in the Blu-ray drive. At the Tokyo Game Show on September 22 2006 Sony announced that it would include an **HDMI port** on the 20 GB system but a chrome trim flash card readers silver logo and Wi-Fi would not be included. Also the launch price of the Japanese 20 GB model was reduced by over 20% and the 60 GB model was announced for an open pricing scheme in Japan. During the event Sony showed 27 playable PS3 games running on final hardware.

Question:
How many **USB ports** did the original PS3 prototype have?

Figure 3: An example of difficult NAQ.

Passage:
PlayStation Home is a virtual 3D social networking service for the PlayStation Network. Home allows users to create a custom avatar which can be groomed realistically. Users can edit and decorate their personal apartments avatars or club houses with free premium or won content. Users can shop for new items or win prizes from PS3 games or Home activities. Users interact and connect with friends and customise content in a virtual world. Home also acts as a meeting place for users that want to play multiplayer games with others.

Question:
What section of What's New can't show links to websites?

Figure 4: An example of an easy NAQ.

4 NAQ Detection Experiments and the Results

We conducted two types of NAQ detection experiments: primary experiments for comparing model architectures, and additional experiments for confirming the validity of the difficulty levels.

4.1 Comparing Model Architectures

In Section 3.2, answerable/not-answerable binary classification experiments were described. They were conducted to explore efficient features for the difficulty-level grading. However, the model architecture for NAQ detection was not necessarily limited to the described one. Rather, we adopted an existing MRC answering model for the present purpose. Namely, we exploited BiDAF (Min et al., 2016), a popular neural network model for MRC/QA in the present NAQ detection experiments.

Figure 5 overviews two BiDAF-based architectures for NAQ detection: (a) binary classification model with answer span confidences, and (b) "null-answer" question detection model.

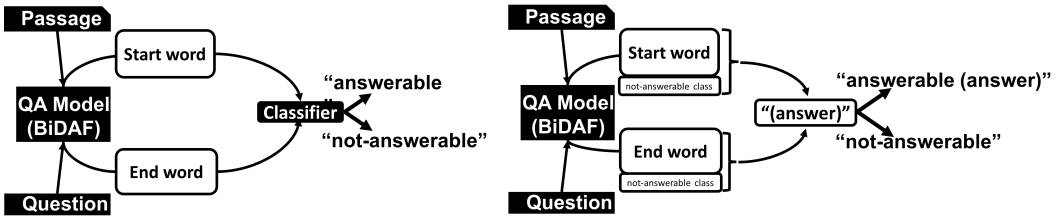

Figure 5: BiDAF-based model architectures for NAQ detection experiments: (left) binary classification model; (right) "null-answer" detection model.

(a) Binary classification model with answer span confidences: Like many existing MRC models, BiDAF estimates both start and end words of an answer candidate in the given text passage, allowing us to utilize two confidences associated with these two words as features. In this paper, we refer to the confidence of a start-word vector as $\boldsymbol{s}$ and that of an end word as $\boldsymbol{e}$. The numbers of dimensions of $\boldsymbol{s}$ and $\boldsymbol{e}$ were aligned with the number of the words in the longest text passage. This resulted in 673 dimensions. In this experiment, 75,155 NAQs and the same number of answerable questions were randomly chosen for training, and 9,762 NAQs and the same number of answerable questions were randomly chosen for testing.

(b) "null-answer" question detection model: The BiDAF model can be leveraged another way. This model explicitly adds a "null-answer" class by properly representing an empty span associated with a null-answer. Through a preliminary experiment, we expressed it by locating both the start and end positions at the very last word of the text passage. The same set of answerable questions and NAQs was also used in this experiment.

4.1.1 The Results

Table 5 summarizes the classification accuracy with the binary classification model, where four types of classifiers (RF, LR, SVM, and AdaBoost) were particularly compared. As seen in Table 5, the highest accuracy of 0.813 was achieved with the RF classifier that employs both features, (yp_{start} and yp_{end}). These results were worse than those of the classifiers with similarity features utilized in the difficulty level grading, presented in Section 3.2.

Table 6, on the other hand, presents the classification results of accuracy with the null-answer detection model, where the accuracy was as high as 0.895, which greatly outperformed other models, including the one described in Section 3.2. Moreover, the recall rate for recovering answerable questions was as high as 0.936, whereas that for recovering NAQ was as low as 0.854, indicating that the detection of NAQs is more difficult. If we only consider the results with answerable questions, the EM score was 0.607, which was moderately worse than 0.680, achieved with the model trained without NAQs. Thus, the percentage

Classifier		RF	LR	SVM	AdaBoost
Features	yp_{start}	0.807	0.774	0.760	0.808
	yp_{end}	0.785	0.756	0.751	0.792
	yp_{start}, yp_{end}	**0.813**	0.780	0.774	0.813

Table 5: Accuracy results with the binary classification model.

	All	Answerable questions	NAQs
Accuracy of NAQ detection	**0.895**	0.936	0.854
EM scores	-	0.607	-

Table 6: Accuracy results with the null-answer detection model.

of misclassifying answerable questions as not-answerable was only 6.36% (1-0.936), whereas that of misclassifying NAQs as answerable was 14.6% (1-0.854).

With the null-answer model, it is expected that correct answers will be recovered. The error rate of answer extraction for the correctly identified answerable questions was 0.33, which is comparable with 0.32, achieved with the model trained without NAQs. This small difference supports the assumption that the model would have misclassified many answerable questions as NAQs.

4.2 Validating the Difficulty Level Grading

We can extract a subset of the entire dataset by choosing the difficulty levels, which enables more detailed evaluation of the machine's NAQ detection performance. If the detection accuracies degrade with the increase of difficulty levels, then the assigned difficulty levels are valid. Moreover, if the NAQ detection accuracies are low enough, the created dataset is useful for the dev of the functionality to distinguish NAQs from answerable questions.

For each class of the difficulty level, we randomly extracted the same number of answerable questions from the SQuAD dataset as the NAQs from our dataset, and conducted the binary classification for the dev set. Again, we compared the binary classification model (with the RF classifier) with the null-answer detection model.

4.2.1 The Results

The results in Table 7 show that the accuracies degrade with the increase of the difficulty level, indicating that the difficulty grading is valid. Additionally, we confirmed that the null-answer model was superior to the present binary classification model. Moreover, the results for the most difficult level NAQs gave significantly lower accuracy figures, signaling that the models for detecting NAQs still have room for improvement. Nevertheless, we can construct a sub-dataset with designated difficulty levels from the entire dataset, which could be effectively exploited in the development of MRC models that deal with NAQs.

4.3 Error Analysis

Errors are divided into two cases, where the machine: (a) judged an NAQ as answerable (false answerable), or (b) judged an answerable question as an NAQ (false not-answerable).

Model	Binary classification	Null-answer detection
LEVEL1	0.860	0.953
LEVEL2	0.855	0.948
LEVEL3	0.748	0.734

Table 7: Accuracy results of NAQ detection experiments for each difficulty level.

4.3.1 False answerable

Figures 6, 7 and 8 respectively display a false answerable error case, where the machine wrongly predicted a question as answerable in each difficulty level.

In the Level-1 question exemplified in Fig. 6, the machine wrongly answered the shape of thylakoid rather than that of pyrenoids. This error could be attributed to the existence of the keyword "shape" appeared in the question. The passage actually had nothing to do with pyrenoids. In the example shown in Fig. 7, the passage contains the sentence, "In 1893, Tesla returned to his birthtown, Smijian." The machine's prediction would have been strongly affected by the existence of not only "Tesla" but "go": "go" in the question and "return" in the passage exhibit a level of semantic similarity. In this example, the machine should have recognize that "Smiljan" and "Karlovac" are totally different placements, whose similarity would not be taken into account. Finally, Fig. 8 displays a Level-3 question. Similar to the example given in Fig. 7, the machine was again not able to recognize the difference in nouns; in this case the focused nouns are compounds, each of them designates a specific event.

These examples suggest that the machine estimated the NAQs as answerable questions especially when some words overlapped between passage and question. In these cases, the machine tends to simply predict a span whose estimated semantic type is matched with the type of the interrogative.

4.3.2 False not-answerable

In false not-answerable cases, we observed differences in the mean length of questions and that of passage as counted in Table 8. This table suggests that the machine tended to recognize answerable questions as NAQs when the passage length is short or when the ground truth answer length is long.

Passage:
Chloroplast (Level 1)
In the helical thylakoid model, grana consist of a stack of flattened **circular** granal thylakoids that resemble pancakes. Each granum can contain anywhere from two to a hundred thylakoids, though grana with 10–20 thylakoids are most common. ...

Question:
What **shape** are pyrenoids?
Wrong Answer: circular

Figure 6: A Level-1 NAQ that the machine misjudged as an answerable question.

Passage:
Nikola_Tesla (Level 2)
In **1873**, **Tesla returned** to his birthtown, Smiljan. Shortly after he arrived, Tesla contracted cholera; he was bedridden for nine months and was near death multiple times. Tesla's father, in a moment of despair, promised to send him to the best engineering school if he recovered from the illness (his father had originally wanted him to enter the priesthood).

Question:
When did **Tesla go** to Karlovac?
Wrong Answer: 1873

Figure 7: A Level-2 NAQ that the machine misjudged as an answerable question.

5 Concluding Remarks

Machine understanding of language is difficult to define and accomplish. However, we must approach this issue by developing a computational mechanism, along with the relevant resources. As a step along this direction, in this paper, an automatic dataset creation method with which NAQs were incorporated was proposed. We created a dataset by altering an existing QA dataset, SQuAD.

Passage:
Super_Bowl_50 (Level 3)
QuickBooks sponsored a "Small Business Big Game" **contest**, in which Death Wish Coffee had a 30-second commercial aired free of charge courtesy of QuickBooks. Death Wish Coffee beat out nine other contenders from across the United States for the free advertisement.

Question:
What brand **sponsored** the "Crash the Super Bowl" **contest**?
Wrong Answer: QuickBooks

Figure 8: A Level-3 NAQ that the machine mistook as an answerable question.

	Answerable questions	
	Correctly predicted as answerable	Incorrectly predicted as NAQ
Passage	777.39	722.01
Answer	2.82	3.25
Answer/Passage Ratio [%]	0.42	0.53

Table 8: The lengths of passages and answers contained answerable questions.

One of the key requirements for such a dataset would be the acquisition of NAQs that are difficult to identify as not-answerable. Given this sub-goal, a method for assigning the difficulty levels to NAQs was also described. The results of NAQ detection experiments demonstrated that the assigned difficulty levels were valid, because the detection accuracies were degraded with the increase in difficulty level. This means that we acquired a way to examine and evaluate NAQ detection methods and models more precisely. Moreover, the lower accuracy results confirmed that there is still scope for improvement in the NAQ detection models. Therefore, the created dataset could be effectively utilized in developing the NAQ detection functionality.

For future work, we should develop a more difficult MRC dataset by further investigating into the notion of the difficulty in NAQ detection, which would inherently require us to incorporate various aspects of human language understanding. Along with this direction, we will devise a set of questions, for which confusing items reside in the target text passages.

Abstract

The task of obfuscating writing style using sequence models has previously been investigated under the framework of obfuscation-by-transfer, where the input text is explicitly rewritten in another style. A side effect of this framework are the frequent major alterations to the semantic content of the input. In this work, we propose obfuscation-by-invariance, and investigate to what extent models trained to be explicitly style-invariant preserve semantics. We evaluate our architectures in parallel and non-parallel settings, and compare automatic and human evaluations on the obfuscated sentences. Our experiments show that the performance of a style classifier can be reduced to chance level, while the output is evaluated to be of equal quality to models applying style-transfer. Additionally, human evaluation indicates a trade-off between the level of obfuscation and the observed quality of the output in terms of meaning preservation and grammaticality.

1 Introduction

The fact that writing style uniquely characterizes a person, and can be leveraged for automatic author identification (Holmes, 1998; Stamatatos et al., 2000), has been well-studied in the field of (computational) stylometry (Neal et al., 2017). Similarly, work on author profiling (Koppel et al., 2002) has demonstrated that such stylometric features can be used to accurately infer an extensive set of personal information, such as age, gender, education, socio-economic status, and mental health issues (Eisenstein et al., 2011; Alowibdi et al., 2013; Volkova et al., 2014; Plank and Hovy, 2015; Volkova and Bachrach, 2016). Traditionally, these techniques relied on expensive human-labelled examples; however, more recent work has demonstrated near equal accuracy when only relying on self-reports as a distant supervision signal (Beller et al., 2014; Emmery et al., 2017; Yates et al., 2017). While these efforts have been greatly beneficial to various research fields such as computational sociolinguistics (Daelemans, 2013), they potentially expose users of such media to attacks where this information can be abused unbeknownst to them. This is particularly harmful to individuals in a vulnerable position regarding race, political affiliation, mental health, or any other personal information made explicitly unavailable.

Adversarial stylometry, or style obfuscation, is one of the proposed methods aimed at protecting users against such attacks. Its objective is to rewrite an input text such that a classifier (the adversary) trained on detecting a particular variable (such as a demographic attribute) is fooled — effectively protecting this variable. The main challenge is to preserve the original meaning of the input, whilst hiding the act of obfuscation (Potthast et al., 2016). Recent work on automatic obfuscation (Shetty et al., 2017; Karadzhov et al., 2017) shows promising results in minimizing performance of the adversary; however, these models (also noted by the authors) struggle with correctly maintaining the semantic content of the input. To illustrate, while rewriting *school* to *wedding*[1] effectively fools an age classifier into thinking the text is written by an adult rather than a teen, the original meaning is not preserved in the output.

[*]Equal contribution.

[1]Example taken from Shetty et al. (2017).

Proceedings of the 27th International Conference on Computational Linguistics, pages 984–996
Santa Fe, New Mexico, USA, August 20-26, 2018.

We propose that this observed shift in meaning is to some extent a by-product of the formulation of the obfuscation task. Content words that are strongly related to a particular attribute often play a significant role in the accuracy of a potential adversary. There is ample evidence for this phenomenon in age and gender classification work (Koppel et al., 2002; Rao et al., 2010; Burger et al., 2011; Sap et al., 2014, inter alia). Taking examples from Sap et al. (2014) specifically, features with strong coefficient weights for gender include e.g. *boxers, shaved, girlfriend, beard, fightin* for males, and *purse, blueberry, pedicure, hubby, earrings* for females. It is therefore not a surprising result that models explicitly tasked to *minimize* the performance of such classifiers perform what we will refer to as obfuscation-by-transfer. To illustrate, the adversary is easily fooled when a sentence looks strongly female even though it was written by a male. As such, the easiest route to obfuscation from this perspective is a form of style-transfer: swapping a few strongly target-associated content words for their contrastive variant (*wife* to *husband*, *school* to *wedding*). When such variants are also close in semantic spaces that sequence models make use of, any reconstruction metrics—such as BLEU (Papineni et al., 2002), METEOR (Banerjee and Lavie, 2005), embedding distances, etc.—might become an inaccurate indication of the change in meaning.

Our contributions In this work we propose a different approach to automatic obfuscation that we hypothesize partly overcomes the limitations to preserving meaning of the input: obfuscation-by-invariance. Here, the objective shifts towards maximizing adversary's *uncertainty*, implying its accuracy on the protected variable should be as close to chance level as possible. Fixing the adversary's performance around chance involves making the input text devoid of stylistic features that strongly correlate with any of the protected variables, thus producing language that is neutral with respect to these style differences. We test our hypothesis in several experimental conditions.[2] The main component in our encoder-decoder architecture to achieve a style-invariant encoding of the input is a Gradient Reversal Layer (GRL) (Ganin and Lempitsky, 2015) inserted between the input sentence embedding and the style classifier. We investigate the effect of this module in isolation, as well as in a style-invariant soft transfer setting by using a conditioned decoder. First, to gauge if this architecture can successfully decode from the style-invariant encoding—and what the effect on adversary performance would be—we train sequence-to-sequence models on a parallel corpus of English Bible styles. Secondly, given that in a realistic obfuscation setting there is no access to such parallel sources, we drop the target pairs to create an autoencoder setting. In our experiments, we demonstrate a trade-off around chance-level performance: obfuscation-by-transfer in a parallel setting works well using a many-to-many translation model, but scores worse in the human evaluation than our style-invariant model. As such, we pose that there is potential in an style-invariant approach to obfuscation, and it deservers further investigation.

2 Related Work

2.1 Adversarial Stylometry

The idea that computational stylometry might be used to compromise anonymity was first explored by Rao et al. (2000). They saw potential in concealing style information using machine translation (MT), but noted that it was not powerful enough at the time. Kacmarcik and Gamon (2006) continued the proposed line of work by informing users regarding characteristic features and deeper linguistic cues in their writing style. Recent related studies can be found in (Caliskan-Islam et al., 2015; Le et al., 2015). Brennan et al. (2012) explicitly frame obfuscation as an adversarial task and use MT (round-trip translation), similar to (Caliskan and Greenstadt, 2012). Rule-based perturbations (Juola and Vescovi, 2011) and mixtures of both (Karadzhov et al., 2017) have also been applied for fully automatic obfuscation. Closest to our approach is recent work by Shetty et al. (2017), who pursue the task of learning obfuscation-by-transfer using a Generative Adversarial Network architecture. In their setup, a generator is trained to produce sentences that maximize the probability assigned by a discriminator that is, in turn, trained to distinguish real from generated sentences. While they incorporate different semantic losses, and demonstrate successful obfuscation on age and gender annotated micro-blog data and political

[2] All code and data to fully replicate the experiments is available at `github.com/cmry/style-obfuscation`.

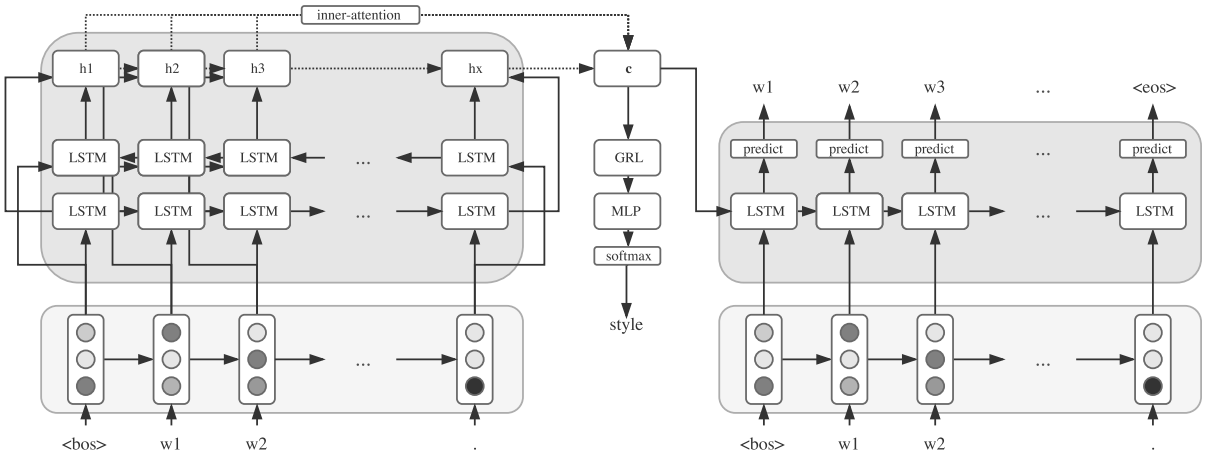

Figure 1: Model architecture with the Gradient Reversal Layer (GRL) module: Left the encoder part, middle the GRL taking the input sentence embedding (also called context vector) **c** as input, and right the decoder part of the architecture. Note that via the GRL working on the context vector, the encoder part of the model tries to minimize the style classification performance of the MLP, whilst still having to produce a useful representation for the decoder.

speeches, their output suffers from the lack of semantic preservation we described before. Finally, a style-transfer approach with potential application to obfuscation is work by Carlson et al. (2017), who investigate textual zero-shot style-transfer using a sequence-to-sequence MT model inspired by zero-shot translation (Johnson et al., 2016). Their work demonstrates successful translation between many different versions of the English Bible.

2.2 Gradient Reversal

The use of a Gradient Reversal Layer (GRL) for learning domain invariant feature representations was proposed by Ganin and Lempitsky (2015), who demonstrated its viability for learning lightning-condition invariance in computer vision. Since then, it has been applied to several language tasks: e.g. textual feature extraction (Pryzant et al., 2017), POS tagging (Kim et al., 2017; Gui et al., 2017), image captioning (Chen et al., 2017), and document classification (Liu et al., 2017; Xu and Yang, 2017). Most importantly, Xie et al. (2017) demonstrate the GRL module can be used to implement an adversarial setting, and to improve performance for a number of language tasks, including generation. These results bode well for its application to obfuscation-by-invariance.

3 Models

Our base architecture is a neural encoder-decoder (Sutskever et al., 2014) model similar to that of Wu et al. (2016), implemented in PyTorch (Paszke et al., 2017). Given an input sequence of one-hot encoded words, the encoder first embeds the words into dense vectors which are then processed by one or more bidirectional (Schuster and Paliwal, 1997) layers with LSTM cells (Hochreiter and Schmidhuber, 1997). The resulting sequence of processed vectors is then merged into a single dense representation using an inner-attention mechanism that will be described below. After encoding, a neural language-model is trained to decode the output sequence conditioned on the sentence embedding (a so called context vector) resulting from the encoder. Training is accomplished by minimizing the locally-normalized per-word cross-entropy of the target sequence.

In an autoencoder setting, the goal of the network is to simply reconstruct the original sentence based on the encoded context vector (Lauly et al., ; Li et al., 2015). This set-up can be combined with the GRL to encourage the encoder to produce attribute-invariant context vectors. The target is the input itself in the case of an autoencoder (AE) architecture, or a paired sentence in the case of a sequence-to-sequence (S2S) architecture. See Figure 1 for a visual representations of the base architecture.

3.1 Architecture Components

In addition to the architecture described above, we introduce a few extra components:

Gradient Reversal Layer (GRL) The GRL (Sutskever et al., 2014) is applied on top of the context vector. During the forward pass the GRL computes the identity function and feeds its input to a shallow Multi-Layer Perceptron (MLP) style classifier. However, during back-propagation the gradient of the style classifier is flipped in sign. The idea is that the encoder parameters are optimized to generate sentence embeddings that do not contain any stylistic information so that the style of the input cannot be recovered.

Conditional Decoder (C) Previous research on neural language modelling has demonstrated the effectiveness of conditioning a language model on sentential and contextual variables (such as tense, modality or voice). In our experiments, we evaluate a conditional autoencoder in which the decoder is conditioned on the input style label. We implement conditioning following the approach by Ficler et al. (2017), which simply concatenates the corresponding attribute embedding vector (in our case, the corresponding style embedding) to each of the word embeddings input to the decoder. Each style is therefore associated with an embedding vector $\mathbf{c}$, which is fed into the architecture at each step. In contrast to the simple autoencoder, the conditional autoencoder allows to choose a desired style at test time. We suspect that by encouraging the decoder to target a certain style, the output would be have more linguistic consistency without fully recovering the targeted style.

Token Transfer (TT) It can be argued that an MT system relying on a parallel corpus of styles (be it attributes or authors) would perform obfuscation-by-transfer. Moreover, it would likely preserve the original meaning as translation is largely a meaning-preserving operation (Ide et al., 2002; Dyvik, 2004). However, such parallel corpora are generally not available and have very high associated compilation costs, as it would require large amounts of identical information (ideally on sentence-level) to be written by e.g. teens and adults. Textual style transfer by MT is therefore not a plausible use-case for obfuscation. However, it does provide a good indication of the performance of an obfuscation model under the framework of obfuscation-by-transfer. For this, we apply a sequence-to-sequence translation model trained on style as discussed by (Carlson et al., 2017). Following the work of (Johnson et al., 2016), we use a target style token, allowing for a model trained on many-to-many translation that can be used to rewrite an input sentence in a different style simply by prepending a target token. This is the only configuration that uses an attention mechanism as it is not tested in combination with the GRL.

3.2 Architecture Details

All our models use 300-dimensional embeddings. Both the encoder and the decoder are implemented with a single layer of 1000 LSTM cells. The sequence of hidden states from the encoder are merged into a single representation using a feature-wise inner-attention mechanism. Let w_t and h_t denote respectively the input word embedding and hidden state of the LSTM for step t for a total of n total steps. The i^{th} feature of the sentence embedding c is computed by a weighted sum over the i^{th} feature of the hidden states:

$$c_i = \sum_{t=1}^{n} a_i^t h_i^t \tag{1}$$

where each weight a_i^t is computed by:

$$a_i^t = \frac{\exp([W^T z^t]_i)}{\sum_{s=1}^{n} \exp([W^T z^s]_i)} \tag{2}$$

In Equation 2, z_t is the concatenation of w_t and h_t, $W \in \mathbb{R}^{(D+H)\times H}$ is an additional projection matrix to be learned, and D and H denote the dimensionalities of the word embedding matrix and the LSTM layer respectively. In comparison to traditional merging models (such as max or mean pooling), the additional parameters help the model to learn what input words and what features are more important for

the task. This is similar to conventional attention over hidden activation vectors with the main difference being that weighting is done feature-wise and all information flow from the encoder to the decoder is passed through the bottleneck of the single output encoding vector. Note that a traditional alignment-style attention mechanism is not compatible with the application of the GRL, since the latter must have scope over all information being passed from the encoder to the decoder.

The decoder is conditioned on the context vector by concatenating the latter to the input of the decoder at each step. This facilitates learning by increasing the gradient signal to the encoder. All model parameters are optimized with Adam (Kingma and Ba, 2014) in mini-batches of 50 examples and a learning rate of 0.001 which is decreased by 0.75 after each epoch. To avoid overfitting, dropout (Srivastava et al., 2014) is applied to the input of each LSTM layer with a dropping probability of 0.25 and we stop training when loss stops decreasing for 3 epochs. During test time, we approximate the global best output sequence applying beam search with a beam of size 5. GRL is implemented with a single-layer MLP with same dimensionality as the encoder.

4 Experimental Set-up

Our main goal is investigating the effectiveness of obfuscation-by-invariance, and more specifically to what extent style-invariant representations preserve sentential semantics of the input. To this end, we perform three experiments for different corpora and obfuscation settings, using the components described above. In each of these settings, there is an adversary trained to detect the variable to be obfuscated. We describe our experiments and evaluations below.

4.1 Data

We use a parallel corpus of five different versions of the English Bible (retrieved from GitHub[3], originally collected from `openbible.info`[4]). These versions are semantically consistent, but vary stylistically across different aspects; BBE is written in simplified English, YLT follows the syntactic structures of the original Greek and Hebrew, and other versions (DBY, ASV) correspond to older editions reflecting diachronic variations. The sentence-level verse coding (book + chapter + verse ID) is used for almost perfect pairing between the different versions (some missing pairs were removed), forming style quintuplets, which were tokenized using `spaCy`[5] (Honnibal and Montani, 2017). The style tuples are divided amongst train (80%), dev (10%), and test (10%) sets—ensuring all sentences in the development and test splits are unseen, regardless of the style combination that they occur in—and all style combinations

[3] `https://github.com/scrollmapper/bible_databases`
[4] `http://www.openbible.info/labs/cross-references/`
[5] `https://spacy.io/`

(excluding a same-style combination) are used to form 620,752 pairs. Further corpus descriptives for the different styles can be found in Figure 2 and Table 1.

4.2 Adversary

The adversary is a sentence-level classifier in the form of `fastText`[6] (Joulin et al., 2017); a simple linear model with one hidden embedding layer that learns sentence representations using bag of words or n-gram input, producing a probability distribution over the given styles using the softmax function. The classifier is trained on the source side of the training split, as these are the instances we intend to obfuscate. It is run for 20 epochs using 100 dimensional embeddings, uni and bi-grams, a learning rate of 0.01, and a bucket size of 1M. It achieves an accuracy of 86.6%, and chance level performance for the adversary is 20% given 5 classes with an even distribution.

4.3 Evaluation

To automatically evaluate the reconstruction and semantic preservation of our generated sentences, we use MT metrics, as well as distance in semantic embedding space. Obfuscation is measured by the difference of the adversary's accuracy compared to chance level.

MT Metrics (BLEU, METEOR) We calculate BLEU-4 and METEOR (Papineni et al., 2002; Banerjee and Lavie, 2005) using `nlg-eval`[7]. Given that this is not a standard MT task, we provide these scores between the generated sentence and the source sentence ($\leftarrow$), as well as the generated sentence and the target sentence ($\rightarrow$). For the sequence-to-sequence models, $\rightarrow$ is the primary indicator of successful obfuscation-by-transfer. However, $\leftarrow$ gives some indication how much the output is still related to the original. Introducing the GRL to this models should decrease scores for both $\leftarrow$ and $\rightarrow$. For the autoencoder, evaluation can only be conducted on $\leftarrow$, for which scores should generally strongly decrease when adding the GRL.

Word Mover's Distance (WMD) To assess the word embedding distance of the obfuscated sentence to the original, we take the Word Mover's Distance (WMD) (Kusner et al., 2015), based on the English `fastText` embeddings for Wikipedia (Bojanowski et al., 2016). WMD takes the distance between two sentences in a weighted point cloud of embedded words as the minimum cumulative distance that this cloud for sentence A needs to travel to align with that of sentence B, and is shown to capture some semantic relations.

Adversary Impact (Δ acc) We compare the accuracy of the adversary on the generated sentence to that of the original to assess obfuscation strength. However, as our goal is to keep the adversary's performance level close to chance, we define Δ accuracy $=$ accuracy $- p$ where p is majority baseline. Therefore, if Δ accuracy is negative, this means the adversary's performance has dropped below chance, and the task is closer to obfuscation-by-transfer rather than by-invariance. Subsequently, a positive score indicates the extent to which obfuscation fails to match both cases.

Gaussian Noise (σ) To enforce a significant change in the decoded output, one can simply add a Gaussian noise mask to the context vector during generation time. We generate this mask as a random vector from a Gaussian Distribution $N(0, \sigma)$, where $\sigma = \{0.01, 0.05, 0.10, 0.15, 0.20\}$ and add this to the values of the context vector. This noise can be utilized to increase obfuscation (due to more random decoding behaviour) at the cost of quality of the output.

4.4 Experiments

Using all components discussed above, we define three experimental settings to measure the effect of applying a GRL and conditional decoder to achieve obfuscation-by-invariance. (**1**) We train our architecture on the style pairs from the English Bible corpus in a many-to-many sequence-to-sequence setting. By introducing a GRL here, words that are highly indicative of the target style are not captured by the

model	C	GRL	TT	PPL	BLEU ←	MTR ←	BLEU →	MTR →	WMD	Δ ACC
S2S				9.08	22.0	25.3	17.8	23.6	1.50	1.6
S2S		x		9.27	21.8	25.2	16.9	22.9	1.50	6.9
S2S			x	7.38	34.9	30.5	39.2	29.9	1.24	-12.0
AE				1.51	79.5	52.9	-	-	0.25	64.4
AE		x		1.99	60.0	41.2	-	-	0.65	50.8
AE	x	x		1.87	51.9	38.1	-	-	0.79	18.3
source					100.0	100.0	36.0	34.5	0.00	66.6

Table 2: Results for the Bible experiments. The first column (model) indicates the setting of our base architecture: either sequence-to-sequence (S2S), or autoencoder (AE). The second column specifies which modules were incorporated: C for the conditioned decoder, GRL for the Gradient Reversal Layer, and `tt` for the prepended style token. The results show perplexity on the dev set (PPL), BLEU-4 and METEOR between source (←) / target (→) and the obfuscated sentence, the Word Mover's Distance score between source and the obfuscated sentence (WMD) and the extent to which the obfuscated sentence pushes the adversary to chance level performance (Δ ACC). In the last row, we note a 'source' baseline, that is achieved by simply copying the source. This shows how overall how much source and target overlap, and the actual above-chance performance of the adversary.

encoder. To achieve an effective many-to-many MT system (and thus style-transfer) setting we prepend the <2{stylename}> token. (**2**) We train an autoencoder on disconnected pairs. Here we introduce both the GRL, plus the conditioned decoder. We hypothesize that the conditioned decoder allows for soft style-transfer from a neutral encoding, implying it would preserve semantic structure better than the MT model. (**3**) We use Gaussian noise to make the sequence-to-sequence and autoencoder models equivalent in obfuscation performance to allow for direct comparison.

5 Results

5.1 Experimental Results

All results and automatic evaluations are shown in Table 2. As we hypothesized, using style-transfer for obfuscation works well overall, performing either at, or below chance level. Looking at the target BLEU and METEOR, the sequence-to-sequence model without the target token generates sentences that are closer to source than they are to the target; and achieves low scores overall, with the sentences being quite far off based on WMD. However, note that this is many-to-many translation without any signal regarding the target, given languages with largely the same vocabulary. As such, TT is a more realistic reflection of style-transfer success. In terms of translation quality it barely improves over the original baseline, but it does successfully perform obfuscation-by-transfer, as indicated by the 12% accuracy below chance. Assessing the performance of the GRL in this setting, it does not seem improve translation, nor obfuscation — which was largely in line with our expectations.

The autoencoder setting provides a clearer look into the performance of the GRL, in particular in terms of obfuscation-by-invariance. The plain autoencoder to some extent successfully reproduces the target; looking at BLEU, the adversary performance, and WMD, it is still closely related to the input. Introducing the GRL does impact the relation to the source sentence, but gains little in comparison on obfuscation performance. However, when the conditioned decoder is added to the architecture, obfuscation performance is visibly impacted more than the decrease in BLEU and METEOR. Lastly, the effect of adding a Gaussian noise mask on the decoder can be found in Table 3. Around 0.15, the metrics seem to be largely comparable in terms of BLEU, METEOR and Δ accuracy. We further investigate the three most suitable models (S2S + TT, AE + GRL + C, and AE + GRL + C + $\sigma = 0.15$) in a human evaluation.

	SEMANTICS	GRAMMATICALITY	CHANGES
1	Semantics are broken; sentence does not mean the same.	Part(s) of, or the complete sentence is garbled.	Change in special characters or flipping a single word.
2	Slight semantic change, but not intrusive.	Slight word order change that is ungrammatical.	Multiple words were changed, but they align with the original.
3	Semantics are intact, changes do not alter the meaning.	Grammaticality has not been affected.	New parts have been introduced / rewritten in the sentence.

Table 4: Explanations per rating for the three dimensions in the human evaluation study.

	SEMANTICS	GRAMMATICALITY	CHANGES
S2S + TT	1.88	2.21	2.43
AE + GRL + C	2.12	2.32	1.99
AE + GRL + C + $\sigma = 0.15$	1.35	1.66	2.65

Table 5: Average scores per model for the three dimensions in the human evaluation.

5.2 Human Evaluation

For the human evaluation, 20 pairs (original, obfuscated) were sampled from the output of the three models of interest (making 60 pairs in total). Each pair was rated by four participants (all with a linguistics background), on three dimensions using a three point scale. These dimensions included semantic consistency between the original and the obfuscated sentence, the syntactical coherence of the latter, and the amount of changes in the output. The participants were made aware of which sentence of the pairs was the original, and were explicitly asked to rate the dimensions with the original as reference. The participants were not aware that there were multiple models, and the pairs were shuffled so that comparing between pairs with the same original was impossible. To simplify the comparison to the original, we only sampled from BBE (Basic English Bible). See Table 5 for a sample of the instructions given to the participants, and Table 4 for the results.

According to the evaluation results, AE + GRL + C has the overall preference of the raters in all three dimensions. Specifically, given that we are interested in semantic preservation, this model is evaluated better than a style-transfer model that has some access to semantic relations between source and target on the SEMANTICS dimension. Note that based on the CHANGES dimension, the AE + GRL + C is the most conservative, which is in line with the BLEU and METEOR scores in Table 2, and likely propagates into the GRAMMATICALITY dimension.

5.3 Qualitative Analysis

In this section we perform a comparison of the behaviour, and the text generated by the three models that were evaluated by our raters in the previous section. Accordingly, we will identify the strengths and weaknesses of our experimental approach, and propose possible lines of future work.

ORIGINAL	For the strong town is without men, an unpeopled living - place; and she has become a waste land: there the young ox will take his rest, and its branches will be food for him.
S2S + TT	For the strong city is powerless, an astonishment living and she is become a corrupt land: a young ox shall rest, and its branches shall be for him.'
AE + GRL + C	For the city is without living men, there is without a waste land; and she makes an dry land: an ox shall take his work, and their branches shall be food for him.
AE + GRL + C + $\sigma = 0.15$	A man dwelleth without an dry land; and, wandering she - place; men shall there become a waste a land: an ox - goat shall take his horses, and his branches shall be prepare for him .

Table 6: Example 1 — Isaiah 27:10

ORIGINAL	Then they made the beryl stones, fixed in twisted frames of gold and cut like the cutting of a stamp, with the names of the children of Israel.'
S2S + TT	Then they made the onyx stones as a hundred stones, burning in engraved stones of gold, and cut as the marks of a seal, with the names of the children of Israel.
AE + GRL + C	Then they wrote the stones, whereupon they bound in the skillfully woven red frames of gold and made like the cutting of a stamp, with the names of the children of Israel.'
AE + GRL + C + $\sigma = 0.15$	Then they presented the pillars that belonged in Henadad. The bottom of fine gold and made like the jewels of a stamp of them, at the dial of the children of Israel.'

Table 7: Example 2 — Exodus 39:6

One of the issues we identified with obfuscation-by-transfer was that of small, localized changes in the input, specifically focussing on words that are most relevant to the adversary. When looking at longer sentences such as Table 6, some (semi-)correct variants can be found in e.g. town → city, waste land → dry land, and in Table 7, beryl → onyx, stamp → seal, but incorrect ones also remain: rest → work. Overall, the longer the sequence, the more variation can be observed.

A more interesting observation is that some parts of sentences are added to by the models, e.g. *there is without a waste land ; and she makes an dry land* — while incorrectly inserting '*without*', the rest can be considered is a correct expansion. The same holds for Table 7, where *fixed in twisted frames of gold* is expanded to *whereupon they bound in the skillfully woven red frames of gold* , partly erroneously, similar to *living men* in Table 6. Contrastively, the autoencoder + GRL in particular also seems to favour somewhat compressed phrases, removing adjectives such as *young* in *young ox*, *strong* in *strong city*, *beryl* in *beryl stones* and not incorporating *an unpeopled living* altogether.

When directly comparing the sequence-to-sequence and autoencoder + GRL examples, it can be inferred that the transfer approach seems (at least in these examples) quite conservative, sticking to an almost exact alignment, and only making small changes. This however also causes the autoencoder to replace words with unrelated variants or insert not directly related ones; the same behaviour can also be observed in the sequence-to-sequence model, however.

The output of the autoencoder shows some evidence that minor *rewrites* of the sentence are employed, which could potentially be an interesting path to further pursue. Including different variables in the conditioned decoder such as sentence length, also demonstrated by Fickler et al. (2017), would make experiments in this direction feasible. Rewrites are not restricted to the autoencoder only, as is demonstrated in Figure 3. We previously noted in Section 5.2 that the AE + GRL + C architecture seems more conservative in changing the input, which can also clearly be induced from the generally equal or higher amount of newly introduced tokens by the S2 + TT model, and its many more outliers (some even ex-

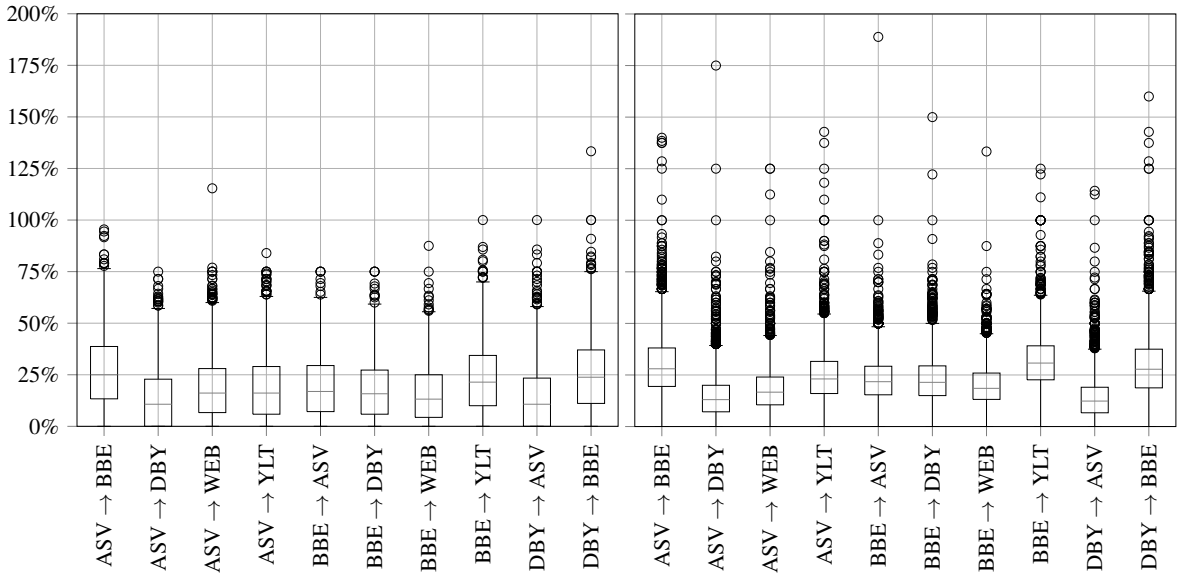

Figure 3: Distributions of the percentage of newly introduced tokens with respect to the original amount of tokens — shown for both the AE + GRL + C obfuscation-by-invariance architecture (left), and the S2S + TT obfuscation-by-transfer model (right). Three out of five source styles are shown.

ceeding the original amount of tokens). This plot also reveals a tendency to add more tokens for BBE and YLT, which is in line with their larger amount of tokens shown in Table 1. The extreme outliers are largely attributable to artefacts of recurrence (*and Benaiah , the son of Zadok , and Eber , and Eliphelet*).

Finally, it must be noted that evidence of style-neutral rewrites is difficult to find in generated output concerning the Bible; not only due to possible archaic constructions (which we attempted to minimize by using BBE), but more so due to the fact that it requires a level of expertise to recognize style shifts. However, most importantly, applying the autoencoder to data that is non-parallel has some viable ground given the current results, and can therefore be extended to other domains in future work.

6 Conclusion

We presented an alternative framing of the task of automatic style obfuscation—obfuscation-by-invariance—and tested several components in a neural encoder-decoder architecture that were hypothesized to achieve style-invariant rewrites of the input text. We tested the effect of a Gradient Reversal Layer and a conditioned decoder for obfuscation in parallel and non-parallel settings. Although strong evidence for style-neutral text was difficult to find for the Bible corpus, we demonstrated through human evaluation that our autoencoder architecture trained on non-parallel data obtained a better evaluation than a model trained on parallel data with partial access to semantic relations between source and target. In our qualitative analysis we found evidence for semantically correct local changes of the input, as well as partial rewrites that fit the context of the verses. These results bode well for extending this architecture to other non-parallel corpora to test obfuscation in a practical use-case, e.g. author attributes such as age and gender.

Abstract

General-purpose pre-trained word embeddings have become a mainstay of natural language processing, and more recently, methods have been proposed to encode external knowledge into word embeddings to benefit specific downstream tasks. The goal of this paper is to encode sentiment knowledge into pre-trained word vectors to improve the performance of sentiment analysis. Our proposed method is based on a convolutional neural network and an external sentiment lexicon. Experiments on four popular sentiment analysis datasets show that this method improves the accuracy of sentiment analysis compared to a number of benchmark methods.

1 Introduction

Sentiment analysis plays an important role in many real-world applications. The objective of sentiment classification is to classify a sentence, message or document according to sentiment, often in the form of ordinal regression (e.g. positive vs. neutral vs. negative). In recent years, deep neural networks, such as convolutional neural networks ("CNNs"), have been widely used for sentiment classification. A simple CNN trained over pre-trained word vectors has been shown to achieve highly competitive results (Kim, 2014). Learning task-specific vectors through fine-tuning may offer further gains in performance, and this is the primary focus of this paper.

Separately, there has been recent work on methods for learning word embeddings based not just on textual contexts, but also external knowledge bases (Wieting et al., 2015; Yu and Dredze, 2014; Xu et al., 2014; Bian et al., 2014; Faruqui et al., 2015; Mrkšić et al., 2016; Mrkšić et al., 2017; Vulić et al., 2017). This has also been applied to sentiment classification (Rouvier and Favre, 2016; Yu et al., 2017), with empirical results indicating that explicitly embedding sentiment resources can improve the performance of sentiment analysis.

Existing methods for encoding external knowledge into word vectors are generally trained independently of the downstream task. In order to leverage sentiment lexicons for sentiment analysis, we propose a novel method to combine a feedforward neural network (denoted "SentiNet") with a CNN classifier to encode sentiment knowledge into word vectors during training. The method tunes word vectors through the CNN and SentiNet, based on independent information from supervised training data and sentiment lexicons. Our hypothesis is that joint training of sentiment-targeted word embeddings should improve the overall accuracy of the resulting sentiment analyzer. We conduct several experiments to verify this hypothesis, and compare our method with competitor methods that use antonymy/synonymy lexicons and paraphrase databases.

The major contributions of this paper are as follows: (1) the sentiment lexicon is encoded into word vectors by a feedforward neural network instead of an objective function based on a fixed metric such as cosine similarity or Euclidean distance, and in doing so are able to dynamically learn how to encode the lexicon; (2) word vectors are fine-tuned based on supervised training data and the sentiment lexicon during the training of the CNN sentiment classifier; and (3) we achieve state-of-the-art accuracy over a range of benchmark sentiment analysis datasets.

2 Related Work

2.1 Encoding External Knowledge into Word Vectors

Existing approaches to leveraging external knowledge for word embedding learning for natural language processing fall into two categories: (1) encoding external knowledge during the word vector learning stage; and (2) encoding external knowledge into pre-trained word vectors. Both styles of approach make use of similar linguistic resources such as WordNet (Miller, 1995), FrameNet (Baker et al., 1998), the Paraphrase Database ("PPDB": Ganitkevitch et al. (2013)), or BabelNet (Navigli and Ponzetto, 2012).

Methods in the first category usually change the objective function of the language model or add regularization terms into the original objective function. Yu and Dredze (2014) combine CBOW (Mikolov et al., 2013) with word relations extracted from WordNet and PPDB. Xu et al. (2014) regard relational knowledge and categorical knowledge as learning regularizers, and combine them with the skip-gram objective function. Bian et al. (2014) also combine the objective function of CBOW with external syntactic and semantic knowledge to improve word vectors for extrinsic tasks. These methods all need large unlabeled corpora to learn word vectors from scratch.

In contrast, methods in the second category are lightweight because they adapt pre-trained word vectors via post-processing. This means these methods are compatible with different kinds of word vectors. Wieting et al. (2015) learn PARAGRAM word vectors by fine-tuning over paraphrase data from PPDB. The resultant embeddings outperform the baseline skip-gram embeddings over an extrinsic sentiment analysis task for low-dimensionality word embeddings. Faruqui et al. (2015) use synonym relations extracted from WordNet and other resources to construct an undirected graph. They then retrofit the undirected graph to pre-trained word vectors to obtain new word vectors, under the constraint that the resulting vectors should be close to the vectors of their neighbours in the semantic graph. Antonyms are generally close in vector space, presenting a problem when learning general-purpose word vectors (as in most scenarios, it is undesirable for antonyms to be closely related) (Mnih and Hinton, 2008; Collobert et al., 2011; Mikolov et al., 2013; Levy and Goldberg, 2014; Pennington et al., 2014). In order to solve this problem, antonym lexicons have been used to fine-tune pre-trained word vectors. Mrkšić et al. (2016) present a method called counter-fitting to inject antonymy and synonymy constraints into word vectors trained with GloVe (Pennington et al., 2014) and PARAGRAM (Wieting et al., 2015). The adapted word vectors trained with PARAGRAM achieve the second-highest SimLex-999 (Hill et al., 2015) score. Mrkšić et al. (2017) extend this previous work using negative sampling, to force synonym pairs to be closer to each other than to their negative examples, and forcing antonyms pairs to be further away from each other than from their negative examples.

Encoding external knowledge into word vectors has shown to be effective for improving pre-trained word vectors for intrinsic evaluation such as WordSim-353 (Finkelstein et al., 2002) and SimLex-999. It has also shown to be effective for improving extrinsic tasks such as dialogue state tracking (Mrkšić et al., 2016; Mrkšić et al., 2017; Vulić et al., 2017), sentiment analysis (Faruqui et al., 2015; Wieting et al., 2015; Yu et al., 2017), document classification (Kiela et al., 2015), and word sense disambiguation (Rothe and Schütze, 2015).

The above two kinds of methods both encode external knowledge into word vector space before applying word vectors in downstream tasks. Our method encodes a sentiment lexicon into word vectors when fine-tuning the word vectors in a downstream task.

2.2 Adapting Word Vectors for Sentiment Analysis

There are many methods of adapting word vectors for sentiment analysis. Maas et al. (2011) combine two components — a probabilistic document model and a sentiment component — to jointly learn word vectors. The probabilistic document model does not require labelled data. The sentiment component uses document-level sentiment annotations to constrain words expressing similar sentiment to have similar representations. Tang et al. (2014) changed the objective function of the C&W (Collobert et al., 2011) model to produce sentiment-specific word vectors for Twitter sentiment analysis, by leveraging large volumes of distant-supervised tweets. In order to capture morphological and shape information from words, dos Santos and Gatti (2014) concatenate character-level embeddings and word-level embeddings to form

a combined word representation for sentiment analysis. Severyn and Moschitti (2015) refine pre-trained word vectors through a CNN based on distant-supervised data. Zhou et al. (2016) introduced three kinds of word vectors as features into their sentiment classifier. One is general purpose, and the the other two are trained by leveraging sentiment information. However, their feature selection experiments indicate that the task-specific trained word vectors do not improve the performance of their system substantially. Ren et al. (2016) use a recursive autoencoder to learn topic-enhanced word vectors, based on the assumption that the same word can vary in sentiment according to topic. Rouvier and Favre (2016) proposed three kinds of word embeddings — lexical embeddings, part-of-speech embeddings, and sentiment embeddings — in order to train three CNN-based sentiment classifiers. The three classifiers are combined into a fusion model to make the final prediction.

Other methods regard sentiment information as a kind of external knowledge. They encode sentiment information into word vectors by using customized objective functions or introducing regularization terms into objective function of the language model. Yu et al. (2017) utilize a sentiment lexicon to re-rank the nearest neighbors in order to capture sentiment information. The refinement model is based on an objective function which calculates the distance among vectors, in order to adapt word vectors for sentiment analysis. Tang et al. (2016) build on their earlier method (Tang et al., 2014) for Twitter sentiment classification, by leveraging a sentiment lexicon instead of large volumes of distant-supervised Twitter data. Our method also leverages a sentiment lexicon to encode sentiment information into word vectors. The difference between our method and the methods proposed by Yu et al. (2017) and Tang et al. (2014) is that our method applies to word vectors directly via the word embedding layer of the neural network in the context of training a sentiment analyzer, rather than over pre-trained word vectors without explicit task-based training. Our method uses a feedforward neural network to encode sentiment information, as distinct from prior work, which has used cosine similarity or Euclidean distance in the objective function to model word embedding (dis)similarity.

3 Methods

Sentiment lexicons are considered to be a critical component of sentiment analysis. Such external knowledge resources — such as SentiWordNet (Baccianella et al., 2010) and the extended version of Affective Norms of English Words (E-ANEW: Warriner et al. (2013)) — are often used to provide more accurate information about the polarity of a word. Encoding sentiment knowledge into word vectors has been proven to be an effective way to enhance the performance of sentiment analysis.

3.1 Encoding Method

A high-level overview of methods for encoding external knowledge into word vectors for CNN classifiers is presented in Figure 1. Word vectors are used to initialize word embeddings in a CNN classifier. The parameters of the CNN and components for fine-tuning the word embeddings are learned based on supervised training data. The differences in approaches to encoding external knowledge into word vectors are indicated with dotted rectangles in Figure 1. There are three rectangles, representing the two categories of existing approaches described in Section 2.1, and our proposed method: (a) the first class of approach, where word vectors are trained based on external knowledge and unsupervised corpora from scratch; (b) the second class of approach, where pre-trained word vectors are fine-tuned based on external knowledge, and the fine-tuned word vectors are then used to initialize the word embeddings for a CNN classifier; and (c) our method, where we combine external knowledge with pre-trained word vectors during joint parameter training. The parameters of the "Embedding" component are therefore trained not only based on supervised training data, but also based on external knowledge.

Figure 2(a) illustrates the architecture of the CNN classifier proposed by Kim (2014). The input to the Embedding component is a document.[1] The Embedding component of the model outputs a real-valued matrix consisting of the word vectors representing the document. The CNN takes the matrix as input and predicts the sentiment class distribution of the document.

[1] In practice, a sentence in the original paper.

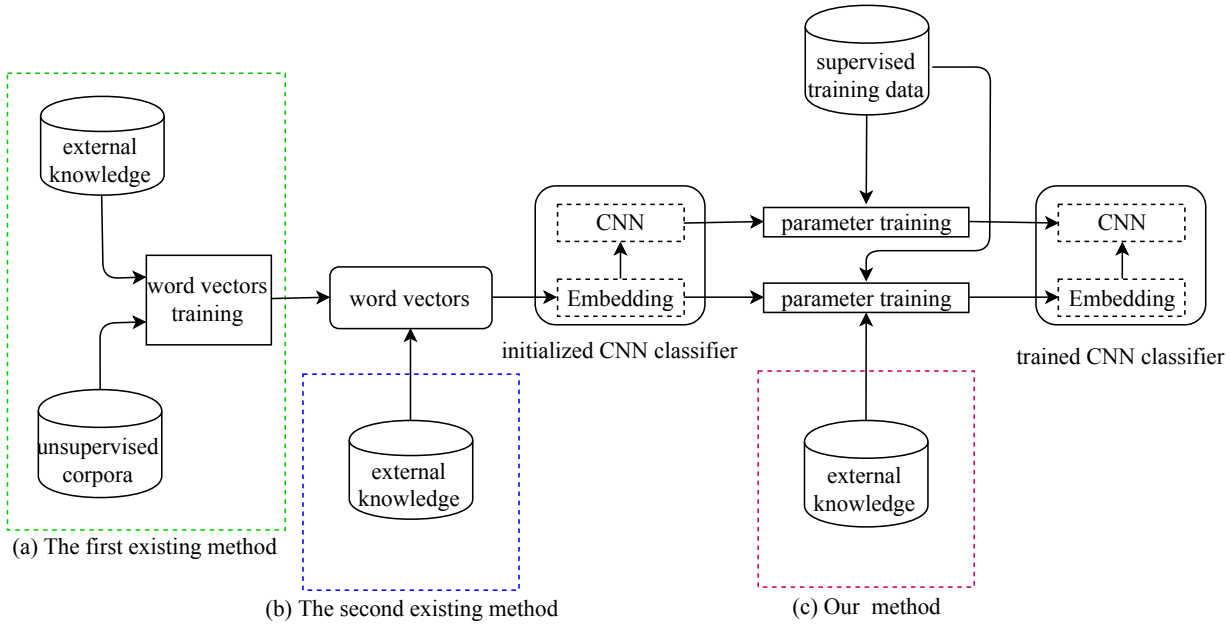

Figure 1: High-level overview of existing methods and our method of encoding external knowledge into word vectors.

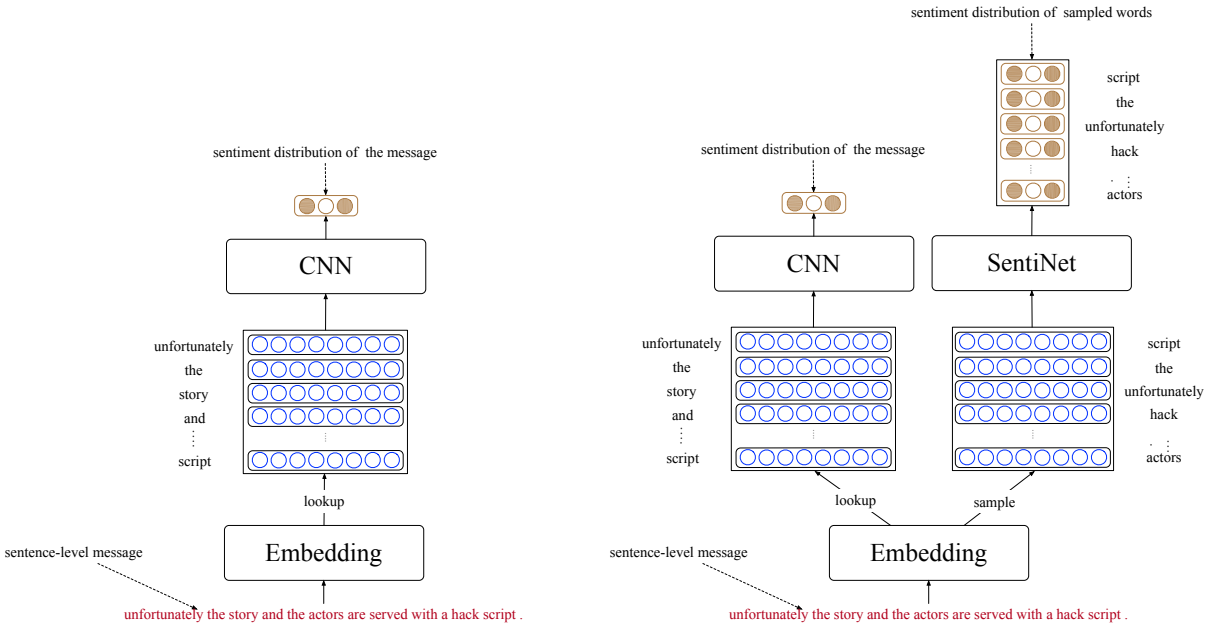

(a) CNN-non-static (b) Our framework with SentiNet based on CNN-non-static

Figure 2: The framework of CNN-non-static (Kim, 2014) vs. our method for encoding a sentiment lexicon into word vectors by SentiNet.

Figure 2(b) shows the architecture of our method. The Embedding component is initialized with pre-trained word vectors to train the CNN classifier, and a feedforward neural network called "SentiNet" is used to encode sentiment information from SentiWordNet into the word vectors. In Figure 2(b), the input to Embedding is a vector of words contained in the document, denoted by $[w_1, w_2, \ldots, w_N]$. Embedding outputs a real-valued matrix, $\boldsymbol{W} = [\boldsymbol{w}_1; \boldsymbol{w}_2; \ldots; \boldsymbol{w}_N]^\intercal$, which consists of the word vectors to represent the document. The CNN sentiment classifier takes the matrix as input and predicts the sentiment distribution of the document. Let $\boldsymbol{f}_m^h(\boldsymbol{W})$ and $\boldsymbol{f}_m^g(\boldsymbol{W})$ be the prediction and gold-standard

distribution of the document. The loss function of the CNN is:

$$\mathcal{L}_{\text{CNN}} = CE(\boldsymbol{f}_m^h(\boldsymbol{W}), \boldsymbol{f}_m^g(\boldsymbol{W}))\,, \tag{1}$$

where $CE(\cdot)$ is a scalar value representing the categorical cross-entropy between the prediction and the gold-standard sentiment distribution. The parameters of the CNN will be updated according to $\mathcal{L}_{\text{CNN}}$. M words are sampled from $[w_1, w_2, \ldots, w_N]$, denoted as $[w_{s_1}, w_{s_2}, \ldots, w_{s_M}]$ where $s_k \in [1, N]$ and $k \in [1, M]$. The word vectors of the sampled words are denoted as $[\boldsymbol{w}_{s_1}, \boldsymbol{w}_{s_2}, \ldots, \boldsymbol{w}_{s_M}]$. SentiNet uses the sampled word vectors to predict the word-level sentiment distribution based on SentiWordNet. Let $\boldsymbol{f}_w^h(\boldsymbol{w}_{s_k})$ and $\boldsymbol{f}_w^g(\boldsymbol{w}_{s_k})$ be the prediction and gold-standard sentiment distribution of the word w_{s_k}. The loss function for SentiNet is:

$$\mathcal{L}_{\text{SentiNet}} = \sum_{k=1}^{M} CE(\boldsymbol{f}_w^h(\boldsymbol{w}_{s_k}), \boldsymbol{f}_w^g(\boldsymbol{w}_{s_k}))\,. \tag{2}$$

The parameters of SentiNet are updated according to $\mathcal{L}_{\text{SentiNet}}$, and the parameters of Embedding are updated according to the combined loss $\mathcal{L}$:

$$\mathcal{L} = \mathcal{L}_{\text{CNN}} + \mathcal{L}_{\text{SentiNet}} \tag{3}$$

Instead of encoding external knowledge into word vectors and training the CNN sentiment classifier separately, the word vectors in our method are fine-tuned with not only the CNN, but also with SentiNet, where SentiNet is regarded as an indicator of word-level sentiment information. If the training of SentiNet converges, the word vectors are considered to have sentiment information.

3.2 SentiNet

Our SentiNet method uses a feedforward neural network with one hidden layer, distinct from previous work which has tended to use an objective function based on cosine similarity or Euclidean distance to capture word embedding similarity. SentiNet takes a word vector $\boldsymbol{w}_{s_k}$ as input, and outputs the sentiment distribution of the word, denoted as $\boldsymbol{f}_w^h(\boldsymbol{w}_{s_k})$. The calculation of the sentiment distribution of the word is based on:

$$\boldsymbol{f}_w^h(\boldsymbol{w}_{s_k}) = \text{softmax}(\boldsymbol{\theta}_2(\sigma(\boldsymbol{\theta}_1 \boldsymbol{w}_{s_k} + \boldsymbol{b}_1)) + \boldsymbol{b}_2)\,, \tag{4}$$

where $\boldsymbol{\theta}_1$, $\boldsymbol{\theta}_2$, $\boldsymbol{b}_1$ and $\boldsymbol{b}_2$ are trainable parameters, and σ is the sigmoid function. The reason for using a feedforward neural network is that it has the same structure as standard word embedding training models such as CBOW, skip-gram and C&W (see Section 2.1).[2]

4 Experiments

4.1 Experimental Setup

Experiments are conducted over four popular, publicly-available sentence-level sentiment classification datasets:

- SemEval2016: The dataset of the SemEval-2016 Message Polarity Classification task. The goal is to classify a given Twitter message according to positive, negative or neutral sentiment (Nakov et al., 2016).
- SemEval2017: The dataset of the SemEval-2017 Message Polarity Classification task. The task formulation is exactly the same as SemEval2016 and the same training data is used, with new test data (Rosenthal et al., 2017).

[2]When training SentiNet with a mini-batch sentences, the words of the mini-batch are classified into positive, neutral and negative according to their sentiment score in the sentiment lexicon. It takes two uniform sample steps to sample a word. First, the word kind (positive, neutral and negative) is sampled uniformly. Then a word is sampled uniformly from the words of the sampled word kind.

	Train			Dev			Test		
	Positive	**Neutral**	**Negative**	**Positive**	**Neutral**	**Negative**	**Positive**	**Neutral**	**Negative**
SemEval2016	9169	8098	4115	—	—	—	7059	10342	3231
SemEval2017	19902	22591	7840	—	—	—	2375	5937	3972
MR	5331	—	5331	—	—	—	—	—	—
SST-2	3610	—	3310	444	—	428	909	—	912

Table 1: Statistical breakdown of the four sentiment classification datasets used in this research.

- MR: Single-sentence movie reviews, labeled as having positive or negative sentiment (Pang and Lee, 2005).
- SST-2: A relabelled version of MR, where the overall review is labeled as having positive or negative sentiment (Socher et al., 2013).

Statistics for the four datasets are shown in Table 1. SemEval2016, SemEval2017 and SST-2 have standard training–test splits. MR does not have such a standard split, so we use 10-fold cross validation, consistent with other work on the dataset. We hold out 10% of the training data for SemEval2016, SemEval2017 and MR for development purposes (e.g. for early stopping), whereas SST-2 has a standard development partition. Consistent with standard practice for the respectivce datasets, we evaluate SemEval2016 and SemEval2017 based on macro-averaged F-score ("F1"), and MR and SST-2 based on classification accuracy.

The CNN sentiment classifier is based on the model proposed by Kim (2014). The differences are that: (1) the penultimate layer of our model is not regularized; and (2) we use the Adam optimizer (Kingma and Ba, 2014), whereas Adadelta (Zeiler, 2012) was used in the original. Hyperparameter tuning was performed over the SemEval2016 development data, based on which we use rectified linear units (ReLU), and a dropout rate of 0.5 on the penultimate layer. Three filter window sizes of 3, 4 and 5 are used, each of which contains 100 feature maps. These values are consistent with the hyperparameter settings of Kim (2014).[3]

4.2 Training Variations

We propose three settings for learning the parameters of Embedding, CNN and SentiNet. Learning all parameters together will lead to co-adaption of the parameters, degrading performance. The number of epochs is set to 100. We use the test result of the epoch with highest performance in dev data. The procedure for training the sentiment classifier is divided into two stages, each made up of 50 epochs. There are three variations according to the training time of Embedding and CNN, named BEFORE, DURING and AFTER, which are optionally integrated with the training of SentiNet:

- **BEFORE**: The parameters of Embedding are updated in the first stage (the first 50 epochs), and the parameters of CNN are updated in the second stage (the second 50 epochs).
- **BEFORE+SentiNet**: The parameters of Embedding and SentiNet are updated in the first stage, and the parameters of CNN are updated in the second stage.
- **DURING**: The parameters of Embedding and CNN are updated synchronously across both stages.
- **DURING+SentiNet**: The parameters of Embedding, SentiNet and CNN are updated synchronously across both stages.
- **AFTER**: The parameters of Embedding are updated in the second stage and the parameters of CNN are updated in the first stage.
- **AFTER+SentiNet**: The parameters of Embedding are updated in the second stage. The parameters of CNN and SentiNet are updated in the first stage.

Baseline (CNN + Embedding)	0.606	0.640	0.782	0.825
BEFORE	**0.607**	0.640	**0.786**	**0.831**
BEFORE+SentiNet	**0.609**	0.636	**0.788**	**0.834**
DURING	**0.608**	**0.646**	**0.789**	0.825
DURING+SentiNet	**0.610**	0.637	**0.794**	**0.840**
AFTER	**0.614**	**0.650**	**0.787**	**0.834**
AFTER+SentiNet	**0.616**	**0.651**	**0.794**	**0.837**

Table 2: Results of three variations with and without SentiNet. The evaluation metric in the second and third columns is Macro-averaged F-score, while the measurement in the fourth and fifth columns is accuracy. Above-baseline results are indicated in **bold**, and the best result over each dataset is underlined.

4.3 Results

Baseline system: The baseline system consists of Embedding and CNN. The parameters of Embedding are static during training.

Experimental results on the four sentiment classification datasets are reported in Table 2.[4] BEFORE+SentiNet performs better than BEFORE on SemEval2016, MR and SST-2 datasets. DURING+SentiNet performs better than DURING on SemEval2016, MR and SST-2 datasets. AFTER+SentiNet performs better than AFTER over all four datasets. These results show that SentiNet improves the performance of the CNN sentiment classifier. AFTER+SentiNet achieves the best performance on SemEval2016 and SemEval2017, while DURING+SentiNet achieves the best performance on MR and SST-2. AFTER+SentiNet performs better than DURING+SentiNet, as fine-tuning Embedding after CNN and SentiNet can avoid the co-adaption of parameters. BEFORE+SentiNet is the worst because CNN has not been trained when Embedding is tuned, meaning Embedding does not benefit from the task-specific supervised training data.

4.4 Comparison with Other Methods

Experimental setup: We compare our method with three existing methods for encoding external knowledge resources into word embeddings: (1) attract-repel (Mrkšić et al., 2017); (2) PARAGRAM (Wieting et al., 2015); and (3) counter-fitting (Mrkšić et al., 2016). We experiment with word embeddings generated by these three methods to initialize Embedding in our model. These embeddings encode different external knowledges. Embedding and CNN are jointly trained over the supervised training data. For our proposed method, we compare against AFTER+SentiNet and DURING+SentiNet, based on the results from Section 4.3.

The benchmark methods we compare our method against are as follows:

- **word2vec**: The 300 dimensional pre-trained word vectors based on Google News data, and distributed by Google.[5]

- **attract-repel-pos-neg**: The attract-repel[6] method of Mrkšić et al. (2017), which is used to encode the sentiment lexicon into word2vec word embeddings. The sentiment lexicon is the same as the one used in our method.

- **attract-repel-ant-syn**: The attract-repel method of Mrkšić et al. (2017) applied to word2vec word embeddings, based on antonym/synonym lexicons.

[4] Based on McNemar's test, the difference between AFTER-SentiNet and AFTER is significant for SemEval2016 ($p < 0.05$) and SST-2 ($p < 0.01$), but not SemEval2017 or MR ($p > 0.05$).

SENSEI-LIF (Rouvier and Favre, 2016)	0.630	—	—	—
UNIMELB (Xu et al., 2016)	0.617	—	—	—
BB_twtr (Cliche, 2017)	—	0.685	—	—
CNN-non-static (Kim, 2014)	—	0.685	—	—
Re(word2vec) (Yu et al., 2017)	—	—	—	0.879

Table 3: Experiment results of word vectors on the four Sentiment Classification Datasets. The measurement of the second and third columns is Macro F1. The measurement of the fourth and fifth columns is Accuracy.

- **PARAGRAM**: The word vectors of PARAGRAM, generated by encoding PPDB into word2vec word embeddings, based on the pre-trained PARAGRAM word embedding set.[7]
- **counter-fitting**: The word vectors of counter-fitting, generated by encoding an antonym/synonym lexicon into PARAGRAM word vectors, based on the pre-trained word embedding set.[8]

Experimental Analysis: The results of the experiment are shown in Table 3. DURING+SentiNet and AFTER+SentiNet are the results of our method, run on the same sentiment lexicons as other methods.[9]

AFTER+SentiNet performs better than the other methods over all four datasets. The reason is that our word vectors encode not only sentiment information through SentiNet, but also propagate supervision signal from the sentiment analysis task. Comparing the same method with different external knowledge sources, the sentiment lexicon has greater utility than the antonym/synonym lexicon for sentiment classification. Counter-fitting and PARAGRAM outperform word2vec only on SST-2, and not the other three datasets.

The last 6 lines in Table 3 detail state-of-the-art results for the four datasets. SwissCheese (Deriu et al., 2016) leverages large amounts of distant-supervised data to train an ensemble of CNNs. SENSEI-LIF (Rouvier and Favre, 2016) trains three kinds of word embeddings: lexical embeddings, part-of-speech embeddings and sentiment embeddings, in order to train three CNN sentiment classifiers. The three classifiers are combined into a fusion model to make the final prediction. UNIMELB (Xu et al., 2016) consists of a soft-voting ensemble of a language model adapted to classification, a CNN, and a long-short term memory network (LSTM). BB_twtr (Cliche, 2017) also uses a large amount of unlabelled data to pre-train word vectors. It also ensembles CNNs and LSTMs to boost performance. All of these methods are based on ensembling classifiers to improve results, while our method uses a single classifier. Additionally, our CNN model is tuned based on the development data of SemEval2016, and not tuned to the respective datasets. In that sense, the results are highly encouraging, and there is every expectation that ensemble methods would benefit from the incorporation of the outputs of our model.

[8] https://github.com/nmrksic/counter-fitting/blob/master/word_vectors/counter-fitted-vectors.txt.zip

[9] In Table 2, the whole vocabulary of pre-trained word2vec is used, whereas in Table 3, we use the intersection of the vocabulary for word2vec, attract-repel-pos-neg, attract-repel-ant-syn, PARAGRAM and counter-fitting. As such, the results are not directly comparable.

5 Conclusion

In this paper, we have proposed a novel method for encoding a sentiment lexicon into word embeddings for sentiment analysis, based on a method we call SentiNet. SentiNet uses a feedforward neural network to lexically encode sentiment information, instead of using an objective function based on cosine similarity or Euclidean distance. Three variations — BEFORE+SentiNet, DURING+SentiNet and AFTER+SentiNet — were proposed to combine SentiNet with Embedding and CNN. Experiments on sentiment classification datasets show that DURING+SentiNet and AFTER+SentiNet are the most effective ways of combining the training of SentiNet with the training of Embedding and the CNN. Our method can combine sentiment information from the training data and the sentiment lexicon to fine-tune word vectors for sentiment classification. For sentiment classification, we have shown sentiment lexicons to have greater utility than antonym/synonym lexicons and paraphrase databases.

In future work, we plan to experiment with encoding other external lexical knowledge beyond sentiment lexicons, and to explore frameworks for encoding external knowledge into deep neural networks.

Abstract

Generating natural language requires conveying content in an appropriate style. We explore two related tasks on generating text of varying formality: monolingual formality transfer and formality-sensitive machine translation. We propose to solve these tasks jointly using multi-task learning, and show that our models achieve state-of-the-art performance for formality transfer and are able to perform formality-sensitive translation without being explicitly trained on style-annotated translation examples.

1 Introduction

Generating language in the appropriate style is a requirement for applications that generate natural language, as the style of a text conveys important information beyond its literal meaning (Hovy, 1987). Heylighen and Dewaele (1999) and Biber (2014) have argued that the formal-informal dimension is a core dimension of stylistic variation. In this work, we focus on the problem of generating text for a desired formality level. It has been recently studied in two distinct settings: (1) Rao and Tetreault (2018) addressed the task of *Formality Transfer* (FT) where given an informal sentence in English, systems are asked to output a formal equivalent, or vice-versa; (2) Niu et al. (2017) introduced the task of *Formality-Sensitive Machine Translation* (FSMT), where given a sentence in French and a desired formality level (approximating the intended audience of the translation), systems are asked to produce an English translation of the desired formality level. While FT and FSMT can both be framed as Machine Translation (MT), appropriate training examples are much harder to obtain than for traditional machine translation tasks. FT requires sentence pairs that express the same meaning in two different styles, which rarely occur naturally and are therefore only available in small quantities. FSMT can draw from existing parallel corpora in diverse styles, but would ideally require not only sentence pairs, but e.g., sentence triplets that contain a French input, its formal English translation, and its informal English translation.

We hypothesize that FT and FSMT can benefit from being addressed jointly, by sharing information from two distinct types of supervision: sentence pairs in the same language that capture style difference, and translation pairs drawn from corpora of various styles. Inspired by the benefits of multi-task learning (Caruana, 1997) for natural language processing tasks in general (Collobert and Weston, 2008; Liu et al., 2015; Luong et al., 2016), and for multilingual MT in particular (Johnson et al., 2017), we introduce a model based on Neural Machine Translation (NMT) that jointly learns to perform both monolingual FT and bilingual FSMT. As can be seen in Figure 1, given an English sentence and a tag (formal or informal), our model paraphrases the input sentence into the desired formality. The same model can also take in a French sentence, and produce a formal or an informal English translation as desired.

Designing this model requires addressing several questions: Can we build a single model that performs formality transfer in both directions? How to best combine monolingual examples of formality transfer and bilingual examples of translation? What kind of bilingual examples are most useful for the joint task? Can our joint model learn to perform FSMT without being explicitly trained on style-annotated translation examples? We explore these questions by conducting an empirical study on English FT and

Proceedings of the 27th International Conference on Computational Linguistics, pages 1008–1021
Santa Fe, New Mexico, USA, August 20-26, 2018.

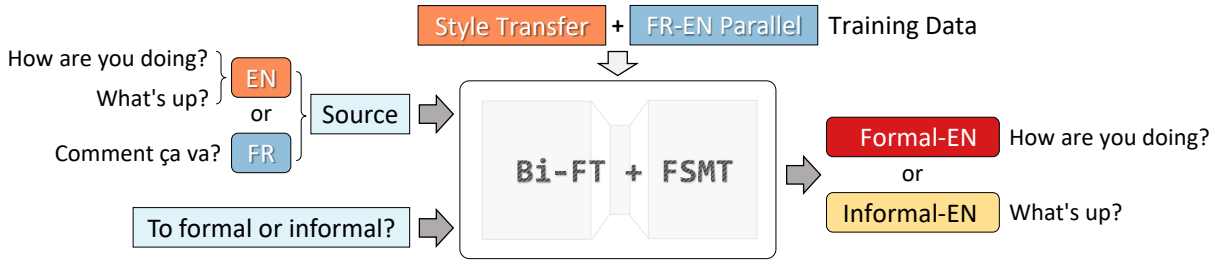

Figure 1: System overview: our multi-task learning model can perform both bi-directional English formality transfer and translate French to English with desired formality. It is trained jointly on monolingual formality transfer data and bilingual translation data.

French-English FSMT, using both automatic and human evaluation. Our results show the benefits of the multi-task learning approach, improving the state-of-the-art on the FT task, and yielding competitive performance on FSMT without style-annotated translation examples. Along the way, we also improve over prior results on FT using a single NMT model that can transfer between styles in both directions.

2 Background

Style Transfer can naturally be framed as a sequence to sequence translation problem given sentence pairs that are paraphrases in two distinct styles. These parallel style corpora are constructed by creatively collecting existing texts of varying styles, and are therefore rare and much smaller than machine translation parallel corpora. For instance, Xu et al. (2012) scrape modern translations of Shakespeare's plays and use a phrase-based MT (PBMT) system to paraphrase Shakespearean English into/from modern English. Jhamtani et al. (2017) improve performance on this dataset using neural translation model with pointers to enable copy actions. The availability of parallel standard and simple Wikipedia (and sometimes additional human rewrites) makes text simplification a popular style transfer task, typically addressed using machine translation models ranging from syntax-based MT (Zhu et al., 2010; Xu et al., 2016), phrase-based MT (Coster and Kauchak, 2011; Wubben et al., 2012) to neural MT (Wang et al., 2016) trained via reinforcement learning (Zhang and Lapata, 2017).

Naturally occurring examples of parallel formal-informal sentences are harder to find. Prior work relied on synthetic examples generated based on lists of words of known formality (Sheikha and Inkpen, 2011). This state of affairs recently changed, with the introduction of the first large scale parallel corpus for formality transfer, GYAFC (Grammarly's Yahoo Answers Formality Corpus). 110K informal sentences were collected from Yahoo Answers and they were rewritten in a formal style via crowd-sourcing, which made it possible to benchmark style transfer systems based on both PBMT and NMT models (Rao and Tetreault, 2018). In this work, we leverage this corpus to enable multi-task FT and FSMT.

Recent work also explores how to perform style transfer without parallel data. However, this line of work considers transformations that alter the original meaning (e.g., changes in sentiment or topic), while we view style transfer as meaning-preserving. An auto-encoder is used to encode a sequence to a latent representation which is then decoded to get the style transferred output sequence (Mueller et al., 2017; Hu et al., 2017; Shen et al., 2017; Fu et al., 2018; Prabhumoye et al., 2018).

Style in Machine Translation has received little attention in recent MT architectures. Mima et al. (1997) improve rule-based MT by using extra-linguistic information such as speaker's role and gender. Lewis et al. (2015) and Niu and Carpuat (2016) equate style with domain, and train conversational MT systems by selecting in-domain (i.e. conversation-like) training data. Similarly, Wintner et al. (2017) and Michel and Neubig (2018) take an adaptation approach to personalize MT with gender-specific or speaker-specific data. Other work has focused on specific realizations of stylistic variations, such as T-V pronoun selection for translation into German (Sennrich et al., 2016a) or controlling voice (Yamagishi et al., 2016). In contrast, we adopt the broader range of style variations considered in our prior work, which introduced the FSMT task (Niu et al., 2017): in FSMT, the MT system takes a desired formality level as

an additional input, to represent the target audience of a translation, which human translators implicitly take into account. This task was addressed via n-best re-ranking in phrase-based MT — translation hypotheses whose formality are closer to desired formality are promoted.

By contrast, in this work we use neural MT which is based on the **Attentional Recurrent Encoder-Decoder** model (Bahdanau et al., 2015; Luong et al., 2016). The input is encoded into a sequence of vector representations while the decoder adaptively computes a weighted sum of these vectors as the context vector for each decoding step.

In the joint model, we employ **Side Constraints** as the formality input to restrict the generation of the output sentence (Figure 1). Prior work has successfully implemented side constraints as a special token added to each source sentence. These tokens are embedded into the source sentence representation and control target sequence generation via the attention mechanism. Sennrich et al. (2016a) append <T> or <V> (i.e. T-V pronoun distinction) to the source text to indicate which pronoun is preferred in the German output. Johnson et al. (2017) and Niu et al. (2018) concatenate parallel data of various language directions and mark the source with the desired output language to perform multilingual or bi-directional NMT. Kobus et al. (2017) and Chu et al. (2017) add domain tags for domain adaptation in NMT.

3 Approach

We describe our unified model for performing FT in both directions (Section 3.1), our FSMT model with side constraints (Section 3.2) and finally our multi-task learning model that jointly learns to perform FT and FSMT (Section 3.3). All models rely on the same NMT architecture: attentional recurrent sequence-to-sequence models.

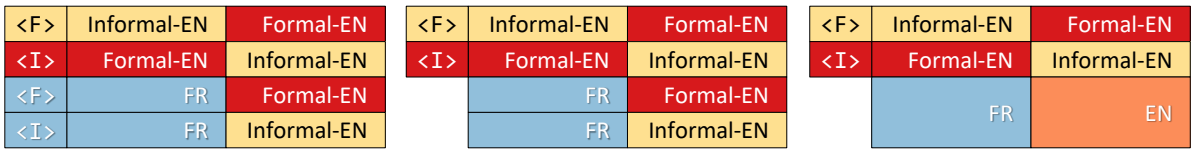
3.1 Bi-Directional Formality Transfer

Rao and Tetreault (2018) used independent neural machine translation models for each formality transfer direction (`informal`→`formal` and `formal`→`informal`). Inspired by the bi-directional NMT for low-resource languages (Niu et al., 2018), we propose a unified model that can handle either direction — we concatenate the parallel data from the two directions of formality transfer and attach a tag to the beginning of each source sentence denoting the desired target formality level i.e. <F> for transferring to formal and <I> for transferring to informal. This enables our FT model to learn to transfer to the correct style via attending to the tag in the source embedding. We train an NMT model on this combined dataset. Since both the source and target sentences come from the same language, we encourage their representations to lie in the same distributional vector space by (1) building a shared Byte-Pair Encoding (BPE) model on source and target data (Sennrich et al., 2016b) and (2) tying source and target word embeddings (Press and Wolf, 2017).

3.2 Formality-Sensitive Machine Translation with Side Constraints

Inspired by Sennrich et al. (2016a), we use side constraints on parallel translation examples to control output formality. At training time, this requires a tag that captures the formality of the target sentence for every sentence pair. Given the vast range of text variations that influence style, we cannot obtain tags using rules as for T-V pronoun distinctions (Sennrich et al., 2016a). Instead, we categorize French-English parallel data into formal vs. informal categories by comparing them to the informal and formal English from the GYAFC corpus.

We adopt a data selection technique, Cross-Entropy Difference (CED) (Moore and Lewis, 2010), to rank English sentences in the bilingual corpus by their relative distance to each style. First, we consider formal English as the target style and define $CED(s) = H_{formal}(s) - H_{informal}(s)$, where $H_{formal}(s)$ is the cross-entropy between a sentence s and the formal language model. Smaller CED indicates an English sentence that is more similar to the formal English corpus and less similar to the informal English corpus. We rank English sentences by their CED scores and select the top N sentences (choice of N discussed in Section 6). Pairing these N English sentences with their parallel French source, we get the formal sample of our bilingual data. Similarly, we construct the informal sample using informal English as the target style. Finally, we combine the formal and the informal samples, attach the <F> and <I>



(a) Formality tags on bilingual data + 2-Style selection

(b) No formality tags on bilingual data + 2-Style selection

(c) No formality tags on bilingual data + Random selection

Figure 2: The training data used for multi-task learning models. The bi-directional formality transfer data and the bilingual data (e.g. FR-EN) of equivalent size are always concatenated.

tags to corresponding source French sentences (i.e. the bottom two rows of data in Figure 2a) and train an NMT model for our FSMT task.

3.3 Multi-Task Learning

We propose a multi-task learning model to jointly perform FT and FSMT using a many-to-one (i.e. multi-language to English) sequence to sequence model (Luong et al., 2016). Following Johnson et al. (2017), we implement this approach using shared encoders and decoders. This approach can use existing NMT architectures without modifications. We design three models to investigate how to best incorporate side constraints at training time, and the benefits of sharing representations for style and language.

MultiTask-tag-style is a straightforward combination of the transfer and translation models above. We hypothesize that using the bilingual parallel data where English is the target could enhance English FT in terms of target language modeling, especially when the bilingual data has similar topics and styles. We therefore combine equal sizes of formality tagged training data (selected as described in Section 3.2) from our FT and FSMT tasks in this configuration (Figure 2a).

MultiTask-style is designed to test whether formality tags for bilingual examples are necessary. We hypothesize that the knowledge of controlling target formality for the FSMT task can be learned from the FT data since the source embeddings of formality tags are shared between the FT and the FSMT tasks. We therefore combine the formality tagged FT data with the MT data without their tags (Figure 2b).

MultiTask-random investigates the impact of the similarity between formality transfer and bilingual examples. Selecting bilingual data which is similar to the GYAFC corpus is not necessarily beneficial for the FSMT task especially when French-English bilingual examples are drawn from a domain distant from the GYAFC corpus. In this configuration, we test how well our model performs FSMT if bilingual examples are randomly selected instead (Figure 2c).

4 Experimental Setup

FT data: We use the GYAFC corpus introduced by Rao and Tetreault (2018) as our FT data. This corpus consists of 110K informal sentences from two domains of Yahoo Answers (*Entertainment and Music (E&M)* and *Family and Relationships (F&R)*) paired with their formal rewrites by humans. The train split consists of 100K informal-formal sentence pairs whereas the dev/test sets consist of roughly 5K source-style sentences paired with four reference target-style human rewrites for both transfer directions.

FSMT data: We evaluate the FSMT models on a large-scale French to English (FR-EN) translation task. Examples are drawn from OpenSubtitles2016 (Lison and Tiedemann, 2016) which consists of movie and television subtitles and is thus more similar to the GYAFC corpus compared to news or parliament proceedings. This is a noisy dataset where aligned French and English sentences often do not have the same meaning, so we use a bilingual semantic similarity detector to select 20,005,000 least divergent examples from ∼27.5M deduplicated sentence pairs in the original set (Vyas et al., 2018). Selected examples are then randomly split into a 20M training pool, a 2.5K dev set and a 2.5K test set.

Preprocessing: We apply four pre-processing steps to both FT and MT data: normalization, tokenization, true-casing, and joint source-target BPE with 32,000 operations for NMT (Sennrich et al., 2016b).

NMT Configuration: We use the standard attentional encoder-decoder architecture implemented in the Sockeye toolkit (Hieber et al., 2017). Our translation model uses a bi-directional encoder with a single

LSTM layer (Bahdanau et al., 2015) of size 512, multilayer perceptron attention with a layer size of 512, and word representations of size 512. We apply layer normalization and tie the source and target embeddings as well as the output layer's weight matrix. We add dropout to embeddings and RNNs of the encoder and decoder with probability 0.2. We train using the Adam optimizer with a batch size of 64 sentences and checkpoint the model every 1000 updates (Kingma and Ba, 2015). Training stops after 8 checkpoints without improvement of validation perplexity. We decode with a beam size of 5. We train four randomly seeded models for each experiment and combine them in a linear ensemble for decoding.[1]

5 Evaluation Protocol

5.1 Automatic Evaluation

We evaluate both FT and FSMT tasks using BLEU (Papineni et al., 2002), which compares the model output with four reference target-style rewrites for FT and a single reference translation for FSMT. We report case-sensitive BLEU with standard WMT tokenization.[2] For FT, Rao and Tetreault (2018) show that BLEU correlates well with the overall system ranking assigned by humans. For FSMT, BLEU is an imperfect metric as it conflates mismatches due to translation errors and due to correct style variations. We therefore turn to human evaluation to isolate formality differences from translation quality.

5.2 Human Evaluation

Following Rao and Tetreault (2018), we assess model outputs on three criteria: *formality*, *fluency* and *meaning preservation*. Since the goal of our evaluation is to compare models, our evaluation scheme asks workers to compare sentence pairs on these three criteria instead of rating each sentence in isolation. We collect human judgments using CrowdFlower on 300 samples of each model outputs. For FT, we compare the top performing NMT benchmark model in Rao and Tetreault (2018) with our best FT model. For FSMT, we compare outputs from three representative models: NMT-constraint, MultiTask-random and PBMT-random.[3]

Formality. For FT, we want to measure the amount of style variation introduced by a model. Hence, we ask workers to compare the source-style sentence with its target-style model output. For FSMT, we want to measure the amount of style variation between two different translations by the same model. Hence, we ask workers to compare the "informal" English translation and the "formal" English translation of the same source sentence in French.[4] We design a five point scale for comparing the formality of two sentences ranging from one being much more formal than the other to the other being much more formal than the first, giving us a value between 0 and 2 for each sentence pair.[5]

Fluency. For both FT and FSMT tasks, we want to understand how fluent are the different model outputs. Hence, we ask workers to compare the fluency of two model outputs of the same target style. Similar to formality evaluation, we design a five point scale for comparing the fluency of two sentences, giving us a value between 0 and 2 for each sentence pair.

Meaning Preservation. For FT, we want to measure the amount of meaning preserved during formality transfer. Hence, we ask workers to compare the source-style sentence and the target-style model output. For FSMT, we want to measure the amount of meaning preserved between two different translations by the same model. Hence, we ask workers to compare the "informal" English translation and the "formal" English translation of the same source sentence in French. We design a four point scale to compare the meaning of two sentences ranging from the two being completely equivalent to the two being not equivalent, giving us a value between 0 and 3 for each sentence pair.

[2] `https://github.com/EdinburghNLP/nematus/blob/master/data/multi-bleu-detok.perl`

[3] Note that we do not compare with the English reference translation. A more detailed description of the human annotation protocol can be found in the appendix.

[4] Evaluating which systems produces the most (in)formal output is an orthogonal question that we leave to future work.

[5] Details on the conversion from a five point scale to a value between 0 and 2 is in the appendix.

Model	Informal→Formal		Formal→Informal	
	E&M	F&R	E&M	F&R
PBMT (Rao and Tetreault, 2018)	68.22	72.94	33.54	32.64
NMT Baseline (Rao and Tetreault, 2018)	58.80	68.28	30.57	36.71
NMT Combined (Rao and Tetreault, 2018)	68.41	74.22	33.56	35.03
NMT Baseline	65.34	71.28	32.36	36.23
Bi-directional FT	66.30	71.97	34.00	36.33
+ training on E&M + F&R	69.20	73.52	35.44	37.72
+ ensemble decoding ($\times$4)	71.36	74.49	36.18	38.34
+ multi-task learning (MultiTask-tag-style)	**72.13**	**75.37**	**38.04**	**39.09**

Table 1: Automatic evaluation of Formality Transfer with BLEU scores. The bi-directional model with three stacked improvements achieves the best overall performance. The improvement over the second best system is statistically significant at $p < 0.05$ using bootstrap resampling (Koehn, 2004).

6 Formality Transfer Experiments

6.1 Baseline Models from Rao and Tetreault (2018)

PBMT is a phrase-based machine translation model trained on the GYAFC corpus using a training regime consisting of self-training, data sub-selection and a large language model.
NMT Baseline uses OpenNMT-py (Klein et al., 2017). Rao and Tetreault (2018) use a pre-processing step to make source informal sentences more formal and source formal sentences more informal by rules such as re-casing. Word embeddings pre-trained on Yahoo Answers are also used.
NMT Combined is Rao and Tetreault's best performing NMT model trained on the rule-processed GYAFC corpus, with additional forward and backward translations produced by the PBMT model.

6.2 Our Models

NMT Baseline: Our NMT baseline uses Sockeye instead of OpenNMT-py and is trained on raw datasets of two domains and two transfer directions.
Bi-directional FT: Our initial bi-directional model is trained on bi-directional data from both domains with formality tags. It is incrementally augmented with three modifications to get the final multi-task model (i.e. MultiTask-tag-style as described in Section 3.3): (1) We combine training sets of two domains (E&M+F&R) together and train a single model on it. (2) We use ensemble decoding by training four randomly seeded models on the combined data. (3) We add formality-tagged bilingual data and train the model using multi-task learning to jointly learn FT and FSMT. Suppose the amount of original bi-directional FT data is n, we always select kn bilingual data where k is an integer. We also duplicate FT data to make it match the size of selected bilingual data.

6.3 Results

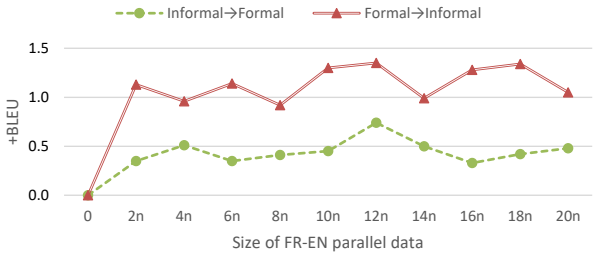
Automatic Evaluation. As shown in Table 1, our NMT baselines yield surprisingly better BLEU scores than those of Rao and Tetreault (2018), even without using rule-processed source training data and pre-trained word embeddings. We attribute the difference to the more optimized NMT toolkit we use.

Initial bi-directional models outperforms uni-directional models. This matches the behavior of bi-directional NMT in low-resource settings studied by Niu et al. (2018) — we work with a relatively small amount of training data ($\sim$50K), and FT models benefit from doubling the size of training data without being confused by mixing two transfer directions. For the same reason, increasing the training data by combining two domains together improves performance further. Ensemble decoding is a consistently effective technique used by NMT and it enhances our NMT-based FT models as expected.

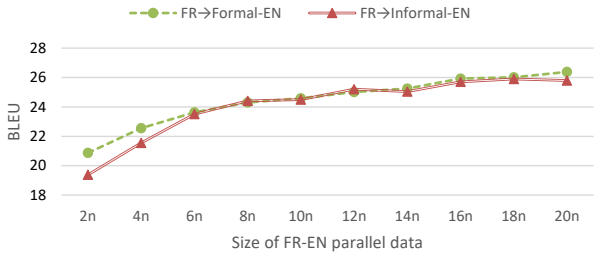
Incorporating the bilingual parallel data by multi-task learning yields further improvement. The target side of bilingual data is selected based on the closeness to the GYAFC corpus, so we hypothesize that the higher quality comes from better target language modeling by training on more English text.

	Model A	Model B	Formality Diff Range = [0,2]		Meaning Preservation Range = [0,3]
			I→F	F→I	
FT	Source	NMT Combined	0.54	0.45	2.94
	Source	MultiTask-tag-style	0.59	**0.64**	2.92
FSMT	NMT-constraint I	NMT-constraint F	**0.35**		2.95
	NMT MultiTask-random I	NMT MultiTask-random F	**0.32**		2.90
	PBMT-random I	PBMT-random F	0.05		2.97

Table 2: Human evaluation of formality difference and meaning preservation. MultiTask-tag-style generates significantly more informal (F→I) English than NMT Combined (p<0.05 using the t-test, see Section 6.3). PBMT-random does not control formality effectively when comparing its informal (I) and formal (F) output (Section 7.2). Formality scores are relatively low because workers rarely choose "much more (in)formal". All models preserve meaning equally well.



(a) BLEU improvements for formality transfer.



(b) BLEU scores for machine translation.

Figure 3: BLEU improvements or scores for four transfer/translation directions vs. the size of FR-EN parallel data. n in x-axis equals to the original size of bi-directional style transfer training data. Formality transfer improves with bilingual data and the performance converges quickly. The translation quality increases monotonously with the size of training data.

Human Evaluation. The superior performance of the best FT model (i.e. MultiTask-tag-style) is also reflected in our human evaluation (see Table 2). It generates slightly more formal English (0.59 vs 0.54) and significantly more informal English (0.64 vs 0.45) than NMT Combined. This is consistent with BLEU differences in Table 1 which show that MultiTask-tag-style yields bigger improvements when transferring formal language to informal. Both models have good quality with respect to meaning preservation (2.94 vs 2.92) and workers can hardly find any fluency difference between outputs of these two models by assigning 0.03 in average in the fluency test (0 means no difference).

Impact of Bilingual Data Size. We evaluate the impact of selected bilingual data size on the combination of development sets from two domains in GYAFC and show the results in Figure 3. The quality of formality transfer improves instantly when using bilingual data and it soon converges when more data is used. Meanwhile, the translation quality increases monotonously with the size of training data. The optimal point is a hyper-parameter that can be determined on the development set. We empirically choose $n = 12$ since it works best for formality transfer and yields reasonable translation quality.

6.4 Qualitative Analysis

We manually inspect 100 randomly selected samples from our evaluation set and compare the target-style output of our best model (MultiTask-tag-style) with that of the best baseline model (NMT-Combined) from Rao and Tetreault (2018). Table 3 shows some samples representative of the trends we find for `informal`→`formal` (3a) and `formal`→`informal` (3b) tasks.

In majority of the cases, the two models produce similar outputs as can be expected since they use similar NMT architectures. In cases where the two outputs differ, in the I→F task, we find that our model produces a more formal output by introducing phrasal level changes (first sample in 3a) or by moving

3a: informal→formal		
1	Original I	chill out sweetie everything will be just fine eventually
	NMT-Combined F	Can you chill out sweetie everything will be just fine eventually.
	MultiTask-tag-style F	Calm down, sweetie, everything will be fine eventually.
2	Original I	Dakota Fanning.....I know that she is only 12 but she is really famous.
	NMT-Combined F	Dakota Fanning.i know that she is only twelve, but she is famous.
	MultiTask-tag-style F	I know that Dakota Fanning is only twelve, but she is really famous.
3	Original I	depends....usully they are about ur personailty but not wat ur gonna do iwith ur life.
	NMT-Combined F	Depends.usully they are about your personailty, but not what your going to do iwith your life.
	MultiTask-tag-style F	It depends. They are about your personality, but not what you are going to do with your life.
4	Original I	THAT DEPENDS...ARE YOU A HOTTIE W/A BODY?
	NMT-Combined F	That depends, are you a hottie with a body?
	MultiTask-tag-style F	That depends. Are you a HOTTIE W / A BODY?
3b: formal→informal		
1	Original F	Therefore I would say that they do succeed but not frequently. I hope this is helpful.
	NMT-Combined I	So I would say that they do failing but not frequently, I hope this is helps.
	MultiTask-tag-style I	so i would say they do it but not all the time, hope this helps.
2	Original F	I am simply inquiring because people behave as though they are no longer interested in them.
	NMT-Combined I	I am just asking because people act as though they are no longer interested in them.
	MultiTask-tag-style I	I'm just asking because people act like they don't like them anymore.
3	Original F	Hello, I am interested in visiting your country.
	NMT-Combined I	Hi, I'm interested in visiting your country.
	MultiTask-tag-style I	hi, I'm going to go to your country.

Table 3: Sample model outputs for the Formality Transfer (FT) task.

phrases around (second sample in 3a), both of which happens frequently during machine translation thus showcasing the benefit of our multi-task approach. Our model very often makes the output sentence more complete (and thereby more formal) by inserting pronouns like 'it', 'they' at the start of the sentence or by removing conjunctions like 'usually', 'and', 'but', 'however' from the beginning of a sentence (sample three in 3a). Likewise, in the F→I task, our model produces more informal sentences compared to the baseline by introducing more phrasal level changes (first and second sample in 3b).

Error analysis: In the I→F task, our model performs worse than the baseline when the original informal sentence consists of all uppercased words (fourth sample in 3a). This is primarily because the baseline model pre-lowercases them using rules. Whereas, we rely on the model to learn this transformation and so it fails to do so for less frequent words. In the F→I task, in trying to produce more informal outputs, our model sometimes fails to preserve the original meaning of the sentence (third sample in 3b). In both tasks, very often our model fails to make transformations for some pairs like ('girls','women'), which the baseline model is very good at. We hypothesize that this could be because for these pairs, human rewriters do not always agree on one of the words in the pair being more informal/formal. This makes our model more conservative in making changes because our bi-directional model combines FT data from both directions and when the original data contains instances where these words are not changed, we double that and learn to copy the word more often than change it.

7 Formality-Sensitive Machine Translation Experiments

7.1 Models

NMT-constraint: We first evaluate the standard NMT model with side constraints introduced in Section 3.2 and then compare it with three variants of FSMT models using multi-task learning as described in Section 3.3 (i.e. **MultiTask-tag-style**, **MultiTask-style** and **MultiTask-random**). The best performing system for FT is MultiTask-tag-style with $12n$ ($\sim$2.5M) bilingual data. For fair comparison, we select this size of bilingual data for all FSMT models either by data selection or randomly.

PBMT-random: We also compare our models with the PBMT-based FSMT system proposed by Niu et al. (2017). Instead of tagging sentences in a binary fashion, this system scores each sentence using a lexical formality model. It requests a desired formality score for translation output and re-ranks n-best

Model	+Tag?	Random?	FR→Formal-EN	FR→Informal-EN
NMT-constraint	✓		27.15	26.70
NMT MultiTask-tag-style	✓		25.02	25.20
NMT MultiTask-style			23.25	23.41
NMT MultiTask-random		✓	25.24	25.14
PBMT-random (Niu et al.)		✓	29.12	29.02

Table 4: BLEU scores of various FSMT models. "+Tag" indicates using formality tags for bilingual data while "Random" indicates using randomly selected bilingual data.

translation hypotheses by their closeness to the desired formality level. We adapt this system to our evaluation scenario — we calculate median scores for informal and formal data (i.e. -0.41 and -0.27 respectively) in GYAFC respectively by a PCA-LSA-based formality model (Niu and Carpuat, 2017; Niu et al., 2017) and use them as desired formality levels.[6] The bilingual training data is randomly selected.

7.2 Results

Automatic Evaluation. We compute BLEU scores on the held out test set for all models as a sanity check on translation quality. Because there is only one reference translation of unknown style for each input sentence, these BLEU scores conflate translation errors and stylistic mismatch, and are therefore not sufficient to evaluate FSMT performance. We include them for completeness here, as indicators of general translation quality, and will rely on human evaluation as primary evaluation method. As can be seen in Table 4, changing the formality level for a given system yields only small differences in BLEU. Based on BLEU scores, we select MultiTask-random as the representative of multi-task FSMT and compare it with NMT-constraint and PBMT-random during our human evaluation.

Human Evaluation. Table 2 shows that neural models control formality significantly better than PBMT-random (0.35/0.32 vs. 0.05). They also introduce more changes in translation: with NMT models, $\sim$80% of outputs change when only the input formality changes, while that is only the case for $\sim$30% of outputs with PBMT-random. Among neural models, MultiTask-random and NMT-constraint have similar quality in controlling output formality (0.32 vs. 0.35) and preserving meaning (2.90 vs. 2.95). They are also equally fluent as judged by humans. Interestingly, multi-task learning helps MultiTask-random perform as well as NMT-constraint with simpler examples that do not require the additional step of data selection to generate formality tags.

7.3 Qualitative Analysis

We randomly sample 100 examples from our test set and manually compare the formal and the informal translations of the French source by MultiTask-random, NMT-constraint and PBMT-random. Table 5 shows representative examples of the observed trends.

We find that in most cases, the difference between the formal and informal style translations is very minor in PBMT-random model, better in NMT-constraint model and the best in our MultiTask-random model (first sample in the table). In general, our MultiTask-random model does a good job of making very large changes while transferring the style, especially into informal (second sample in the table). We hypothesize that this is because our joint model is trained on the GYAFC corpus which consists of parallel sentences that differ heavily in style.

Error analysis: All FSMT models perform well in terms of meaning preservation, yet the human scores are not perfect (Table 2). They occasionally change not only the style but also the meaning of the input (e.g. the third sample of MultiTask-random in Table 5). This motivates future work that penalizes meaning changes more explicitly during training. In general, none of the models do a good job of changing the style when the source sentence is not skewed in one style. For example, consider the French sentence "Combien de fois vous l'ai-je dit?" and its English reference translation "How many

[6]The PCA-LSA-based formality model achieves lowest root-mean-square error on a scoring task of sentential formality as listed on https://github.com/xingniu/computational-stylistic-variations.

times have I told you, right?". All models produce the same translation "How many times did I tell you?". In such cases, changing style requires heavier editing or paraphrasing of the source sentence that our current models are unable to produce.

8 Conclusion

We explored the use of multi-task learning to jointly perform monolingual FT and bilingual FSMT. Using French-English translation and English style transfer data, we showed that the joint model is able to learn from both style transfer parallel examples and translation parallel examples. On the FT task, the joint model significantly improves the quality of transfer between formal and informal styles in both directions, compared to prior work (Rao and Tetreault, 2018). The joint model interestingly also learns to perform FSMT without being explicitly trained on style-annotated translation examples. On the FSMT task, our model outperforms previously proposed phrase-based MT model (Niu et al., 2017), and performs on par with a neural model with side-constraints which requires more involved data selection.

These results show the promise of multi-task learning for controlling style in language generation applications. In future work, we plan to investigate other multi-task architectures and objective functions that better capture the desired output properties, in order to help address current weaknesses such as meaning errors revealed by manual analysis.

Acknowledgments

We thank the three anonymous reviewers for their helpful comments and suggestions. We thank Joel Tetreault for useful discussions and for making the GYAFC corpus available, as well as members of the Computational Linguistics and Information Processing (CLIP) lab at University of Maryland for helpful discussions. Appendix A. Details of Human-Based Evaluations

As described in the main paper, we assess the model outputs on three criteria of formality, fluency and meaning preservation. We collect these judgments using CrowdFlower.

Since we want native English speakers to perform this task, we restrict our set of annotators only to these three native English speaking countries: United States, United Kingdom and Australia. We create a sample of 51 gold questions for each of the three tasks (criteria). Annotators have to continually maintain an accuracy of above 70% to be able to contribute to the task.

We collect judgments on 300 samples of each model output and we collect three judgments per sample (i.e. sentence pair). Given the three judgments per sample, we calculate the aggregate score using the weighted average:

$$\frac{\sum_{i=1}^{3} score_i \times trust_i}{\sum_{i=1}^{3} trust_i}$$

where $score_i$ is the score given by an annotator and $trust_i$ is our trust on that annotator. This trust is the accuracy of the annotator on the gold questions.

Formality: Given two sentences, we ask workers to compare their formality using one of the following categories, regardless of fluency and meaning. We do not enumerate specific rules (e.g. typos or contractions) and encourage workers to use their own judgment.

Score	Category
2	*Sentence 1 is much more formal than Sentence 2*
1	*Sentence 1 is more formal than Sentence 2*
0	*No difference or hard to say*
-1	*Sentence 2 is more formal than Sentence 1*
-2	*Sentence 2 is much more formal than Sentence 1*

Fluency: Given two sentences, we ask workers to compare their fluency using one of the following categories, regardless of style and meaning. We define fluency as follows: *A sentence is fluent if it has a meaning and is coherent and grammatical well-formed.*

Score	Category
2	*Sentence 1 is much more fluent than Sentence 2*
1	*Sentence 1 is more fluent than Sentence 2*
0	*No difference or hard to say*
-1	*Sentence 2 is more fluent than Sentence 1*
-2	*Sentence 2 is much more fluent than Sentence 1*

Meaning preservation: Given two sentences, we ask workers to answer "how much of the first sentence's meaning is preserved in the second sentence", regardless of style.

Score	Category
3	*Equivalent since they convey the same key idea*
2	*Mostly equivalent since they convey the same key idea but differ in some unimportant details*
1	*Roughly equivalent since they share some ideas but differ in important details*
0	*Not equivalent since they convey different ideas*

While collecting formality and fluency annotations for sentence pairs, to avoid system-level bias, we randomly swap the two items in the pair and collect annotations on a symmetric range of [-2,2]. But while aggregating these scores, we recover the order and hence the final scores in Table 2 are only in the range of [0,2].

Towards a Language for Natural Language Treebank Transductions

Abstract

This paper describes a transduction language suitable for natural language treebank transformations and motivates its application to tasks that have been used and described in the literature. The language, which is the basis for a tree transduction tool allows for clean, precise and concise description of what has been very confusingly, ambiguously, and incompletely textually described in the literature also allowing easy non-hard-coded implementation. We also aim at getting feedback from the NLP community to eventually converge to a *de facto* standard for such transduction language.

1 Introduction

Linguists have always liked to use trees to theorize about the structure of natural language sentences (Marcus et al., 1983). In the 1990's, computer scientists also started to grow excited with the possibility of getting those proposed structures reasonably accurately from a computer. The advent of large corpora with annotated syntactic structures, the treebanks, among which the Penn Treebank (PTB) (Marcus et al., 1993; Marcus et al., 1994) is a notable representative, made it possible to build statistical parsers with an accuracy that was not feasible before. From the early work of (Magerman, 1994; Magerman, 1995; Charniak, 1997; Collins, 1997), state-of-the-art accuracy has been progressively raising, achieving now scores above 92% in the English Penn Treebank, as reported, for instance, in (Shindo et al., 2012).

As for dependency representations (Nivre et al., 2016; Nivre and Fang, 2017), although they capture syntactic structure in a different way, they are still generally represented as trees, even if not necessarily caring for the order among the children of a node.

Of course, not everybody is expected to agree on any given tree-structure style. On the linguistic side, each practitioner has their own theoretical conceptions on what is an adequate syntactic structure for a sentence, which may in turn differ from that of a specific treebank. Often all the information that is needed to promote the intended change is already present in the tree, either with some structure different than the desired, or "latent" in the annotation (Chiang and Bikel, 2002), in the form of secondary attributes on the nodes. When the change to the desired structure can be mechanically accomplished by applying to the trees a precisely defined rule, we call it a transduction. In order to perform more complex transformations we may instead define sequences of simpler transductions to be applied as a pipeline.

A few tree transducers have been proposed in the literature, among them the ones described in (Chiang and Bikel, 2002), based on context-free style rules, (Blahetta, 2003), based on Richard Pitto's **TGrep** (see (Rohde, 2005)), **Tsurgeon** (Levy and Andrew, 2006) and **TTT** (Purtee and Schubert, 2012). There are also transducers for other purposes, perhaps the currently most well known of them being W3C's **XPath** (World Wide Web Consortium, 2017), but those do not meet the needs of natural language and computational linguists practitioners (see for instance (Purtee and Schubert, 2012) for an initial discussion.) Although also built from Pitto-Rohde **TGrep** tools, the transduction language we propose in this paper is substantially diverse from that described in Blahetta's thesis (which, according to (Levy and Andrew, 2006) is no longer available).

Proceedings of the 27th International Conference on Computational Linguistics, pages 1022–1032
Santa Fe, New Mexico, USA, August 20-26, 2018.

Our main, initial motivation for designing the language and the tool we describe here came from perceiving the impact tree transduction can have in natural language parsing technology. There has been many really interesting proposals for parsers over these past 20 to 30 years, but what is even more striking is that they arose side by side with an intensive practice of what is often referred to as *hacking the trees*, which is now known to have played an important role in their success. For example, since his early work, Collins realized that it would be important, as a statistical parameter for deciding the correct tree structure of a sentence, to learn about the boundaries of *non-recursive* noun phrases, or *base NPs*, in the sentence.[1] However, his statistical parsing models would not be able to learn that particular parameter directly from the treebank, because base NPs were not explicitly marked as constituents in the tree, even if all necessary information was there: a human or a computer can easily follow some definition rules for base NPs, with no other external knowledge, and tell where they are in the annotated sentences. So, given a Penn Treebank tree like in Figure 1 the base non-recursive NPs, according to Collins, would be the following spans:

- (NP (DT A) (NNP SEC) (NN proposal) (S ...))
- (NP (NN reporting) (NNS requirements))
- (NP (DT some) (NN company) (NNS executives))
- (NP (DT the) (NN usefulness))
- (NP (NN information))
- (NP (NN insider) (NNS trades))
- (NP (DT a) (JJ stock-picking) (NN tool))

Collins realized that, inserting a node with a new label he called NPB to delimit the span, those constituents would help his training process so as to increase by a statistically significant amount his parser accuracy. After the transductions, the trees would be as following. Notice that whenever the entire NP span is itself immediately under some other NP, instead of adding a fresh NPB, the lower NP that dominates the spam is replaced with an NPB. That is the case in the first, third and the last two NPs below.

- (NP (NPB (DT A) (NNP SEC) (NN proposal) (S ...)))
- (NPB (NN reporting) (NNS requirements))
- (NP (NPB (DT some) (NN company) (NNS executives)))
- (NPB (DT the) (NN usefulness))
- (NPB (NN information))
- (NP (NPB (NN insider) (NNS trades)))
- (NP (NPB (DT a) (JJ stock-picking) (NN tool)))

The particular *tricks* used by Collins were reported in (Bikel, 2004). In fact, what once could have been perceived by some as a trick, is increasingly being acknowledged as an opportunity to recover relevant latent information, in principled ways, and making it available to the parser's training model.

Having this in mind we designed a general transduction language, based on Richard Pitto's **TGrep**.[2] We named it **tsed** after Unix **sed**, the string transduction tool counterpart to **grep**.

The obvious test suite was the set of Collins transformations as very precisely described (although in plain English, not in a formal language) in (Bikel, 2004), and also in Section 3.

Most tree transformations used in parsing have been hard-coded into the training and parsing algorithms. In particular, that was the case in the Collins implementation and even in Bikel's version. Although the latter claims to be highly parameterizable, which is indeed true to a great extent, one still has to hard-code in a programming language all the tree transformation processes.

In the following sections we describe the transduction language, and validate its expressive power replicating Collins's transformations as a test case. Of course the tool can be used for many other purposes as already mentioned. We conclude and discuss what is still planned for the future.

2 The Language

We describe here the transduction language. Appendix A contains a concise grammar for the language.

[1] See, for instance, (Collins, 2003) for his particular precise definition of the term.

[2] **TGrep** stands for *Tree Grep*, for the fact that it searches trees in a away which is parallel to the way Unix **grep** searches strings, and is currently available through Douglas Rohde's improved **TGrep2** version (Rohde, 2005).

```

```

Figure 1: A Penn Treebank tree

2.1 Overview

A transduction is a pair (s, r) (or $s ==> r$ in the syntax of the language) where s is a *search expression* and r is a *replacement expression*. Together they define how to transform a treebank input tree into a new one.[3] The search expression describes what we look for in the input trees, and the replacement expression defines how to build the output tree based on the patterns found during the search phase.

The search expression is based on restrictions to be met by the input tree in order for a match to succeed. There are two kinds of patterns in the search expression: the *node specifications*, intended to match with nodes of the input tree that comply with the pattern; and the *operators* that relate the node patterns defining a layer of restrictions that has to be respected by the nodes. So, a search expression such as $NP < PP$ will look for a node with label "NP", that immediately dominates another node, labeled "PP". This syntax is strongly based on **Tgrep2**.

However, while **Tgrep** is designed only to find patterns, **tsed** has to handle transformations, so we added the concept of *placeholders*, in a somewhat similar way as Unix **grep** was extended into **sed**. When a transduction is applied to an input tree, if the search is successful we say that there is a *match*, and as a byproduct each placeholder will be assigned a subtree of the input. Of course, there can generally be several ways a match can succeed, leading to different assignments of placeholders into subtrees. For instance, in the tree of Figure 1 we can find three NPs that immediately dominate a PP and also the second of this NPs dominates the third one. Indeed it is a very important issue the precise semantics that govern the specifics of search order and disambiguation. This is the subject of a later section of this paper.

The *main placeholder*, marked by enclosing the node specifier with square brackets, also defines the point where the transformation will take place. So a transduction such as $[NP] < PP ==> dog$ will succeed in a tree that has an NP immediately dominating a PP. The match will assign to the main placeholder [] the subtree for the NP found. And the transformation phase will replace the whole subtree of the NP, by the single node "dog". We will see ahead how to express more complex replacement patterns. For now, we just want to note that if the pattern was $NP < [PP] ==> dog$, then the substitution would take place at the PP subtree and the NP would be preserved in the tree as well as all other trees sibling to the PP.

[3]The transducer tool assumes boot input and output trees in the Penn Treebank format - label bracketed, constituent trees representation format, - and this format is used in the examples throughout the paper, though, of course, this format is not a relevant conceptual issue.

2.2 Search Expression

The search expression is in fact a *primary node specification* and an optional Boolean layer of restrictions. This is very much imported from **TGrep2**, with minor changes. So, in the search expression $[NP](< NN| < NNP)\&\$.PP$, "|" means disjunction (logical "or"), "&" means conjunction (logical "and"), "<" stands for immediate domination, and "$." stands for the first node having as an immediate sibling the node to the right. Then the expression instantiates the placeholder [] to a subtree labeled NP that either immediately dominates (<) an NN or that immediately dominates an NNP, and, additionally, the NP has to have as an immediate sibling of its parent a node labeled PP.

The search expression allows embedded restrictions, so $[NP](< NN| < NNP)\&\$.(PP < (IN < of))$, forces that additionally to the restrictions above, the PP (not the NP) should immediately dominate a node labeled IN (the preposition in the English Treebank), and that preposition has to be "of". The reader familiar with **TGrep2** might notice that we used the parenthesis both to disambiguate precedence among the restrictions and for embedded restrictions.[4]

2.3 Place Holders

There are two types of placeholder: *cut* and *copy*. Cut placeholders are marked by enclosing the node specifier with square brackets in the search expression. Once they match and are assigned to a certain subtree, that subtree will be excised from its parent during the transformation, and will not be at its original place anymore in the output tree, unless explicitly reinserted according to the replacement expression. The copy placeholder uses curly brackets ($\{\}$) instead of square brackets. The subtree assigned to it can be copied elsewhere in the output tree, as specified by the replacement expression, but will not be removed from its original place. Copy and cut placeholders are numbered. The main or primary placeholder presented in the previous sections is assigned number 0 by default.

Currently **tsed** is centered in the replacement of the hole which is left in the original tree when the the subtree assigned to the main placeholder is excised. The other cut placeholders are not replaced. An example is given right below.

Advancing a little in the details of the replacement expression, the transduction $[NP] < [1 : PUNCT] \Rightarrow (NP\ [NP]\ [1 : PUNCT])$ helps us exemplify the concept of the cut placeholder. It assigns to [] (same as [0 :], the default). a subtree labeled NP that dominates a node PUNCT. This node PUNCT is assigned to the the other cut placeholder, with number 1 ([1 :]). The output tree will be formed replacing the whole NP tree (placeholder [] or [0 :]), by a new tree defined by the pattern in the replacement expression as a fresh NP, that has two children: the NP subtree matched to $[NP]$, and the subtree matched to $[1 : PUNCT]$. Moreover, the PUNCT subtree will be removed from below the old NP. The reader may have recognized this as a very simple mechanism for raising a node in the tree. If the expression were $[NP] < \{1 : PUNCT\} \Rightarrow (NP\ [NP]\ \{1 : PUNCT\}\}$, then the PUNCT subtree would not be excised from its original place and the effect would be to have two copies of it in the output tree.

At this point the reader should be wondering that the reference to the placeholders could be shorted, and indeed the above expressions are equivalent to $[NP] < [1 : PUNCT] \Rightarrow (NP\ []\ [1 :])$ and $[NP] < \{1 : PUNCT\} \Rightarrow (NP\ []\ \{1 :\})$. We call this shortened representations such as [], $\{1 :\}$ *back references*.

2.4 Replacement Expression

The replacement expression is a sequence of trees. Each tree has the same syntax as the PTB representation of a tree, except that we can use the placeholders instead of labels. In this representation, a leaf node is represented just by its label, such as "NN". A subtree which is not a leaf is represented, recursively by the sequence, enclosed in parenthesis, formed by the label of the subtree root followed by the representation of the subtrees of the root node from left to right. Thus a replacement expression such as

[4] In **TGrep2** embedded restrictions use square brackets instead. This change makes things more uniform, preserves the brackets for placeholders, and does not lead to ambiguity in interpretation. We also force explicit inclusion of & for conjunction which makes the search expression more readable, though, well, for the sake of compatibility with TGrep we allow dropping &.

$(PP\ (IN\ from)\ (NP\ (NNP\ Santa)(NNP\ Fe)))$ represents the usual English PTB representation for the prepositional phrase "from Santa Fe." Now, the reader can go back to the transductions of the previous subsection to recognize that this interpretation has been applied there, for instance to $(NP\ []\ [1:])$ as a subtree rooted at an NP, with two children subtrees. That is the main application for the placeholders and the back references.

The possibility of having a sequence of trees instead of just one, fits nicely the rest of the language. So if one wants to flatten a little more the English Penn Treebank, transductions such as $[NP] < (\{1 : NP\}\ \$.\ \{2 : PP\}) \Rightarrow \{1:\}\ \{2:\}$ replaces the NP subtrees that stand for an NP modified by a PP (the lower NP has an immediate right sibling PP) by a flattened one with the higher NP eliminated.[5] [6]

2.5 Restrictions

We have imported exactly the same very rich set of restriction operators defined in **TGrep2**. These are called "links"in the **Tgrep2** documentation. As for Boolean operators, we took the hard decision of only allowing negation as part of the restriction operators. So $! <$ means "do not immediately dominate, as in **TGrep2**. But using the negation higher in the search expression would be pretty confusing and non-intuitive to interpret in the transduction. [7]

2.6 Node Specification

Node specification in the transduction was one of the hardest issues in the design of **tsed**. Due the characteristics of treebank labels, we felt it would be desirable to have both pattern matching internal to the node label and some amount of editing capability.

In the examples so far we defined a node in the search expression as a constant string possibly enclosed in brackets or braces. This is very limited in many senses and we now extend the syntax in a few ways.

First, the part inside the brackets/braces is allowed to be edited in the replacement expression. Moreover fixed context patterns can be provided outside the brackets/braces, both to the left and to the right.

A node specification is then a triple (l, m, r) where m stands for middle and is the part enclosed in the brackets or braces; l is the left context and r is the right context. So the transduction. $[NP] - TMP \Rightarrow [NPT]$ looks for a node with label NP-TMP, and changes the NP portion of the label to [NPT], keeping the left and right context, therefore resulting in a label $NPT - TMP$. Notice that the left context in the example is empty, so the match will only occur for labels that start with the NP sequence of characters. Moreover, the matched label for the example can not have anything beyond the TMP suffix. In this sense, up to this point, label matching has to be exact given the pattern.

In each of the three parts a "*" matches with any character sequence and "?" is a wild card, like in file specifications in Linux. This is a pretty easy and powerful resource. Then $[NP] * -TMP* \Rightarrow [NPT]$ will replace all NPs that contain the feature TMP to NPT (maintaining the context). So an $NP - SBJ - TMP$ would be replaced to $NPT - SBJ - TMP$.

Escaped characters are allowed as well as substrings enclosed either in single or double quotes.

Finally, POSIX regular expressions are allowed protected by "//" as in **sed**. This provides a very great flexibility to node specification for the experienced user. We only should enforce as we said in the last paragraph, that that behavior is not like in **grep** or **TGrep2**, that looks for the pattern anywhere in the node. Instead it requires full match. So, a node specifier to match any node with the TMP feature should be expressed as something like $*/ - TMP/*$ or using only POSIX regular expression syntax $/.*-TMP.*/$, but not just $/-TMP/$. The interesting point is that all the node-specifier expressions is ultimately converted to a POSIX regular expression, the semantics of which is widely known and very well documented. In the conversion, the separation of the left, middle and right part of the labels are provided by inserting parenthesis, supported by POSIX regex functions that then automatically locate them in the labels of the input tree.

[5] In fact a slight more complex expression should be used since this one is ignoring that extra material on the right of the PP or on the left of the lower NP would be lost.

[6] It is just an example, we are not advocating flattening the PTB!

[7] This was one of the few points where we found important to restrict the language in favor of usability and avoiding unpredictable behavior.

2.7 A Precise Semantics for the Transduction Driver

Avoiding non-deterministic behavior is a crucial issue in the project of artificial languages, often overlooked in its importance by people unfamiliar with language design and implementation. Indeed, it is an essential part of a language definition to provide clear rules specifying exactly what will be the output given any context of application of a valid transduction specification to a valid input tree.

For transduction languages based on patter matching it is essential to state clearly how the driver that executes the transformation works. For instance if we ask to eliminate a subtree labeled A that dominates a B, suppose that there happens to be in the corpus a tree with a path where an A immediately dominates a lower A, and the lower A immediately dominates a B. The question is whether the lower or higher subtree labeled A will be removed. Another issue is that of what to do after a match is performed: should it move on to the next tree, or should it try to reapply the transduction again to the same tree? And in the latter case, should it start it at the beginning of the output tree of the previous application? This issues could be treated as reasonable divergence among designers with regards to preference of behavior. However, it turns out that different behaviors are required depending on each particular situation. This section is intended to make precise the possible behaviors of the driver made available to the user by setting some execution options in the tool.

First, the search expression is seen as if parsed into an abstract, syntax tree like structure (see for example (Aho and Ullman, 1972)) in which operators are internal nodes and operands are their children. The leftmost leaf is the primary node specifier. Then the search is applied against input trees as if reading the syntax tree in an in-order traversal, that is, looking for a node, then looking for the restriction operator, and then to the subexpression to the right of the operator.

The Boolean layer is interpreted as in modern implementation of programming languages where the ”OR” is a ”conditional or” and the ”AND” is a ”conditional and”. This is essential to understand how the placeholders are assigned to subtrees. For instance once a full match succeeds on a tree, through a certain branch of an ”OR”, it will not try other paths. Then it will proceed according to the following algorithm:

1. Let *start* be the root of the input tree.

2. Assign *start* to *current node*

3. Search the input tree from the *current node* in a preorder left-to-right traversal order looking for a node that matches the primary node of the search expression (leftmost leaf of the syntax tree).

4. Proceed according to the syntax tree operators. Each operator dictates its one intuitive behavior. In a nutshell it searches from the *current node* ”outwards”in the tree. For example: ”dominates”search the next node in the same way as the primary node; ”is dominated”searches upwards till a match is found or it tries to move above the root; search for siblings move from the current node to the endpoints (left or right) In fact each operator has its own semantics which we cannot exhaust here, but the principles stated so far should be enough to understand most if not all of the behavior.

5. Whenever a restriction fails, backtrack. Failing branches in an OR layer remove internal assignments made to placeholders on this branch.

6. If the match fails, output the tree as it is at that moment.

7. If the match succeeds,

   (a) Apply the replacement expression, modifying the current tree.

   (b) Assign to *current node* the node that would follow, in a preorder left-to-right traversal, the one that replaced the primary placeholder after the transformation just concluded. Usually this is the leftmost child of the root of the subtree inserted there, unless these subtree is just a leaf.

   (c) Resume at step 3

The way we defined at 7.(b) the reentrant behavior to resume the process after a successful match transformation seems to be the most desirable from our modeling experience so far. It is a compromise to an alternative behavior of restarting over again from the root, which causes many non-termination problems and unpredictable behavior.

However two alternatives still being considered as options at the command line are: to resume from the leftmost child of the node matching the primary node specifier (which usually is the primary placeholder, though not always); and also resuming from the node which would be the next, in a preorder left-to-right traversal, after the whole subtree substituted at primary placeholder was visited. This latter behavior is extremely safe in that it would completely prevent non-termination. And it is certainly faster. But it generally does not correspond to the user's desired behavior.

2.8 Back references

Back references are essential at the replacement expression, but they also have an important use in the search expression. Because we require back references to be previously declared and have strict rules of scope of visibility enforcing the well-formedness of the search expression we do not experience the strange behaviors reported in (Rohde, 2005) by the expression "crossing link".

2.9 Ranges of subtrees and endmarkers

There are situations where being able to express tree-range fillers may be very useful. Tree-range fillers are represented by "..." enclosed as placeholders. Thus, the transduction $[NP] < (\{1 : NP\}(\$, \{3 : ...\}\&\$.(\{2 : PP\}\$.\{4 : ...\}))) \Rightarrow \{3 :\}\{1 :\}\{2 :\}\{4 :\}$ is a more robust version of the flattening example above. $\{3 :\}$ matches with the sequence of siblings to the left of the lower NP, and $\{4 :\}$ matches with the sequence of siblings to the right of the PP, thus the extra material below the higher NP is preserved. Of course there are other ways of doing this. However this greatly simplifies the transductions that have to eliminate intermediate nodes.

Another feature is the endmarker which stands for the lack of nodes. So $\# < SBAR$ means an SBAR at the root of the tree. Similarly the endmarker can be used to capture the notions of leaf node and right- and leftmost child.

2.10 "Semantic"consistency of the Boolean layer with respect to placeholders

Every artificial language has those issues related to allowing only well-formed expressions. For instance in **tsed**, we enforce that a placeholder cannot be defined twice in the search expression, and that a back reference can only appear if the corresponding full placeholder has been defined earlier in the expression. We are not going to exhaust these aspects here. However it is important to notice that the definition and use of placeholders interact very dangerously with the logical operators. For instance, a back reference in a restriction in a branch of a logical OR cannot refer to a placeholder defined in an earlier branch. This is not a problem if the restrictions are in the branches of an AND operator. Natural language semanticists will quickly perceive this asymmetry which is generally not an issue in programming language implementation. Another issue is that a placeholder is visible outside of an OR layer of restrictions only if it has been declared in all branches. We have considered very intuitive and indeed interesting rules of scope and visibility for the placeholders but will refrain from entering in a morass of detail that would be required to explain them here.

3 A Case Study

We present in this section examples of transductions that implement Collins pre-processing steps as described in in (Bikel, 2004). All the quotations in this section are from his article, with references to figures removed to avoid confusion.

3.1 Base NP node insertion

This transformation was exemplified earlier in the previous section. Bikel describes it as follows:

An NP is basal when it does not itself dominate an NP; such NP nodes are relabeled NPB. More accurately, an NP is basal when it dominates no other NPs except possessive NPs, where a possessive NP is an NP that dominates POS, the preterminal possessive marker for the Penn Treebank. These possessive NPs are almost always themselves base NPs and are therefore (almost always) relabeled NPB. For consistency's sake, when an NP has been relabeled as NPB, a normal NP node is often inserted as a parent nonterminal. This insertion ensures that NPB nodes are always dominated by NP nodes. The conditions for inserting this "extra" NP level are slightly more detailed than is described in Collins' thesis, however. The extra NP level is added if one of the following conditions holds:

- *The parent of the NPB is not an NP.*
- *The parent of the NPB is an NP but constitutes a coordinated phrase.*
- *The parent of the NPB is an NP but*
  - *the parent's head-child is not the NPB, and*
  - *the parent has not already been relabeled as an NPB.*[8]

The transformation is accomplished by the following **tsed** transduction sequence. We well apply the sequence to the following PTB annotated sentence:

```
(S (NP-SBJ (NP (NP (DT The) (NNP SEC))
               (POS 's))
           (NNP Mr.) (NNP Lane))
   (VP (ADVP-MNR (RB vehemently))
       (VF disputed)
       (NP (DT those) (NN estimates)))
   (. .))
```

1. We first replace NP labels that dominate some POS with a new fresh label POSNP: We find some NP nodes which dominates (operator <<, not necessarily immediate domination) a POS node as stated in the search string. The $*$ means that the labels, either POS or NP, may be followed by any character sequence, so it can match, say, an NP-SBJ. The brackets [] are used as placeholders once a match is found. That means that (1) the subtree rooted at the NP node is the one going to be replaced; (2) the brackets have been matched to that subtree in case we want to refer to that tree in the replacement string; and (3) we have the chance to replace the part of the string inside the brackets in case we want to use it. In this case it selects only the NP part of the label, not the additional suffix. That is because the "*"is outside the brackets. The replacement string tells us then that the same subtree will be kept there (because it puts the brackets back there). But the NP part of the label is replaced with POSNP, so, if that was an NP-SBJ, it will become POSNP-SBJ.

   search string: '[NP]* <<POS*' **replacement string:** '[POSNP]'
   output:

```
(S ( POSNP-SBJ ( POSNP (NP (DT The) (NNP SEC))
                       (POS 's))
               (NNP Mr.) (NNP Lane))
   (VP (ADVP-MNR (RB vehemently))
       (VF disputed)
       (NP (DT those) (NN estimates)))
   (. .))
```

   The search is made in a preorder traversal and finds all matching occurrences, each one being subject to the replacement.

2. In this rule we replace with NPB the labels of NPs that do not dominate another NP (those are the base NPs). The exclamation mark means negation as in **Tgrep**. Notice that we have already preclude the possibility of targeting NPs dominating POS, since we changed their names to POSNP.

   search string: '[NP]* !<<NP*' **replacement string:** '[NPB]'
   output:

```
(S (POSNP-SBJ (POSNP ( NPB (DT The) (NNP SEC))
                       (POS 's))
               (NNP Mr.) (NNP Lane))
   (VP (ADVP-MNR (RB vehemently))
       (VF disputed)
       ( NPB (DT those) (NN estimates)))
   (. .))
```

[8] Only applicable if relabeling of NPs is performed using a preorder traversal.

3. Then we switch the POSNP labels back to NP.

search string: '[POSNP]*' **replacement string** '[NP]'

output:

```
(S ( NP-SBJ ( NP (NPB (DT The) (NNP SEC))
                 (POS 's))
             (NNP Mr.) (NNP Lane))
   (VP (ADVP-MNR (RB vehemently))
       (VF disputed)
       (NPB (DT those) (NN estimates)))
   (. .))
```

4. And finally we add an extra NP node on top of the NPB, in case it is not immediately dominated by some other NP (again following **TGrep**, a single > means that it has to be **immediately** dominated in order to match.

search string '[NPB]* !>NP*' **replacement string** 'NP <[NPB]'

output:

```
(S (NP-SBJ (NP (NPB (DT The) (NNP SEC))
                 (POS 's))
             (NNP Mr.) (NNP Lane))
   (VP (ADVP-MNR (RB vehemently))
       (VF disputed)
       ( NP (NPB (DT those) (NN estimates))))
   (. .))
```

The reverse transformation is described by Bikel as:

> *I*n post-processing, when an NPB is an only child of an NP node, the extra NP level is removed by merging the two nodes into a single NP node, and all remaining NPB nodes are relabeled NP.

This is easily accomplished by a single transduction rule

search string '[NPB]* !>NP*' **replacement string** 'NP <[NPB]'

We have implemented also other transductions from (Bikel, 2004) and the reverse versions whenever well defined. Some of them depend on location the head node on a constituent. That could be accomplished through a pre-processing tool that could mark the head nodes with a "-HEAD"tag. We have considered replicating the head finding rules but we have not done it yet.

4 Conclusion and Future Work

Of course the appeal of tree transductions is not only its use for parsing pre- and post-processing tasks. We used this application in this paper to show that **tsed** language is sufficiently powerful so that it can be used to replace transformations originally made by programming language code pieces, that were never subject to a restriction in power of expression. That is, Collins defined and coded the transformations that he thought as useful and that he could mechanically express having all the Turing machine power of a general programming language at his disposition. Those transformations can be elegantly and succinctly captured by a special purpose transducer language, stripping them out of the main learning algorithm.

By inspection, we extensively observed that the application of all the transductions generated the new trees as we think they should. In fact there is no easy way to directly check against what Collins would generate, because the latter are never explicitly realized. They are internal to the parsing process. We have considered instead, comparing the parsing accuracy of the original parser with that of the parser with the transformations made by **tsed**. Unfortunately this requires removing the corresponding pieces of code in either Collins' or Bikel's implementation, and we have not done it yet.

The examples in the test case have been successfully implemented in an existing implementation that have some limitations in expressive power. Still it could model the rules described in (Bikel, 2004).

Tsed will be used in projects to experiment on parsing accuracy enhancement through sound corpora transformations.

We hope to get feedback from the NLP community joining efforts to eventually converge to a *de facto* standard for a transduction language.

Generating Reasonable and Diversified Story Ending Using Sequence to Sequence Model with Adversarial Training

Abstract

Story generation is a challenging problem in artificial intelligence (AI) and has received a lot of interests in the natural language processing (NLP) community. Most previous work tried to solve this problem using *Sequence to Sequence* (Seq2Seq) model trained with *Maximum Likelihood Estimation* (MLE). However, the pure MLE training objective much limits the power of Seq2Seq model in generating high-quality stories. In this paper, we propose using adversarial training augmented Seq2Seq model to generate reasonable and diversified story endings given a story context. Our model includes a generator that defines the policy of generating a story ending, and a discriminator that labels story endings as human-generated or machine-generated. Carefully designed human and automatic evaluation metrics demonstrate that our adversarial training augmented Seq2Seq model can generate more reasonable and diversified story endings compared to purely MLE-trained Seq2Seq model. Moreover, our model achieves better performance on the task of Story Cloze Test with an accuracy of 62.6% compared with state-of-the-art baseline methods.

1 Introduction

The task of story generation was first proposed in the field of artificial intelligence (AI) (Schank and Abelson, 1977). Recently, benefiting from deep learning technology, story generation again received increasing interests in the natural language processing (NLP) community. In this paper, we propose using adversarial training augmented Seq2Seq model to generate story ending given a story context. For example, given the story context "Sara had lost her cat. She was so sad! She put up signs all over the neighborhood. Then a wonderful thing happened.", our goal is to generate a possibly reasonable story ending "Somebody found her cat".

Much previous work in story generation or prediction focused on learning statistical models of event sequences from large-scale text corpora. Chambers and Jurafsky (2008) proposed unsupervised induction of *narrative event chains* from raw newswire texts, with *narrative cloze* as the evaluation metric. However, they utilized a very impoverished representation of events as the form of (*event, dependency*). To overcome the drawback of this event representation, Pichotta and Mooney (2014) presented a script learning approach that employed events with multiple arguments. Pichotta and Mooney (2016a) showed that the LSTM-based event sequence model outperformed previous co-occurrence-based methods for event prediction. However, this line of work build their models based on discrete verbs and tokens, which is far from being a complete sentence or a story.

There have been a number of recent work for story generation focusing on complete sentences. Kiros et al. (2015) described an approach for unsupervised learning of a generic, distributed sentence representations called *skip-thought* vectors. Such vectors can be used to predict neighboring sentences in the context. Pichotta and Mooney (2016b) used Seq2Seq framework directly operating on raw tokens to predict sentences, finding it is roughly comparable with systems operating on structured verb-argument

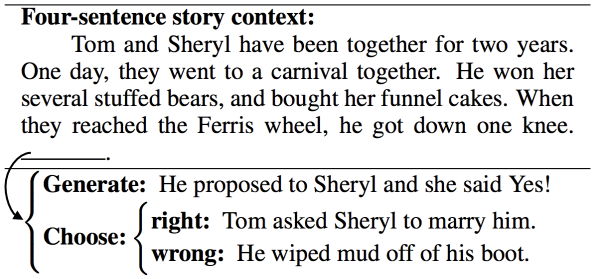

Figure 1: The task of generating or choosing the right story ending.

events in terms of predicting missing events in documents. Hu et al. (2017) also developed an end-to-end model for future subevent prediction. However, they use large-scale news corpus as training data, which is quite noisy and far from being reasonable stories. Moreover, traditional Seq2Seq model are usually trained purely by *Maximum Likelihood Estimation* (MLE). This makes sense in some tasks, such as, machine translation, where the gold-standard target sequence is unique, and the goal is to produce a target sequence as much like the gold-standard one as possible. However, this training objective is not enough for the task of story ending generation. Because this task essentially has no gold-standard answers, and any reasonable story ending can be the right one. On the other hand, purely MLE trained Seq2Seq model tends to generate frequent words or phrases in the test stage, which is a well known intractable obstacle. Hence, it is crucial to explore new ways to enhance Seq2Seq model in the task of story ending generation.

As shown in Figure 1, given a four-sentence story context, our target is to generate a possibly reasonable story ending. To this end, Story ending generation is modeled as a sequence to sequence generation process. In order to understand the context better and generate more reasonable and diversified story endings, we adopt the idea of adversarial training from *Generative Adversarial Nets* (Goodfellow et al., 2014) in recent image generation advances, which includes a generator that defines the probability of generating a story ending, and a discriminator that labels story endings as human-generated or machine-generated. In adversarial training augmented Seq2Seq model, the generator is encouraged to generate story endings that are indistinguishable from human generated story endings, and the discriminator gives a score of judging whether the current story ending is generated by the human or the machine, which can be used as a reward for the generator. Then the generator is trained to maximize the expected reward of the generated story ending using REINFORCE algorithm (Williams, 1992).

We conducted extensive experiments on the ROCStories corpus (Mostafazadeh et al., 2016). Carefully designed human evaluation demonstrates that adversarial training augmented Seq2Seq model can generate logically better story endings than conventional Seq2Seq model. Automatic evaluation metrics also suggest that adversarial training can improve the diversity of the generated story endings. Furthermore, we evaluate the effectiveness of our approach on the task of Story Cloze Test, which requires to choose the right story ending from two candidates given a story context. Our model chooses the right ending based on average word embedding similarities between our generated ending and the two candidates, and achieves the best performance on the task of Story Cloze Test compared to state-of-the-art baseline methods.

2 Sequence to Sequence Learning with Adversarial Training

As shown in Figure 2, our adversarial training augmented Seq2Seq model consists of three components. First, the generator $\mathcal{G}$ defines the policy that generates the story ending Y given the story context X. Second, the discriminator $\mathcal{D}$ is a binary classifier that takes as input a complete story $\{X, Y\}$ and outputs a label indicating whether the input is generated by human-beings or machines. The third component is an adversarial training process between the former two components.

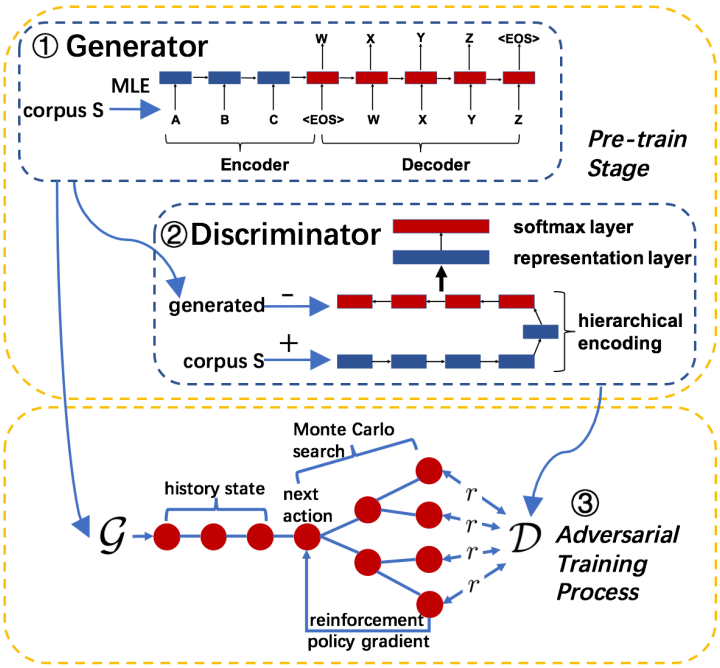

Figure 2: Framework of adversarial training augmented Seq2Seq model.

2.1 Sequence to Sequence Model as the Generator

In our task, the input is a four-sentence story context, and the output is a reasonable story ending. Hence, it is natural to use Seq2Seq model (Sutskever et al., 2014; Cho et al., 2014) as the generator (see ① in Figure 2). In Seq2Seq model, the story context is mapped to a vector representation using a recurrent neural network (Elman, 1990), and then the model computes the probability of generating each token in the target sequence (story ending) using a softmax function.

In recent work on Seq2Seq model, long-short term memory (LSTM) (Hochreiter and Schmidhuber, 1997) and gated recurrent unit (GRU) (Cho et al., 2014) have shown their power on a wide variety of NLP tasks. Here, we use LSTM as the computation unit in our Seq2Seq generator, and sigmoid is used as the nonlinear activation function. Given a sequence of inputs $X = \{x_1, x_2, ..., x_N\}$, the generator defines a distribution over outputs and sequentially predicts tokens using a softmax function:

$$\begin{aligned} p(Y|X) &= \prod_{t=1}^{T} p(y_t|x_1, x_2, ..., x_N, y_1, y_2, ..., y_{t-1}) \\ &= \prod_{t=1}^{T} \frac{exp(f(h_{t-1}, e_{y_t}))}{\sum_{y'} exp(f(h_{t-1}, e_{y'}))} \end{aligned} \tag{1}$$

where $f(h_{t-1}, e_{y_t})$ denotes the activation function between h_{t-1} and e_{y_t} , and h_{t-1} is the representation output from the LSTM at time $t-1$. Each sentence concludes with a special end-of-sentence symbol *EOS*. Commonly, input and output use different LSTMs with separate compositional parameters to capture different compositional patterns.

In the decoding procedure, the algorithm terminates when an *EOS* token is predicted. Beam search is adopted for next word prediction, the embedding of which is then combined with preceding output for next step token prediction.

2.2 Discriminator

In the idea of adversarial training, we want to produce more natural, diversified and logically reasonable story endings. To this end, we introduce a discriminator (see ② in Figure 2) that judges whether the input is generated by human-beings or machines, and transfers this signal to the Seq2Seq generator, to help adjust its parameters for generating our expected story endings.

The discriminator $\mathcal{D}$ is a binary classifier. We use a hierarchical sequence encoder (Li et al., 2015) to map a complete story $\{X, Y\}$ into a vector representation, which is then fed to a 2-class softmax function, returning the probability of the story being a machine-generated story ending (denoted by $\mathcal{R}_-(\{X, Y\})$) or a human-generated one (denoted by $\mathcal{R}_+(\{X, Y\})$).

2.3 Adversarial Training Process

In the adversarial training augmented Seq2Seq model, the generator is encouraged to generate story endings that are indistinguishable from human generated story endings. We use *policy gradient* methods to achieve such goal (see ③ in Figure 2). The score $\mathcal{R}_+(\{X, Y\})$ of the current generated story ending is assigned by the discriminator. And then it is used as a reward for the generator. At last, the generator (we use θ to denote the parameters of the generator) is trained to maximize the expected reward of generated story ending using the REINFORCE algorithm (Williams, 1992):

$$J(\theta) = \mathbb{E}_{Y \sim p(Y|X)}(\mathcal{R}_+(\{X, Y\})|\theta). \tag{2}$$

We consider the story ending generation procedure as a sequential decision making process. Given the input story context X, the generator generates a story ending Y by sampling from the policy. The concatenation of the generated ending Y and the input X is fed to the discriminator.

Following Yu et al. (2016), we use reward for every intermediate token to update the generator. In our model, Monte Carlo (MC) search is used to assign the reward score for every intermediate token. Given a partially decoded sentence S, the model keeps sampling tokens from the generator until the decoding finishes. Such a process is repeated M times and the M generated sequences will share a common prefix S. These M sequences are fed to the discriminator, the average score of which is used as a reward for S.

For each machine-generated story ending Y, the discriminator gives a classification score $\mathcal{R}(X, Y)$. The gradient of eq. (2) is approximated using the likelihood ratio trick (Glynn, 1990; Williams, 1992), which is used to update the generator:

$$\begin{aligned} \nabla J(\theta) \approx & [\mathcal{R}_+(\{X, Y\}) - b(\{X, Y\})] \\ & \nabla \sum_t \log p(y_t|X, y_{1:t-1}), \end{aligned} \tag{3}$$

where $b(\{X, Y\})$ denotes the baseline value to reduce the variance of the estimate while keeping it unbiased. The discriminator is simultaneously updated with the human generated story ending including story context $\{X, Y\}$ as a positive example, and the machine-generated ending along with story context $\{X, \hat{Y}\}$ as a negative example.

To train the Seq2Seq model in adversarial manner, we need to first pre-train a Seq2Seq model on training corpus $\mathcal{S}$ with MLE. Then pre-train the discriminator use the instance $\{X, Y\}$ in training corpus $\mathcal{S}$ as positive examples, and generated ending along with story context $\{X, \hat{Y}\}$ as negative examples. Subsequently, the generator and discriminator are trained alternatively. During this process, discriminator $\mathcal{D}$ is first trained for *d-steps* with a similar way like pre-train stage. Then generator $\mathcal{G}$ is trained for *g-steps* using the REINFORCE algorithm. At last, we get the adversarially-trained generator $\mathcal{G}$.

3 Experiments

The performance of our adversarially-trained Seq2Seq model is compared with state-of-the-art baselines by evaluating the quality of generated sequences on two tasks: story ending generation and Story Cloze Test (choosing the right story ending from two candidates).

3.1 Dataset

The dataset used in this paper is ROCStories corpus, which is released by (Mostafazadeh et al., 2016). This corpus is a collection of five-sentence commonsense stories by crowd sourcing. Each story has the following major characteristics: (1) is realistic and non-fictional; (2) has a clear beginning and ending where something happens in between; (3) does not include anything irrelevant to the core story. These

	Training	Development	Test
#stories	98,161	1,871	1,871
#words	4,887,555	107,336	107,402

Table 1: Statistics of datasets.

stories are full of stereotypical causal and temporal relations between events, making them a great resource for commonsense reasoning and script knowledge learning. A two-step quality control step makes sure that there are no vague or boundary cases in the test dataset, making human performance of 100% accuracy possible.

The dataset is split into training, development and test datasets. Each instance in the training dataset is a five-sentence story. But in the development and test datasets, each instance is a four-sentence story and two candidate endings (one is the right ending and the other is the wrong ending). Specifically, the wrong endings are purposely designed to fit to the story context but logically wrong. Hence, sampling negative wrong endings from other stories is unreasonable. Detailed statistics of training, development and test datasets are shown in Table 1. All methods are evaluated on the test dataset, and only the development dataset could be used for tuning purposes.

3.2 Evaluation Metrics

For the task of Story Cloze Test, we use accuracy to evaluate the effectiveness of our approach. For the task of story ending generation, we ask human annotators to evaluate the performance of our approach, as it is difficult to find a generally accepted automatic metric for this task. Following Shang et al. (2015), we carefully designed the human evaluation procedure to evaluate the ability of our proposed model on generating story endings. We randomly pick 100 story endings generated by the baseline method and our approach on the test dataset respectively, and distribute them to three annotators. The annotators read the story context, and judge whether the generated story ending is appropriate and reasonable according to the story context. Four levels are assigned to each ending with scores from 0 to 3:

- **Bad (0)**: The ending doesn't make sense and unrelated to the story context.
- **Relevant (+1)**: The ending is partially related to the story context.
- **Good (+2)**: The ending is highly related to the story context.
- **Perfect (+3)**: The ending is high-quality, context-related and logically correct to the story context.

We give the following three aspects judgement criteria for the annotators: (a) **Grammar and Fluency:** Endings should be natural language and free of fluency and grammar errors. (b) **Context Relevance:** Person names, pronouns and phrases in the endings should be relevant to the story context. (c) **Logic Consistency:** Endings should be logically consistent with the story context.

Furthermore, we ask the annotators to directly compare the story endings that generated by the baseline method and our approach, and choose the better one.

We did not use perplexity or BLEU (Papineni et al., 2002) as evaluation metric, as neither of them is likely to be an effective evaluation metric in our scenario. Because our proposed model is designed to steer away from the standard Seq2Seq model, in order to generate more reasonable and diversified story endings. Following Li et al. (2016), we report the degree of diversity by calculating the number of distinct unigrams and bigrams in generated story endings. In order to avoid favoring long sentences, the value is scaled by total number of generated tokens.

3.3 Baselines and Proposed Models

For the evulation of story ending generation quality, the compared models are listed below:

- **Seq2Seq-MLE**: Seq2Seq model purely trained with MLE.
- **Seq2Seq-Adversarial**: Seq2Seq model pre-traind with MLE and then augmented with adversarial training.

	Models	
	Seq2Seq-MLE	**Seq2Seq-Adversarial**
Bad (0)	26.7%	17.7%
Relevant (+1)	23.3%	21.0%
Good (+2)	26.3%	27.0%
Perfect (+3)	23.7%	34.3%
Mean Score	1.47	**1.78 (+21.1%)**
Agreement	0.339	0.344

Table 2: Human evaluation results of story ending generation. Mean score is the average evaluation scores over three annotators.

Both good	6.7%
Both bad	11.3%
Seq2Seq-MLE is better	33.0%
Seq2Seq-Adversarial is better	**49.0**%
Agreement	0.443

Table 3: Pairwise model comparison of story ending generation.

We also evaluate the generated endings in the Story Cloze Test task, compare with the baseline methods used in (Mostafazadeh et al., 2016).

- **Word2Vec**: Choose the ending with closer average word2vec (Mikolov et al., 2013) to the average word2vec of four-sentence context.
- **Skip-thoughts**: (Kiros et al., 2015)'s Sentence2Vec encoder which models the semantic space of sentences, according to which we can choose the ending having a closer embedding to the four-sentence context.
- **Deep Structured Semantic Model (DSSM)**: MSR Sentence2Vector model (Huang et al., 2013), according to which we can choose the ending that has a closer embedding to the context.
- **Conditional Generative Adversarial Networks (CGAN)**: The Conditional GAN model proposed in (Wang et al., 2017), in which the discriminator is used to choose the correct story ending.

We choose the right story ending based on average embedding similarities between endings generated by **Seq2Seq-MLE** and **Seq2Seq-Adversarial** models, and the two candidates.

3.4 Results and Analysis

Human evaluation results of story ending generation are shown in Table 2 and Table 3. From Table 2, we find that Seq2Seq-Adversarial achieves better results than Seq2Seq-MLE model. Seq2Seq-Adversarial achieves a mean score of 1.78, which is 21.1% improvement over Seq2Seq-MLE (1.47). For the **Perfect** and **Good** levels, Seq2Seq-Adversarial outperforms Seq2Seq-MLE. While for the **Relevant** and **Bad** levels, Seq2Seq-Adversarial gets smaller percentage scores. The annotation agreements for Seq2Seq-MLE and Seq2Seq-Adversarial are evaluated by Fleiss' kappa (Fleiss, 1971), as a statistical measure of inter-rater consistency, which are 0.339 and 0.344, respectively. Considering the complex judgement criteria, they can demonstrate high agreement between three annotators (Shang et al., 2015).

As shown in Table 3, we directly compare the performance of Seq2Seq-MLE and Seq2Seq-Adversarial model. There are 49% story endings generated from Seq2Seq-Adversarial model better than that from Seq2Seq-MLE model. In turns, Seq2Seq-MLE model can only achieve better performance than

	UnigramDiv	**BigramDiv**
Seq2Seq-MLE	0.038	0.104
Seq2Seq-Adversarial	0.064 (+68.4%)	0.236 (+126.9%)

Table 4: Diversity evaluation of the generated endings on test dataset. **UnigramDiv** and **BigramDiv** are respectively the number of distinct unigrams and bigrams divided by total number of generated words.

Methods	Accuracy
Word2Vec (Mikolov et al., 2013)	53.9%
Skip-thoughts (Kiros et al., 2015)	55.2%
DSSM (Huang et al., 2013)	58.5%
Seq2Seq-MLE (Cho et al., 2014)	58.6%
CGAN (Wang et al., 2017)	60.9%
Seq2Seq-Adversarial (ours)	**62.6%**

Table 5: Experimental results of Story Cloze Test on test dataset.

Seq2Seq-Adversarial model on 33% story endings. And we get a higher Fleiss' kappa value for pairwise model comparison, which is up to 0.443.

Diversity evaluation results are shown in Table 4. We find that by integrating adversarial training, Seq2Seq model can generate more diversified story endings. Seq2Seq-Adversarial model achieves 68.4% higher unigram diversity and 126.9% higher bigram diversity score than Seq2Seq-MLE model respectively.

The main reasons for these results are as follows. First, MLE tends to generate constant phrases regardless of the story context. Especially when it reads an unfamiliar story context as input, it will generate some frequent phrases appearing in the training dataset, but unrelated to the story context. Second, adversarial training always tries to understand the whole semantics of story context and generates endings as human-beings. Hence, is will generate some context-related or even semantic and logically related endings. Third, adversarial training is dependent on MLE pre-trained Seq2Seq model. Hence, it inherits the advantages of MLE training. During the adversarial training process, it will update its parameters under another criteria (the reward scores given by the discriminator). Hence, adversarial training augmented Seq2Seq model is indeed an ensemble of two different training objectives. MLE training guarantees fluency of the generated endings, and adversarial training adds diversity to them by exploring more words in MC search process.

Results of Story Cloze Test on the ROCStories test dataset are shown in Table 5. The best baseline model is CGAN and it achieves an accuracy of 60.9%. This indicates the difficulty of this task. Seq2Seq-MLE (accuracy: 58.6%) achieves comparable result with the DSSM model (accuracy: 58.5%), and Seq2Seq-Adversarial gets the highest accuracy of 62.6% on the task of Story Cloze Test.

Indeed, all baseline models cannot generate story endings. They either try to directly compare the similarity between story context and two candidate endings or try to map the story context into a hidden vector representation, and then choose a similar ending. While our model try to address the problem of Story Cloze Test from a generation perspective. We first generate real story endings, and then choose the right ending based on the average embedding similarities between them and the candidates. This is easier to understand for readers. Because human readers can read both the generated endings and the candidates, and understand why we can choose the right ending.

Word2Vec method tends to choose the candidate ending whose average word embedding is more similar to the average word embedding of four-sentence context. Comparing with it, our model achieves a huge boost of accuracy (from 53.9% to 62.6%). This is mainly because our model can understand the global semantic of the story context, other than the local meaning of words. Our model achieves better performance than DSSM model, mainly because DSSM model needs to sample negative examples from other stories in its training process, but there are no negative examples in the training dataset. Our model also outperforms the CGAN model, which doesn't generate real story ending but use the discriminator to choose the correct one. This demonstrates the effectiveness of our model, which solve the problem based on real genrated endings.

3.5 Case Study

Three typical cases are shown in Table 6. In case one, both Seq2Seq-MLE and Seq2Seq-Adversarial models generate perfect story endings, that are fluent, grammatical and logically correct. In case two, Seq2Seq-MLE model generate relatively poor ending, which is not relevant to the story context. We argue that in the MLE-training process, it cannot see a similar story context in the training dataset, so

Case one	**Context**	Eric was overly excited for lunch today.The cafeteria was serving his absolute favorite meal.He loved the school's pizza and french fries.He sprinted to the lunch line but it was too late.
	Right	Eric had to settle for cold peanut butter and jelly for lunch.
	Wrong	Eric got a second plate of pizza and french fries.
	Seq2Seq-MLE	eric had to go to the store and buy a pizza instead.
	Seq2Seq-Adversarial	eric decided to go to the store for lunch instead.
Case two	**Context**	Aya wanted to paint a picture.She bought canvas and paints.Then she sat down by a window for inspiration.She began to paint an image of the landscape.
	Right	Aya became famous for her landscape pictures.
	Wrong	Aya put the finishing strokes on a picture of a skyscraper.
	Seq2Seq-MLE	aya was thrilled with her purchase.
	Seq2Seq-Adversarial	by the end of the day she had a picture.
Case three	**Context**	Ivy was scared to go to summer camp.But she steeled herself and got on the bus.When she got there, she went to talk to the other campers.Soon she had made a few new friends.
	Right	Ivy ended up loving summer camp.
	Wrong	But she wanted to go home.
	Seq2Seq-MLE	ivy had a great time with her friends.
	Seq2Seq-Adversarial	ivy decided to go to church instead.

Table 6: Example story endings generated by our models, along with the original right and wrong story endings in the test dataset.

it tends to generate some frequent phrases. While Seq2Seq-Adversarial model generates a perfect story ending, which really amazed us: it is even better than the original right story ending. Moreover, this ending is far from being similar to the gold-standard right ending. But it fits to the story context perfectly. Hence, we believe that Seq2Seq-Adversarial model can generate more diversiform knowledge for this world. In case three, Seq2Seq-MLE generates a better story ending than Seq2Seq-Adversarial. This is mainly because in the adversarial training process, the MC search sampled the *go to church* phrase and it got a high reward score from the discriminator. This can be improved by carefully controlling the MC search process and filtering the meaningless words or phrases.

4 Related Work

4.1 Script Learning

The use of scripts in AI dates back to the 1970s (Minksy, 1975; Schank and Abelson, 1977; Mooney and DeJong, 1985). In this conception, *scripts* are composed of complex events without probabilistic semantics. In recent years, a growing body of research has investigated learning probabilistic co-occurrence-based models with simpler events. Chambers and Jurafsky (2008) proposed unsupervised induction of *narrative event chains* from raw newswire text, with *narrative cloze* as the evaluation metric, and pioneered the recent line of work on statistical script learning (Jans et al., 2012; Pichotta and Mooney, 2014; Pichotta and Mooney, 2016b; Granroth-Wilding and Clark, 2016). However, they utilized a very impoverished representation of events as the form of (*event, dependency*). To overcome the drawback of this event representation, Pichotta and Mooney (2014) presented a script learning approach that employed events with multiple arguments.

There have been a number of recent neural models for script learning. Pichotta and Mooney (2016a) showed that the LSTM-based event sequence model outperformed previous co-occurrence-based methods for event prediction. Pichotta and Mooney (2016b) used a Seq2Seq model directly operating on raw tokens to predict sentences, finding it is roughly comparable with systems operating on structured verb-argument events. Granroth-Wilding and Clark (2016) described a feedforward neural network which composed verbs and arguments into low-dimensional vectors, evaluating on a multiple-choice version of the Narrative Cloze task. However, most of this line of work build their models based on discrete verbs and tokens, which is far from being a complete sentence or story segment as used in this paper.

A line of works has studied the problem of Story Cloze Test on ROCStories corpus (Mostafazadeh et al., 2016). Chaturvedi et al. (2017) explored three distinct semantic aspects including sequence of

events, emotional trajectory and plot consistency, and used a hidden variable coherence model to join these aspects together. Lin et al. (2017) adopted a similar method, and also exploited heterogeneous knowledge for this task. Wang et al. (2017) applied adversarial networks on this task, which is most similar to our work. However, all these studies put their focuses on choosing the correct story ending through discriminative approaches. We mainly aim to generate reasonable and diversified story endings.

4.2 Sequence to Sequence Learning

Sequence to sequence learning (Seq2Seq) aims to directly model the conditional probability $p(Y|X)$ of mapping an input sequence $X = \{x_1, ..., x_N\}$, into an output sequence $Y = \{y_1, ..., y_T\}$. It accomplishes such goal through the encoder-decoder framework proposed by (Sutskever et al., 2014) and (Cho et al., 2014). The encoder computes a representation s for each input sequence. Based on the input representation, the decoder generates an output sequence one word at a time.

A natural model for sequential data is the recurrent neural network (RNN) (Elman, 1990), which is used by most of the recent Seq2Seq work. These work, however, differ in terms of: (a) architecture - from unidirectional, to bidirectional, and deep multi-layer RNNs, (b) RNN type - which is long-short term memory (LSTM) (Hochreiter and Schmidhuber, 1997) or gated recurrent unit (GRU) (Cho et al., 2014).

Another important difference among Seq2Seq work lies in what constitutes the input representations. The early Seq2Seq work (Sutskever et al., 2014; Cho et al., 2014) used only the last encoder state to initialize the decoder state. While, Bahdanau et al. (2015) proposed an attention mechanism, a way to provide Seq2Seq models with a random access memory, to handle long input sequences. Recent work such as (Xu et al., 2015; Yin et al., 2017; Ayana et al., 2017) has found that it was crucial to empower Seq2Seq models with the attention mechanism. Despite its success, many issues emerge due to its over-simplified training objective. In this paper, we propose training Seq2Seq model with adversarial strategy.

4.3 Generative Adversarial Networks

The idea of generative adversarial nets is proposed by (Goodfellow et al., 2014), which has achieved great success in computer vision (Mirza and Osindero, 2014; Radford et al., 2015). Training is formalized as a game in which the generator is trained to generate outputs fooling the discriminator.

However, this idea has not achieved comparable success in the NLP field. This is mainly due to the fact that unlike in image generation, the discrete property of text generation makes the error computed by the discriminator hard to backpropagate to the generator. Some recent work try to address this issue: (Lamb et al., 2016) proposed providing the discriminator with intermediate hidden vectors of the generator, which makes the system differentiable and achieves promising results in language modeling and handwriting generation tasks. Yu et al. (2016) used policy gradient reinforcement learning to back-propagate the error from the discriminator, showing improvement in multiple generation tasks such as poem, speech language and music generation. Li et al. (2017) used a similar strategy to boost the dialogue generation quality, which achieved good experimental results.

Not limited to the task of sequence generation, Chen et al. (2016) applied the idea of adversarial training to sentiment analysis, and (Zhang et al., 2017) investigated the problem of domain adaptation based on adversarial networks. To our knowledge, this is the first paper to study adversarial training augmented Seq2Seq model on the task of generating story endings.

5 Conclusion

Story generation is a challenging problem in AI. In this paper, we explore new ways to generate story ending given a four-sentence story context. In order to generate high-quality story endings, we adopt the idea of adversarial training from *Generative Adversarial Nets* and propose using adversarial training augmented Seq2Seq model to generate reasonable and diversified story endings. Carefully designed human evaluation shows that the adversarial training augmented Seq2Seq model can generate higher quality story endings than purely MLE-trained Seq2Seq model, with 21.1% mean human annotation score improvement and 126.9% bigram diversity improvement. Furthermore, our model can choose the

right ending based on the generated story ending, and achieves the best performance. This verifies the potential of solving the Story Cloze Test problem from a generation perspective.

Point Precisely: Towards Ensuring the Precision of Data in Generated Texts Using Delayed Copy Mechanism

Liunian Li **Xiaojun Wan**
Institute of Computer Science and Technology, Peking University
The MOE Key Laboratory of Computational Linguistics, Peking University
{liliunian, wanxiaojun}@pku.edu.cn

Abstract

The task of data-to-text generation aims to generate descriptive texts conditioned on a number of database records, and recent neural models have shown significant progress on this task. The attention based encoder-decoder models with copy mechanism have achieved state-of-the-art results on a few data-to-text datasets. However, such models still face the problem of putting incorrect data records in the generated texts, especially on some more challenging datasets like ROTOWIRE. In this paper, we propose a two-stage approach with a delayed copy mechanism to improve the precision of data records in the generated texts. Our approach first adopts an encoder-decoder model to generate a template text with data slots to be filled and then leverages a proposed delayed copy mechanism to fill in the slots with proper data records. Our delayed copy mechanism can take into account all the information of the input data records and the full generated template text by using double attention, position-aware attention and a pairwise ranking loss. The two models in the two stages are trained separately. Evaluation results on the ROTOWIRE dataset verify the efficacy of our proposed approach to generate better templates and copy data records more precisely.

1 Introduction

One important task in the natural language generation (NLG) area is to generate a natural language description for some structured data (i.e., a number of database records), a.k.a., the data-to-text generation task. Applicable to wide areas such as weather forecasting, financial reporting, game broadcasting, data-to-text generation systems have been studied for decades (Gatt and Krahmer, 2018). Traditionally this task is addressed by using templates or statistically learned shallow models with hand-crafted features (van Deemter et al., 2005; Belz, 2008; Konstas and Lapata, 2012). Recently, neural generation systems have shown significant progress on this task. The attention based encoder-decoder models with the copy mechanism have achieved state-of-the-art results on a few data-to-text datasets (Wiseman et al., 2017; Sha et al., 2017).

In this paper, we try to address the problem of faithfully describing the data in the generated texts, i.e., how to generate a descriptive text that contains correct entities and numeric values. Intuitively speaking, when a human writer writes weather forecasts or game summaries, he may not consider the exact entities or numbers right away. Rather, he may have finished the whole sentence (without the actual entities or numbers) in his mind, then look up the data table and fill in those exact entities and numbers at last.

Likewise, we don't have to train our models to construct sentences and fill in the data at the same time. If we take out the entities and numeric values from the text, what is left can be considered some kind of templates with data slots waiting to be filled in. Therefore, the process of generating descriptions can be naturally divided into two stages: template generation and slot filling. An encoder-decoder based generator can be in charge of generating the templates with entities and numeric values left blank. A delayed copy network can be in charge of filling in those data slots with proper data records. Compared to traditional copy mechanisms, our approach has the following advantages:

Proceedings of the 27th International Conference on Computational Linguistics, pages 1044–1055
Santa Fe, New Mexico, USA, August 20-26, 2018.

- Traditional copy mechanisms generate and copy words at the same time, which involves merging a score distribution over the input words and a score distribution over the words in the vocabulary. It remains unclear exactly how different merging strategies affect performance. We avoid this uncertainty by leaving the task of generating words to the template generator, the task of deciding which word to copy to the delayed copy network. The two-stage approach also allows us to use a more effective pairwise ranking loss function.

- Relieved of the burden of having to both generate and copy words, the template generator can now concentrate on generating better templates. This can be addressed by using a typical encoder-decoder model, which has proven to be easy to train and tune.

- The delayed copy mechanism can now concentrate on slot filling, and it can utilize all the information in the input data records and the full generated template text by using double attention and position-aware attention, making the delayed copy mechanism point more precisely.

We evaluate our approach on the public ROTOWIRE dataset and evaluation results verify the efficacy of our approach, which makes a boost on the data precision of generated texts and brings a noticeable increase on BLEU score.

We organize the paper as follows. We introduce some background knowledge in Section 2 and describe our approach in Section 3. In Section 4 we present the experiments and have discussion. In Section 5 we note some additional related works. In Section 6 we conclude this paper.

2 Background

The Data-to-text Task Following the notations in Liang et al. (2009) and Wiseman et al. (2017), let $S = \{r_j\}$ be a set of records, where for each $r \in S$, $r.type$, $r.entity$ and $r.value$ are the record's type, entity and value, respectively. For example, there could be a record r in a basketball dataset such that $r.type$ = POINTS FIRST QUARTER, $r.entity$ = LEBRON JAMES, and $r.value = 10$, which means LeBron James scored 10 points in the first quarter. From these records, we are interested in generating an descriptive summary $\hat{\boldsymbol{y}} = \hat{y}_1, \ldots, \hat{y}_T$ of T words. A data-to-text dataset consists of pairs like $(S, \boldsymbol{y})$, where $\boldsymbol{y}$ is a gold (human generated) summary for the record set S. In this paper, we develop our system on the ROTOWIRE dataset (Wiseman et al., 2017), which consists of documents summarizing NBA basketball games and the corresponding game data. For every entity that appears in S, we add an additional record r^* to S, with $r^*.entity$ and the $r^*.value$ both set to the entity's name. For example, if LEBRON JAMES appears in the game, a record r^* with $r^*.entity$ = LEBRON JAMES, $r^*.value$ = LEBRON JAMES, $r^*.type$ = PLAYER NAME is added to S. This aims to copy entity in a neat and uniform way, which will be discussed later.

If a record is mentioned in the text, we consider the text as "faithfully describing the data" if the sentence in which $r.entity$ and $r.value$ are both present correctly reflects $r.type$. For example, for the fore-mentioned record r, if the sentence is "LeBron James got 10 rebounds in the second quarter", it is considered unfaithful to the record. Instead, a sentence correctly reflecting the record should be "LeBron James scored 10 points in the first quarter." Generating texts conditioned on the records is a non-trivial problem because a sentence could likely contain several records. However, there have been few works explicitly addressing this issue due to the lack of challenging datasets. Previous datasets (Liang et al., 2009; Chen and Mooney, 2008; Murakami et al., 2017) generally use relatively simple language and record structure, where some simple approaches suffice. For instance, some models (Mei et al., 2016) generate entities and numeric values as other normal words while some works (van Deemter et al., 2005; Liang et al., 2009; Murakami et al., 2017) employ a *"tag-then-replace"* method, where they train their models to generate special tags which will be replaced with true entities or numeric values using hand-written rules. However, these approaches may fail under more complicated situations. For example, in the ROTOWIRE dataset, there are over 40 $type$s of records and the entity names that appear in the $entity$ portion of records change from game to game, making it hard, if not impossible, to devise hand-written rules for the *"tag-then-replace"* method.

Copy Mechanism Copy mechanism in encoder-decoder models (Vinyals et al., 2015; Gu et al., 2016; Gülçehre et al., 2016; Yang et al., 2017) provides a way to directly copy words from the input. At each time step of decoding, an attention-like function is used to produce an unnormalized score distribution over the inputs, denoted as P^*_{copy}. The decoder also produces an unnormalized distribution P^*_{word} over the words in the vocabulary. These two unnormalized score distributions are then merged into a normalized distribution P_{joint}. The loss function is defined as the negative log likelihood function of vanilla encoder-decoder models: $L = \sum_t -\log P_{joint}(w^*_t|w_{1:t-1}, S)$, where w^*_t is the target word at time step t, $w_{1:t-1}$ are previous words, and S is the inputs. We now illustrate how copy mechanism is used in this task. A copy means the $value$ portion (could be a numeric value or an entity name) of a record r is copied into the output text. To train a copy network, one has to specify which token in the output text is copied and from which input record it is copied. For some token y_t in the gold text, we assume y_t to be copied from some input record r only if the following constraint is met: $y_t = r.value$ and $r.entity$ is present in the same sentence with y_t. Therefore, for every token y_t, if we can find a non-empty set of records C, where every $r \in C$ meets the constraint, y_t is considered to be copied, and C is the set of valid records that is the source of y_t.

3 Our Approach

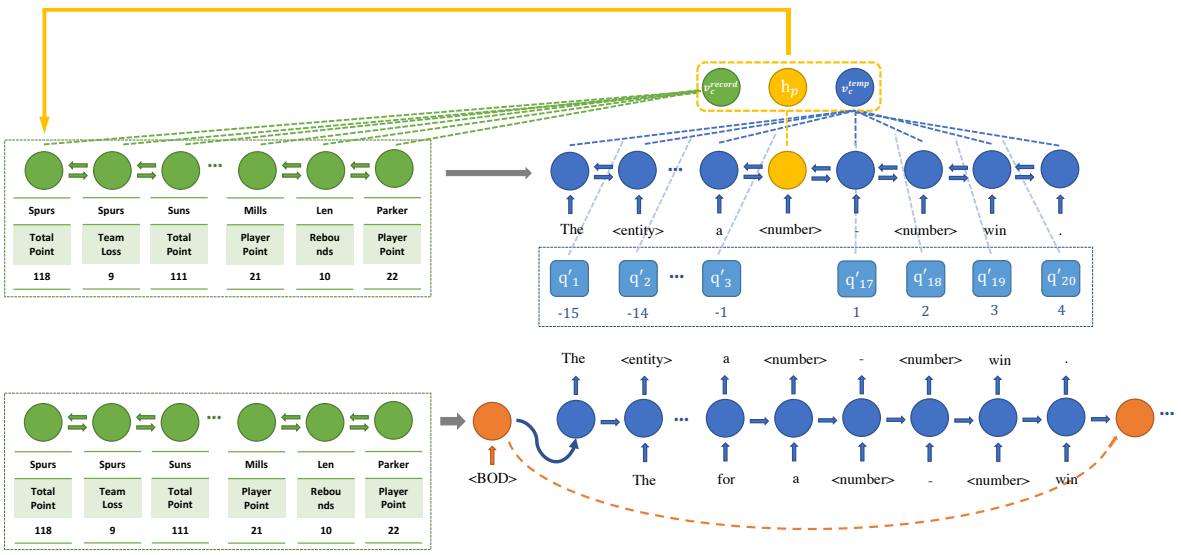

Figure 1: Our Framework: The template generator (below) generates templates and then the delayed copy network (above) fills in the slots.

Our system consists of two models, an encoder-decoder based template generator that constructs the whole sentence with data slots left blank and a delayed copy network that fills in those data slots informed by both the input and the generated sentence. From a computational perspective, this two-stage method has many practical advantages. The template generator is freed from the burden of having to both generate and copy words while the copy network could benefit from utilizing the information from the full templates. This is somewhat similar to Xia et al. (2017), where they observed performing a second decoding using information from the first decoding could boost performance. In addition, detaching the copy network from the text decoder allows room for alternative loss functions, opening up a new possibility for our model. We divided the task in a neat and intuitive way, avoiding the uncertainty in the merging procedure in traditional copy mechanisms. At last, we can reduce training time by training the template generator and the copy network concurrently.

Original Text: The San Antonio Spurs (47 - 9) held off the Phoenix Suns (14 - 42) for a 118 - 111 win. Spurs 's three - point shooting was the key , as they went 10 - for - 16 from long distance in the victory .
Target Template: The <entity> (<number> - <number>) held off the <entity> (<number> - <number>) for a <number> - <number> win. <entity> 's three - point shooting was the key , as they went <number> - for - <number> from long distance in the victory .

Table 1: An example of the original text and the corresponding target template.

3.1 Template Generation with Encoder-Decoder Model

Overview The template generator generates the major part of the text while leaving the task of actually copying to the delayed copy network. It is essentially an encoder-decoder model and any well-performing model would suffice. In this work, we use a hierarchical model similar to the one in Li et al. (2015).

While the template generator does not decide which input record to copy from, it is responsible for deciding whether to copy a token from the input records. At each time step t, if the template generator finds it necessary to copy a token, it outputs a special placeholder (a data slot), which will be replaced with actual entities and numeric values by the copy network. The special placeholder could be "<data>". However in this specific task, we make a distinction between entities and numeric values, and define two placeholders, "<entity>" and "<number>". We denote the templates as $\boldsymbol{y'}$. Now instead of learning to generate the original text $\boldsymbol{y}$, the template generator learns to generate $\boldsymbol{y'}$. An example is shown in Table 1.

The placeholders are added to the vocabulary of the template generator. The template generator outputs the placeholders just like other words. In this way, the process of deciding whether to copy a token is incorporated naturally into the text decoding process, cleverly avoiding the merging operation in traditional copy mechanisms. As mentioned in Section 2, traditional copy mechanisms have to merge P^*_{copy} and P^*_{word} into a normalized distribution P_{joint}. This was designed to allow the input records to "compete" with the words in the vocabulary but there is no clear conclusion about how different merging operations affect performance. In this task, we find that the template generator is fully capable of deciding whether to copy or not.

Structure An input encoder Enc_{input} first encodes every record $r \in S$ by embedding $r.type$, $r.entity$ and $r.value$ and applying a 1-layer MLP followed by an LSTM over the embedding vectors, i.e. $\{\tilde{r}_j\} = Enc_{\text{input}}(\{r_j\})$. We also note that in this paper, all embedding vectors and hidden states are in $\mathbb{R}^D$ unless stated otherwise, where D is the dimension. The input encoder is followed by a hierarchical decoder consisting of a sentence decoder Dec_{sent} and a word decoder Dec_{word}. The sentence decoder outputs sentence representations while the word decoder predicts words in a sentence sequentially. The hidden states of the word decoder Dec_{word} are denoted as $\{h^{word}_t\}$. At test time, beam search can be applied to the word decoder of the template generator. For more details, please refer to Li et al. (2015).

3.2 Slot Filling with Delayed Copy Network

Overview Our copy network fills in the data slots (placeholders) in the generated template. For every placeholder in the template $\boldsymbol{y'}$, the delayed copy network takes in the following inputs: an input vector h_p corresponding to the placeholder; a series of input-record-based vectors $\{h^{\text{record}}_j\}$, each corresponding to an input record r; another series of template-text-based vectors $\{h^{\text{temp}}_t\}$, each corresponding to a word in the template sentence that the placeholder is in. After applying the attention mechanism to both the input records and the template text, it generates a score distribution over the input records and selects the record with the highest score to copy from.

Let us assume the placeholder in question is the m-th word in the template sentence. We always let $h_p = h^{\text{temp}}_m$. We now discuss how we can obtain $\{h^{\text{record}}_j\}$ and $\{h^{\text{temp}}_t\}$. There are actually two ways to do this. We can reuse the hidden states from the template generator to get $\{h^{\text{record}}_j\}$ and $\{h^{\text{temp}}_t\}$[1]. Or we

[1]Concretely, the input-record-based vectors are from the encoder, i.e. $\{h^{\text{record}}_j\} = \{\tilde{r}_j\}$; the template-text-based vectors are from the word decoder, i.e. $\{h^{\text{temp}}_t\} = \{h^{word}_t\}$

can fully detach the delayed copy network from the template generator by using a template text encoder Enc_{temp} to get $\{h_t^{\text{temp}}\}$, a separate input encoder Enc^*_{input} to get $\{h_j^{\text{record}}\}$[2].

Although in the first method, models can be trained in an end-to-end fashion, the burden of actually copying tokens still falls back to the template generator as its hidden states are reused in the copy network. In the second method, which we call a "two-stage" method, the template generator and the copy network are trained separately. This allows the template generator to focus on generating templates. Moreover, since the copy happens after template generation, a bi-directional RNN (Schuster and Paliwal, 1997) can be used in Enc_{temp}, which enables the hidden state of each word to summarize not only the preceding words but also the following words.

In this specific task, we always fill in the <entity> placeholders first and when we do that, we only consider the additional records r^* mentioned in Section 2. When we fill in the <number> placeholders, we only consider the records whose $entity$ portions have been copied into the sentence. In short, when we replace a certain placeholder, only a subset of S, which we denote as S^*, are considered. This small S^* trick ensures the copy network does not copy numeric values whose $entity$ portion is not present in the same sentence. This trick is not applicable in traditional copy networks where the order in which we copy tokens can not be adjusted.

Double Attention Attention mechanism (Bahdanau et al., 2014; Luong et al., 2015) can be described as a function mapping a query vector v_q and a series of source vectors $\{v_s\}$ to a context vector v_c, i.e. $v_c = Atten(v_q, \{v_s\})$. More concretely,

$$v_c = \sum a_s v_s \tag{1}$$

where

$$a_s = \frac{\exp(u_s)}{\sum_{s'} \exp(u'_s)}, \quad u_s = v_q^T \cdot W \cdot v_s \tag{2}$$

and W is a parameter matrix in $\mathbb{R}^{D \times D}$.

To point more precisely, attention mechanism is employed to the input records as well as to the generated template. Given the input vector h_p, the input-record-based vectors $\{h_j^{\text{record}}\}$ and the template-text-based vectors $\{h_t^{\text{temp}}\}$, an input-record-based context vector $v_c^{\text{record}} = Atten(h_p, \{h_j^{\text{record}}\})$ is computed to utilize information from the input records. Likewise, a template-text-based context vector $v_c^{\text{temp}} = Atten(h_p, \{h_t^{\text{temp}}\})$ is computed to utilize information from the template. In contrast, the traditional copy network only applies attention mechanism to the input records.

v_c^{record}, v_c^{temp} and the input vector h_p are then combined to produce a score for a i-th input record r_i:

$$Score(r_i) = [v_c^{\text{record}}; v_c^{\text{temp}}; h_p]^T \cdot W_1 \cdot \tilde{r}_i \tag{3}$$

where W_1 is a parameter matrix in $\mathbb{R}^{3D \times D}$.

Position-aware Attention In the task of relationship classification, which involves determining the relationship of a pair of entities, it has been observed that the relative distances from other words in the sentence to the entities could be informative (Zeng et al., 2014; dos Santos et al., 2015). Inspired by Zhang et al. (2017), we employ a modified position-aware attention mechanism to the template text. When replacing some placeholder using the copy network, the distances between every word in the generated text and the placeholder are incorporated into the calculation of the template-text-based context vector v_c^{temp}. Compared to simply using $Atten(h_p, \{h_t^{\text{temp}}\})$ to calculate v_c^{temp}, this method allows the network to pay attention to words according to their relative locations to the placeholder.

Formally, let's assume $\{y'_1, y'_2, ..., y'_n\}$ is the generated template sentence and the placeholder we are replacing is the m-th token. For every word in the sentence other than the placeholder itself, we calculate its distance to the placeholder to obtain a position sequence $\{q_1, q_2, ..., q_{m-1}, q_{m+1}, ..., q_n\}$,

[2]Concretely, $\{h_t^{\text{temp}}\} = Enc_{\text{temp}}(\{y'_t\})$, where $\{y'_t\}$ is the sentence the placeholder is in; the separate input encoder has identical settings with the input encoder in template generator, so $\{h_j^{\text{record}}\} = Enc^*_{\text{input}}(\{r_j\})$; the hidden state of the Enc_{temp} is initialized using the hidden state of Enc^*_{input}.

where $q_t = t - m$. Using a position embedding matrix Q, we can then obtain a positional embedding sequence$\{q'_1, q'_2, ..., q'_{m-1}, q'_{m+1}, ..., q'_n\}$. Combining $\{q'_t\}$ and $\{h_t^{\text{temp}}\}$, we can calculate the template-text-based context vector v_c^{temp} as:

$$v_c^{\text{temp}} = \sum_{t \in [1,n]; t \neq m} a_t h_t^{\text{temp}} \tag{4}$$

where

$$a_t = \frac{\exp(u_t)}{\sum_{t'} \exp(u'_t)}, \quad u_t = h_p^T \cdot W_2 \cdot [h_t^{\text{temp}}; q'_t] \tag{5}$$

and W_2 is a parameter matrix in $\mathbb{R}^{D \times 2D}$.

Pairwise Ranking Loss As mentioned in Section 2, in traditional copy mechanisms, the unnormalized distribution over input records P^*_{copy} and the unnormalized distribution over words in the vocabulary P^*_{word} are merged into a normalized distribution P_{joint}, which involves somehow applying a softmax function to P^*_{copy}[3]. This method limits the possibility of alternative loss functions for the copy network. In fact, choosing the right input record to copy can also be viewed as ranking the records according to their relative appropriateness, which justifies the use of a ranking loss function. It has been observed in the task of relationship classification that a pairwise ranking loss function is better than a log-likelihood loss function following the softmax function (dos Santos et al., 2015). Following the notation in Section 2, for any y_t that is considered to be copied from the input, C is the set of valid input records that is the source of y_t while S^* is the record set worth considering. A score can be calculated for every record in S^* using Equation 3. We reward the scores of the valid input records and penalize the highest score among all invalid input records by minimizing a pairwise ranking loss function, defined as:

$$L = log(1 + exp(\gamma(m^+ - \sum_{r_i \in C} Score(r_i))) + log(1 + exp(\gamma(m^- + \max_{r_i \in S^*; r_i \notin C} Score(r_i))) \tag{6}$$

where m^+ and m^- are margins and γ is a scaling factor that magnifies the difference between the score and the margin, and helps to penalize more on the prediction errors.

4 Experiments

4.1 Setup

Dataset We experiment our method on the ROTOWIRE dataset (Wiseman et al., 2017). The average text length is 337.1, while the average text lengths of previous datasets (Chen and Mooney, 2008; Liang et al., 2009; Lebret et al., 2016) do not exceed 30. The average number of input records is 628, while those of other datasets do not exceed 200. The text in this dataset also contains a decent percentage of entities and numeric values. This is indeed a challenging enough dataset to test our model on.

Implementation We perform an additional step in preprocessing called "relexicalization"[4]. We used PyTorch (Paszke et al., 2017) for implementation. For encoders and decoders, we use two layers of LSTM. The hidden states and the embedding vectors are all in $\mathbb{R}^{600}$. General-style attention and input-feeding (Luong et al., 2015) are employed. The models are trained using Adam (Kingma and Ba, 2014). The hyper parameters for pairwise ranking loss are set to those provided in dos Santos et al. (2015) without further tuning.

[3] In some models (Gu et al., 2016) P^*_{copy} is not directly normalized. It is mixed with P^*_{word} and then normalized jointly. But generally, we can say that P^*_{copy} is somehow "normalized" using a softmax function.

[4] An entity may have different aliases. For example, "Phoenix Suns" can be referred to as "Suns", "Phoenix" or "Phoenix Suns"; a player can be referred to using his first name or second name or full name. In this work, we didn't make our model learn this naming strategy for processing simplicity. We replace all different alias of the same entity with a uniform name. However, there might be need for diverse naming strategies in a real world situations and we leave that to future work.

	Development					
	RG		CS		CO	BLEU

Table 2: Comparison results. All results are tested after "relexicalization".

Evaluation Metrics For a long time, the automatic evaluation metrics for the data-to-text task have been limited to ones like BLEU (Papineni et al., 2002) and ROUGE (Lin, 2004). However, Wiseman et al. (2017) proposed to use relationship classification techniques for evaluation. Given a sentence and a pair of an entity and a numeric value in the sentence, a relationship classification system can predict the relationship between the entity and the numeric value. Therefore, such a system can be used to assess the quality of automatic generations by extract correctly described records from the generated text. We follow Wiseman et al. (2017) and evaluate our models on these three automatic metrics:

Relation Generation (RG): precision ($P\%$) and number ($\#$) of unique records correctly reflected in the generated text.

Content Selection (CS): precision ($P\%$) and recall ($R\%$) of unique records correctly reflected in the generated text that are also reflected in the gold text.

Content Ordering (CO): normalized Damerau-Levenshtein Distance ($DLD\%$) (Brill and Moore, 2000) between the sequences of records extracted from the generated text and those from the gold text.

Among the three metrics, we argue that the RG metrics is the most crucial one as it evaluates the data fidelity of the system. In this task, it could be considered okay if the system decides to report the game from a different angle and describe some data that are not present in the gold text or describe them in a different order, as the saying goes, "There are a thousand Hamlets in a thousand people's eyes." However, it would be intolerable if it got the scores wrong. We also note that these automatic metrics provided in Wiseman et al. (2017) can achieve over 94% accuracy on held-out data, making it practical for evaluation.

4.2 Comparison with the State-of-the-art Models

Model	Dev Set BLEU	Test Set BLEU
Joint Copy with Rec & TVD	11.53	11.83
Conditional Copy	13.08	12.59
Our Model	**14.66**	**14.33**

Table 3: Template quality

Here we present the comparison results against models with state-of-the-art traditional copy mechanisms[5] in Table 2, including the Joint Copy with Rec & TVD model, which is an augmented version of

[5]We also tried to train a Conditional Copy model with a hierarchical structure, however the results are not satisfying. We argue that this could be because the hierarchical structure is interfering with the copy network, let alone the fact that this Conditional Copy model has been observed to require extra consideration in training procedure.

the Joint Copy model (Gu et al., 2016), and the Conditional Copy model (Gülçehre et al., 2016). Here we used trained models provided by Wiseman et al. (2017) and performed "relexicalization" on the results to keep things fair.

It is clear that our model outperformed other models by a large margin on data fidelity. The precision of record generation (RG) boosted by more than 10%, achieving 85%. The number of correctly generated records also went up by more than 2.5.

We also observed an increase in BLEU score by about two points. We argue that it is not only because the entities and numbers are filled in more precisely, but also because the templates are generated better. In fact, we compared the template quality of different models in Table 3. We take out all the entities and numeric values in the generated text as well as the gold text and calculate their BLEU score. Results show that our model indeed generates better templates.

With the precision up, we also observed a decent increase on the content ordering (CO) metrics. It is worth noting that an increase on RG does not guarantee improvement on content selection (CS). This is perhaps because models that learn to generate records more accurately may not learn to generate records more like human writers. In fact, all models achieved close scores on the recall of CS. It is worth noting that the Joint Copy model, worst on RG, achieved the highest recall on CS.

4.3 Model Validation

We conduct experiments to show how the model's performance is affected by removing some components in the delayed copy network. We used the same template generator for all these models. Results (Table 3) reveal some interesting characteristics about our models.

The biggest boost comes from the pairwise ranking loss we employed. Replacing the ranking loss with a log-likelihood loss in traditional copy mechanisms ("*-ranking loss*") would result in a drop in RG. The BLEU suffered less, which we argue is due to the well-performing template generator. The "*-ranking loss*" model still outperforms the Conditional Copy model, with higher precision of record generation, more correct records and higher BLEU score. Removing the template-text-based attention ("*-double attention*") or replacing the template-text-based position-aware attention with a vanilla attention ("*-pos attention*") also results in a decline on mostly RG and BLEU, showing the efficacy the double attention and position-aware attention. We also tested a model without the S^* trick ("*-S^* trick*") mentioned in Section 2. It can be seen that this trick makes a small improvement to our model yet it is not a defining factor.

4.4 Case Study

Our Model: The Magic (25 - 53) defeated the Bulls (46 - 32) 105 - 103 on Wednesday at the Amway Center in Orlando . The Magic got off to a quick start in this one , out - scoring the Bulls 29 - 21 in the first quarter alone . The Magic were the superior shooters , going 46 percent from the field and 35 percent from the three - point line , while the Bulls went 43 percent from the floor and just 46 percent from beyond the arc . The Magic were also able to force the Bulls into 25 turnovers , while committing only 15 of their own , which may have been the difference in this one . The Magic were led by Tobias Harris , who posted 8 points (2 - 13 FG , 4 - 4 FT) , 3 rebounds and three steals ...
Conditional Copy: The Magic (25 - 53) defeated the Magic (25 - 53) 105 - 105 on Wednesday at the Amway Center in Orlando . The Bulls got off to a quick start in this one , out - scoring the Bulls 29 - 21 right away in the first quarter . The Magic were the superior shooters in this game , going 46 percent from the field and 46 percent from the three - point line , while the Magic went just 43 percent from the floor and 35 percent from deep . The Bulls were also able to force the Magic into 16 turnovers , while committing only 16 of their own . The Bulls were led by the duo of Nikola Vucevic and Nikola Vucevic . Nikola Vucevic went 9 - for - 16 from the field and 3 - for - 4 from the three - point line to score a game - high of 22 points , while also adding two rebounds and two assists ...
Gold: The Magic (25 - 53) defeated the Bulls (46 - 32) 105 - 103 on Wednesday at the Amway Center in Orlando . Down two with just over six seconds left in the game , it was Pau Gasol who was able to force his way to the free throw line and hit a pair of free throws to tie the game up . Victor Oladipo then came up clutch for the Magic , driving for a layup with just a second left in the game , therefore giving them a two point lead and eventually the victory . With the loss , the Bulls move into a tie with the Toronto Raptors for the third projected playoff seed in the Eastern Conference . With just four games left in the regular season , it will be a battle for future playoff positioning from here on out . The Magic were superior shooters in this one , going 46 percent from the field , while the Bulls finished at 43 percent ...

Table 4: Example texts generated by different models. Only a part of the texts are showed due to space limitation. The erroneous text has been marked red. Unmarked text correctly reflects records.

We show an example of the text generated by our model, the Conditional Copy model and the corresponding gold text in Table 4. It is clear that our model made fewer mistakes when it comes to accurately describing the data. One interesting finding is that the Conditional Copy model suffers from a common issue found in language-model based models, repetition. The repetition is not shown in repeated sentence

Model	Correct	Wrong	Repeated
Conditional Copy	3.34	1.58	0.35
Our Model	**3.78**	**1.03**	**0.10**

Table 5: Average number of correct , wrong and repeated records in the generated text per sentence.

patterns like in language-model based models but in the repeatedly copied entities and numbers. There are more than 7 repetitions in this short text. However, in our model, the delayed copy network avoided such problem since it is actually not based on language models. We conducted human evaluations to support our assumption. We manually checked 100 sentences randomly selected from summaries for 8 randomly selected games. We checked for correct records, wrong records and repeated records in the text. A record is considered repeated if it is mentioned twice in a short segment. Results (Table 5) show that our model generates records more precisely and makes much fewer repetitions.

We also inspected the attention heat map of the decoding-side attention. The attention weights seem to concentrate heavily on a single word, rather than spread across words. We argue that this is probably because the attention mechanism in our delayed copy network works somehow differently from the traditional attention mechanism. In machine translation (Bahdanau et al., 2014; Luong et al., 2015), the attention mechanism is applied between a language-model based decoder and an encoder. However, in our model, the template-text-based attention mechanism is applied within a bi-directional text encoder. So the bi-directional encoder in our model could have learned to condense the information into the hidden state of a single word.

5 Related Work

Traditionally, data-to-text tasks are decomposed into two subproblems (Kukich, 1983; Goldberg et al., 1994): *content selection*, which involves choosing a subset of relevant records to talk about, and *surface realization*, which is concerned with generating natural language descriptions for this subset. There is also an alternative decomposition in Reiter and Dale (1997), where they break the problem down to three modules: *content selection*, *micro planning*, and *surface realization*. There is also a corresponding work (Mellish et al., 2006) that challenges this decomposition. In early stages, *surface realization* is often realized using templates (van Deemter et al., 2005) or statistically learned models with hand-crafted features (Belz, 2008; Konstas and Lapata, 2012). Machine learning approaches have also been applied to *content selection*. Barzilay and Lapata (2005) models it as a classification problem, whereas Liang et al. (2009) uses a generative semi-Markov model.

With the rise of neural networks, some recent work has focused on generating text from data using neural networks, for example, generating weather forecasts as well as game descriptions (Mei et al., 2016), generating short biographies from Wikipedia Tables (Lebret et al., 2016; Hachey et al., 2017; Sha et al., 2017; Liu et al., 2017), and generating market comments from stock prices (Murakami et al., 2017). With these models achieving excellent results on traditional evaluation metrics such as BLEU (Papineni et al., 2002) or ROUGE (Lin, 2004), Wiseman et al. (2017) proposed to evaluate data-to-text systems from three aspects using relationship classification systems: data fidelity, content selection and content ordering. While there has been some work (Liu et al., 2017; Sha et al., 2017) related to the last two aspects, we find little work explicitly tackling the data fidelity problem.

Here we point out a parallel and independent work (Lu et al., 2018) on image caption that also employs a similar framework. They also generate slotted templates first and then fill in those slots with a separate model, though the exact models used in their work is quite different from ours.

6 Conclusion and Future Work

In this paper, we present a novel two-stage approach with a delayed copy mechanism to improve the precision of data in generated texts. Experiments show that our model points more precisely than other state-of-the-art models and also generates better templates. There is lots of future work we can do. The content selection ability of the model has the potential to be improved and we would like to further

improve the precision of copy mechanism. Another appealing direction is to adopt our delayed copy mechanism to other NLG domains.

Enhancing General Sentiment Lexicons for Domain-Specific Use

Tim Kreutz **Walter Daelemans**

University of Antwerp
{tim.kreutz,walter.daelemans}@uantwerpen.be

Abstract

Lexicon based methods for sentiment analysis rely on high quality polarity lexicons. In recent years, automatic methods for inducing lexicons have increased the viability of lexicon based methods for polarity classification. SentProp is a framework for inducing domain-specific polarities from word embeddings. We elaborate on SentProp by evaluating its use for enhancing DuOMan, a general-purpose lexicon, for use in the political domain. By adding only top sentiment bearing words from the vocabulary and applying small polarity shifts in the general-purpose lexicon, we increase accuracy in an in-domain classification task. The enhanced lexicon performs worse than the original lexicon in an out-domain task, showing that the words we added and the polarity shifts we applied are domain-specific and do not translate well to an out-domain setting.

1 Introduction

Work in sentiment analysis can roughly be divided into two approaches: corpus based techniques and lexicon based techniques (Taboada et al., 2011). Corpus based techniques use supervised learning on large target domain corpora to learn classification models. Currently, implementations using deep learning make up the state of the art in binary polarity classification on Twitter (Rosenthal et al., 2017).

Lexicon based techniques rely on high quality polarity lexicons. Document-level polarity can be predicted by looking at occurrences of lexical units in the document and doing some form of averaging on their respective polarity values. Despite not yielding the state of the art results of corpus based methods, lexicon based methods still see frequent use since they do not rely on big (labelled) data and allow for more interpretability. In recent years, polarity lexicons have been improved by adding new phrases from web data (Velikovich et al., 2010) or by automatically learning domain-specific polarities (Hamilton et al., 2016).

Sentprop is a framework for inducing domain-specific polarities (Hamilton et al., 2016). SentProp has been shown to accurately reproduce domain-specific lexicons from in-domain word embeddings. Additionally, it has been used to examine interesting historical and community-specific polarity shifts.

We elaborate on SentProp by evaluating its use for domain adaptation of a general-purpose lexicon. Starting from a Dutch general polarity lexicon and a corpus of political forum posts, we automatically expand and enhance the general lexicon entries. We show that the enhanced lexicon outperforms the general-purpose lexicon on an in-domain classification task and we further add to the existing body of work by evaluating the enhanced lexicon on an out-domain task. In the out-domain task the general purpose-lexicon yields better accuracy, showing that our proposed method learns domain-specific polarities that do not translate well to other domains.

The paper is organized as follows. Section 2 will embed SentProp in a larger context of semi-supervised lexicon expansion research. In section 3 we describe the corpus used for inducing polarities, our extensions to the SentProp framework and the setup for the classification experiments. In section 4 we describe findings from a qualitative viewpoint and discuss the results of our experiments. We conclude with some final remarks and possible future directions for the research.

2 Related work

In this section we discuss related work to better embed our selected methods for lexicon induction. We first give a broad overview of work done in predicting word polarity. We then address the work that incorporates generated lexicons in polarity classification experiments. The last subsection will discuss research into lexicon adaptation in a domain-specific setting.

2.1 Polarity prediction

Early work in polarity prediction used linguistic rules to extract word relations. Hatzivassiloglou and McKeown (1997) extract conjunctions of adjectives to infer semantic oriëntation (SO; i.e. polarity). The resulting graph modelled similarity links ("and" conjunctions) and dissimilarity links ("but" conjunctions) and clustering was performed to further separate the positive from the negative polarity words. This approach yielded high accuracy (90%) in predicting word polarity, even when using only seven links per adjective.

Turney (2003) used statistical association between seed words and unseen words to induce SO. Specifically, the point-wise mutual information (PMI) of word co-occurrence statistics was used to find similarities of a word to a seed set. The evaluation setup compared induced SO to existing lexicons at different confidence intervals. The highest accuracy (98.20 percent) was found when comparing the top 25 percent most confident SO words induced from the largest corpus (10^{11} tokens). Using lower confidence words and smaller corpora harmed performance significantly.

Another vein in the lexicon expansion literature uses lexical graphs to draw word associations. Rao and Ravichandran (2009) use WordNet to leverage its rich relational structure. They construct a lexical graph by linking words through their synonymy and hypernymy relations. Polarities are propagated over the lexical graph using the label propagation algorithm from Zhu and Ghahramani (2002). Even when reducing the seed set to ten percent of its original size, this yields around 80 percent F-score for nouns and verbs. Adjectives suffer somewhat more from using fewer seed words.

2.2 Classification using induced polarity lexicons

Moving away from the intrinsic evaluation in the papers mentioned above, task-based evaluation is more relevant to our current work.

Velikovich et. al (2010) combine the statistical approach (Turney and Littman, 2003) with simplified label propagation (Zhu and Ghahramani, 2002; Rao and Ravichandran, 2009) to derive a web-based polarity lexicon. Co-occurrence statistics from a large web corpus ($4*10^9$ tokens) were used to construct a lexical graph. Polarities were then propagated over the graph starting from a positive and a negative seed set of respectively 187 and 192 words. The break with predefined lexical resources such as WordNet allows for finding new lexical entries in spelling variations, slang and multi-word expressions (they consider n-grams up to length 10). As such, the purpose of the work is not to compare induced polarities with existing lexicons, but rather to derive a lexicon with high coverage for sentiment analyses.

This results in a 178,104 phrase polarity lexicon which can be applied to a diversity of sentiment analysis subtasks. The web-derived lexicon outperforms two other automatically generated polarity lexicons, including one based on label-propagating WordNet, in a polarity classification and polarity ranking task. Velikovich et. al (2010) show that statistical similarity measures work even when the obtained corpus is very noisy. They also demonstrate the practical usefulness of a web-derived polarity lexicon.

One drawback that remains however, is the neglect of domain-specific information in these general-purpose lexicons. The next subsection will discuss work that has been done in generating lexicons for domain-specific purposes.

2.3 Domain adaptation

There is a large variety of recent work in obtaining domain-specific polarity lexicons. Most are concerned with generating a new lexicon for a target domain (Bross and Ehrig, 2013; Tai and Kao, 2013), while others aim to augment existing lexicons for domain-specific use with a variation of polarity clues.

Choi and Cardie (2009) use linear programming to find the most likely polarity label for words based on their occurrence in opinion expressions. Two types of clues; word-to-word relations within each expression and word-to-expression relations, are exploited to adapt a general-purpose lexicon. The adapted lexicon significantly improves expression classification with regards to the original lexicon.

Du et. al (2010) adapt the information bottleneck (IB) method to take domain-specific knowledge into account. This slightly changes the problem of adapting a general-purpose lexicon to fit a specific domain, because IB is used to adapt an in-domain lexicon to fit out-domain properties. To infer polarity values for words in the unseen domain, the authors use three clues: the relationships between out-of-domain words and out-of-domain documents, the relationships between out-of-domain words and in-domain words and the relationships between out-of-domain words and in-domain documents. To evaluate the domain adaptations, three domain-specific lexicons are manually composed and used as a basis for adaptation. When using IB to adapt an in-domain lexicon for out-domain purposes, polarity classification accuracy of the adapted lexicon is higher than most baselines that use only word occurrence statistics to infer in-domain polarities.

Lu et. al (2011) present an optimization framework that takes a range of signals such as sentiment scores from general lexicons, domain-specific document level sentiment, WordNet and linguistic clues to produce a unified domain-specific lexicon. The framework is tested on hotel reviews and printer reviews and significantly outperforms other lexicon-based methods in a polarity classification task.

2.4 SentProp

The work on domain adaptation for polarity lexicons mirrors the polarity lexicon induction literature in that there are a wide range of possible lexical resources to use as polarity clues and a wide range of induction methods that are all similarly feasible. SentProp implements word-embeddings with label propagation to offer a uniform approach for domain-specific lexicon generation (Hamilton et al., 2016). It further promises accurate performance even when using smaller corpora ((10^7 tokens). Hamilton et. al (2016) demonstrate their method by reproducing existing domain-specific lexicons. They outperform other induction methods including PMI (Turney and Littman, 2003) and graph propagation (Velikovich et al., 2010) in the domain-specific configuration and for standard English with a 1000x reduction of the corpus.

3 Methods

We elaborate on the SentProp method to evaluate it in domain-specific polarity classification tasks. Instead of pursuing state of the art performance in a target domain task, we seek to provide insight into the domain-specificity of polarities derived from the Sentprop method and the applicability of a generated domain-specific lexicon to an in-domain and an out-domain task.

3.1 Word embeddings

The data for the domain-specific input to our lexicon is derived from discussion boards on politics. We use two sources: politics.be and 9lives.be.

Politics.be features a dedicated political discussion board that has seen active use since 2002. It has more than 60,000 registered members and hosts close to 250,000 discussions.

9lives.be is a website originally dedicated to video game news, but also features a discussion board with general topics. We targeted the politics and actuality sub-forum for our data set. The sub-forum hosts close to 2,000 discussions on news and politics since 2004.

Using the Scrapy package for Python, we were able to download close to 20,000 discussion threads with $2x10^6$ posts. Specifications of the collection are reflected in Table 1.

In the choice for a word embedding method we followed Hamilton et. al. (2016), who find that vectors containing positive point-wise mutual information (PPMI) with singular-value decomposition (SVD) outperformed SGNS and GloVe embeddings in lexicon reproduction. This is further supported by Levy et. al. (2015) who also provide a useful overview of hyper parameters in each of the discussed methods. In particular this led us to run 500-dimensional SVD-embeddings with a context-window of

Source	Documents	Types	Tokens
Politics.be	1,778,101	824,978	68,596,562
9lives.be	434,261	315,266	28,006,269
Total	2,212,362	935,292	96,602,831

Table 1: Corpus specifications.

size six (Velikovich et al., 2010) with context-distribution smoothing and eigenvalue weighting (Levy et al., 2015).

3.2 General-purpose lexicon

We used the DuOMAn subjectivity lexicon as our general-purpose lexicon (Jijkoun and Hofmann, 2009). With 8,782 entries, it is the largest polarity lexicon for Dutch. Polarity scores range from -2 (very negative) to 2 (very positive) and contains 3,631 zero (neutral) values.

3.3 Seed sets

SentProp's default pipeline requires the word embeddings and a positive and negative seed word set. We extracted 10 positive and 10 negative seed words by sorting candidates from DuOMan by polarity first and by occurrences in our corpus second. This provided us with a selection of the most positive and negative words that are also used relatively frequently. We then manually filtered words that have any sort of semantic ambiguity. It is important that the seed words are unambiguously positive or negative because they serve as anchors in our graph (Hamilton et al., 2016).

Positive seeds (occurrences)		**Negative seeds** (occurrences)	
perfect (1.926)	leuk (1.368)	probleem (7.542)	slecht (2.834)
gelukkig (1.306)	effectief (1.304)	onzin (1.805)	onmogelijk (1.600)
correct (1.288)	winnen (887)	jammer (1.321)	dom (1.175)
top (789)	positief (771)	spijtig (919)	hypocriet (771)
succes (667)	prachtig (263)	kwaad (718)	discriminatie (709)

Table 2: Seed words as first sorted by polarity in the DuOMAn lexicon, then sorted by their occurrences in the discussion-board corpus. Some semantically ambiguous words were manually filtered like 're-delijk' which translates to 'reasonable' as an adjective but to 'fairly' as an adverb. All positive seed words have a polarity of 2.0 in the lexicon and all negative seed words have a polarity of -2.0 in the lexicon.

3.4 Lexicon expansion

We ran SentProp with default parameters. Starting from the seed words, positive and negative polarity labels are propagated from a word to their nearest neighbor using random walks. The nearest neighbors for any given word are determined by calculating the cosine-similarities between its embedding vector and the vectors of all other words. This theoretically composes a ranking of words with the most similar meanings to the given word. For our purposes we further imply that words with similar meanings have similar polarities. Although this is likely not plausible for all words, on an aggregate level we hope to at least rely on regularities tying positive words to positive words and negative words to other negative words.

The induced polarity score reflects the probability of a random walk reaching the word from the positive set versus reaching it from the negative set. A score closer to 1 reflects a high likelihood for the polarity to be positive and a score closer to 0 reflects the high likelihood for it be negative (Hamilton et al., 2016).

We considered a vocabulary that is much larger than the size of our general-purpose lexicon. In theory, all words in the vocabulary and their induced polarities could be added to DuOMAn, but we

No.	Configuration rule
#1	Apply all full polarity shifts
#2	Apply all weighted polarity shifts
#3	Apply full polarity shifts for x% largest shifts
#4	Apply full polarity shifts for x% smallest shifts
#5	Apply weighted polarity shifts for x% largest shifts
#6	Apply weighted polarity shifts for x% smallest shifts

Table 3: Polarity shift configuration rules. Each of the percentage-based configurations is applied with 5-percent increments to find the best settings. Full polarity shifts entail applying the induced polarity for any word, weighted polarity shifts take the average of the induced polarity and the polarity from the general-purpose domain and applying the average.

expect words with predominantly neutral polarities to only add noise to the lexicon. To only consider sentiment-bearing words and be able to plot them to the scale the general-purpose domain adheres to, we determined the limits to the amount of positive and negative words with two parameters:

$$num\_neg(X, \beta, \gamma) = \gamma\beta|X| \tag{1}$$

$$num\_pos(X, \beta, \gamma) = (1 - \gamma)\beta|X| \tag{2}$$

Where β is the fraction of vocabulary words that will be treated as sentiment-bearing, γ is the proportion of negative polarities to positive polarities in the vocabulary, and $|.|$ is the cardinality operator.

Our algorithm distributes the negative and positive words evenly over the granularity of the general-purpose lexicon. The words with the highest likelihood of being negative hence end up in the -2 group. There is no theoretical rule of thumb for determining the distribution of words over polarity labels and we expect this to be highly domain-dependent. We used a uniform distribution over the labels to make minimal assumptions.

3.5 Enhancing general entries

The algorithm also produces new labels for words already present in the general-purpose lexicon. We do not expect each of these induced polarities to better reflect word polarities than the values in the pre-existing lexicon. Correct label assignment depends on quality of the word embeddings and can change due to the simplified approach to label assignment we described above. We experimented with a few possible configuration rules that combine the information from the general-purpose lexicon and the induced polarities to decide on the size of polarity shifts. We considered applying weighted polarity shifts that average the polarity in the general-purpose lexicon and the induced polarity. We also considered only shifting polarities when the difference between the existing entry and the induced polarity is relatively large or when it is relatively small (Table 3).

3.6 Classification setup

For evaluation, we designed an in-domain and an out-domain binary polarity classification task. The in-domain data consists of over 4,000 polarity annotated tweets that mention the name of a Flemish politician. The out-domain data consists of product reviews from two online web shops: Bol.com and Coolblue.be. The products under review are mostly books, dvd's, games and some consumer electronics. The reviews have a rating that ranges from one to five stars. To match the in-domain binary polarity, we grouped one and two star reviews and four and five star reviews and assigned them negative and positive labels respectively.

The in-domain documents contain 2,126 positive and 2,126 negative tweets. The out-domain documents contain 3,959 positive reviews and the same number of negative reviews. We developed our in-domain lexicon on 90 percent of the twitter data and tested on the remaining 10 percent. We also tested the lexicon on the reviews to see if the enhanced lexicon improved classification in general, or mainly in the domain-specific setting.

Positive words			Negative words		
Word	Type	Translation	Word	Type	Translation
Geniaal	Regular addition	Genius	Verzuurd	Regular addition	Soured
Hoera	Regular addition	Hooray	Brainwashen	Regular addition	Brainwashing
Boeiend	Regular addition	Interesting	Oogkleppen	Regular addition	(horse) blinkers
Goei	Spelling variation	Good	Aggressief	Spelling variation	Aggressive
Perfekt	Spelling variation	Perfect	Groffe	Spelling variation	Rough
Intersant	Spelling variation	Interesting	Associaal	Spelling variation	Anti-social
Chapeau	Non-Dutch	Hats off	Debiel	Vulgarity	Imbecile
Style	Non-Dutch	Style	Dement	Vulgarity	Dementing
Zeitgeist	Non-Dutch	Zeitgeist	Pipo	Vulgarity	Idiot

Table 4: Example additions to the enhanced lexicon. The positive additions contain regular word additions, spelling variations and non-dutch words. The negative additions contain a lot of vulgarities.

For classification we implemented a majority-vote algorithm. Since we respect the granularity of the polarity labels in the original lexicon, words carry different weights. Instead of using binary values to vote on a document's polarity, we took the average of the occurring polarity values. If the average is a positive value we judged the document to have a positive label, and vice versa.

4 Results and discussion

We will now discuss our findings with regards to the best configuration for our proposed method, and the eventual classification accuracy this yielded on the proposed tasks. Moreover, in our qualitative evaluation we look at which words were added and which polarities adapted, and in which regard they reflect the domain-specificity of the generated lexicon.

4.1 Lexicon induction

We induced polarities for words with at least 100 occurrences in the corpus (n $\approx$ 1 per million). This resulted in a vocabulary of 26,563 words. We performed grid search for the parameters in equations (1) and (2) and the possible configurations from Table 3, comparing accuracy for each of the settings. The optimal β-value we found was 0.06, which signifies that 6 percent of all words in the vocabulary, which amounts to 1,303 words that were not already present in DuOMAn, were added to the general-purpose lexicon. The optimal γ-value we found was 0.58 which signifies that 58 percent of the added words are negative polarity words. Applying the average of the induced polarity and the lexicon polarity value for words that shift less than 25 percent works best for enhancing general entries (configuration #6 in Table 3). This resulted in 1,165 polarity shifts in the general lexicon. The resulting enhanced lexicon will be used for our qualitative inspection as well as the classification experiments on test data.

4.2 Qualitative evaluation

The 1,303 additions in the enhanced lexicon are a mixture of new words, spelling variations and words borrowed from other languages (Table 4). Some words are not inherently positive or negative but can be expected to occur mostly in a positive or negative context. The negative additions contain a lot of insults and other vulgarities. Generally speaking the additions seem more applicable in the domain of political discussion than in other domains.

The polarity shifts that were applied to further enhance the general-purpose lexicon had a positive effect on the classification performance for the development data, but since we only applied the subtle polarity shifts we cannot easily discern why the shifts improve results. Of the 3,292 entries in the DuOMAn lexicon that also appeared in the vocabulary, 993 had no polarity difference from the induced polarities, 1,165 had only a small polarity difference ($<$25%) and 1,134 had big polarity differences ($>$25%).

	Political tweets					Product Reviews				
	Positive		Negative		Overall	Positive		Negative		Overall
Lexicon	P	R	P	R	Acc.	P	R	P	R	Acc.
Majority baseline	50.0	0.0	50.0	100.0	50.0	50.0	0.0	50.0	100.0	50.0
DuOMan	65.0	54.0	60.6	**70.9**	62.4	**72.9**	79.7	76.5	**66.2**	**72.9**
Enhanced lexicon	**66.0**	**65.7**	**65.9**	66.2	**66.0**	62.6	**89.7**	**81.8**	46.4	68.0

Table 5: Precision, recall and classification accuracy for the original and the enhanced lexicon. The added out-domain task shows that the general-purpose domain was solely enhanced for the in-domain task.

In 1,078 of the 1,165 applied shifts, the polarity of a word is reduced. This leads us to believe the induced polarities had a lot of neutral values for words that were sentiment-bearing in the general-purpose lexicon. This weakening of sentiment in part of the lexicon did have a positive effect on classification.

4.3 Quantitative evaluation
