Table 4: The upper five rows are the results of the classification with the proposed vectors. For comparison, three types of experiments were also conducted: one in which the vectors were made only from formulaic expressions (FE), another is in which they were made only from voting for majority class and the third in which Sen - CW + Sec vectors were learned only with example sentences in Academic Phrasebank, without using a sentence corpus (no SC).

Our method	54% (60/111)	32% (8/25)	67% (62/93)	26% (10/37)
High frequency	14% (15/110)	-	14% (14/102)	-
High MI	15% (16/106)	-	12% (12/100)	-

Table 5: Our method outperforms mere extraction of word sequences with high frequency or mutual information (MI).

in the annotated dictionary. Then, we randomly chose FEs in each class of the distance. This is based on the idea that FEs similar to those originally recorded in Academic Phrasebank are more likely to meet the criteria than FEs quite different from them. Three annotators conducted the evaluation with small samples to calculate inter-annotator agreement: 0.800. About 100 FEs were evaluated by one annotator. For comparison, we extracted word sequences with high frequency or high mutual information, which was adopted by Simpson-Vlach and Ellis (2010).

Table 5 presents the ratio of good FEs in each result. Comparing with previous methods, the proposed method extracted continuous FEs more successfully. Discontinuous FEs are more difficult to extract correctly. Some examples are shown in Table 6.

6 Discussion

6.1 Error Analysis of Extracted FEs

We analysed the errors in the extracted continuous FEs. We first divided errors into two categories: spanning and semantics errors. The former occur when one word is unnecessary or when the words are insufficient to make a good FE. Consequently, errors of four types occur, one in which a word to the left or right is unnecessary or missing. The remaining errors are classified into three types: too general, too specific and nonsensical. Overly general and overly specific FEs were explained in Section 3.3. Nonsensical expressions are word sequences that are unlikely to be helpful in writing.

The distribution of errors is presented in Figure 4. In any case nonsensical errors are the most frequently occurring, but the remaining errors differ across datasets and methodologies. Examining the errors made in ACL Anthology using our method, unnecessary words (right) and insufficient words (left) stand out. The former error occurs mainly when 'if' is included in a FE, such as *there be evidence to suggest that if*. The latter error includes phrases such as *be important to note that*. Most missing words are 'it'. However, 'if' is sometimes necessary and 'it' is sometimes unnecessary. For example, when 'if' can be replaced with 'whether' in expressions such as *check if*, appending 'if' to a FE is very helpful.

	ACL Anthology	PubMed
Our method	have(has) shown significant improvement(s) over is(are) a key component in it be possible to * to determine whether *to that of Figure* *has been observed that the thematic role*	previous studies have demonstrated the aim of this study is to investigate it is possible that * may have influence *the number of investigated* *to measure * suffer from*
High freq.	we can see that in this paper we propose *state of the art* *shown in Figure 2* *the words in the*	it is important to play an important role *(Figure 1)* *et al 2010)* *$p < 0.05$)*
High MI	this paper is organized as follows to the best of our knowledge *statistical machine translation (SMT)* *on the other hand* *a large number of*	it is important to play an important role *of this study is to* *et al 2011)* *($p < 0.05$)*

Table 6: Examples of extracted FEs. Expressions that are not regarded as good FEs are written in italics.

Additionally, 'it' as a formal subjective should appear along with a real subject, such as a to-infinitive or a that-clause. However, in the PubMed dataset, insufficient words (left) stand out. The words missing the most are 'it' and 'there'. For example, 'it' should be appended to *be clear from the figure that* and *be important to investigate if* and 'there' to *be significant difference between* and *be some limitation to this study*.

Specifically examining FEs extracted using the existing methods, it is apparent that there are many overly general expressions. These expressions mainly include prepositional and idiomatic phrases such as *on the basis of*, *at the time of*, *on the other hand*, *be more likely to* and *for the purpose of*. A different categorisation system is necessary to make the use of these expressions.

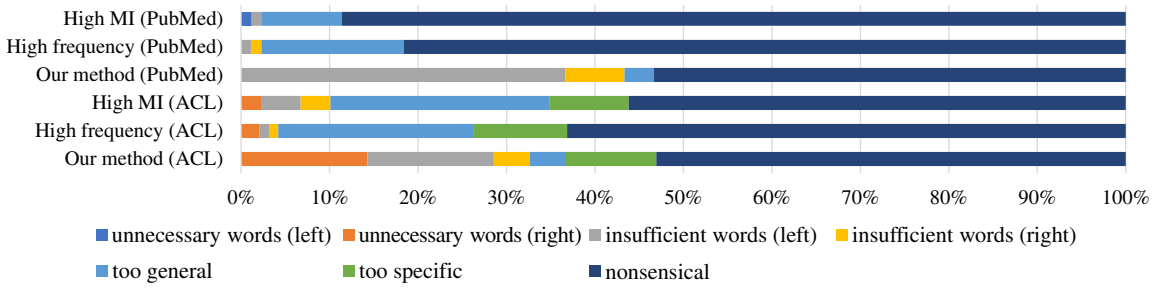

Figure 4: Distribution of error types among results.

6.2 Difference between Domains

For this work, we used two corpora, ACL Anthology and PubMed. Here we discuss the differences in the extracted FEs between the two corpora. First, there were 339 FEs occurring in both corpora (16% of ACL Anthology; 18% of PubMed).

Domain-specific technical terms, such as *natural language processing* or *reactive oxygen species*, are unlikely to be extracted using the proposed method. However, the usage of FEs is shown to differ across domains, which implies that the expressions should be re-ranked according to the users' discipline when candidate expressions are presented to users of the writing assistance system. In addition, it is interesting to note that section information seems more critical in PubMed's classification than in that of ACL.

7 Conclusion

We proposed a new framework for semantic searches of FEs with incomplete user input. We also proposed a method to classify FEs into categories and showed that context information improves the accuracy of the classification. Further, we reformulated FE extraction as a sequential labelling problem and found that this method works well to build a domain-specific FE dictionary.

On the basis of our approach, further research will be conducted to improve the classification and extraction. For classifying FEs, vector representations of a sentence should probably be improved focusing on FE. For acquiring new FEs, an advanced machine learning algorithm should be used to reduce nonsensical FEs and syntactic information would be useful to alleviate the spanning problem.

What's in Your Embedding, And How It Predicts Task Performance

Anna Rogers, Shashwath Hosur Ananthakrishna, Anna Rumshisky
Department of Computer Science,
University of Massachusetts Lowell, Lowell, MA, USA
{arogers,sha,arum}@cs.uml.edu

Abstract

Attempts to find a single technique for general-purpose intrinsic evaluation of word embeddings have so far not been successful. We present a new approach based on scaled-up qualitative analysis of word vector neighborhoods that quantifies interpretable characteristics of a given model (e.g. its preference for synonyms or shared morphological forms as nearest neighbors). We analyze 21 such factors and show how they correlate with performance on 14 extrinsic and intrinsic task datasets (and also explain the lack of correlation between some of them). Our approach enables multi-faceted evaluation, parameter search, and generally – a more principled, hypothesis-driven approach to development of distributional semantic representations.

1 Introduction

Dense lexical embeddings are the most common distributional semantic representations in both industrial and academic natural language processing (NLP) systems (Bengio et al., 2003; Collobert and Weston, 2008; Mikolov et al., 2013a; Pennington et al., 2014; Ruppert et al., 2015). They are used in task-specific neural network models, solving such tasks as named entity recognition (Guo et al., 2014), semantic role labeling (Chen et al., 2014), syntactic parsing (Chen and Manning, 2014), and more.

Each year dozens of new models are proposed, each of them with multiple hyper-parameters that may dramatically influence performance (Lapesa and Evert, 2014; Kiela and Clark, 2014; Levy et al., 2015; Lai et al., 2016; Melis et al., 2017). Equally important are the source corpus, its domain, and the type of context (Padó and Lapata, 2007; Levy and Goldberg, 2014a; Li et al., 2017; Lapesa and Evert, 2017). This amounts to an exponential explosion of options in the quest for the best model for a given task.

Ideally, there would be a single intrinsic metric for identifying "good" embeddings – and there are many proposals for such a metric (including word relatedness and analogies). However, none of them have been shown to predict performance on a wide range of tasks, and there is evidence to the contrary (Chiu et al., 2016).

We hypothesize that *different extrinsic tasks may rely on different aspects of word representations*. In that case, the only way to reliably predict what an embedding can do is to know what aspects of language it captures, and what aspects of language are relevant for different tasks.

To that end, we propose *Linguistic Diagnostics* (LD), a new approach to automated qualitative analysis of vector neighborhoods. To the best of our knowledge, this is the first large-scale attempt to identify and quantify the factors that make word embeddings successful with different tasks. We evaluate 60 models (the popular GloVe and Word2Vec with varying vector sizes and 4 types of context), identifying 21 factors that, to varying extent, correlate with the models' performance on 14 extrinsic and intrinsic task datasets. LD scores can be used not only for evaluation, but also for model development and optimization.

LD is implemented in LDT (Linguistic Diagnostics Toolkit), an open-source Python library[1] that offers a wide range of analysis options with corpus-based statistics, psychological association norms, and dictionaries. LDT provides broad lexical coverage thanks to a combination of the English WordNet, Wiktionary, and BabelNet, and is potentially extensible to many languages.

2 Related Work

Perhaps the most popular kind of intrinsic evaluation of word embeddings are the **semantic relatedness** tests (Finkelstein et al., 2002; Bruni et al., 2014; Luong et al., 2013; Radinsky et al., 2011). They rely on the idea that the distance between word vectors should correlate with human judgements of how related the two words are (e.g., *cat* should be closer to *tiger* than to *hammer*). A more sophisticated version of this task is the **semantic similarity** (Agirre et al., 2009; Hill et al., 2015), which basically restricts relatedness to synonymy and co-hyponymy.

This evaluation paradigm has come under fire for methodological reasons (Faruqui et al., 2016; Batchkarov et al., 2016), in particular, due to the unreliability of the "middle" judgments: while *cat* should be closer to *tiger* than to *hammer*, it is not clear whether it should be closer to *lion* or to *tiger* (Gladkova and Drozd, 2016). Furthermore, only 1 out of 10 datasets was a good predictor of performance on sequence labeling tasks (Chiu et al., 2016). The proposal for evaluation via coherence of semantic space (Schnabel et al., 2015) inherits all the problems with relatedness (Gladkova and Drozd, 2016).

There are multiple proposals for "subconscious intrinsic evaluation" (Bakarov, 2018) based on **correlations with psycholinguistic data** such as N400 effect (Van Petten, 2014; Ettinger et al., 2016), fMRI scans (Devereux et al., 2010; Søgaard, 2016), eye-tracking (Klerke et al., 2015; Søgaard, 2016), and semantic priming data (Lund et al., 1995; Lund and Burgess, 1996; Jones et al., 2006; Lapesa and Evert, 2013; Ettinger and Linzen, 2016; Auguste et al., 2017). However, there are no large-scale studies that would show the utility of these methods in predicting downstream task performance. It is also possible that any psychological measure would share the subjectivity problem of relatedness judgments.

The idea behind the **word analogy task** (Mikolov et al., 2013b) is that the "best" word embedding is the one that encodes linguistic relations in the most regular way: simple vector offset should be sufficient to capture semantic shifts such as $France : Paris$ to $Japan : Tokyo$. However, this view of linguistic relations (and analogical reasoning) is oversimplified, and performance on word analogies has also been shown to depend on cosine similarity between source word vectors (Rogers et al., 2017; Linzen, 2016; Levy and Goldberg, 2014b). Furthermore, the original vector offset method is underestimating the amount of semantic information captured by the embedding (Drozd et al., 2016). Last but not the least, analogies also fail to yield results consistent with downstream task performance (Ghannay et al., 2016).

One more line of research could be called **linguistically motivated evaluation**. The idea is that a "good" embedding would be somehow similar to a representation that could be constructed from a gold-standard linguistic resource (Tsvetkov et al., 2015; Tsvetkov et al., 2016; Acs and Kornai, 2016).

Crucially, all these approaches make the same core assumption: that there is *one* feature of a representation that would make it the "best" (the highest correlation with human judgements, the most regular vector offsets, the closest approximation of a linguistic resource, etc.) However, language is a multi-faceted phenomenon, and different NLP tasks may rely on its different aspects – which would doom any one-metric-to-rule-them-all approach. This is the starting point for our solution.

3 LDT: the methodology

Consider two published modifications of the word2vec model, both trained on Wikipedia: the dependency-based embeddings (DEPS) (Levy and Goldberg, 2014a) and FastText (Bojanowski et al., 2017).

Table 1 lists the first 7 nearest neighbors of *color* (as measured by cosine similarity). Both models output the British spelling of the target word (*colour*). However, DEPS also includes derivatives and synonyms, while FastText favors misspellings and compounds, as could be expected of a subword-level model.

Rank	Deps		FastText	
1	colour	0.93	$color	0.75
2	colors	0.72	color…	0.69
3	coloration	0.69	colour	0.69
4	colouration	0.68	color#ff	0.69
5	colours	0.68	color#d	0.68
6	hue	0.66	@color	0.67
7	hues	0.65	barcolor	0.67

Table 1: Top 7 neighbors of *color* in dependency-based and FastText embeddings.

Which of these models is "better"? Without the context of some application, the question is meaningless. There is no theoretical reason why plural forms of nouns would make better/worse neighbors than their synonyms or misspellings.

This is a more meaningful question: *what are the properties of embedding X that could predict its performance on tasks Y and Z?* For example, question answering would likely benefit from synonymy more than morphology induction. Consider that relatedness tests were found to poorly correlate with performance on sequence labeling tasks, but SimLex (Hill et al., 2015) performed better (Chiu et al., 2016). This could be due to its focus on a particular type of semantic relations (synonymy, co-hyponymy), which turned out to be relevant for the labeling tasks.

Our solution is based on "linguistic diagnostic" tests, achieved by large-scale automatic annotation of linguistic, psychological and distributional relations between words vectors and their neighbors. The resulting data can then be used to find what features are useful for what extrinsic tasks. This work is inspired by the BLESS categorization dataset (Baroni and Lenci, 2011) and by evaluation via a set of representative extrinsic tasks (Nayak et al., 2016).

LD analysis starts with sampling the corpus vocabulary, as will be described in Section 4.2. For each word, top n neighbor vectors are extracted from each embedding. Each neighbor undergoes spelling normalization and is paired with the source word for analysis of possible morphological, semantic, distributional and psychological relations between them, as shown in Figure 1. The annotated data is analyzed to produce direct or statistically derived measures of the degree to which a given embedding is characterized by a given factor (e.g. how many synonyms or morphologically related words are neighbors of a given word vector). The exact set of LD factors considered in this study will be described in Section 5.1.

Since linguistic relations (especially semantic relations such as hypernymy and antonymy) cannot yet be classified accurately by purely distributional means[2], LDT relies on the largest freely available lexicographic resources: WordNet (Fellbaum, 1998) and Wiktionary[3], with the option of BabelNet (Navigli and Ponzetto, 2012). Currently, only English is supported, but (thanks to Wiktionary and BabelNet) LDT can be extended to other languages.

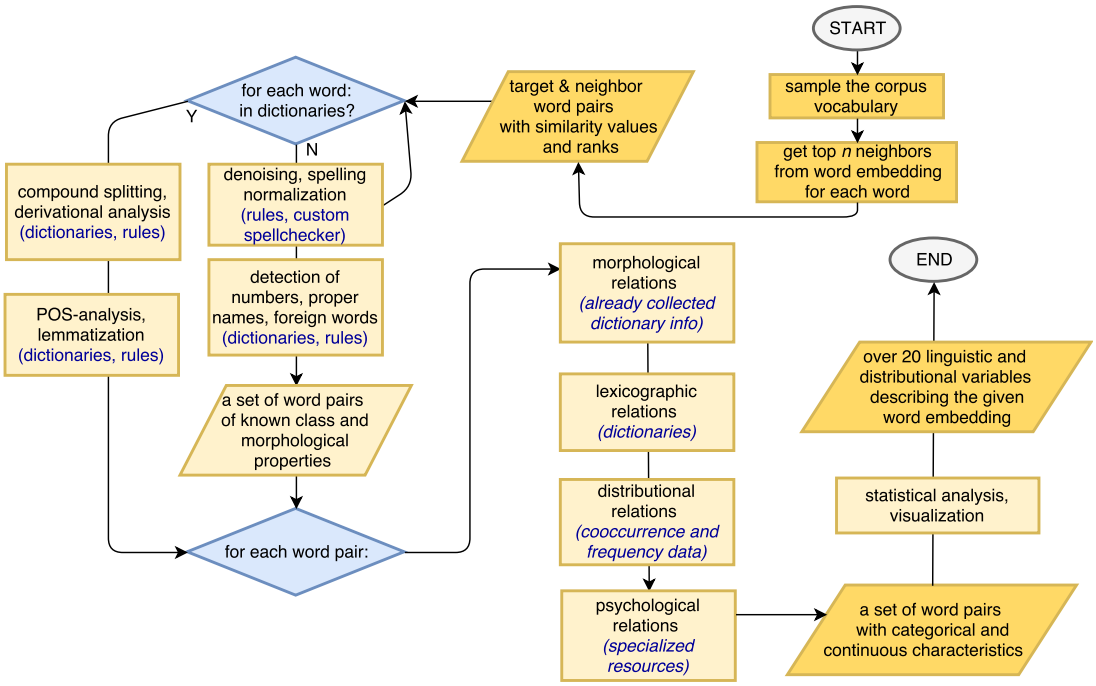

Figure 1: LDT analysis pipeline

[2]For example, the best performing system in the recent CogALex-V shared task (Santus et al., 2016) achieved only 45% accuracy in classifying only 5 semantic relations.

[3]https://en.wiktionary.org

4 Experiment set-up

4.1 Word embeddings

This work explores 3 popular word embedding algorithms: GloVe (Pennington et al., 2014), CBOW, and Skip-Gram (SG) (Mikolov et al., 2013a). The pre-trained vectors we used were published[4] by Li et al. (2017) who experimented with 4 different types of contexts on sequence labeling tasks. Additionally, they provided models with different vector sizes (25, 50, 100, 250, 500). In total, there were 60 models.

Table 2 shows that there are two types of context (linear and dependency-based), and two context representations: bound and unbound. The linear unbound context is the classic bag-of-words context (window size 2). The linear bound context is the same, except that words to the left and to the right are counted separately (Levy and Goldberg, 2014b; Ling et al., 2015). In the "bound" DEPS context (Levy and Goldberg, 2014a), the corpus is syntactically parsed, and only the words that are connected with the target word by some dependency relation are taken into account. Li et al. (2017) extended this idea into the "unbound" DEPS context, where the labels of syntactic roles are ignored.

Context Representation \ Context Type	Linear (Bag-of-Words)	DEPS
unbound	every, non-trivial, has, at	every, non-trivial, has
bound	every/-2, non-trivial/-1, has/+1, at/+2	every/+det, non-trivial+amod, has+nsubj

Table 2: Bound and unbound linear/dependency contexts for the word *program* in the sentence "*Every non-trivial program has at least one bug*". Adapted from (Li et al., 2017).

All embeddings were trained on English Wikipedia (August 2013 dump), with a minimum frequency of 100. After dependency parsing by Stanford CoreNLP (Manning et al., 2014), the corpus was lowercased. Negative sampling was set to 5 for SG and 2 for CBOW, no "dirty" sub-sampling. Distribution smoothing was set to 0.75. SG was trained for 2 epochs, CBOW - for 5, and GloVe - for 30.

4.2 Vocabulary Filtering and Sampling

Fair evaluation must take into account the amount of information that was available during training. It is possible to run LDT on any embeddings, but it yields the most information when the source corpus is available, and it is possible to estimate raw frequencies and cooccurence counts.

The source Wikipedia dump from which the embeddings were produced contains 14,404,885 token types. Only 273,229 of these occur over 100 times, but because of 4 context representations, the vocabulary of the different models is not the same (the DEPS vocabularies are particularly large, up to 5 times as many words). Since LDT methodology is based on the content of vector neighborhoods, to level the playing field for all models we filtered[5] the vocabulary down to 269,860 that were present in all models.

In this study, we focus on the general vocabulary and exclude proper nouns. We use LDT to draw a balanced sample of WordNet lemmas for four parts of speech (nouns, verbs, adjectives, adverbs) in 4 logarithmic frequency bins in the source corpus: 100, 1,000, 10,000, 100,000 (lower boundary inclusive). Following Baroni and Lenci (2011), we control for the polysemy of the words in the sample. For each part of speech at most 30 monosemous and polysemous words were drawn. Polysemy was defined as a word having over 2 meanings in WordNet[6]. The structure of the resulting sample is shown in Table 3.

Note that we also exclude the words belonging to several parts of speech (e.g. *a dog* (noun), *to dog* (verb)) to preserve the morphological class variable. This discards a lot of high-frequency vocabulary, which is why the higher frequency bins for verbs and adjectives were not populated fully. The total number of words in the sample is 908.

[4] `http://vecto.space/data/embeddings/en`

[5] Preliminary experiments showed that the filtering was beneficial to the performance on some tasks, and detrimental to others. The scope of this paper does not permit full investigation of the matter, but the effect was consistent across embeddings.

[6] This measure is not perfect, as numbers of senses in WordNet do not necessarily correspond to the number of senses in which a given word is used in Wikipedia, but it does provide a useful estimate.

4.3 Running LDT

We extract the 1,000 nearest neighbors for each word in the above sample. While most words will not have 1,000 meaningful relations, high-frequency words might have more than that. For example, a SG model with bound DEPS context has *rather* as the neighbor of *quite* at rank 920.

Frequency bin	Nouns	Verbs	Adj.	Adv.
100∼1,000	30 / 30	30 / 30	30 / 30	30 / 30
1,000∼10,000	30 / 30	30 / 30	30 / 30	30 / 30
10,000∼100,000	30 / 30	21 / 30	30 / 30	30 / 30
100,000 >	30 / 30	2 / 29	22 / 24	30 / 30

Table 3: The number of words sampled in each frequency bin per POS (monosemous / polysemous).

In total, 908,000 word pairs were processed for each of 60 embeddings. We limited the used resources to Wiktionary and WordNet, since BabelNet's maximum usage quota for research purposes (50,000 queries per day) would not be sufficient for this large-scale experiment.

The dictionaries covered 76,946 (28.51%) of all the neighbor words; another 124,511 (46.14%) were detected as proper nouns (as could be expected of a Wikipedia corpus). Thus, only 25.35% of the total vocabulary was not covered by LDT.

4.4 Extrinsic tasks

Each of 60 embeddings was evaluated on 8 extrinsic tasks[7]. The selection is similar to what Nayak et al. (2016) proposed as a representative suite of tasks for evaluation purposes. We also follow the recommendation of Nayak et al. (2016) in selecting simpler models for evaluation: more complex models often yield better accuracy, but they could smooth out the performance of different word embeddings and also raise the question of whether the gains are due to the model or the embeddings.

The morphological and syntactic information is targeted by two sequence labeling tasks: **POS-tagging** and **chunking**. We use the CoNLL 2003 shared task dataset (Tjong Kim Sang and De Meulder, 2003), following the method by Li et al. (2017). The model is a softmax classifier on the window-based concatenation of word embeddings of every training example (window size 3, 20 training epochs).

Semantic information at the word level is targeted by one more CoNLL 2003 shared task: **named entity recognition (NER)**, evaluated in the same way as POS-tagging and chunking. We also consider the task of **multi-way classification of semantic relations (Relation class.)** between pairs of nominals in the SemEval 2010 task 8 dataset (Hendrickx et al., 2010). The model we use is similar to the model by Zeng et al. (2014): a CNN equipped with word and distance embeddings.

Next, we have 3 tasks relying on how the word embeddings encode semantic information, and to what degree individual word vectors can be combined into an accurate sentence representation. The **sentence-level sentiment polarity classification (Sentiment (sent.))** task is tested with the MR dataset of short movie reviews (Pang and Lee, 2005). Binary classification is performed by a simplified version of the model proposed by Kim (2014).

We also add the **document-level polarity classification (Sentiment (text))** with the Stanford IMDB movie review dataset (Maas et al., 2011). Polarity is harder to estimate at the document than at the sentence level, because sentiment is more likely to be mixed. The task is performed with a single layer LSTM with 100 hidden units.

The **classification of subjectivity and objectivity (Subjectivity class.)** is tested on Rotten Tomato user review snippets vs official movie plot summaries (Pang and Lee, 2004). We follow the method by Li et al. (2017), employing a simple logistic regression model for the binary classification task. The input sentences are represented as a sum of their constituent word vectors.

Finally, the **natural language inference** task is represented with the SNLI dataset (Bowman et al., 2015). Similarly to the original proposal, we use two separate LSTMs to get a representation of the premise and the hypothesis using the last hidden state. The two hidden representations are merged and fed into a 50-unit dense layer, over which 3-class classification with softmax is performed.

4.5 Intrinsic tasks

Section 2 mentioned the reported lack of correlation between the performance of word embedding models on relatedness and sequence labeling tasks (Chiu et al., 2016). Ghannay et al. (2016) also report that the best-performing embedding on sequence labeling and mention detection tasks is not necessarily the embedding that performs the best on analogy and relatedness datasets. However, these studies have a limited selection of word embeddings (amounting to 9 and 5 data points, correspondingly). Crucially, they also focus on the same sequence labeling CoNLL tasks.

We explore the problem with our set of 60 embeddings, and a wider selection of extrinsic tasks. The intrinsic task datasets are WordSim353 (Finkelstein et al., 2002), together with its split into similarity and relatedness sections (Agirre et al., 2009), RareWords (Luong et al., 2013), MTurk (Radinsky et al., 2011), MEN (Bruni et al., 2014), and also the SimLex999 (Hill et al., 2015) similarity dataset. For the analogy task we use BATS dataset (Gladkova et al., 2016), which is currently the largest analogy dataset for English. We report separate scores for inflectional and derivational morphology, lexicographic and encyclopedic semantics, and the average of all categories.

The evaluation on similarity and relatedness datasets is performed as Spearman's correlation with the human judgement scores. The evaluation on analogies is performed with the state-of-the-art LRCos method (Drozd et al., 2016).

5 Results

5.1 Correlation analysis

In this study we experimented with 21 morphological, lexicographic, psychological, and distributional factors of word vector neighborhoods. For better readability, they are presented in Figure 2 together with their correlations with each other and the performance on 14 extrinsic and intrinsic task datasets (based on the data from 60 GloVe and Word2Vec embeddings described above).

Binary relations (e.g. synonymy is either detected or not) were quantified as a simple count of all cases of that relation in all target:neighbor pairs for each embedding. Directed lexicographic relations (hypernymy, hyponymy, meronymy) are counted when the target word is e.g. a hypernym of the neighbor. Continuous variables are broken down into bins, the size of which is chosen empirically: e.g. instead of frequency of the target word we count the number of low-frequency or high-frequency neighbors.

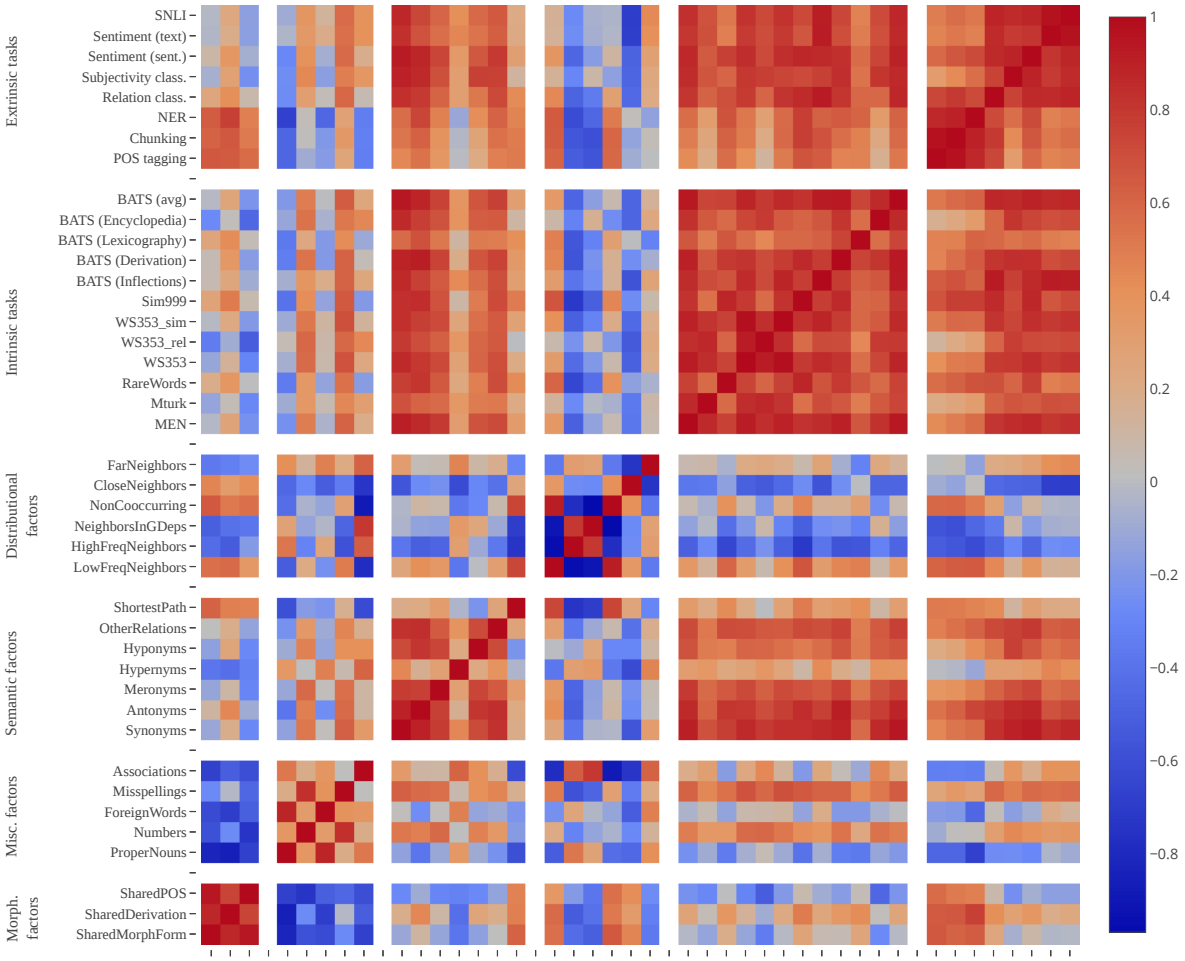
We experimented with the scores from 1,000, 5000, and 100 top neighbors of the sample words. The overall correlation patterns were similar, suggesting that it will be sufficient for future work to limit the selection to the top 100 neighbors. We thus report the results for the top 100 neighbors in this section.

The largest immediately observable pattern is the high correlation between *almost all* intrinsic tasks. The correlations are lower (but still over 0.5) for the lexicography and encyclopedic section of BATS; but the performance on these categories is generally rather low (Drozd et al., 2016) and could be unreliable. On the other hand, the high correlation between analogy and all relatedness and similarity datasets confirms the conclusion of (Rogers et al., 2017) that accuracy on analogy depends on the similarity between the source word pairs (even for LRCos method).

As for the extrinsic tasks, the immediate observation is the low correlation between all the intrinsic and 3 sequence labeling tasks. These are the same tasks that were reported by Chiu et al. (2016) and Ghannay et al. (2016) as the tasks for which higher performance does not correspond to higher performance on intrinsic tasks. However, all the non-sequence-labeling tasks in our sample *do* correlate with the intrinsic datasets.

This is a crucial finding; it shows that the traditional intrinsic tasks are after all useful for predicting performance on *some* downstream tasks. Their disadvantage is that they offer no explanation about why this is the case, and what could be expected of other extrinsic tasks not in our sample.

This is where LD methodology comes in. Figure 2 shows 4 groups of factors that we analyzed, together with their correlations with both extrinsic and intrinsic tasks. An immediate observation is that a large amount of neighbors that are in some lexicographic semantic relation with the target word is a good predictor of performance on both traditional intrinsic datasets and all the extrinsic tasks *except for the sequence labeling*. On the other hand, these particular tasks correlate highly with the three



Distributional factors
LowFreqNeighbors, HighFreqNeighbors: the frequency of the neighbor in the source Wikipedia corpus is under/above 10,000
NeighborsInGDeps: whether the two words co-occur in the Google dependency ngrams
NonCooccurring: the number of word pairs that do not co-occur in the source Wikipedia corpus (bag-of-words window size 2).
CloseNeighbors: the number of top 100 neighbors with cosine distance to the target word over 0.8.
FarNeighbors: the number of top n neighbors with cosine distance to the target word less than 0.7.

Semantic factors
Synonyms, Antonyms, Hypernyms, Hyponyms, Meronyms: the corresponding lexicographic relations established by the dictionaries.
OtherRelations: holonymy, troponymy, coordinate terms, and "otherwise related" in Wiktionary.
ShortestPath: the minimum path between synsets of two words in the WordNet ontology

Miscellaneous factors
ProperNouns: the neighbor is a proper noun.
Numbers: the neighbor is a numeral, or contains a number.
ForeignWords: the neighbor is not found in English, but found in German, French or Spanish spellechecker dictionaries.
Misspellings: the neighbor is not found in dictionaries and contains an unusual combination of letters and punctuation or numbers.
Associations: the two words constitute an associative pair (in either direction), according to EAT[8] (Wilson et al.,) and USF-FAN[9] (Nelson et al., 2004).

Morphological factors
SharedMorphForm: the two words share their morphological form (in this case, both are lemmas).
SharedDerivation: the two words share affix(es) or stem(s), or are both compounds (based on Wiktionary and custom LDT tools).
SharedPOS: the two words have the same part of speech (any overlap counts).

Figure 2: Pairwise Spearman's correlations of extrinsic and intrinsic tasks between themselves and LDT scores for top 100 neighbors. An interactive version of this chart, as well as numerical data and data for top 1000 neighbors can be found at `http://ldtoolkit.space/analysis`.

morphological factors we considered: the neighbors sharing morphological form, derivational pattern and/or part-of-speech of the target word. This finding confirms our original hypothesis: *different tasks rely on different information, making a single-number intrinsic evaluation unfeasible.*

At the same time, the border between morphology and semantics is not a stone wall. The derivational morphology factor does have weak positive correlations with all the intrinsic and extrinsic tasks, since shared derivation does indicate at least partially shared semantics. The performance on sequence labeling tasks also does correlate with the scores on lexicographic semantic relations. We attribute this to the fact that dictionaries usually store relations between words of the same part of speech, so these scores implicitly contain the *SharedPOS* factor.

The semantic factors that appear to be the least useful across all tasks are the *ShortestPath* and hypernymy. The latter is surprising in the light of such tasks as SNLI that seems to clearly rely on it.

The psychological associations turn out to be only weakly useful in the semantic extrinsic tasks (presumably to the same degree to which they correlate with relatedness tests, and relatedness tests correlate with extrinsic tasks). This is in line with Gladkova and Drozd (2016)'s suggestion that human relatedness scores depend on the psychological factors such as speed of association, rather than pure semantics.

It could be expected that, in the sample of general English vocabulary, the neighbors that are proper nouns or foreign words would be detrimental to any task. However, we observe a positive correlation with the amount of neighbors that contain numbers (presumably due to the meaningful hyponymy that they could indicate, such as model numbers, addresses etc.). A large number of misspelled neighbors is also apparently good for all tasks: since all the models in this study are word-level, this could indicate their ability to mitigate the lack of subword information.

Among the distributional factors, the clearest positive effect is observed for the models that have the highest number of low-frequency vocabulary (under 10,000 occurrences in the corpus) in the word vector neighborhoods. Since most word types fall in this range, this indicates that a "good" model should be able to populate vector neighborhoods with related words, even if they are not particularly frequent. The *NonCooccurring* factor is apparently useful for sequence labeling and some intrinsic tasks to find more *latent* relations between words that do not actually co-occur in the corpus, i.e. deduce relations on the basis of the "second-hand" rather than direct similarity between distributional patterns of words. Finally, the scores on the *FarNeighbors* factor suggest that high-level semantic tasks benefit from more neighbors that are less than 0.7 similar to the target word. This could be interpreted as follows: if a neighborhood is packed with words that are all quite similar, many of them will end up being within 0.00000001 from each other, making the margin of error very small for the models that use these representations in tasks.

One more important observation from this experiment is that all the extrinsic and intrinsic tasks have high correlations with more than one LD factor, which illustrates the point about tasks being complex *ensembles* of various linguistic features. However, it is only by breaking them down into smaller, controllable factors that we can explain and improve on them.

Note also that all the factors we considered correlate considerably with each other within their subclasses: the morphological features have mostly *negative* correlations with the lexicographic ones, while the sequence labeling tasks only weakly correlate with the high-level semantic tasks. This raises the question of what it would take for a representation to do both equally well.

5.2 Profiling embeddings with LD

As a brief demonstration of explanatory power of LD methodology, let us consider CBOW, SG, and GloVe models and their performance on the 8 above tasks in one condition: linear bag-of-words context, 500-dimensional vectors (the LD scores for top 1000 neighbors are reported). Table 4 lists some of the LD factors identified in Section 5.1 together with performance on our 8 extrinsic tasks.

We see that the 3 models are very close in most of factors; yet it is SG that is always slightly ahead in semantic, morphological and distributional LD factors and actual performance. CBOW is consistently slightly behind SG on these accounts, and slightly ahead on the scores for misspellings, foreign words, numbers and proper nouns (apparently at the cost of the meaningful relations).

The key difference between GloVe and Word2Vec appears to be the *LowFreqNeighbors* (amount of

low-frequency words as neighbors) and *NonCooccurring* words (words that end up as neighbors in spite of not co-occurring in the source corpus). This suggests that the success of SG is due to its ability to bring together related words even if they were rare, and/or did not co-occur in the corpus. This apparently outweighs even GloVe's significant advantage in sparser vector neighborhoods.

It is interesting that comparable or even superior scores on "morphological" factors did not give GloVe an advantage in POS-tagging and chunking tasks. Apparently specialized information is necessary but not sufficient for top performance, and it is successful ensembles of features that matter.

5.3 LD for parameter search

LD factors are equally useful for studying the effect of hyperparameters as well as underlying algorithms. As a brief demonstration, consider the behavior of the *NonCooccurring* factor discussed above when varying the size of SG, GloVe, and CBOW vectors (linear unbound context, top 1000 neighbors).

The larger representations are often assumed to be more informative, but Figure 3a shows that this is not the case for GloVe. The questions of why the compression effect is the smallest for the smallest vectors, and what other factors are at play here, merit a separate investigation. As in the case discussed in 5.2, Skip-Gram is consistently slightly ahead of CBOW, except for the lowest dimensionality.

As a final example, let us take a quick look at the idea that the dependency-based contexts pack more synonyms than linear contexts. This does not seem to be the case in Fig. 3b: the positive effect is rather due to unbound vs bound representation than to dependency-based or linear context. Thus, if the goal is to maximize the number of synonyms, the effort of parsing is not justified. This result is consistent with the finding that dependency-based vector space models do not outperform the optimized window-based models on the TOEFL synonym task (Lapesa and Evert, 2017).

6 Discussion and Future Work

We have presented the LD methodology for quantitative/qualitative exploration of word embeddings. As proof of concept, our analysis of GloVe and Word2Vec showed that LD can effectively identify the linguistic and distributional factors that make word embeddings more or less successful on the downstream and traditional intrinsic tasks. We are hoping that this work will contribute to the NLP community efforts in the following directions:

- *comparison of word embedding algorithms* (e.g. different modifications of the Word2Vec);
- *hyperparameter effects* on encoding of different linguistic relations;
- a more informed, *hypothesis-driven design of new distributional representations*;
- *informed choice of word embeddings for various downstream tasks*;
- the degree to which different relations are useful for different tasks and to which they can be combined in a *generalized representation without sacrificing too much accuracy on specialist tasks*.
- interaction between *preference for different linguistic relations and performance on different tasks*.

LD methodology itself can be expanded by expanding LDT to other languages and by formulating the criteria for comparing representations of proper nouns. For example, the co-hyponymy relation between names of composers would be covered with the current implementation, but giving a higher score to a model that places *violin* closer to *Bach* than to *Beatles* would require evaluating frame-semantic, or at least topical relations, going beyond the traditional dictionaries.

A major caveat is the instability of word embeddings: different runs of the same model may yield word vector neighborhoods with significantly different lexical content. Some models are more stable than others (in particular, GloVe was found to be more stable than word2vec) Wendlandt et al. (2018), but most models published in the recent years do not explore their stability. This fact does not disqualify evaluations based on vector neighborhoods (not only LD, but also the traditional relatedness and analogy tasks), but it does highlight the absolute necessity of large-scale studies to reach any definitive conclusions about the relative (de)merits of different models. At the moment, most work on word embeddings still report experiments with less than ten models, each trained just once.

Important directions for future research also include going beyond simple word-level word embeddings. Some of the questions to investigate include the balance between semantic and morphological information in subword-level models (Bojanowski et al., 2017) and their ensembles with word-level models (Yang et al., 2017). It would also be interesting to expand LD to sense-aware embeddings (Melamud et al., 2016), particularly for contextualized representations (Peters et al., 2018).

7 Conclusion

We presented LD, a methodology for quantitative/qualitative intrinsic evaluation of word embeddings implemented in an open-source Python library. Moving away from unrealistic single-number evaluations, LD identifies precisely what kinds of information a given word embedding encodes in its vector neighborhoods. Unlike traditional intrinsic tasks, LD can also be used to *explain* the correlation between performance on different tasks, or the lack thereof.

The effectiveness of LD was shown in a large-scale experiment with 60 GloVe and Word2Vec models on 14 intrinsic and extrinsic task datasets. We have identified 21 morphological, semantic and distributional factors that are useful for predicting and interpreting the performance patterns of word embeddings. In addition to providing practical guidelines for choosing the best embeddings for a given task, LD opens new possibilities for more informed, hypothesis-driven development of distributional representations.

Abstract

Word sense disambiguation (WSD) is the task to determine the sense of an ambiguous word according to its context. Many existing WSD studies have been using an external knowledge-based unsupervised approach because it has fewer word set constraints than supervised approaches requiring training data. In this paper, we propose a new WSD method to generate the context of an ambiguous word by using similarities between an ambiguous word and words in the input document. In addition, to leverage our WSD method, we further propose a new word similarity calculation method based on the semantic network structure of BabelNet. We evaluate the proposed methods on the SemEval-2013 and SemEval-2015 for English WSD dataset. Experimental results demonstrate that the proposed WSD method significantly improves the baseline WSD method. Furthermore, our WSD system outperforms the state-of-the-art WSD systems in the Semeval-13 dataset. Finally, it has higher performance than the state-of-the-art unsupervised knowledge-based WSD system in the average performance of both datasets.

1 Introduction

In natural language text, it is very common for a word to have more than one sense. For example, in a sentence "An airline hires new cabin crews" of Figure 1, the words 'airline,' 'hires,' 'new,' 'cabin' and 'crews' have more than two senses. In this case, we can map 'airline' to 'airline Noun#2', 'hires' to 'hire Verb#1,' 'new' to 'new Adjective#6,' 'cabin' to 'cabin Noun#3' and 'crews' to 'crew Noun #7' by the context of this sentence. The word sense disambiguation (WSD) is the task to determine the correct meaning of an ambiguous word in a given context. WSD is being used as a key step for performance improvement in many natural language processing tasks such as machine translation (Vickrey et al., 2005; Chan et al., 2007), information retrieval (Sanderson 1994; Stokoe et al., 2003) and so on.

WSD can be divided into supervised approaches and knowledge-based unsupervised approaches. In the supervised approach, machine learning models are trained by a corpus, in which the correct senses of ambiguous words are already annotated by human annotator (Weissenborn et al., 2015; Melamud et al., 2016; Raganato et al., 2017). However, constructing training corpus for all languages and words is tremendously expensive, so the supervised approaches generally have some limitations on the set of the words that can be disambiguated. On the other hand, the knowledge-based unsupervised approaches utilize lexical knowledge bases (LKBs) such as a Wordnet (Banerjee and Pederson., 2003; Chaplot et al., 2015). These approaches have performed WSD by combining contextual information and semantic knowledge on the LKBs. Thus, there is much number of words that can be disambiguated when compared to the supervised approaches. For this reason, it is known that the knowledge-based approach is more suitable than supervised approach for the practical WSD systems (Moro et al., 2014; Chaplot and Salakhutdinov 2018).

* Both authors contributed equally to this work.

Proceedings of the 27th International Conference on Computational Linguistics, pages 2704–2714
Santa Fe, New Mexico, USA, August 20-26, 2018.

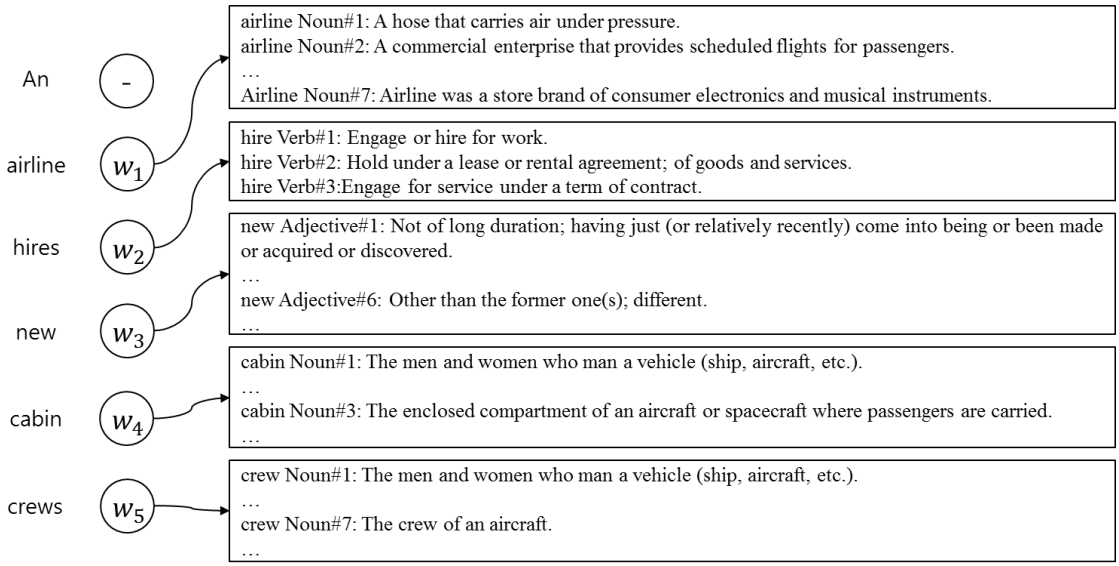

Figure 1: Example for the WSD task.

The most popular approach for the knowledge-based unsupervised ones is the graph-based WSD approach determining the answer sense by linking the senses and context of the ambiguous words on the LKBs to generate a semantic subgraph and measure the connectivity of the senses corresponding to a node in the subgraph. Therefore, establishing an efficient strategy for generating subgraphs of those senses directly affects the performance of WSD. Conventional knowledge-based unsupervised approaches tried to construct the subgraph of all the words that appear in the document and concurrently disambiguate all ambiguous words in the document (Navigli and Lapata, 2007; Navigli and Lapata, 2010). This joint optimization strategy has the advantage of being able to derive the optimal sense set for ambiguous words, but there is a limitation in that the computational complexity increases exponentially as the number of ambiguous words is increasing. To ameliorate above problem, Manion et al. (2014) proposed a subgraph construction strategy using the iterative subgraph reconstruction approach that greedily analyzes the ambiguous words according to a specific priority. However, the iterative subgraph uses entire words in the document as a context to determine the sense of each ambiguous word and it makes sometimes the subgraph of a word overcomplicated with unnecessary information.

Based on this iterative subgraph reconstruction approach, we propose a new subgraph construction strategy to avoid the abovementioned problems by selectively restricting the context when constructing a subgraph of an ambiguous word. In our proposed approach, contextual words of an ambiguous word for constructing the subgraph are selected by thresholding the word similarities to the ambiguous word. In addition, we propose a new word similarity measure method by using word vector representations, generated from the knowledge graph of LKBs and a neural network, for the efficient contextual word selection. In the experiments, we prepared the three publicly accessible English WSD datasets of SemEval-2007 (Pradhan et al., 2007), SemEval-2013 (Navigli et al., 2013) and SemEval-2015 (Moro and Navigli, 2015). We used the SemEval-2007 dataset as a development set for parameter tuning and other datasets as test sets. Experimental results show that our proposed WSD approach with the new subgraph construction strategy has significantly better performance than the baseline iterative subgraph reconstruction approach of Manion et al. (2014). Moreover, when we apply our proposed word similarity method to our WSD approach, it achieved better performance than the WSD systems using other existing word similarity methods. Eventually, the final proposed WSD system with all of the new subgraph construction and word similarity methods achieved higher performance than the state-of-the-art unsupervised knowledge-based WSD systems.

The remainder of the paper organized as follows. In section 2, we introduce previous studies for the WSD system and our sense repository BabelNet (Navigli and Ponzetto, 2012). Section 3 is allocated to introduce our proposed WSD system in detail. Experimental environments and results are described in section 4. Finally, conclusion and future work are discussed in section 5.

2 Related Work

2.1 Word Sense Disambiguation

Recently, the graph-based WSD method become the most popular a method for the knowledge-based WSD (Navigli and Velardi, 2005). The graph-based method selects the answer sense of the ambiguous word based on the semantic structure of LKBs. Generally, the answer sense is chosen from the semantic subgraph that connects the senses of the words in the input document using the semantic relationships defined in LKBs. Navigli and Lapata (2007) built a semantic subgraph of the entire words including senses and then used graph connectivity measures to determine the combination of answer senses. Agirre et al. (2014) suggested a knowledge-based WSD approach used personalized page rank (PPR) over the semantic subgraph. They calculated the relative importance of senses using PPR and the sense with the highest score was chosen as an answer sense. Babelfy (Moro et al., 2014) presented another graph-based approach that jointly selects answer of WSD and entity linking (Xiao et al., 2015). Utilizing the random walk algorithm with a restart, it extracted a dense subgraph and reweighted the edges of a BabelNet. They iteratively disambiguate words by reconstructing a semantic subgraph at each word. Based on the assumption that word with a minimum sense is an easiest word among the entire ambiguous words, Manion et al. (2014) disambiguated the ambiguous words in order of the number of their senses. Chaplot et al. (2015) maximized the joint probability of whole senses in the context using WordNet and dependency. Tripodi and Pelillo (2017) suggested to apply the idea of the evolutionary game theory to their WSD system. By exploiting the semantic similarity of the words, they formulated WSD as a constraint satisfaction problem and derived it utilizing game theorem tools.

In addition to these abovementioned methods, several methods for WSD have been proposed. Chaplot and Salakhutdinov (2018) proposed a topic modeling based WSD approach to ameliorate computational complexity of graph-based WSD. Zhong and Ng (2010) tried to disambiguate words using support vector machine (Suykens and Vandewalle, 1999) with rich linguistic features such as part-of-speech, local collocations and surrounding contextual words. Weissenborn et al. (2015) jointly optimized WSD and entity linking model in an extensible multi-objective optimization. Pasini and Navigli (2017) built a large-scale training corpus for WSD from scratch using Wordnet. Raganato et al. (2017) suggested a supervised WSD approach using bidirectional long short-term memory and attention mechanism.

Our WSD method is based on the iterative subgraph reconstruction approach (Manion et al., 2014). However, our WSD approach is crucially different in that it selectively constructs subgraphs by thresholding the contents words of the input document based on the similarity with the ambiguous words.

2.2 BabelNet

Most unsupervised WSD systems utilize LKBs such as Wordnet[1] to obtain a set of possible senses for each ambiguous word. BabelNet[2] is a multi-lingual lexicalized semantic network and ontology. It pro-

[1] https://wordnet.princeton.edu/
[2] http://babelnet.org

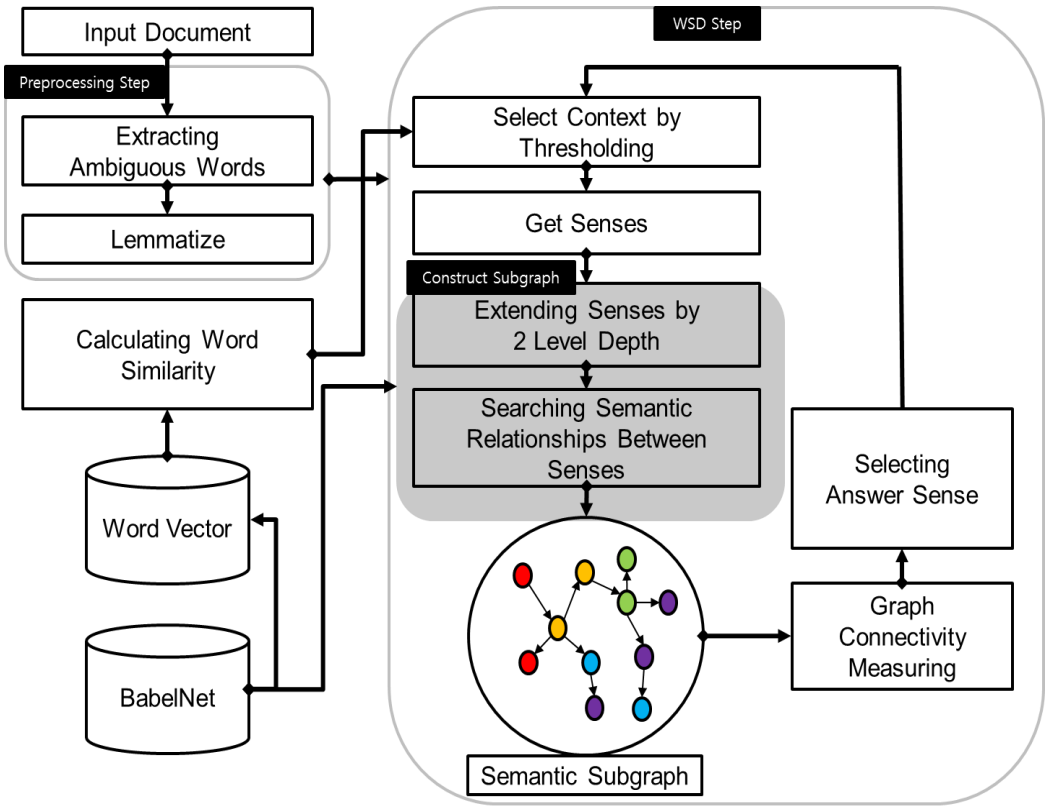

Figure 3: Overall processes of the proposed system.

vides the senses of content words[3], semantic relationship between the senses and the set of synonyms of the sense.

As shown in Figure. 2, BabelNet has a graph structure that consists of nodes and edges. A node indicates the sense of a word and an edge denotes the semantic relationship between the senses. The synonym information for a sense is accessible from Babel synset, which provides multi-lingual synonyms. Semantic relationship between senses contains the relationship defined by both Wikipedia (ACADEMIC_DEGREE, COUNTRY_OF_CITIZENSHIP, DEPICTED_BY, etc) and Wordnet (IS_A, PART_OF, etc). For example, a word 'Obama' contains six possible noun senses such as "bn:03330021n: 'Barack Hussein Obama II is an American politician who served as the 44th President of the United States from 2009 to 2017.'," and an adjective sense of "bn:13705874a: 'Of or pertaining to the political figure and 44th president of the United States of America Barack Obama.'." In addition, 'Obama' with a noun sense of 'bn: 03330021n' has an 'IS-A' semantic relationship with 'Human' with a noun sense of 'bn: 00044576n' and has a semantic relationship of 'COUNTRY_OF_CITIZENSHIP' with 'United States' with a noun sense of 'bn: 00003341n.'

As mentioned above, BabelNet provides the senses and their semantic relationships to multi-lingual, it is advantageous to extend a WSD system to other language. This makes many recent studies for WSD systems choosing BableNet as a sense repository (Moro et al., 2014; Manion et al., 2014; Tripodi and Pelillo 2017).

3 Proposed WSD System

This section describes our fundamental ideas to improve the performance of WSD and how they are integrated into our WSD system as illustrated in Figure 3. The subsection 3.1 is allocated to introduces a novel word similarity calculation method for the contextual word selection. Next, we explain our new iterative subgraph construction method that combine contextual word selection in the traditional WSD approach.

[3] Verbs, adverbs, nouns and adjectives

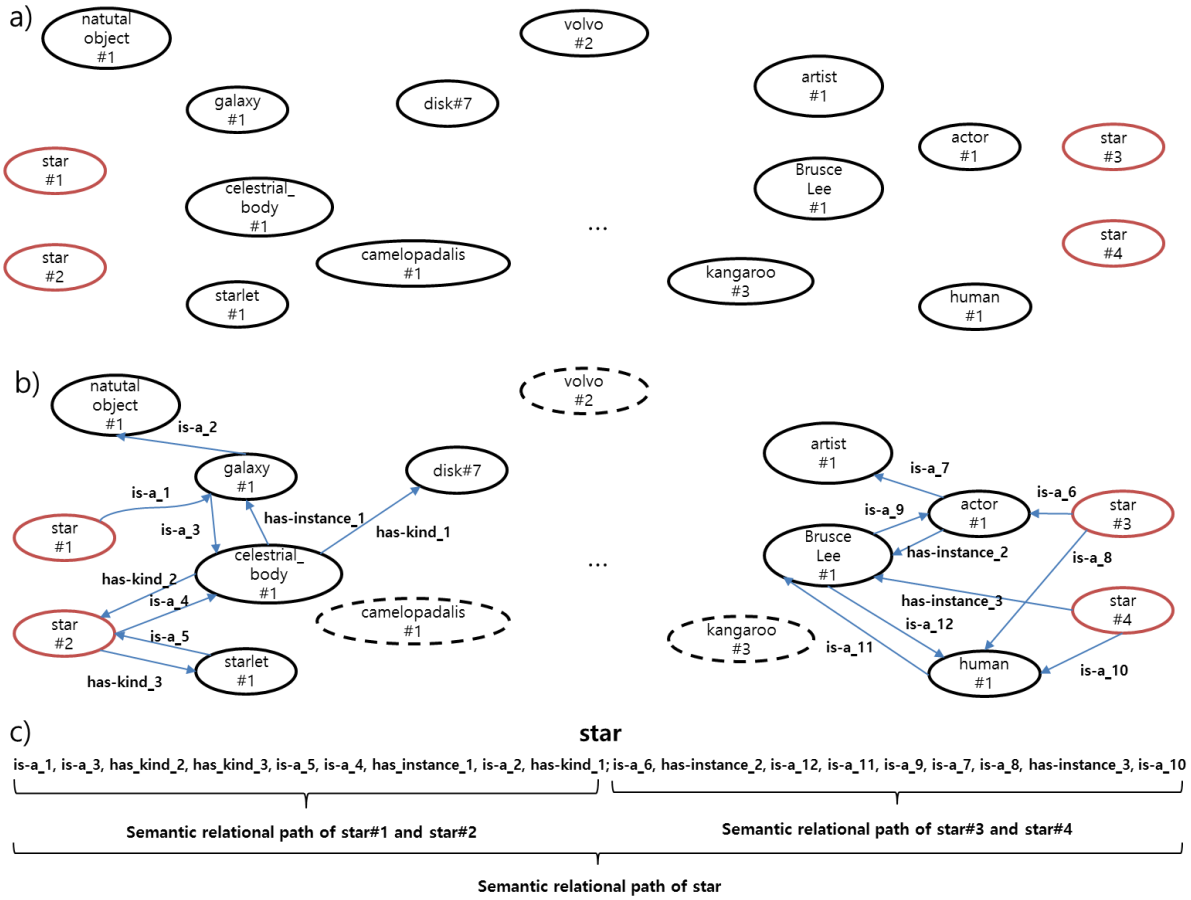

Figure 4: Example of the semantic relational path extracting process of a word 'star'. An ellipse means a sense and an arrow indicates the semantic relationship between the senses. a) Initial state, b) Extending the senses by 2 level depth and c) Generating Semantic relational path of 'star' using DFS algorithm.

3.1 Word Similarity Calculation Through the Word Vector Representation from the BabelNet Graph Structure for the Contextual Words Selection

In order to determine the correct sense of the ambiguous words in the WSD, it is very important to use the context around to find the sense of the ambiguous word. However, not all the contextual words are equally important for WSD (Karov and Edelman, 1998). If we can choose more important contextual words for each ambiguous word in the document, then we can more accurately disambiguate the sense of an ambiguous word by reducing unnecessary information. From this point of view, we assume that the higher a word has similarity to the ambiguous word, the more it can contribute to determining the sense of an ambiguous word.

In WSD, we determine the sense of a word based on context. At this time, the context in which we are interested is the theme of the entire document or sentence. For this reason, semantic information such as theme words will have a much more impact on WSD than syntactic information such as part-of-speech or sentence component information. Under this assumption, we propose a novel method of generating the word vector representations for the semantic information using knowledge graph structure as follows.

The senses of a word can be connected by a series of the semantic relationships in the semantic network. Figure 4 illustrates an example of representing a word as the sequence of the semantic relationships by connecting the senses of the word on the BabelNet knowledge graph. In Figure 4 (a), a noun word 'star' has four different senses; star#1: "A celestial body of hot gases", star#2: "Any celestial body visible from the Earth at night.", star#3: "An actor who plays a principal role" and star#4: "A widely known person." To connect these senses, we extend the senses by L level depth around each sense of the word as shown in Figure 4 (b). In this example, there are two connected graphs are generated. The

first one connects the extended senses of star#1 and star#2 and the second one does those of star#3 and star#4. In this example, each subgraph is related to the common theme of the connected senses. A graph connecting star#1 and star#2 contains common senses associated with astronomical phenomena. On the other hand, a graph connecting star#3 and star#4 consists of senses related to human or occupation. As shown in the Figure 4 (c), the DFS algorithm is applied to easily handle subgraphs that make up the meaning of a word. By the DFS algorithm, we can represent each graph connecting the sense of a word as a sequence of semantic relationships, which we refer to the semantic relational path. Finally, the concatenated semantic relational path of all subgraphs is considered as the overall representation of the word (see Figure 4 (c)).

The semantic relational path of a word from the previous paragraph consists of three structures: relations that connect senses, subgraph that is connected with the senses and sharing a theme and words that are represented as a set of subgraphs. If we match a relation to a word and a subgraph to a sentence in this structure, we can regard the semantic relation path of word as a kind of a pseudo-document. To effectively encode information of the semantic relational path of word, we used Doc2vec (Le and Mikolov, 2014). Doc2vec is an unsupervised learning algorithm that generates a document vector based on words contained in the document. The vectors of documents having a similar meaning are projected into the similar vector space. In our case, the semantic relational path, as a pseudo-document, of the word is an input and the word vector representation of the word is an output of the Doc2vec. Thus, if words sharing semantic relationships will be projected into the similar vector space, otherwise they will be projected in the totally different vector space. To measure the similarity of the words by regarding both distance and direction, the cosine similarity measure of Eq.1 is used to calculate the word similarity of the vector representation of the words $\boldsymbol{w_1}$ and $\boldsymbol{w_2}$.

$$word\_similarity(\boldsymbol{w_1}, \boldsymbol{w_2}) = \frac{\boldsymbol{w_1} \cdot \boldsymbol{w_2}}{||\boldsymbol{w_1}|| \times ||\boldsymbol{w_2}||} \quad (1)$$

3.2 Iterative Subgraph Reconstruction Approach with Word Similarity-based Context Words Selection

In order to determine the correct sense of ambiguous words in a graph-based WSD approach, it is essential to establish an efficient strategy for constructing a subgraph that connects the correct senses by taking into account the structure of the semantic network and words in the context. In our study, we suggest a new WSD strategy that constructs a set of context words that have a similarity value to the ambiguous word beyond a threshold.

Proposed Word Sense Disambiguation System

Input: input document (*Input*)
Output: disambiguated sense (*A*nswer)

1: $I \leftarrow Extracting\_ambiguous\_words(Input)$
2: $\mathcal{L} \leftarrow Lemmatize(I)$
3: $Answers \leftarrow \emptyset$
4: **For** $l_i \; in \; \mathcal{L} \; do$
5: $C_i \leftarrow SelectContext(l_i, Other\_Words)$
6: $S_{l_i} \leftarrow GetSenseSet(l_i)$
7: $S_{C_i} \leftarrow GetSenseSet(C_i)$
8: $G_i \leftarrow ConstructSubGraph(S_{l_i}, S_{C_i}, Answer)$
9: $\hat{s}_* \leftarrow argmax_{s_j \in S_{l_i}} \phi(G_i, S_{l_i})$, where ϕ *indicates graph conectivity*
10: put $\hat{s}_*$ in $Answer$
11: **Return** $Answer$

Our WSD system is made up of two steps: the preprocessing step (line 1 to 3) and the WSD step (line 4 to 11). In the preprocessing step, we extract the sequence of the ambiguous words $I = \{w_1 \ldots w_m\}$ in an input document, $Input$, and the order of sequence follows to the occurrence order of the ambiguous

words in the input document. The sequence of ambiguous words, I, is mapped to their lemmatized form, $\mathcal{L} = \{l_1 \dots l_m\}$ and the answer set of disambiguated senses from our WSD system, $Answer$, is initialized by a null set. In the WSD step, our proposed WSD method iteratively determine the answer sense in order of $\mathcal{L}$. To do this, it first selects the contextual words, C_i, of an ambiguous word, l_i, by measuring similarities between the ambiguous word and other words in the document. To do this, our system calculates all the similarities between l_i and other words. Words whose similarity to l_i exceeds a threshold are selected as C_i. If there is no word exceed the threshold, its context is created by choosing a word that has the highest similarity (line 5). Then the senses ($S_{l_i} and\ S_{C_i}$) of l_i and C_i are extracted from BabelNet (line 6 &7). Next, the whole senses of S_{l_i}, S_{C_i} and *Answer* are extended by the depth of level L and they are connected as the semantic relation by the depth-first search (DFS) algorithm (line 8). Finally, the graph connectivity of the sense, s_j, is calculated by the PPR algorithm (Gutiérrez et al., 2013) and the sense with the highest connectivity is selected as answer sense (line 9 and 10). This process is repeated until no more ambiguous words remained in the set of $\mathcal{L}$ (line 4 to 11).

4 Experiments

4.1 Datasets

We evaluated our WSD system on the three publicly available English WSD corpora: SemEval-2007, SemEval-2013 and SemEval-2015.

- The SemEval-2007 dataset consists of three documents with 465 noun and verb words annotated with Wordnet entries. In our experiment, 414 words in the BabelNet entry were selected and this dataset was used for the development set.
- The SemEval-2013 dataset consists of 13 news articles, including various domains from 2010 to 2012. All the noun words were annotated and there are 1,931 words to be disambiguated.
- The SemEval-2015 dataset consists of four documents from several heterogeneous domains. This dataset annotated WSD and entity linking tasks at the same time. The answer senses were annotated for all content words in the dataset and there are 1,261 words to be disambiguated.

4.2 Experimental Settings

Gensim Doc2vec library[4] was used to generate word vector representation introduced in the subsection 3.2. The dimension of the word vector was allocated to 200 and window size is set to 3. In addition, we set the initial learning rate of Doc2vec to 0.5. All the other Doc2vec parameters were set to default. Finally, threshold for the contextual words was set to 0.5. The resources for our word vector revector representation is available at `https://github.com/nlpbank/SRP2Vec`. Furthermore, we set up the hyperparameters of our system at the highest score on the SemEval-2007 dataset as the development set.

As a performance evaluation measure of the WSD systems, we used a F_1-score criteria of Eq.2 that is a harmonic mean of precision of Eq.3 and recall of Eq.4. Besides, to determine statistically significant difference between the performance of the system, we carried out macro student *t*-test (Yang and Liu, 1999).

$$Precision = \frac{\#\ of\ correctly\ disambiguated\ answers}{\#\ of\ words\ that\ outcome\ is\ positive} \tag{2}$$

$$Recall = \frac{\#\ of\ correctly\ disambiguated\ answers}{\#\ of\ true\ answers} \tag{3}$$

$$F_1 - score = \frac{2 \times Precision \times Recall}{Precision \times Recall} \tag{4}$$

[4] https://radimrehurek.com/gensim/models/doc2vec.html

4.3 Experimental Results

To verify the effectiveness of our proposed WSD system, we compared our WSD approach (*Wordsim_iter*) to a baseline WSD approach (*Sudoku_iter*) (Manion et al., 2014). The results of the SemEval-2013 and SemEval-2015 datasets are the same as those reported by Manion et al, (2014). On the other hand, because Manion et al, (2014) have not reported score on the SemEval-2007 dataset, we re-implemented and evaluated *Sudoku_iter* on the SemEval-2007 dataset. Furthermore, in order to verify our hypothesis that semantically similar words are more important than syntactically similar words in the WSD task, we compare our word similarity (*SRP2vSim*) calculation method with an existing word vector representation-based similarity calculation method as follows:

- *W2vSim*: It is based on the Word2vec that an unsupervised algorithm to generate word vector representation (Mikolov et al., 2013). We obtained word vector representations in the official word2vec website[5]. The word vector representation pretrained in the general text corpus has both the semantic and syntactic features of the words (Mikolov et al., 2013).

WSD Approach	Word Similarity Measurement	Dev			Test					
		SemEval-2007			SemEval-2013			SemEval-2015		
		Prec.	Rec.	F_1	Prec.	Rec.	F_1	Prec.	Rec.	F_1
Sudoku_iter	–	52.9	52.9	52.9	67.2	67.2	67.2	60.8	59.1	59.9
Wordsim_iter	*W2vSim*	48.5	48.5	48.5	72.1	72.1	72.1	57.8	51.1	54.2
	SRP2vSim	**56.1**	**56.1**	**56.1**	**75.0**	**75.0**	**75.0**	**69.2**	**62.6**	**65.8**

Table 1: Performance comparison of our WSD systems with the baseline WSD system (*Sudoku_iter*).

Table 1 shows that our proposed WSD system, *Wordsim_iter,* achieved the significantly improved performance compared to our baseline system, *Sudoku_iter* (p-value < 0.01), in all of the datasets. From these results, we are able to confirm that WSD performance can be improved by ignoring the words that are less similar with the ambiguous word. It also proved that WSD performance is determined by the criteria for selecting the contextual words. In case of word similarity measurement, our WSD system using *SRP2vSim* achieved significant improvement in performance compared to one using *W2vSim* (p-value < 0.05). Meanwhile, when we used *W2vSim* in the SemEval-2015 dataset, its result was significantly lower than the baseline (p-value < 0.01). On the other hand, *Wordsim_iter with SRP2vSim* has higher performances (4.5 %p and 10 %p) than *Sudoku_iter* and *Wordsim_iter* with *W2vSim,* respectively. Through these results, we think that the word vector representation from the knowledge-based graph is more adaptable than the traditional word vector representation for WSD tasks because the semantic information is more important than the syntactic information of words in the WSD tasks.

[5] https://github.com/mmihaltz/word2vec-GoogleNews-vectors

"[Alimta] is a [powder] that is [made_up] into a [solution] for [infusion] (drip into a [vein])."

Alimta: Chemotherapy drug manufactured and marketed by Eli Lilly and Company.
powder: A solid substance in the form of tiny loose particles.
make up: Form or compose
solution: A homogeneous mixture of two or more substances
infusion: The passive introduction of a substance into a vein or between tissues
vein: A blood vessel that carries blood from the capillaries toward the heart

Figure 5: An example sentence and definitions of the correct word senses. The term '[]' denotes an ambiguous word.

the Section 2, such as Moro 14 (Moro et al., 2014), Agirre 14 (Agirre et al., 2014), Apidianaki 15 (Apidanaki and Gong, 2015) and Tripodi 17 (Tripodi and Pelillo, 2017). In addition, we compared Wordsim_iter$_{SCP2vSim}$ to several supervised WSD systems, such as Zhong 10 (Zhong and Ng, 2010), Weissenborn 15 (Weissenborn et al., 2015), Raganato 17 (Raganato et al., 2017) and Pasini 17 (Pasini and Navigli., 2017). The results show that our WSD system surpassed all other state-of-the-art WSD systems with a large margin in the SemEval-2013 dataset. In the SemEval-2015 dataset, our WSD system has similar performance to the Agirre 14 and Apidianaki 15 and it has somewhat less performance than the state-of-the-art knowledge-based WSD system, Moro 14. This is due to the nature of the SemEval-2015 data, Moro 14 is designed to simultaneously analyzes WSD and entity linking. However, in terms of the macro average score of SemEval-2013 and SemEval-2015, Wordsim_iter$_{SRP2vSim}$ shows higher performance than the Moro 14. On the other hands, unsupervised knowledge-based approaches, including our system, generally has poorer performance than supervised approaches in the SemEval-2015 dataset. Especially, Weissenborn 15, a hybrid supervised WSD system that jointly has trained the WSD model and the entity linking model, achieved higher performance on macro average than our WSD system. Nevertheless, fewer limitation on the analyzable word set of our model makes it relatively more competitive than its counterpart state-of-the-art supervised-based WSD models.

4.4 Error Analysis

Despite the competitiveness of our system, the greedy algorithmic characteristic of the iterative subgraph-based algorithm has a negative effect on its performance. In particular, some previously analyzed words can affect other words and it makes them mis-disambiguated. For example, in the sentence of Figure 5, there are 6 ambiguous words: 'Alimta', 'powder', 'made up', 'solution', 'infusion' and 'vein'. Our WSD system wrongly determined 'made up' as "Apply make-up or cosmetics to one's face to appear prettier" because this wrong sense is more related with a previously determined sense 'powder' than correct sense in Figure 5. In addition, the mis-disambiguated 'made up' and previously analyzed words of 'powder' and 'solution' leads the meaning of 'infusion' as a wrong sense "A solution obtained by steeping a substance." If we decide the meaning of 'made up' and 'infusion' by regarding a word 'vein,' then we can disambiguate the words 'made up' and 'infusion' correctly.

5 Conclusions and Future Work

In this paper, we propose a knowledge-based WSD method that restricts contextual words based on the similarities between the ambiguous words and content words. We first measure the similarities of the words in an input document and ambiguous word and selectively create context of the ambiguous word with the words over the certain threshold. In addition, we further suggest a novel similarity calculating method suitable for our WSD method. Our WSD system significantly improves a baseline WSD system and has a higher performance than the state-of-the-art unsupervised knowledge-based WSD systems.

Our WSD system is based on an iterative subgraph reconstruction approach that determines the sense of a word in order. This method has been proposed to solve the computational complexity problem of finding the optimal combination among all possible set of senses. However, due to the nature of the greedy search, sometimes it makes hard to inference correct sense of the ambiguous word because of the error propagation from a previous result can determined answer.

For the future work, we plan to extend our WSD system to the multi-lingual system. In particular, we are going to research to generate of multi-lingual word vector representation using the Babel synset information. Another possible future work is to use the Beam search (Ow and Morton, 1988) to compensate for the drawbacks of the iterative subgraph reconstruction's greedy algorithmic characteristics.

Abstract

In this paper, we propose a method for obtaining sentence-level embeddings. While the problem of securing word-level embeddings is very well studied, we propose a novel method for obtaining sentence-level embeddings. This is obtained by a simple method in the context of solving the paraphrase generation task. If we use a sequential encoder-decoder model for generating paraphrase, we would like the generated paraphrase to be semantically close to the original sentence. One way to ensure this is by adding constraints for true paraphrase embeddings to be close and unrelated paraphrase candidate sentence embeddings to be far. This is ensured by using a sequential pair-wise discriminator that shares weights with the encoder that is trained with a suitable loss function. Our loss function penalizes paraphrase sentence embedding distances from being too large. This loss is used in combination with a sequential encoder-decoder network. We also validated our method by evaluating the obtained embeddings for a sentiment analysis task. The proposed method results in semantic embeddings and outperforms the state-of-the-art on the paraphrase generation and sentiment analysis task on standard datasets. These results are also shown to be statistically significant.

1 Introduction

The problem of obtaining a semantic embedding for a sentence that ensures that the related sentences are closer and unrelated sentences are farther lies at the core of understanding languages. This would be relevant for a wide variety of machine reading comprehension and related tasks such as sentiment analysis. Towards this problem, we propose a supervised method that uses a sequential encoder-decoder framework for paraphrase generation. The task of generating paraphrases is closely related to the task of obtaining semantic sentence embeddings. In our approach, we aim to ensure that the generated paraphrase embedding should be close to the true corresponding sentence and far from unrelated sentences. The embeddings so obtained help us to obtain state-of-the-art results for paraphrase generation task.

Our model consists of a sequential encoder-decoder that is further trained using a pairwise discriminator. The encoder-decoder architecture has been widely used for machine translation and machine comprehension tasks. In general, the model ensures a 'local' loss that is incurred for each recurrent unit cell. It only ensures that a particular word token is present at an appropriate place. This, however, does not imply that the whole sentence is correctly generated. To ensure that the whole sentence is correctly encoded, we make further use of a pair-wise discriminator that encodes the whole sentence and obtains an embedding for it. We further ensure that this is close to the desired ground-truth embeddings while being far from other (sentences in the corpus) embeddings. This model thus provides a 'global' loss that ensures the sentence embedding as a whole is close to other semantically related sentence embeddings. This is illustrated in Figure 1. We further evaluate the validity of the sentence embeddings by using them for the task of sentiment analysis. We observe that the proposed sentence embeddings result in state-of-the-art performance for both these tasks.

* Equal contribution

Proceedings of the 27th International Conference on Computational Linguistics, pages 2715–2729
Santa Fe, New Mexico, USA, August 20-26, 2018.

Our contributions are: a) We propose a model for obtaining sentence embeddings for solving the paraphrase generation task using a pair-wise discriminator loss added to an encoder-decoder network. b) We show that these embeddings can also be used for the sentiment analysis task. c) We validate the model using standard datasets with a detailed comparison with state-of-the-art methods and also ensure that the results are statistically significant.

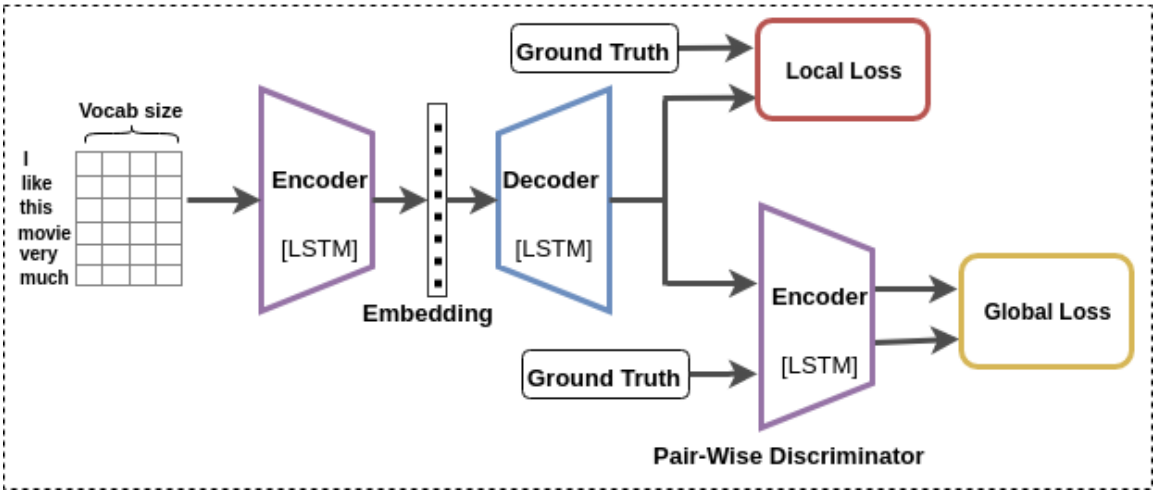

Figure 1: Pairwise Discriminator based Encoder-Decoder for Paraphrase Generation: This is the basic outline of our model which consists of an LSTM encoder, decoder and discriminator. Here the encoders share the weights. The discriminator generates discriminative embeddings for the Ground Truth-Generated paraphrase pair with the help of 'global' loss. Our model is jointly trained with the help of a 'local' and 'global' loss which we describe in section 3.

2 Related Work

Given the flexibility and diversity of natural language, it has always been a challenging task to represent text efficiently. There have been several hypotheses proposed for representing the same. (Harris, 1954; Firth, 1957; Sahlgren, 2008) proposed a distribution hypothesis to represent words, i.e., words which occur in the same context have similar meanings. One popular hypothesis is the bag-of-words (BOW) or Vector Space Model (Salton et al., 1975), in which a text (such as a sentence or a document) is represented as the bag (multiset) of its words. (Lin and Pantel, 2001) proposed an extended distributional hypothesis and (Deerwester et al., 1990; Turney and Littman, 2003) proposed a latent relation hypothesis, in which a pair of words that co-occur in similar patterns tend to have similar semantic relation. Word2Vec(Mikolov et al., 2013a; Mikolov et al., 2013b; Goldberg and Levy, 2014) is also a popular method for representing every unique word in the corpus in a vector space. Here, the embedding of every word is predicted based on its context (surrounding words). NLP researchers have also proposed phrase-level and sentence-level representations (Mitchell and Lapata, 2010; Zanzotto et al., 2010; Yessenalina and Cardie, 2011; Grefenstette et al., 2013; Mikolov et al., 2013b). (Socher et al., 2011; Kim, 2014; Lin et al., 2015; Yin et al., 2015; Kalchbrenner et al., 2014) have analyzed several approaches to represent sentences and phrases by a weighted average of all the words in the sentence, combining the word vectors in an order given by a parse tree of a sentence and by using matrix-vector operations. The major issue with BOW models and weighted averaging of word vectors is the loss of semantic meaning of the words, the parse tree approaches can only work for sentences because of its dependence on sentence parsing mechanism. (Socher et al., 2013; Le and Mikolov, 2014) proposed a method to obtain a vector representation for paragraphs and use it to for some text-understanding problems like sentiment analysis and information retrieval.

Many language models have been proposed for obtaining better text embeddings in Machine Translation (Sutskever et al., 2014; Cho et al., 2014; Vinyals and Le, 2015; Wu et al., 2016), question generation (Du et al., 2017), dialogue generation (Shang et al., 2015; Li et al., 2016b; Li et al., 2017a),

document summarization (Rush et al., 2015), text generation (Zhang et al., 2017; Hu et al., 2017; Yu et al., 2017; Guo et al., 2017; Liang et al., 2017; Reed et al., 2016) and question answering (Yin et al., 2016; Miao et al., 2016). For paraphrase generation task, (Prakash et al., 2016) have generated paraphrases using stacked residual LSTM based network. (Hasan et al., 2016) proposed a encoder-decoder framework for this task. (Gupta et al., 2017) explored a VAE approach to generate paraphrase sentences using recurrent neural networks. (Li et al., 2017b) used reinforcement learning for paraphrase generation task.

3 Method

In this paper, we propose a text representation method for sentences based on an encoder-decoder framework using a pairwise discriminator for paraphrase generation and then fine tune these embeddings for sentiment analysis task. Our model is an extension of *seq2seq* (Sutskever et al., 2014) model for learning better text embeddings.

3.1 Overview

Task: In the paraphrase generation problem, given an input sequence of words $X = [x_1, ..., x_L]$, we need to generate another output sequence of words $Y = [q_1, ..., q_T]$ that has the same meaning as X. Here L and T are not fixed constants. Our training data consists of M pairs of paraphrases $\{(X_i, Y_i)\}_{i=1}^{M}$ where X_i and Y_i are the paraphrase of each other.

Our method consists of three modules as illustrated in Figure 2: first is a Text Encoder which consists of LSTM layers, second is LSTM-based Text Decoder and last one is an LSTM-based Discriminator module. These are shown respectively in part 1, 2, 3 of Figure 2. Our network with all three parts is trained end-to-end. The weight parameters of encoder and discriminator modules are shared. Instead of taking a separate discriminator, we shared it with the encoder so that it learns the embedding based on the 'global' as well as 'local' loss. After training, at test time we used encoder to generate feature maps and pass it to the decoder for generating paraphrases. These text embeddings can be further used for other NLP tasks such as sentiment analysis.

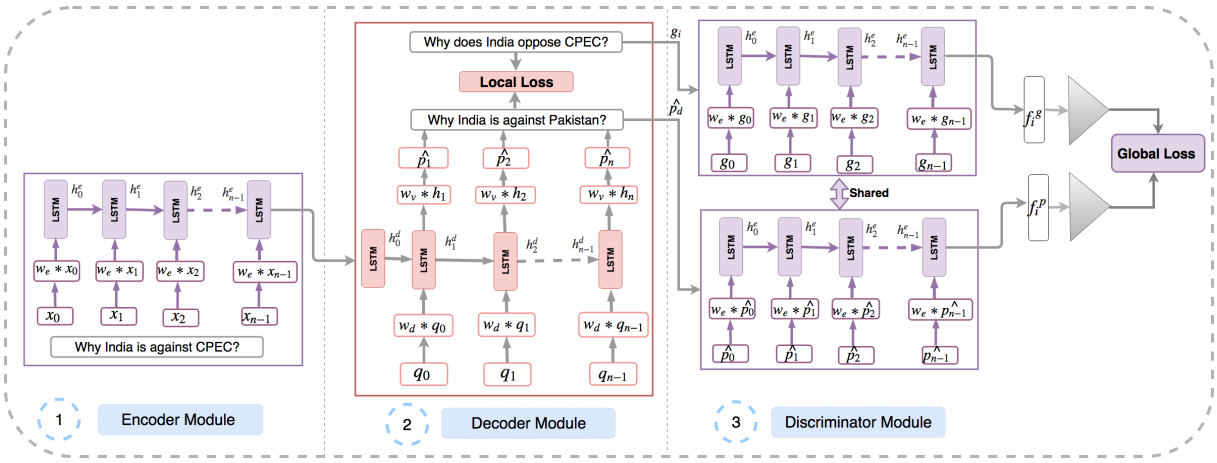

Figure 2: This is an overview of our model. It consists of 3 parts: 1) LSTM-based Encoder module which encodes a given sentence, 2) LSTM-based Decoder Module which generates natural language paraphrases from the encoded embeddings and 3) LSTM-based pairwise Discriminator module which shares its weights with the Encoder module and this whole network is trained with local and global loss.

3.2 Encoder-LSTM

We use an LSTM-based encoder to obtain a representation for the input question X_i, which is represented as a matrix in which every row corresponds to the vector representation of each word. We use a one-hot vector representation for every word and obtain a word embedding c_i for each word using a Temporal

CNN (Zhang et al., 2015; Palangi et al., 2016) module that we parameterize through a function $G(X_i, W_e)$ where W_e are the weights of the temporal CNN. Now this word embedding is fed to an LSTM-based encoder which provides encoding features of the sentence. We use LSTM (Hochreiter and Schmidhuber, 1997) due to its capability of capturing long term memory (Palangi et al., 2016). As the words are propagated through the network, the network collects more and more semantic information about the sentence. When the network reaches the last word (L_{th} word), the hidden state h_L of the network provides a semantic representation of the whole sentence conditioned on all the previously generated words $(q_0, q_1..., q_t)$. Question sentence encoding feature f_i is obtained after passing through an LSTM which is parameterized using the function $F(C_i, W_l)$ where W_l are the weights of the LSTM. This is illustrated in part 1 of Figure 2.

3.3 Decoder-LSTM

The role of decoder is to predict the probability for a whole sentence, given the embedding of input sentence (f_i). RNN provides a nice way to condition on previous state value using a fixed length hidden vector. The conditional probability of a sentence token at a particular time step is modeled using an LSTM as used in machine translation (Sutskever et al., 2014). At time step t, the conditional probability is denoted by $P(q_t|f_i, q_0, .., q_{t-1}) = P(q_t|f_i, h_t)$, where h_t is the hidden state of the LSTM cell at time step t. h_t is conditioned on all the previously generated words $(q_0, q_1.., q_{t-1})$ and q_t is the next generated word.

Generated question sentence feature $\hat{p_d} = \{\hat{p_1}, \ldots, \hat{p_T}\}$ is obtained by decoder LSTM which is parameterized using the function $D(f_i, W_{dl})$ where W_{dl} are the weights of the decoder LSTM. The output of the word with maximum probability in decoder LSTM cell at step k is input to the LSTM cell at step $k+1$ as shown in Figure 2. At $t = -1$, we are feeding the embedding of input sentence obtained by the encoder module. $\hat{Y_i} = \{\hat{q_0}, \hat{q_1}, ..., \hat{q}_{T+1}\}$ are the predicted question tokens for the input X_i. Here, we are using $\hat{q_0}$ and $\hat{q}_{T+1}$ as the special START and STOP token respectively. The predicted question token ($\hat{q_i}$) is obtained by applying Softmax on the probability distribution $\hat{p_i}$. The question tokens at different time steps are given by the following equations where LSTM refers to the standard LSTM cell equations:

$$
\begin{aligned}
&d_{-1} = \text{Encoder}(f_i) \\
&h_0 = \text{LSTM}(d_{-1}) \\
&d_t = W_d * q_t, \forall t \in \{0, 1, 2, ...T-1\} \\
&h_{t+1} = \text{LSTM}(d_t, h_t), \forall t \in \{0, 1, 2, ...T-1\} \\
&\hat{p}_{t+1} = W_v * h_{t+1} \\
&\hat{q}_{t+1} = \text{Softmax}(\hat{p}_{t+1}) \\
&\text{Loss}_{t+1} = \text{loss}(\hat{q}_{t+1}, q_{t+1})
\end{aligned}
\tag{1}
$$

Where $\hat{q}_{t+1}$ is the predicted question token and q_{t+1} is the ground truth one. In order to capture local label information, we use the Cross Entropy loss which is given by the following equation:

$$
L_{local} = \frac{-1}{T} \sum_{t=1}^{T} q_t \text{logP}(\hat{q}_t|q_0, ..q_{t-1}) \tag{2}
$$

Here T is the total number of sentence tokens, $\text{P}(\hat{q}_t|q_0, ..q_{t-1})$ is the predicted probability of the sentence token, q_t is the ground truth token.

3.4 Discriminative-LSTM

The aim of the Discriminative-LSTM is to make the predicted sentence embedding f_i^p and ground truth sentence embedding f_i^g indistinguishable as shown in Figure 2. Here we pass $\hat{p_d}$ to the shared encoder-LSTM to obtain f_i^p and also the ground truth sentence to the shared encoder-LSTM to obtain f_i^g. The discriminator module estimates a loss function between the generated and ground truth paraphrases. Typically, the discriminator is a binary classifier loss, but here we use a global loss, similar to (Reed et al.,

2016) which acts on the last hidden state of the recurrent neural network (LSTM). The main objective of this loss is to bring the generated paraphrase embeddings closer to its ground truth paraphrase embeddings and farther from the other ground truth paraphrase embeddings (other sentences in the batch). Here our discriminator network ensures that the generated embedding can reproduce better paraphrases. We are using the idea of sharing discriminator parameters with encoder network, to enforce learning of embeddings that not only minimize the local loss (cross entropy), but also the global loss.

Suppose the predicted embeddings of a batch is $e_p = [f_1^p, f_2^p, ..f_N^p]^T$, where f_i^p is the sentence embedding of i^{th} sentence of the batch. Similarly ground truth batch embeddings are $e_g = [f_1^g, f_2^g, ..f_N^g]^T$, where N is the batch size, $f_i^p \in \mathbb{R}^d$ $f_i^g \in \mathbb{R}^d$. The objective of global loss is to maximize the similarity between predicted sentence f_i^p with the ground truth sentence f_i^g of i^{th} sentence and minimize the similarity between i^{th} predicted sentence, f_i^p, with j^{th} ground truth sentence, f_j^g, in the batch. The loss is defined as

$$L_{global} = \sum_{i=1}^{N}\sum_{j=1}^{N} \max(0, ((f_i^p \cdot f_j^g) - (f_i^p \cdot f_i^g) + 1)) \tag{3}$$

Gradient of this loss function is given by

$$\left(\frac{dL}{de_p}\right)_i = \sum_{j=1, j\neq i}^{N} (f_j^g - f_i^g) \tag{4}$$

$$\left(\frac{dL}{de_g}\right)_i = \sum_{j=1, j\neq i}^{N} (f_j^p - f_i^p) \tag{5}$$

3.5 Cost function

Our objective is to minimize the total loss, that is the sum of local loss and global loss over all training examples. The total loss is:

$$L_{total} = \frac{1}{M}\sum_{i=1}^{M}(L_{local} + L_{global}) \tag{6}$$

Where M is the total number of examples, L_{local} is the cross entropy loss, L_{global} is the global loss.

	EDD-LG	44.2	31.6	22.1	17.9	43.6	22.1
	EDD-LG(shared)	**45.7**	**32.4**	**23.8**	**17.9**	**44.9**	**23.1**

Table 1: Analysis of variants of our proposed method on Quora Dataset as mentioned in section 4.1.3. Here L and G refer to the Local and Global loss and shared represents the parameter sharing between the discriminator and encoder module. As we can see that our proposed method EDD-LG(shared) clearly outperforms the other ablations on all metrics and detailed analysis is present in section 4.1.3.

4 Experiments

We perform experiments to better understand the behavior of our proposed embeddings. To achieve this, we benchmark Encoder Decoder Discriminator Local-Global (shared) (EDD-LG(shared)) embeddings on two text understanding problems, Paraphrase Generation and Sentiment Analysis. We use the Quora question pairs dataset [1] for paraphrase generation and Stanford Sentiment Treebank dataset (Socher et al.,

[1]website: `https://data.quora.com/First-Quora-Dataset-Release-Question-Pairs`

2013) for sentiment analysis. In this section we describe the different datasets, experimental setup and results of our experiments.

4.1 Paraphrase Generation

Paraphrase generation is an important problem in many NLP applications such as question answering, information retrieval, information extraction, and summarization. It involves generation of similar meaning sentences.

4.1.1 Dataset

We use the newly released Quora question pairs dataset for this task. The dataset consists of over 400K potential question duplicate pairs. We have IDs for each question in the pair, the full text for each question, and a binary value that indicates whether the questions in the pair are truly a duplicate of each-other. Wherever the binary value is 1, the question in the pair are not identical; they are rather paraphrases of each-other. So, for our study, we choose all such question pairs with binary value 1. There are a total of 149K such questions. Some examples of question and their generated paraphrases can be found in Table 3. More results are present in the appendix.

Dataset	Model	BLEU1	METEOR	TER
50K	Unsupervised VAE (Gupta et al., 2017)	8.3	12.2	83.7
	VAE-S (Gupta et al., 2017)	11.9	17.4	69.4
	VAE-SVG (Gupta et al., 2017)	17.1	21.3	63.1
	VAE-SVG-eq (Gupta et al., 2017)	17.4	**21.4**	61.9
	EDD-G (**Ours**)	40.7	19.7	51.2
	EDD-LG(**Ours**)	40.9	19.8	51.0
	EDD-LG(shared)(**Ours**)	**41.1**	20.1	**50.8**
100K	Unsupervised (Gupta et al., 2017)	10.6	14.3	79.9
	VAE-S (Gupta et al., 2017)	17.5	21.6	67.1
	VAE-SVG (Gupta et al., 2017)	22.5	24.6	55.7
	VAE-SVG-eq (Gupta et al., 2017)	22.9	**24.7**	55.0
	EDD-G (**Ours**)	42.1	20.4	49.9
	EDD-LG(**Ours**)	44.2	22.1	48.3
	EDD-LG(shared)(**Ours**)	**45.7**	23.1	**47.5**

Table 2: Analysis of Baselines and State-of-the-Art methods for paraphrase generation on Quora dataset. As we can see clearly that our model outperforms the state-of-the-art methods by a significant margin in terms of BLEU and TER scores. Detailed analysis is present in section 4.1.4. A lower TER score is better whereas for the other metrics, a higher score is better. Details for the metrics are present in the appendix.

4.1.2 Experimental Protocols

We follow the experimental protocols mentioned in (Gupta et al., 2017) for the Quora dataset. In our experiments, we divide the dataset into 2 parts 145K and 4K question pairs. We use these as our training and testing sets. We further divide the training set into 50K and 100K dataset sizes and use the rest 45K as our validation set. We trained our model end-to-end using local loss (cross entropy loss) and global loss. We have used RMSPROP optimizer to update the model parameter and found these hyperparameter values to work best to train the Paraphrase Generation Network: learning rate $= 0.0008$, batch size $= 150, \alpha = 0.99, \epsilon = 1e-8$. We have used learning rate decay to decrease the learning rate on every epoch by a factor given by:

$$\text{Decay\_factor} = exp\left(\frac{log(0.1)}{a * b}\right)$$

where $a = 1500$ and $b = 1250$ are set empirically.

S.No	**Original Question**	**Ground Truth Paraphrase**	**Generated Paraphrase**
1	Is university really worth it?	Is college even worth it?	Is college really worth it?
2	Why India is against CPEC?	Why does India oppose CPEC?	Why India is against Pakistan?
3	How can I find investors for my tech startup?	How can I find investors for my startup on Quora?	How can I find investors for my startup business?
4	What is your view/opinion about surgical strike by the Indian Army?	What world nations think about the surgical strike on POK launch pads and what is the reaction of Pakistan?	What is your opinion about the surgical strike on Kashmir like?
5	What will be Hillary Clinton's strategy for India if she becomes US President?	What would be Hillary Clinton's foreign policy towards India if elected as the President of United States?	What will be Hillary Clinton's policy towards India if she becomes president?

Table 3: Examples of Paraphrase generation on Quora Dataset. We observe that our model is able to understand abbreviations as well and then ask questions on the basis of that as is the case in the second example.

4.1.3 Ablation Analysis

We experimented with different variations for our proposed method. We start with baseline model which we take as a simple encoder and decoder network with only the local loss (ED-Local) (Sutskever et al., 2014). Further we have experimented with encoder-decoder and a discriminator network with only global loss (EDD-Global) to distinguish the ground truth paraphrase with the predicted one. Another variation of our model is used both the global and local loss (EDD-LG). The discriminator is the same as our proposed method, only the weight sharing is absent in this case. Finally, we make the discriminator share weights with the encoder and train this network with both the losses (EDD-LG(shared)). The analyses are given in table 1. Among the ablations, the proposed EDD-LG(shared) method works way better than the other variants in terms of BLEU and METEOR metrics by achieving an improvement of 8% and 6% in the scores respectively over the baseline method for 50K dataset and an improvement of 10% and 7% in the scores respectively for 100K dataset.

4.1.4 Baseline and State-of-the-Art Method Analysis

There has been relatively less work on this dataset and the only work which we came across was that of (Gupta et al., 2017). We further compare our method EDD-LG(shared) model with their VAE-SVG-eq which is the current state-of-the-art on Quora datset. Also we provide comparisons with other methods proposed by them in table 2. As we can see from the table that we achieve a significant improvement of 24% in BLEU score and 11% in TER score (A lower TER score is better) for 50K dataset and similarly 22% in BLEU score and 7.5% in TER score for 100K dataset.

4.1.5 Statistical Significance Analysis

We have analysed statistical significance (Demšar, 2006) for our proposed embeddings against different ablations and the state-of-the-art methods for the paraphrase generation task. The Critical Difference (CD) for Nemenyi (Fišer et al., 2016) test depends upon the given α (confidence level, which is 0.05 in our case) for average ranks and N (number of tested datasets). If the difference in the rank of the two methods lies within CD, then they are not significantly different, otherwise they are statistically different. Figure 3 visualizes the post hoc analysis using the CD diagram. From the figure, it is clear that our embeddings work best and the results are significantly different from the state-of-the-art methods.

Model	Error Rate (Fine-Grained)
Naive Bayes (Socher et al., 2013)	59.0
SVMs (Socher et al., 2013)	59.3
Bigram Naive Bayes (Socher et al., 2013)	58.1
Word Vector Averaging (Socher et al., 2013)	67.3
Recursive Neural Network (Socher et al., 2013)	56.8
Matrix Vector-RNN (Socher et al., 2013)	55.6
Recursive Neural Tensor Network (Socher et al., 2013)	54.3
Paragraph Vector (Le and Mikolov, 2014)	51.3
EDD-LG(shared) (**Ours**)	**35.6**

Table 4: Performance of our method compared to other approaches on the Stanford Sentiment Treebank Dataset. The error rates of other methods are reported in (Le and Mikolov, 2014)

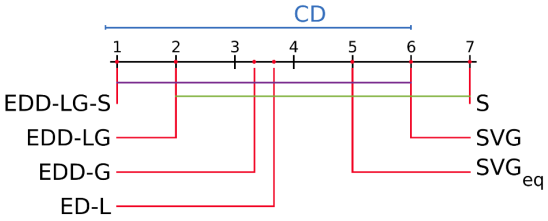

Figure 3: The mean rank of all the models on the basis of BLEU score are plotted on the x-axis. Here EDD-LG-S refers to our EDD-LG shared model and others are the different variations of our model described in section 4.1.3 and the models on the right are the different variations proposed in (Gupta et al., 2017). Also the colored lines between the two models represents that these models are not significantly different from each other. CD=5.199,p=0.0069

4.2 Sentiment Analysis with Stanford Sentiment Treebank (SST) Dataset

4.2.1 Dataset

This dataset consists of sentiment labels for different movie reviews and was first proposed by (Pang and Lee, 2005). (Socher et al., 2013) extended this by parsing the reviews to subphrases and then fine-graining the sentiment labels for all the phrases of movies reviews using Amazon Mechanical Turk. The labels are classified into 5 sentiment classes, namely {Very Negative, Negative, Neutral, Positive, Very Positive}. This dataset contains a total 126k phrases for training set, 30k phrases for validation set and 66k phrases for test set.

4.2.2 Tasks and Baselines

In (Socher et al., 2013), the authors propose two ways of benchmarking. We consider the 5-way fine-grained classification task where the labels are {Very Negative, Negative, Neutral, Positive, Very Positive}. The other axis of variation is in terms of whether we should label the entire sentence or all phrases in the sentence. In this work we only consider labeling all the phrases. (Socher et al., 2013) apply several methods to this dataset and we show their performance in table 4.

4.2.3 Experimental Protocols

We follow the experimental protocols as described in (Socher et al., 2013). To make use of the available labeled data, in our model, each subphrase is treated as an independent sentence and we learn the representations for all the subphrases in the training set. After learning the vector representations for training sentences and their subphrases, we feed them to a logistic regression to learn a predictor of the movie rating. At test time, we freeze the vector representation for each word, and learn the representations for the sentences using gradient descent. Once the vector representations for the test sentences are learned, we input them to a logistic regression model to predict the movie

Phrase ID	Phrase	Sentiment
162970	The heaviest, most joyless movie	Very Negative
159901	Even by dumb action-movie standards, Ballistic : Ecks vs. Sever is a dumb action movie.	
158280	Nonsensical, dull "cyber-horror" flick is a grim, hollow exercise in flat scares and bad acting	
159050	This one is pretty miserable, resorting to string-pulling rather than legitimate character development and intelligent plotting.	
157130	The most hopelessly monotonous film of the year, noteworthy only for the gimmick of being filmed as a single unbroken 87-minute take.	
156368	No good jokes, no good scenes, barely a moment	Negative
157880	Although it bangs a very cliched drum at times	
159269	They take a long time to get to its gasp-inducing ending.	
157144	Noteworthy only for the gimmick of being filmed as a single unbroken 87-minute	
156869	Done a great disservice by a lack of critical distance and a sad trust in liberal arts college bumper sticker platitudes	
221765	A hero can stumble sometimes.	Neutral
222069	Spiritual rebirth to bruising defeat	
218959	An examination of a society in transition	
221444	A country still dealing with its fascist past	
156757	Have to know about music to appreciate the film's easygoing blend of comedy and romance	
157663	A wildly funny prison caper.	Positive
157850	This is a movie that's got oodles of style and substance.	
157879	Although it bangs a very cliched drum at times, this crowd-pleaser's fresh dialogue, energetic music, and good-natured spunk are often infectious.	
156756	You don't have to know about music to appreciate the film's easygoing blend of comedy and romance.	
157382	Though of particular interest to students and enthusiast of international dance and world music, the film is designed to make viewers of all ages, cultural backgrounds and rhythmic ability want to get up and dance.	
162398	A comic gem with some serious sparkles.	Very Positive
156238	Delivers a performance of striking skill and depth	
157290	What Jackson has accomplished here is amazing on a technical level.	
160925	A historical epic with the courage of its convictions about both scope and detail.	
161048	This warm and gentle romantic comedy has enough interesting characters to fill several movies, and its ample charms should win over the most hard-hearted cynics.	

Table 5: Examples of Sentiment classification on test set of kaggle competition dataset.

rating. In order to train a sentiment classification model, we have used RMSPROP, to optimize the classification model parameter and we found these hyperparameter values to be working best for our case: learning rate $= 0.00009$, batch size $= 200, \alpha = 0.9, \epsilon = 1e-8$.

4.2.4 Results

We report the error rates of different methods in table 4. We can clearly see that the bag-of-words or bag-of-n-grams models (NB, SVM, BiNB) perform poorly. Also the advanced methods (such as Recursive Neural Network (Socher et al., 2013)) perform much better on the task of fine-grained sentiment analysis. Our method outperforms all these methods by an absolute margin of 15.7% which is a significant increase considering the rate of progress on this task. We have also uploaded our models to the online competition on Rotten Tomatoes dataset [2] and obtained an accuracy of 62.606% on their test-set of 66K phrases.
We also provide 5 examples for each sentiment in table 5. We can see clearly that our proposed embeddings are able to get the complete meaning of smaller as well as larger sentences. For example, our model classifies 'Although it bangs a very cliched drum at times' as Negative and 'Although it bangs a very cliched drum at times, this crowd-pleaser's fresh dialogue, energetic music, and good-natured spunk are often infectious.' as positive showing that it is able to understand the finer details of language. More results and visualisations showing the part of the phrase to which the model attends while classifying are present in the appendix. The link for the project website and code is provided here [3].

5 Conclusion

In this paper we have proposed a sentence embedding using a sequential encoder-decoder with a pairwise discriminator. We have experimented with this text embedding method for paraphrase generation and sentiment analysis. We also provided experimental analysis which justifies that a pairwise discriminator outperforms the previous state-of-art methods for NLP tasks. We also performed ablation analysis for our method, and our method outperforms all of them in terms of BLEU, METEOR and TER scores. We plan to generalize this to other text understanding tasks and also extend the same idea in vision domain.

A Appendix

A.1 Quantitative Evaluation

We use automatic evaluation metrics which are prevalent in machine translation domain: BLEU (Papineni et al., 2002), METEOR (Banerjee and Lavie, 2005), ROUGE-n (Lin, 2004) and Translation Error Rate (TER) (Snover et al., 2006). Previous work has shown that these metrics can perform well for the paraphrase recognition task (Madnani et al., 2012) and correlate well with human judgments in evaluating generated paraphrases (Wubben et al., 2010). BLEU considers exact match between reference paraphrases and system generated paraphrases using the concept of modified n-gram precision and brevity penalty, whereas ROUGE considers recall for the same. METEOR also uses stemming and synonyms (using WordNet) while calculating the score and is based on a combination of unigram-precision and unigram-recall with the reference paraphrases. TER is based on the number of edits (insertions, deletions, substitutions, shifts) required for a human to convert the system output into one of the reference paraphrases. We provided our results using all these metrics and compared it with existing baselines.

A.2 Paraphrase Generation

Here we provide some more examples of the paraphrase generation task in table 6. Our model is also able to generate sentences which capture higher level semantics like in the last example of table 6.

A.3 Sentiment Analysis

We also provide visualization of different parts of the sentence on which our model focuses while predicting the sentiment in Figure 4 and some more examples of the Sentiment analysis task on SST dataset in Table 7.

A.3.1 Sentiment Visualization of the sentence

(Li et al., 2016a) have proposed a mechanism to visualize language features. We conducted a toy experiment for our EDD-LG(shared) model. Figure 4 represents saliency heat map for EDD-LG(shared) model sentiment analysis. We obtained 60 dimensional feature maps for each word present in the target sentence. The heat map captures the measure of influence of the sentimental decision. In the heat map, each word of a sentence (from top to bottom, first word at top) represents its contribution for making the

sentimental decision. For example in the first image in 4, the word ‘comic’ contributed more (2nd word, row 10-20). Similarly in the second image, first, second, and third (‘A’,‘wildly’,‘funny’) words have more influence for making this sentence have a positive sentiment.

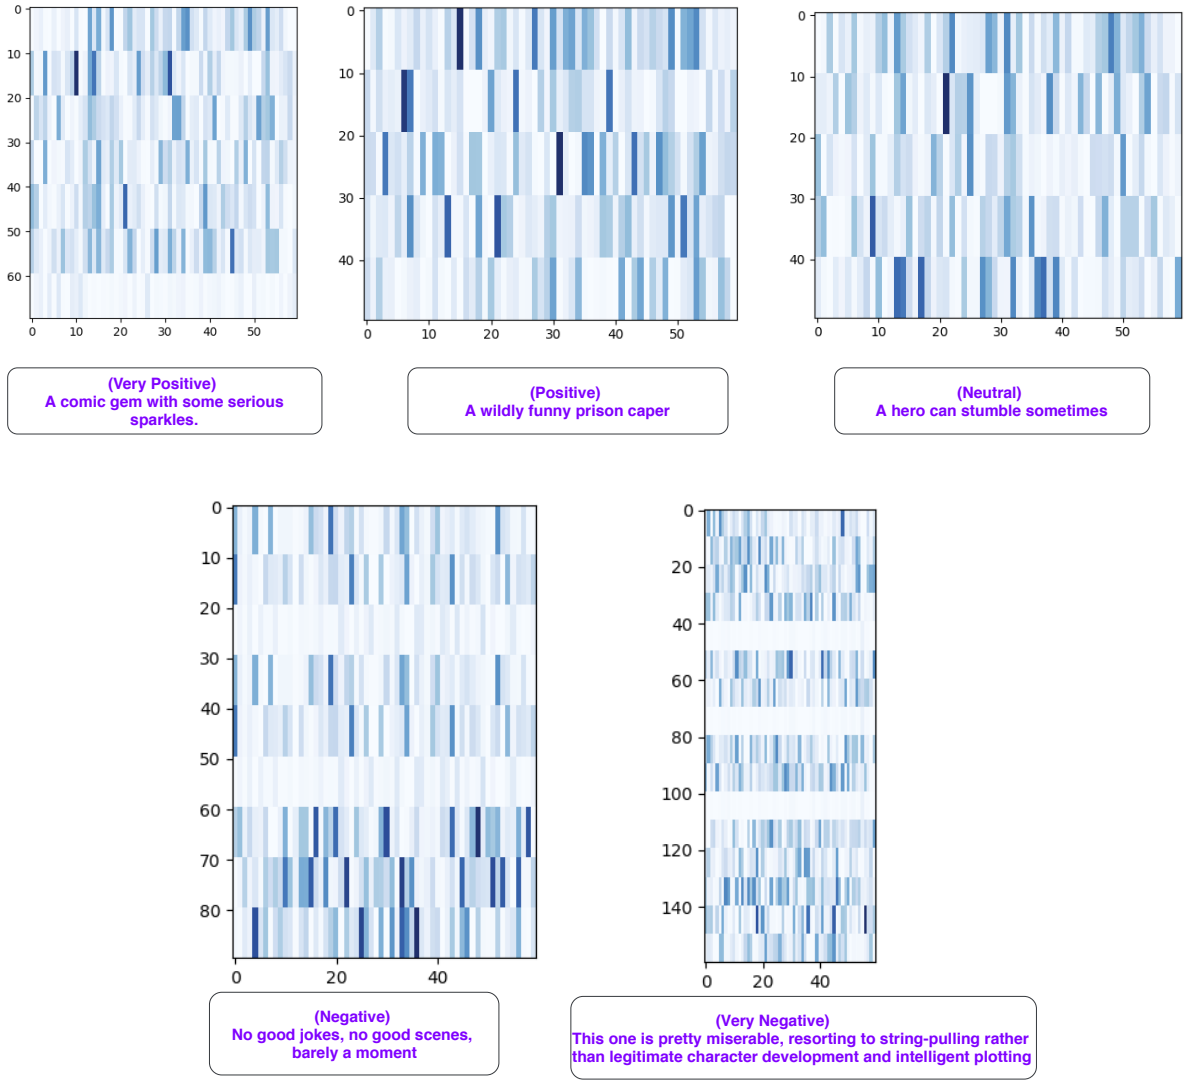

Figure 4: These are the visualisations for the sentiment analysis for some examples and we can clearly see that our model focuses on those words which we humans focus while deciding the sentiment for any sentence. In the second image, ‘wildly’ and ‘funny’ are emphasised more than the other words.

Phrase ID	Phrase	Sentiment
156628	The movie is just a plain old monster	Very Negative
157078	a really bad community theater production of West Side Story	
159749	Suffers from rambling , repetitive dialogue and the visual drabness endemic to digital video .	
163425	The picture , scored by a perversely cheerful Marcus Miller accordionharmonicabanjo abomination , is a monument to bad in all its florid variety .	
163483	lapses quite casually into the absurd	
163882	It all drags on so interminably it 's like watching a miserable relationship unfold in real time .	
164436	Your film becomes boring , and your dialogue is n't smart	
165179	Another big , dumb action movie in the vein of XXX , The Transporter is riddled with plot holes big enough for its titular hero to drive his sleek black BMW through .	
156567	It would be hard to think of a recent movie that has worked this hard to achieve this little fun	Negative
156689	A depressing confirmation	
157730	There 's not enough here to justify the almost two hours.	
157695	a snapshot of a dangerous political situation on the verge of coming to a head	
158814	It is ridiculous , of course	
159281	A mostly tired retread of several other mob tales.	
159632	We are left with a superficial snapshot that , however engaging , is insufficiently enlightening and inviting .	
159770	It 's as flat as an open can of pop left sitting in the sun .	
156890	liberal arts college bumper sticker platitudes	Neutral
160247	the movie 's power as a work of drama	
160754	Schweig , who carries the film on his broad , handsome shoulders	
160773	to hope for any chance of enjoying this film	
201255	also examining its significance for those who take part	
201371	those who like long books and movies	
221444	a country still dealing with its fascist past	
222102	used to come along for an integral part of the ride	
157441	the film is packed with information and impressions .	Positive
157879	Although it bangs a very cliched drum at times , this crowd-pleaser 's fresh dialogue , energetic music , and good-natured spunk are often infectious.	
157663	A wildly funny prison caper.	
157749	This is one for the ages.	
157806	George Clooney proves he 's quite a talented director and Sam Rockwell shows us he 's a world-class actor with Confessions of a Dangerous Mind .	
157850	this is a movie that 's got oodles of style and substance .	
157742	Kinnear gives a tremendous performance .	Very Positive
160562	The film is painfully authentic , and the performances of the young players are utterly convincing .	
160925	A historical epic with the courage of its convictions about both scope and detail.	
161048	This warm and gentle romantic comedy has enough interesting characters to fill several movies , and its ample charms should win over the most hard-hearted cynics .	
161459	is engrossing and moving in its own right	
162398	A comic gem with some serious sparkles .	
162779	a sophisticated , funny and good-natured treat , slight but a pleasure	
163228	Khouri then gets terrific performances from them all .

A Reassessment of Reference-Based Grammatical Error Correction Metrics

Shamil Chollampatt[1] and **Hwee Tou Ng**[1,2]

Abstract

Several metrics have been proposed for evaluating grammatical error correction (GEC) systems based on grammaticality, fluency, and adequacy of the output sentences. Previous studies of the correlation of these metrics with human quality judgments were inconclusive, due to the lack of appropriate significance tests, discrepancies in the methods, and choice of datasets used. In this paper, we re-evaluate reference-based GEC metrics by measuring the system-level correlations with humans on a large dataset of human judgments of GEC outputs, and by properly conducting statistical significance tests. Our results show no significant advantage of GLEU over MaxMatch (M^2), contradicting previous studies that claim GLEU to be superior. For a finer-grained analysis, we additionally evaluate these metrics for their agreement with human judgments at the sentence level. Our sentence-level analysis indicates that comparing GLEU and M^2, one metric may be more useful than the other depending on the scenario. We further qualitatively analyze these metrics and our findings show that apart from being less interpretable and non-deterministic, GLEU also produces counter-intuitive scores in commonly occurring test examples.

1 Introduction

Grammatical error correction (GEC) refers to the task of automatically detecting and correcting grammatical, spelling, and word choice errors in written text. As newer approaches are being developed for this task, it becomes essential to have reliable means to compare them. In the related field of machine translation (MT), human judgments are used as ground truth to rank systems in the evaluation campaigns as part of the Workshop on Machine Translation (WMT) (Bojar et al., 2016a) held annually. In the absence of annual evaluations and periodic human-judged shared tasks for GEC, robust automatic evaluation metrics are necessary to reliably assess improvements. Automatic evaluation methods can also help in system development and validation.

Previous shared tasks on GEC relied on automatic evaluation metrics to evaluate the performance of participating systems (Dale and Kilgarriff, 2011; Dale et al., 2012; Ng et al., 2013; Ng et al., 2014; Rozovskaya et al., 2015). The CoNLL-2014 shared task test set and evaluation metric, M^2 (Dahlmeier and Ng, 2012), have been used as the primary benchmark for evaluating English GEC. After the CoNLL-2014 shared task, two reference-based evaluation metrics, namely I-measure (Felice and Briscoe, 2015) and GLEU (Napoles et al., 2015; Napoles et al., 2016a), were proposed for GEC. More recently, some reference-less metrics were also proposed (Napoles et al., 2016b; Asano et al., 2017). A standard way to identify the best metric among them is to compare their correlation to human judgments. In the case of MT, WMT organizes a metrics shared task each year, where the correlation of system-level rankings generated by metrics and humans is measured. There is also a segment-level evaluation subtask where the agreement of metrics is measured at the sentence level. Prior work in GEC has followed the system-level evaluation approach to compare metrics (Grundkiewicz et al., 2015; Napoles et al., 2015; Sakaguchi et al., 2016). However, there has been no prior work on sentence-level evaluation. From prior studies,

Proceedings of the 27th International Conference on Computational Linguistics, pages 2730–2741
Santa Fe, New Mexico, USA, August 20-26, 2018.

it may appear that GLEU performs better than the de-facto M^2 metric. However, previous system-level correlation studies turn out to be inadequate, primarily due to the absence of significance tests and the choice of datasets and methods used. In this paper, we re-evaluate reference-based GEC metrics using appropriate significance tests to measure if previous conclusions can be trusted. We find that there is no evidence to suggest that GLEU is significantly better than M^2. Contrary to system-level evaluation, I-measure is found to be a reasonably useful metric at the sentence level and has a positive correlation with human judgments at the sentence level. In our sentence-level evaluation, we find scenarios where M^2 outperforms GLEU and vice versa. Our qualitative assessment of these metrics on example sentences reveals the shortcomings of GLEU in comparison to the other metrics.

2 Evaluation Metrics

We study three popular reference-based evaluation measures that have been proposed for GEC, namely, MaxMatch (M^2), I-measure, and GLEU.

2.1 MaxMatch (M^2)

The M^2 metric (Dahlmeier and Ng, 2012) computes precision, recall, and F-measure by maximally matching phrase-level edits made by a system to gold-standard edits annotated by humans. A gold-standard edit used by M^2 includes the location of the error within the tokenized input sentence and the proposed correction. Although annotations about the type of errors can be included in the gold standard, they are not used while scoring. For computing scores for specific error types, a variant of M^2 has been proposed (Bryant et al., 2017).

The standard M^2 computation is defined as follows. Consider a set of input sentences $S = \{s_1, ..., s_n\}$ and their corresponding system corrected hypotheses $H = \{h_1, ..., h_n\}$. The set of gold-standard edits for each input sentence s_i is denoted by $\mathbf{g}_i$ and the set of edits made by the system to transform s_i to h_i is denoted by $\mathbf{e}_i$. Precision, recall, and F-measure are given by:

$$\text{precision} = \frac{\text{No. of correct edits made by the system}}{\text{Total no. of edits made by the system}} = \frac{\sum_{i=1}^{n} |\mathbf{e}_i \cap \mathbf{g}_i|}{\sum_{i=1}^{n} |\mathbf{e}_i|}$$

$$\text{recall} = \frac{\text{No. of correct edits made by the system}}{\text{Total no. of gold-standard edits}} = \frac{\sum_{i=1}^{n} |\mathbf{e}_i \cap \mathbf{g}_i|}{\sum_{i=1}^{n} |\mathbf{g}_i|}$$

$$F_\beta = (1 + \beta^2) \cdot \frac{\text{precision} \cdot \text{recall}}{(\beta^2 \cdot \text{precision}) + \text{recall}}.$$

A β value of 0.5 is used in standard M^2 (since CoNLL-2014 shared task), in order to weight precision twice as much as recall. This penalizes incorrect feedback more severely, which is especially important in the context of language learning, where we would like to minimize giving incorrect feedback to language learners. When several sets of annotations (by different annotators) are available for an input sentence s_i, the set that maximizes the F-measure is chosen as $\mathbf{g}_i$.

The set of system edits $\mathbf{e}_i$ for the ith sentence is obtained by first constructing a token-level edit lattice from the Levenshtein distance matrix. Additional edges are added to the lattice to represent phrase-level edits by combining adjacent edges, subject to a constraint on the maximum number of unchanged words (set to 2 in standard M^2). Edges of the lattice are appropriately weighted such that a minimum distance path computation yields the set of edits $\mathbf{e}_i$ that maximally overlaps with the gold-standard edits.

2.2 I-measure

I-measure (Felice and Briscoe, 2015) is a token-level accuracy-based metric proposed to address the inability of M^2 to distinguish between a system that does not correct any errors and a system that only makes wrong changes. Annotations for I-measure can involve non-contiguous tokens as well. The computation of I-measure begins by first aligning the input, hypothesis, and reference corrections in a three-way token-level alignment. Gaps in the alignment can be assumed to be marked by NULL (ϵ) tokens at appropriate positions (Table 1). Let the aligned input, hypothesis, and reference tokens at

POSITIONS	1	2	3	4	5	6	7	8	9	10	11	12	13
INPUT:	Thus	,	advice	from	ϵ	hospital	plays	the	important	role	for	this	.
HYPOTHESIS:	Thus	,	advice	from	ϵ	hospital	plays	an	important	role	for	this	.
REFERENCE:	Thus	,	advice	from	the	hospital	plays	an	important	role	in	this	.

Table 1: An example of three-way token-level alignments produced by I-measure.

position j be denoted by w_j^{inp}, w_j^{hyp}, and w_j^{ref}, respectively. True positives (TP), true negatives (TN), false positives (FP), and false negatives (FN) are defined as follows:

$$\text{TP} : w_j^{\text{inp}} \neq w_j^{\text{ref}} \text{ and } w_j^{\text{hyp}} = w_j^{\text{ref}} \qquad \text{FP} : w_j^{\text{inp}} \neq w_j^{\text{hyp}} \text{ and } w_j^{\text{hyp}} \neq w_j^{\text{ref}}$$
$$\text{TN} : w_j^{\text{inp}} = w_j^{\text{ref}} = w_j^{\text{hyp}} \qquad \text{FN} : w_j^{\text{inp}} \neq w_j^{\text{ref}} \text{ and } w_j^{\text{hyp}} \neq w_j^{\text{ref}}$$

An additional class FPN is defined to balance cases that can be classified as both FP and FN ($\text{FPN} : w_j^{\text{inp}} \neq w_j^{\text{ref}} \neq w_j^{\text{hyp}}$). A weighted accuracy is computed using TP, FP, TN, and FN counts:

$$\text{WAcc} = \frac{\lambda \cdot \text{TP} + \text{TN}}{\lambda \cdot \text{TP} + \text{TN} + \lambda \cdot \left(\text{FP} - \frac{\text{FPN}}{2}\right) + \left(\text{FN} - \frac{\text{FPN}}{2}\right)}$$

The weight λ, which is set to 2, rewards correct changes and penalizes incorrect changes more than preserving erroneous input tokens. When multiple references are used, similar to M^2, the gold-standard reference that maximizes the WAcc is chosen. Then, the weighted accuracy of the input (WAcc_{inp}) is computed by considering the input sentences as the hypothesis, with the same set of references chosen to compute WAcc. I-measure is given by,

$$\text{I} = \begin{cases} \lfloor \text{WAcc} \rfloor, & \text{if WAcc} = \text{WAcc}_{\text{inp}} \\ \dfrac{\text{WAcc} - \text{WAcc}_{\text{inp}}}{1 - \text{WAcc}_{\text{inp}}}, & \text{if WAcc} > \text{WAcc}_{\text{inp}} \\ \dfrac{\text{WAcc}}{\text{WAcc}_{\text{inp}}} - 1, & \text{otherwise.} \end{cases}$$

I-measure denotes the relative improvement or degradation with respect to the input text. I-measure falls in the range[1] $[-1, 1]$, a negative value indicates degradation and a positive value indicates improvement. Unlike M^2, I measure can mix and match annotations from different annotators to produce more alternative references[2].

2.3 GLEU

Unlike M^2 and I-measure, GLEU (Napoles et al., 2015; Napoles et al., 2016a) only requires human annotators to correct by re-writing the source sentence without requiring annotations for individual errors. GLEU computes the precision of n-grams in the hypothesis that match part of the reference sentence, similar to the MT metric BLEU (Papineni et al., 2002). Additionally, GLEU penalizes n-grams in the hypotheses that match part of the input but not the reference. The original formulation (Napoles et al., 2015) included a weight parameter that had to be re-tuned according to the number of reference corrections used. Following the recommendation of Napoles et al. (2016a), we use the new formulation of GLEU[3] which does not include this weight parameter and can work for any number of references.

The computation of GLEU is done as follows. Consider a set of input sentences $S = \{s_1, ..., s_n\}$, their corresponding corrected hypotheses $H = \{h_1, ..., h_n\}$, and reference sentences, $R = \{r_1, ..., r_n\}$.

[1] I-measure may also be represented as a percentage (%) with a range $[-100, 100]$ as used in the rest of the paper.

[2] To use this ability of mixing annotations, alternative corrections for the same underlying error must be grouped together during annotation. However, since the data we use was not annotated in this manner, we disable the mixing ability of I-measure by using `-nomix` to prevent generating invalid references.

[3] This is referred to as GLEU+ in (Napoles et al., 2016a).

Here, we assume that there is a single reference sentence for each input sentence. First, a precision term p_k is computed for n-grams of size k ($k = 1, 2, ..., N$ and $N = 4$ for standard GLEU):

$$p_k = \frac{\sum_{h_i \in H} \left(\sum_{\substack{\text{k-gram in} \\ h_i \text{ and } r_i}} \text{count}_{h_i,r_i}(\text{k-gram}) - \sum_{\substack{\text{k-gram in} \\ h_i \text{ and } s_i}} \max\left[0, \text{count}_{h_i,s_i}(\text{k-gram}) - \text{count}_{h_i,r_i}(\text{k-gram})\right] \right)}{\sum_{h_i \in H} \sum_{\substack{\text{k-gram} \\ \text{in } h_i}} \text{count}_{h_i}(\text{k-gram})}$$

$\text{count}_a(\text{n-gram}) = \#$ occurrences of n-gram in a

$\text{count}_{a,b}(\text{n-gram}) = \min(\#\text{occurrences of n-gram in } a, \#\text{occurrences of n-gram in } b)$

Similar to BLEU, a brevity penalty (BP) is computed to penalize short hypotheses:

$$\text{BP} = \begin{cases} 1, & \text{if } l_h > l_r \\ \exp(1 - l_r/l_h), & \text{if } l_h \leq l_r \end{cases}$$

where l_r is the reference corpus length (sum of the number of tokens of the reference sentences) and l_h is the total hypothesis corpus length (sum of the number of tokens of all hypotheses). GLEU is given by:

$$\text{GLEU}(\text{S}, \text{H}, \text{R}) = \text{BP} \cdot \exp\left(\frac{1}{N} \sum_{k=1}^{N} \log p_k\right)$$

When multiple references are available, GLEU does not include reference n-grams from all references to compute n-gram precision like BLEU, nor picks the best like M^2 and I-measure. Instead, for each input sentence, a random reference correction is chosen from the set of reference corrections to compute the GLEU score. This makes GLEU non-deterministic, unlike M^2 and I-measure. The average GLEU score over m GLEU score computations is reported as the final score ($m = 500$ in standard GLEU).

3 Quantitative Evaluation

The three GEC metrics are evaluated by measuring their correlation with human quality judgments treated as the ground truth. Following the experimental methodology in WMT metrics shared tasks (Macháček and Bojar, 2014; Stanojević et al., 2015; Bojar et al., 2016b; Bojar et al., 2017), we evaluate system-level correlation as well as sentence-level agreement of metrics with human judgments.

We utilize the collection of human judgments of GEC outputs released in (Grundkiewicz et al., 2015). The dataset is annotated similar to the relative-ranking method adopted in the WMT metrics shared tasks in (Macháček and Bojar, 2014; Stanojević et al., 2015). Human judgments are obtained for the system outputs of the 12 participating systems from the CoNLL-2014 shared task (Ng et al., 2014) and the input text as the thirteenth system (referred to as INPUT). Each human judgment consists of a 5-way ranking of hypotheses corrections from randomly chosen systems for an input sentence. Systems that produce the same hypothesis for an input sentence are grouped together. The 5-way rankings are then converted to pairwise rankings that include ties. A total of 109,098 pairwise rankings can be obtained if systems with the same hypothesis that were grouped together in the 5-way rankings are included (henceforth, referred to as *expanded set*). Grundkiewicz et al. (2015) observed that there were a large number of ties due to the high overlap in system outputs. Trivial ties of systems that produce the same hypothesis can be removed by including only one randomly chosen system among grouped systems. This results in 20,516 pairwise rankings (henceforth, referred to as *unexpanded set*).

3.1 Measuring System-Level Correlation

System-level correlation is computed by comparing the ranking of the participating systems by humans and the ranking generated by the metric scores. Generating a ranking using metric scores is straightforward. However, human pairwise comparisons need to be converted into a ranking of systems. To do this,

two methods are employed in (Grundkiewicz et al., 2015)[4], namely *Expected Wins* (Bojar et al., 2013) and *Trueskill* (Sakaguchi et al., 2014).

The Expected Wins model computes an intuitive score for a system based on the probability that a system wins (ranks higher according to human judgments) over a randomly chosen system on a randomly chosen input sentence. This model ignores ties. The Trueskill model computes a score representing the average relative ability of the system compared to other systems, accounting for the uncertainty surrounding the system's ability as well. In the context of GEC, on this dataset, Grundkiewicz et al. (2015) empirically found that Expected Wins performs better than Trueskill. However, almost all subsequent work ignored this finding and used the Trueskill model instead. We compute correlations using both methods in order to ensure comparability to prior work.

We measure both Pearson and Spearman correlation coefficients between metric rankings and human rankings. Pearson correlation (r) compares the system-level scores produced by a metric against human, under the assumption that the two measured variables have a linear relationship:

$$r = \frac{\sum_{i=1}^{q}(x_i - \bar{x})(y_i - \bar{y})}{\sqrt{\sum_{i=1}^{q}(x_i - \bar{x})^2}\sqrt{\sum_{i=1}^{q}(y_i - \bar{y})^2}}$$

where $x_1, ..., x_q$ are metric scores for q systems for a particular metric with $\bar{x}$ as the mean metric score, and $y_1, ..., y_q$ are human scores computed by Trueskill or Expected Wins with $\bar{y}$ as the mean human score. On the other hand, Spearman correlation (ρ) computes a correlation coefficient based on ranks instead of scores:

$$\rho = 1 - \frac{6\sum_{i=1}^{q}(d_i)^2}{q(q^2-1)}$$

where d_i represents the difference in the human rank and metric rank of the ith system. Spearman correlation is more relaxed compared to Pearson correlation in terms of the assumptions made about variables and also less sensitive to outliers in the sample.

In order to determine if a metric outperforms another, it is inadequate to measure differences in correlation alone. Following the recommendations in (Graham and Baldwin, 2014), we evaluate for significance of differences of correlation between metrics using William's test (Williams, 1959). Note that prior work in human evaluation of GEC systems has not reported significance tests that account for the dependence between two metrics and hence the derived conclusions are not justified.

3.2 Measuring Sentence-Level Agreement

Since system-level evaluation is done on a few systems (13 in our case), we also compute a fine-grained sentence-level agreement of metrics to human pairwise rankings. For this, sentence-level metric scores are computed[5]. Agreement to humans is computed in a similar manner as segment-level evaluation in the WMT metrics shared task and variants of the Kendall's Tau (τ) are used:

$$\tau = \frac{|\text{Concordant}| - |\text{Discordant}|}{\text{Total \# Pairwise Comparisons}} \quad (1)$$

where |Concordant| refers to the number of times a metric agrees with the sentence-level human pairwise comparisons, and |Discordant| refers to the number of times they disagree. The variants of τ are related to the way in which human ties are handled. In the variant used in the WMT metrics shared task from WMT14 (Macháček and Bojar, 2014) onwards (henceforth referred to as *NoTies*), human ties are ignored completely and metric ties are added to the denominator alone, without contributing to Concordant or Discordant sets. For GEC, since there is a large number of ties, particularly in the expanded set, we include another variant that incorporates human ties as well (henceforth, referred to as *HTies*). In this

[4]We use the scripts released by Grundkiewicz et al. (2015) to compute human ranking of systems.

[5]Similar to BLEU, sentence-level GLEU needs smoothing to avoid zero n-gram counts. We use the sentence-level scores produced by GLEU using the `-d` flag, where smoothing is performed by replacing a zero count with one.

Metric	Expected Wins		Trueskill	
	r	ρ	r	ρ
GLEU	0.691	0.407	0.733	0.478
I-MEASURE	–0.250	–0.385	–0.316	–0.423
M^2	0.623	0.687	0.672	0.720

Table 2: Results of system-level Pearson (r) and Spearman (ρ) correlations of GEC metrics using the Expected Wins model and Trueskill model of human rankings.

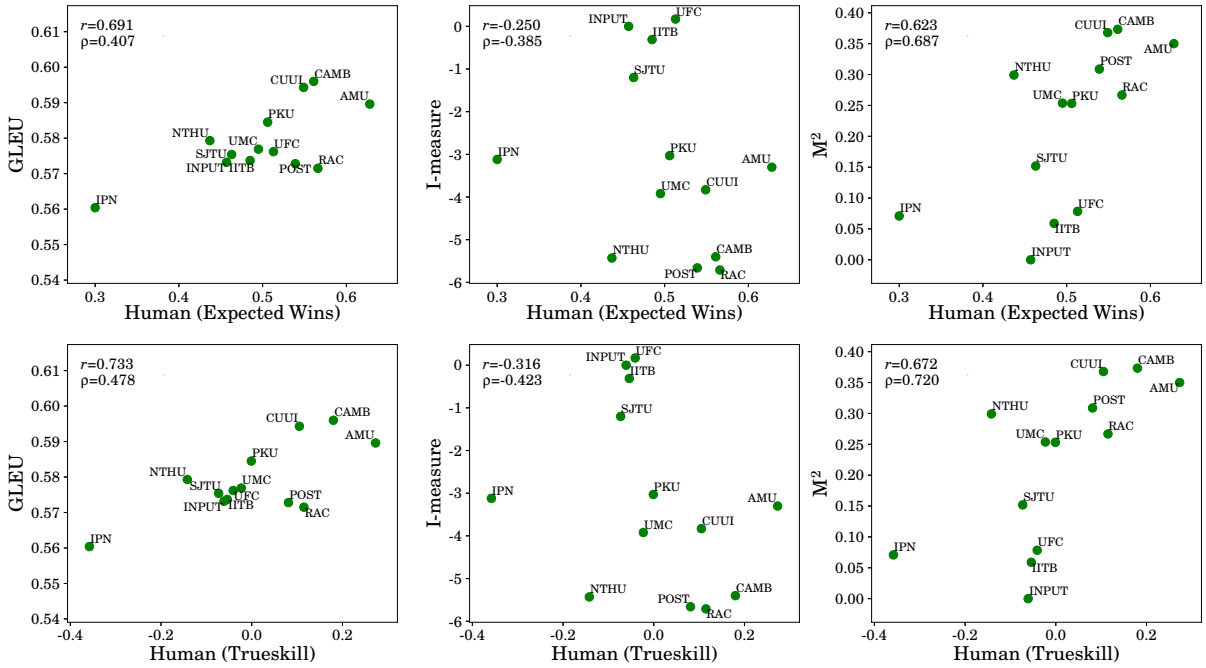

Figure 1: Scatter plots showing the metric scores and human scores of CoNLL-2014 shared task systems.

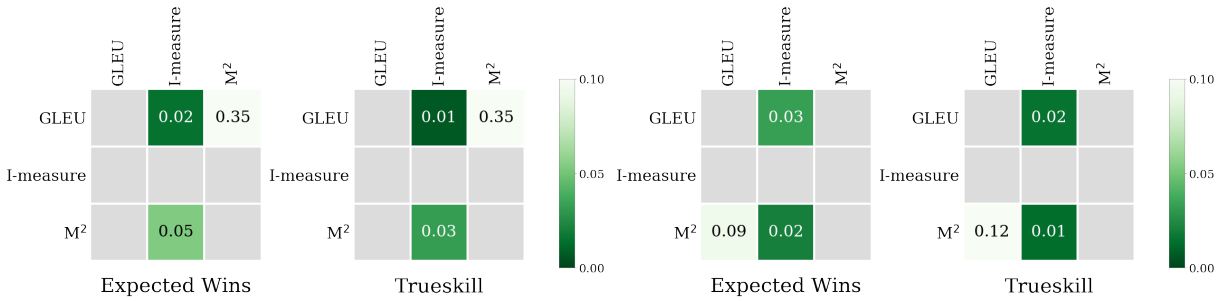
variant, when a human judges a tie and metric predicts a tie as well for a given pair of hypotheses, it is treated as a concordant pair. However, when a human predicts a tie and a metric does not, or vice versa, it contributes only to the denominator and not to the Discordant set. We test for significance similar to (Bojar et al., 2017), by employing bootstrap resampling over 1,000 samples and those metrics with non-overlapping 95% confidence intervals are treated as having statistically significant improvements compared to the lower performing metrics.

3.3 Results

3.3.1 System-Level Evaluation

The results of the system-level correlation tests are given in Table 2. In both Expected Wins and Trueskill methods of human ranking, GLEU achieves a higher Pearson correlation compared to the rest. M^2 achieves moderately high Pearson correlations and the highest Spearman correlations using both methods of human ranking. As noted in prior studies (Grundkiewicz et al., 2015; Napoles et al., 2016a), I-measure achieves a negative correlation. In order to decide which correlation measure is more suitable and to understand the cause of disagreement in both correlation measures, it may be worth looking at the bivariate scatter plot of metric and human scores (Figure 1). The presence of an outlier (the leftmost point – IPN) indicates that Pearson correlation may not be the ideal choice as it is sensitive to outliers in the data. To demonstrate this, we remove the system IPN from the ranking. Pearson correlation of GLEU then becomes lower than that of M^2 (0.500 for GLEU vs 0.593 for M^2 using Expected Wins and



(a) p-values for Pearson correlation.

(b) p-values for Spearman correlation

Figure 2: Results of William's significance tests for correlations between metrics. A green non-empty cell denotes that the row metric has a higher correlation coefficient compared to the column metric with the specified p-value. A gray empty cell indicates that the row metric has equal or lower correlation coefficient compared to the column metric.

0.584 for GLEU vs 0.638 for M^2 using Trueskill). The relative performance under Spearman correlation, however, remains the same (0.245 for GLEU vs 0.643 for M^2 using Expected Wins and 0.336 for GLEU vs 0.692 for M^2 using Trueskill). The high Spearman correlation for M^2 indicates that it is a good metric for ranking systems, which is the primary goal of automatic evaluation metrics.

To understand if one metric significantly outperforms another, we perform William's significance tests (Figure 2). As expected, we find that GLEU is not significantly better than M^2 in terms of Pearson correlation (p-value of 0.35 for both Expected Wins and Trueskill). In the case of Spearman correlation for Expected Wins, M^2 is significantly better than GLEU at the level of significance 0.10, but does not significantly outperform GLEU for the Trueskill model. The significance test results show that neither GLEU nor M^2 can be conclusively shown to be better than the other.

3.3.2 Sentence-Level Evaluation

Table 3 shows the results of sentence-level agreement of metrics to human pairwise rankings when human ties are considered (HTies) or ignored (NoTies). We also consider the unexpanded set where systems that produce the same hypothesis for an input sentence are grouped together. This removes the trivial ties (two identical hypotheses judged to be a tie) from the pairwise rankings. In the HTies variant, M^2 achieves statistically significant improvements compared to the other two metrics in both expanded and unexpanded sets. However, for NoTies variant, GLEU achieves the best result. The results show that M^2 may be better at judging ties and performs well overall when complete pairwise rankings are considered. On the other hand, GLEU does a better job at discriminating hypotheses, likely due to its ability to judge fluency like humans do (Sakaguchi et al., 2016). This difference in behavior of GLEU and M^2 between the two variants, HTies and NoTies, is expected given a large number of ties for GEC (Grundkiewicz et al., 2015) as indicated by the difference in the number of pairwise comparisons (Table 3) and that M^2 generally assigns more ties compared to GLEU. Surprisingly, I-measure achieves a positive correlation at the sentence level as opposed to a negative correlation at the system level, suggesting that it can be a useful metric at the sentence level.

4 Qualitative Assessment

We illustrate the strengths and weaknesses of the three metrics with the help of two examples (Table 4). We compare the metrics based on two criteria, interpretability and intuitiveness, which we believe are necessary for good GEC metrics.

Interpretability: The scores produced by a good GEC metric should be interpretable as a measure of a system's ability to correct errors and improve the text. M^2 and I-measure are based on minimal annotations and their results are interpretable. For example, M^2 measures the precision and recall of a system, in terms of the number of phrase-level errors that it corrects in a given input text. Similarly, I-measure is computed based on the relative weighted accuracy between a system and a do-nothing

Metric	Expanded		Unexpanded	
	HTies (109098)	NoTies (49981)	HTies (20516)	NoTies (14584)
GLEU	0.567	0.388*	0.237	0.321
I-MEASURE	0.564	0.368	0.242	0.293
M^2	0.617*	0.300	0.348*	0.266

Table 3: Results of sentence-level agreement in terms of two variations of Kendall's τ (HTies and NoTies) on expanded and unexpanded sets. The number of human pairwise comparisons used is given in parentheses. * indicates that the 95% confidence interval of the metric does not overlap with those of the other metrics.

		(GLEU, I%, M^2)
	Example 1	
INP:	The weekly quizzes in this course makes it challenging and fun .	
HYP1:	The weekly quizzes in this course makes it challenging and fun .	(0.392, 0.00, 0.000)
HYP2:	The weekly quizzes in this course ***making*** it challenging and fun .	(0.735, –4.00, 0.000)
REF:	The weekly quizzes in this course ***make*** it challenging and fun .	
	Example 2	
INP:	The senior student who failed have to retake the course next year .	
HYP1:	The senior student who failed ***has*** to retake the course next year .	(0.661, 100.00, 1.000)
HYP2:	The senior ***students*** who failed have to retake the course next year .	(0.656, 100.00, 1.000)
HYP3:	The senior ***students*** who failed ***has*** to retake the course next year .	(0.776, –6.11, 0.556)
REF1:	The senior student who failed ***has*** to retake the course next year .	
REF2:	The senior ***students*** who failed have to retake the course next year .	

Table 4: Illustrating examples and scores produced by the metrics.

baseline. In contrast, GLEU measures the precision of n-grams of the output text similar to BLEU. The scores that it produces have no clear relation to the system's ability to correct or improve a text. For example, in Example 1, Hypothesis 1 (Table 4), when the system hypothesis is exactly the input sentence itself, there is no evidence about the system's ability to correct errors. While I and M^2 give a zero score, GLEU gives a non-zero score (GLEU = 0.392). In the case of its counterpart BLEU, if some n-grams of the hypothesis and reference match, it rightly assigns a non-zero score as the system shows some ability to perform translation. However, for GEC, simply copying the input can result in matching several n-grams from the reference despite the system showing zero ability to perform correction. Moreover, the GLEU score will vary with the length of the input sentence without the system having to fix any error or even modify the input. Similarly, for Example 2, Hypothesis 1 and 2 (Table 4), despite being grammatical and matching one of the reference corrections exactly, GLEU gives a non-perfect score for both hypotheses, whereas I and M^2 correctly gives perfect scores. This is an artefact of GLEU randomly selecting one among the two references for scoring and averaging over multiple iterations. Also, due to its non-deterministic behavior, the scores for Hypothesis 1 and 2 differ despite having the same n-gram statistics compared to the references.

Intuitiveness: In Example 1, GLEU produces a non-zero score for a hypothesis that is exactly the same as the input sentence (Hypothesis 1). When an incorrect change is introduced (Hypothesis 2), the score becomes even higher (GLEU=0.735). This is counter-intuitive. If a change results in an ungrammatical sentence, the score should remain the same or decrease as in the case of M^2 and I. This unintuitive behavior of GLEU is due to the additional term in GLEU that penalizes preservation of n-grams in the

input sentence that were supposed to be changed according to the reference. It can be argued that GLEU intends to reward GEC systems for detecting errors by assigning a partial credit to systems that make spurious changes at locations where corrections are deemed necessary by human annotators. However, this will encourage building GEC systems that provide inaccurate feedback and potentially mislead the end users (primarily language learners). Hence, it is better to build and evaluate grammatical error detection systems separately (Rei and Yannakoudakis, 2016). I-measure, on the other hand, assigns a negative score for Hypothesis 2 as it is considered to 'degrade' the input, although it is arguable that both hypotheses 1 and 2 are equally ungrammatical. In Example 2, when multiple references are used, GLEU gives a higher score to Hypothesis 3 (ungrammatical) than Hypothesis 1 and 2, both of which are grammatical and each matches one of the two references exactly. On the other hand, both M^2 and I-measure assign a lower score to Hypothesis 3 and conform to our intuition.

5 Related Work

5.1 GEC Evaluation

When GEC was restricted to specific error types, measures such as accuracy, precision, recall, and F-score were employed (Chodorow et al., 2012) as done in the earlier shared tasks (Dale and Kilgarriff, 2011; Dale et al., 2012). Dahlmeier and Ng (2012) identified weaknesses in evaluation methods used in these shared tasks in extracting phrase-level edits that correctly match the reference and proposed MaxMatch scoring (Dahlmeier and Ng, 2012), which can also work for sentence correction over all error types. M^2 does not distinguish between a do-nothing baseline and a system that changes the input incorrectly, and hence I-measure (Felice and Briscoe, 2015) was proposed. Later, GLEU (Napoles et al., 2015) was proposed. It relied on whole sentence rewrites instead of span-based error annotations. However, our analysis shows that GLEU has several weaknesses in its formulation and has a non-deterministic behavior that makes it an unreliable alternative to prior metrics. A few reference-less evaluation methods have been proposed of which (Napoles et al., 2016b) considers the grammaticality of the output sentences alone to evaluate GEC systems. Recently, Asano et al. (2017) proposed improvements to (Napoles et al., 2016b) by additionally accounting for fluency and meaning preservation. Sakaguchi et al. (2017) suggested future directions of improving GEC evaluation such as considering whole document rewrites.

5.2 Human Judgments and Metric Quality

Inspired from WMT, two collections of human judgments of GEC system outputs were released (Grundkiewicz et al., 2015; Napoles et al., 2015). We use the former in our study as it has a much higher number of human pairwise comparisons (109,098) compared to the latter (28,146). Also, (Napoles et al., 2015) includes references as one of the compared systems in order to act as a control measure to ensure quality of human judgments. However, this is unfair to systems that compare more often against the reference as noted by Callison-Burch et al. (2012), since human raters may prefer the reference corrections more often. This bias is further worsened by explicitly displaying the reference corrections to the human judges in (Napoles et al., 2015). Reference translations are neither included in rankings nor shown to judges in (Grundkiewicz et al., 2015). Also, all subsequent studies used the judgments released by Grundkiewicz et al. (2015) for comparing GEC metrics. Grundkiewicz et al. (2015), however, did not compare to GLEU as it was not available at the time. Later work which measured system-level correlation using GLEU failed for a number of reasons which motivate this paper. Apart from using different variations of GLEU, there was a mistake[6] in GLEU computation that produced different results and incorrect conclusions in earlier studies. Moreover, no proper significance tests to compare the differences in correlations between metrics were done. Significance tests that reject the null hypothesis of having no correlation to humans is not adequate for comparing differences in correlations between metrics (Graham and Baldwin, 2014). Also, (Napoles et al., 2016b; Asano et al., 2017) use 18 references for CoNLL-2014 sentences for generating metric rankings, of which 2 are the references used in the shared task, 8 are from (Bryant and Ng, 2015), and another 8 are annotated by both experts and non-experts as sentence-rewrites (Sakaguchi

[6]The brevity penalty was incorrectly implemented as $\exp(1-l_h/l_r)$ instead of $\exp(1-l_r/l_h)$. This was fixed in the version that we use (fixed on 10 June, 2017: https://github.com/cnap/gec-ranking/commit/50b503)

et al., 2016). Automatically constructing M^2 and I-measure annotations from sentence rewrites will be sub-optimal. Also, we observed that the non-determinism of GLEU scores is more pronounced when more number of references are used, resulting in large differences in correlation values. In the end, we decided to use the standard two references for CoNLL-2014 as used in the original shared task and continues to be the standard benchmark used to evaluate GEC systems to date. Also, prior studies had not conducted sentence-level agreement with human judgments, which we did in this paper. Sakaguchi et al. (2017) qualitatively compared metrics using contrived, gamed examples, which are rather irrelevant in practice (such as a system that outputs a dummy hypothesis "a", "a a", or "a a a" for any input sentence) and showed that M^2 under-penalized such systems. On the contrary, our qualitative assessment is based on naturally occurring examples and highlights the practical strengths and weaknesses of current GEC metrics.

6 Conclusion

Through carefully designed experiments and significance tests, we find no evidence of GLEU being a better metric than M^2 for ranking systems as claimed in prior work (Napoles et al., 2015; Sakaguchi et al., 2016; Napoles et al., 2016b). In fact, at the sentence level, when correctly predicting human ties are rewarded, M^2 works better than GLEU. We believe that GEC metrics should be interpretable and must provide intuitive scores. In our qualitative assessment, we find that GLEU is less interpretable and produces absurd scores in common scenarios. Our analysis suggests that GLEU cannot be considered as a replacement of existing GEC metrics. The code to replicate the evaluations in this paper is available at `https://github.com/nusnlp/gecmetrics`.

Information Aggregation via Dynamic Routing for Sequence Encoding

Jingjing Gong, Xipeng Qiu*, Shaojing Wang, Xuanjing Huang

Abstract

While much progress has been made in how to encode a text sequence into a sequence of vectors, less attention has been paid to how to aggregate these preceding vectors (outputs of RNN/CNN) into fixed-size encoding vector. Usually, a simple max or average pooling is used, which is a bottom-up and passive way of aggregation and lack of guidance by task information. In this paper, we propose an aggregation mechanism to obtain a fixed-size encoding with a dynamic routing policy. The dynamic routing policy is dynamically deciding that *what* and *how much* information need be transferred from each word to the final encoding of the text sequence. Following the work of Capsule Network, we design two dynamic routing policies to aggregate the outputs of RNN/CNN encoding layer into a final encoding vector. Compared to the other aggregation methods, dynamic routing can refine the messages according to the state of final encoding vector. Experimental results on five text classification tasks show that our method outperforms other aggregating models by a significant margin. Related source code is released on our github page[1].

1 Introduction

Learning the distributed representation of text sequences, such as sentences or documents, is crucial to a wide range of important natural language processing applications. A primary challenge is how to encode the variable-length text sequence into a fixed-size vector, which should fully capture the semantics of text.

Many successful text encoding methods usually contain three key steps: (1) converting each word in a text sequence into its embedding; (2) taking as input the sequence of word embeddings, and computing the context-aware representation for each word with a recurrent neural network (RNN) (Hochreiter and Schmidhuber, 1997; Chung et al., 2014) or convolutional neural network (CNN) (Collobert et al., 2011; Kim, 2014); (3) summarizing the sentence meaning into a fixed-size vector by an aggregation operation. Then, these models are trained by combining a downstream task in a supervised or unsupervised way.

Currently, much attention is paid to the first two steps, while the aggregation step is less emphasized on. Some simple aggregation methods, such as max (or average) pooling, is used to sum the RNN hidden states or convolved vectors, computed in the previous step, into a single vector. This kind of methods aggregate information in a bottom-up and passive way and are lack of the guide of task information. Recently, several works employ self-attention mechanism (Lin et al., 2017; Yang et al., 2016) on top of the recurrent or convolutional encoding layer to replace simple pooling. A basic assumption is that the words (or even sentences) are not equally important. One or several task-specific context vectors are used to assign a different weight to each word and select task-specific encodings. The context vectors are parameters learned jointly with other parameters during the training process. These attentive aggregation can select task-dependent information. However, the context vectors are fixed once learned.

Santa Fe, New Mexico, USA, August 20-26, 2018.

In this paper, we regard the aggregation as a routing problem of how to deliver the messages from source nodes to target nodes. In our setting, the source nodes are the outputs of a recurrent or convolutional encoding layer, and the target nodes are one or several fixed-size encoding vectors to represent the meaning of the text sequence.

From this viewpoint, both the pooling and attentive aggregations are a *fixed* routing policy without considering the state of the final encoding vectors. For example, the final encoding vectors could receive some redundancy information from different words. The fixed routing policy cannot avoid this issue. Therefore, we wish for a new way to aggregate information according to the state of the final encoding.

In recent promising work of capsule network (Sabour et al., 2017), a dynamic routing policy is proposed and proven to be more effective than the max-pooling routing. Inspired by their idea, we introduce a text sequence encoding model with dynamic routing mechanism. Specifically, we propose two kinds of dynamic routing policies. One is the standard dynamic routing policy same as the capsule network, in which the source node decides what and how many messages are sent to different target nodes. The other is the reversed dynamic routing policy, in which the target node decides what and how many messages may be received from different source nodes.

Experimental results on five text classification tasks show that the dynamic routing policy outperforms other aggregation methods, such as max pooling, average pooling, and self-attention by a significant margin.

2 Background: general sequence encoding for text classification

In this section, we are going to introduce a general text classification framework. It consists of an Embedding Layer, Encoding Layer, Aggregation Layer and Prediction Layer.

2.1 Embedding Layer

Given a text sequence with words $S = w_1, w_2, \cdots, w_L$. Since the words are symbols that could not be processed directly using prominent neural architectures, so we first map each word into a d dimensional embedding vector,

$$X = [\mathbf{x}_1, \mathbf{x}_1, \mathbf{x}_2, \cdots, \mathbf{x}_L]. \tag{1}$$

In order to transfer knowledge from a vast unlabeled corpus, the embeddings can be taken from the pre-trained word embedding, such as Glove (Pennington et al., 2014).

2.2 Encoding Layer

However, each word representation in X is still independent with each other. To gain some dependency between adjacent words, we then build a bi-directional LSTM (BiLSTM) layer (Hochreiter and Schmidhuber, 1997) to incorporate forward and backward context information of a sequence. Then we can get phrase-level encoding $\mathbf{h}_t$ of a word by concatenating forward $\mathbf{h}_t^f$ and backward output vector $\mathbf{h}_t^b$ correspond to the target word.

$$\mathbf{h}_t^f = \text{LSTM}(\mathbf{h}_{t-1}^f, \mathbf{x}_t), \tag{2}$$

$$\mathbf{h}_t^b = \text{LSTM}(\mathbf{h}_{t+1}^b, \mathbf{x}_t), \tag{3}$$

$$\mathbf{h}_t = [\mathbf{h}_t^f; \mathbf{h}_t^b]. \tag{4}$$

Thus, the outputs of BiLSTM encoder are a sequence of vectors

$$H = [\mathbf{h}_1, \mathbf{h}_2, \cdots, \mathbf{h}_L]. \tag{5}$$

2.3 Aggregation Layer

Encoding layer only models dependency between adjacent words, but the final prediction of the text requires a fix-length vector. Therefore we need aggregate information from variable length sequence to a single fix-length vector. There are several different ways of aggregation such as max or average pooling, and context-attention.

Max or Average Pooling Max or Average pooling is a simple way of aggregating information, which does not require extra parameters and is computationally efficient (Kim, 2014; Zhao et al., 2015; Lin et al., 2017). In the process of modeling natural language, max or average pooling is performed along the time dimension.

$$\mathbf{e}^{max} = \max([\mathbf{h}_1, \mathbf{h}_2, \cdots, \mathbf{h}_L]), \tag{6}$$

$$\mathbf{e}^{avg} = \frac{1}{L}\sum_{i=1}^{L}\mathbf{h}_i, \tag{7}$$

For example,in Equation 6 the $\max$ operation is performed on each dimension of $\mathbf{h}$ along time dimension. And in Equation 7 the average operation is performed along time dimension.

Max pooling is empirically better at aggregating long sentences than average pooling. We assume it's because that, the actual word that contributes to the classification problem is far less than the number of words that contain in a long sentence. Information from important words is weakened by a large population of "boring" words.

Self-Attention As has been stated previously, average pooling is prone to weaken important words when the sentence is longer. Self-Attention assigns each word a weight to indicate the importance of a word depending on the task on hand. A few words that are crucial to the task will be emphasized while the "boring" words are ignored. The self-attention process is formulated as follows:

$$u_i = \mathbf{q}^T\mathbf{h}_i, \tag{8}$$

$$a_i = \frac{\exp(u_i)}{\sum_k \exp(u_k)}, \tag{9}$$

$$\mathbf{e}^{attn} = \sum_{i=1}^{L} a_i \cdot \mathbf{h}_i \tag{10}$$

First, we need a task-specific trainable query $\mathbf{q} \in \mathbb{R}^d$ to calculate similarity weight between query and each contextually encoded word. Then the corresponding weights are normalized across time dimension using softmax normalization function Eq. 9, after that the aggregated vector is simply a weighted sum of the input sequence in Eq. 10.

2.4 Prediction Layer

Then we feed the encoding $\mathbf{e}$ to the input of a multi-layer perceptron (MLP), followed by a softmax classifier.

$$\mathbf{p}(\cdot|\mathbf{e}) = \mathrm{softmax}(\mathrm{MLP}(\mathbf{e}))$$

where $\mathbf{p}(\cdot|\mathbf{e})$ is the predicted distribution of different classes given the representation vector $\mathbf{m}$.

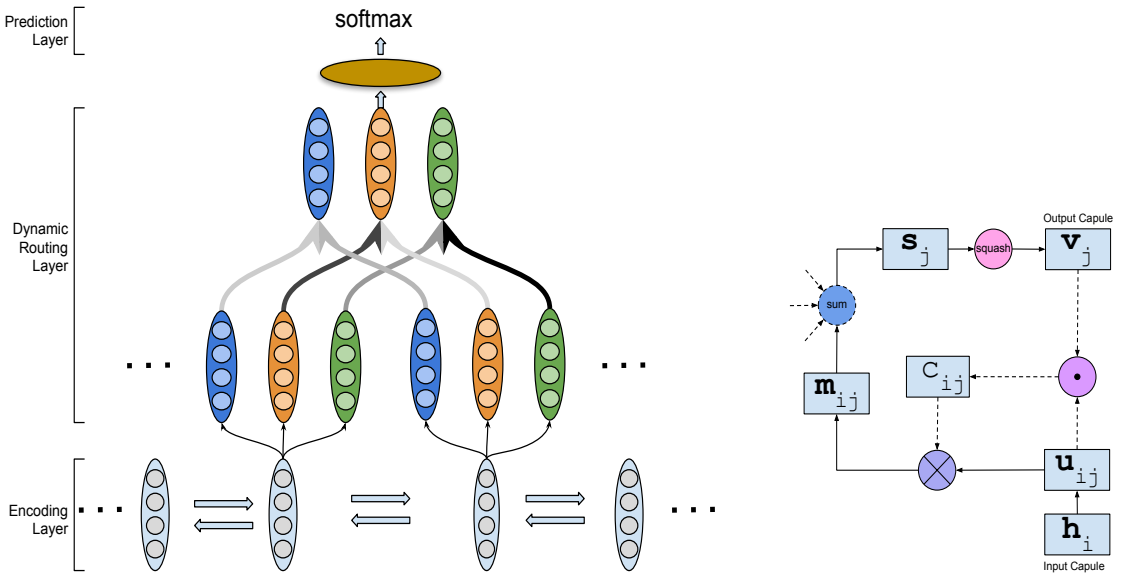
3 Aggregation via Dynamic Routing

In this section, we will formally introduce dynamic routing in detail. The goal of dynamic routing is to encode the meaning of X into M fix-length vectors

$$V = [\mathbf{v}_1, \mathbf{v}_2, \cdots, \mathbf{v}_M]. \tag{11}$$

To transfer information from a variable number of representation H to a fixed number of vectors V, a key problem we need to slove is to properly design a routing policy of information transfer. In other words, *what* and *how much* information is to be transferred from $\mathbf{h}_i$ to $\mathbf{v}_j$.

Although self-attention has been applied in aggregation, the notion of summing up elements in the attention mechanism is still very primitive. Inspired by the capsule networks (Sabour et al., 2017), we propose a dynamic routing aggregation (DR-AGG) mechanism to compute the final encoding of text sequence.



(a) Aggregation via Dynamic Routing

(b) Detialed dynamic routing process

Figure 1: Diagram of dynamic routing for sequence encoding. (a) is the overall dynamic routing diagram, the width of edges between capsules indicate the amount of information transfered, which is refined iteratively. (b) is a detailed iterative process of transferring information from capsule $\mathbf{h}_i$ to capsule $\mathbf{v}_j$, where $\odot$ is a inner product operation and $\otimes$ is a element-wise product.

Following the definition of capsule networks, we call each encoding vector, or a group of neurons, as a capsule. Thus, H denotes the input capsules, and V denotes the output capsules.

A message vector $\mathbf{m}_{i\to j}$ denotes the information to be transferred from $\mathbf{h}_i$ to $\mathbf{v}_j$.

$$\mathbf{m}_{i\to j} = c_{ij} f(\mathbf{h}_i, \theta_j), \tag{12}$$

where c_{ij} indicates proportionally how much information is to be transferred, and $f(\mathbf{h}_i, \theta_j)$ is a one-layer fully-connected network parameterized by θ_j, indicating which aspect of information is to be transferred.

The output capsule $\mathbf{v}_j$ first aggregates all the incoming messages

$$\mathbf{s}_j = \sum_{i=1}^{L} \mathbf{m}_{i\to j}, \tag{13}$$

and then squashes $\mathbf{s}_j$ to confine $|\mathbf{s}_j| \in (0, 1)$ to a probability,

$$\mathbf{v}_j = \frac{\|\mathbf{s}_j\|^2}{1 + \|\mathbf{s}_j\|^2} \frac{\mathbf{s}_j}{\|\mathbf{s}_j\|} \tag{14}$$

Dynamic Routing Process The dynamic routing process is implemented by an iterative process of refining the coupling coefficient c_{ij}, which define proportionally how much information is to be transferred from $\mathbf{h}_i$ to $\mathbf{v}_j$.

The coupling coefficient c_{ij} is computed by

$$c_{ij} = \frac{\exp(b_{ij})}{\sum_k \exp(b_{ik})}, \tag{15}$$

$$b_{ij} \leftarrow b_{ij} + \mathbf{v}_j^{\mathrm{T}} f(\mathbf{h}_i, \theta_j), \tag{16}$$

where b_{ij} is the log probabilities, initialized with 0.

The coefficients c_{ij} is computed using a softmax function, and $\sum_{j=1}^{M} c_{ij} = 1$. Therefore, the total amount of information transferred from capsule h_i is proportionally summed to one.

When an output capsule $\mathbf{v}_j$ receives the incoming messages, its state will be updated and the coefficient c_{ij} is also re-computed for each input capsule. Thus, we iteratively refine the route of information passing, towards an instance dependent and context aware encoding of a sequence. After the text sequence is encoded into M capsules, We map these capsules into vector representation by simply concatenating all capsules,

$$\mathbf{e} = [\mathbf{v}_1; \ldots; \mathbf{v}_M]. \tag{17}$$

Figure 1 gives an illustration of the dynamic routing mechanism. The detailed dynamic routing algorithm is further described in detail in Algorithm 1.

Algorithm 1: Dynamic Routing Algorithm

Data: Input Capsules: $\mathbf{h}_1, \mathbf{h}_2, \cdots, \mathbf{h}_L$, Maximum number of Iterations: T
Result: Output Capsules: $\mathbf{v}_1, \mathbf{v}_2, \cdots, \mathbf{v}_M$
Initialize $b_{ij} \leftarrow 0$;
for $t = 1$ **to** T **do**
  Compute the routing coefficients c_{ij} for all $i \in [1, L], j \in [1, M]$; /* Eq.15 */
  Update all the output capsule $\mathbf{v}_j, j \in [1, M]$; /* Eq. 13 and 14 */
  Update b_{ij} for all $i \in [1, L], j \in [1, M]$; /* Eq. 16 */
end for
return $\mathbf{v}_1, \mathbf{v}_2, \cdots, \mathbf{v}_M$

Reversed Dynamic Routing Process In standard DR-AGG, an input capsule decides what proportion of information can be transferred to an output capsule. We also explore a reversed dynamic routing, in which the output capsule decides what proportion of information should be received from an input capsule. The only difference between reversed dynamic routing and standard dynamic routing is how the softmax function was applied to the log probabilities $[b_{ij}]_{L\times M}$. Instead of normalizing each row of $[b_{ij}]_{L\times M}$ as is done in standard DR-AGG, reverse dynamic routing normalizes each column of $[b_{ij}]_{L\times M}$,

$$c_{ij} = \frac{\exp(b_{ij})}{\sum_k \exp(b_{kj})} \tag{18}$$

Other detail of reversed dynamic routing is the same as the standard dynamic routing.

The reversed DR-AGG works like the multi-hop memory network in iteratively aggregating information (Sukhbaatar et al., 2015; Kumar et al., 2015).

3.1 Analysis

The DR-AGG is somewhat like attention mechanism (Bahdanau et al., 2014; Vaswani et al., 2017).however, there are differences.

In standard DR-AGG, each input capsule (encoding of each word) is employed as query vector to assign a proportion weight to each output capsule, and then sends messages to the output capsules in proportion. Thus, for all input capsules the total amount of messages sent from an input capsule are the same.

In reversed DR-AGG, each output capsule is used as query vector to assign a proportion weight to each input capsule and then receives messages from the input capsules in proportion. Thus, for all output capsules the total amount of message received by an output capsule is same.

The major difference between DR-AGG and self-attention (Lin et al., 2017; Yang et al., 2016) is that the query vector of self-attention is task dependent trainable parameters learned during the training phase, while the query vector of DR-AGG is each input or output capsule which is instance dependent and dynamically updated.

Dataset	Type	Train Size	Dev. Size	Test size	Classes	Averaged Length	Vocabulary Size
Yelp 2013	Document	62522	7773	8671	5	189	29.3k
Yelp 2014	Document	183019	22745	25399	5	197	49.6k
IMDB	Document	67426	8381	9112	10	395	61.1k
SST-1	Sentence	8544	1101	2201	5	18	16.3k
SST-2	Sentence	6920	872	1821	2	19	14.8k

Table 1: Statistics of the five datasets used in this paper

Additionally, the self-attention aggregation collects information in a bottom-up way, without considering the state of the final encoding. It is hard to avoid the problems of information redundancy and information loss. While in the standard DR-AGG, each word can iteratively decide *what* and *how much* information is to be sent to the final encoding.

4 Hierarchical Dynamic Routing for Long Text

The dynamic routing mechanism can aggregate the text sequence with any length, therefore it is able to handle long texts directly, such as the whole paragraphs or documents.

To further enhance the efficiency and scalability of information aggregation, we adopt a hierarchical dynamic routing mechanism to handle the long text. The hierarchical routing strategy can exploit more parallelization and speed up training and inference process. A similar strategy is also used in (Yang et al., 2016).

Concretely, we split a document into sentences, and apply the proposed dynamic routing mechanism on word and sentence levels separately. We first encode each sentence into a fixed-length vector, then convert the sentence encodings into document encoding.

5 Experiment

We test the empirical performance of our proposed model on 5 benchmark datasets for document and sentence level classification and compare our proposed model to other competitor models.

5.1 Datasets

To evaluate the effectiveness of our proposed aggregation method, we have conducted experiments on 5 datasets, the statistics of experimented datasets are shown in Table 1. As shown in the table, Yelp-2013, Yelp-2014, and IMDB are document level datasets, while SST-1 and SST-2 are sentence level datasets. Note that we use the same document level datasets provided in (Tang et al., 2015).

Yelp reviews Yelp-2013 and Yelp-2014 are reviews from Yelp, each example consists of several review sentences and a rating score range from 1 to 5 (higher is better).

IMDB is a movie review dataset extracted from IMDB website. It is a multi-sentence dataset that for each example there are several review sentences. A rating score range from 1 to 10 is also associated with each example.

SST-1 Stanford Sentiment Treebank is a movie review dataset which has been parsed and further splited to train/dev/test set (Socher et al., 2013). For each example in the dataset, there exists only one sentence and a label associated with it. And the labels can be one of {negative, somewhat negative, neutral, somewhat positive, positive}.

SST-2 This dataset is a binary-class version of SST-1, with neutral reviews removed and the remaining reviews categorized to either negative or positive.

	Yelp-2013	Yelp-2014	IMDB	SST-1	SST-2
Embedding size	300	300	300	300	300
LSTM hidden unit	200	200	200	200	200
Capsule dimension	200	200	200	200	200
Capsule number	5	5	5	5	5

Batch size low bound	32	32	32	16	16
Dropout rate	0.2	0.2	0.2	0.2	0.5

Table 2: Detailed hyper-parameter settings

5.2 Training

Given a training set $\{x^{(i)}, t^{(i)}\}_{i=1}^{N}$, where $x^{(i)}$ is an example of the training set and $t^{(i)}$ is the corresponding label, the goal is to minimize the cross-entropy loss $\mathcal{J}(\theta)$:

$$\mathcal{J}(\theta) = -\frac{1}{N}\sum_{i} \log p(t^{(i)}|x^{(i)};\theta) + \lambda||\theta||_2^2, \tag{19}$$

where θ represents all of the parameters.

The Adam optimizer is applied to update the parameters (Kingma and Ba, 2014). Table 2 displays the detailed hyper-parameter settings. To prevent overfitting, the L2 regularization term is introduced to our loss function. We also adopt early stop strategy, The training process will be stopped after seven epochs of no improvement on development set is observed.To further avoid overfitting, dropout is applied before the biLSTM encoder and hidden layer of classifier **MLP**.

The mini-batch size is set to 32 for document level dataset, 64 for sentence level dataset, examples are sampled from a sliding bucket to speed up the training process. Data is sorted by the length of sentence, and we first sample a window on the sorted data, we call the window "sliding bucket" and then sample a batch of examples from the sliding bucket, we double the window size after an epoch of no improvement on development set, through such a strategy, we are able to considerably speed up training while retaining randomness. Also, batch size is halved after an epoch of no improvement on development set until it reaches the low bound batch size. We also utilize a data preparation queue to parallelize data preparation and training.

Word embedding is initialized from pre-trained Glove (Pennington et al., 2014). We randomly initialize word vectors for words that doesn't appear in Glove. Network weights are initialized with Xavier Normalization (Glorot and Bengio, 2010). A more detailed hyper-parameter setting can be referred to hyper-parameter Table 2. And hyper-parameters are determined using grid search strategy.

5.3 Experimental Results

We evaluate several aggregation methods on five text classification datasets, in which Yelp-2013, Yelp-2014 and IMDB are document-level datasets, and SST-1 and SST-2 are sentence-level datasets. Since max pooling, average pooling and self-attention are most related to our proposed DR-AGG, we mainly compare DR-AGG to these three methods.

Table 3 gives the results for different methods, the last two rows are our model (standard DR-AGG and reversed DR-AGG), the table shows that our proposed dynamic routing performed the best on all datasets. In document-level text classification, specifically Yelp 2013 Yelp 2014 and IMDB, DR-AGG outperforms previous models best results by 2.5%, 3.0% and 1.6% respectively. In sentence-level text

	Yelp-2013	Yelp-2014	IMDB	SST-1	SST-2
RNTN+Recurrent (Socher et al., 2013)	57.4	58.2	40.0	-	-
CNN-non-static (Kim, 2014)	-	-	-	48.0	87.2
Paragraph-Vec (Le and Mikolov, 2014)	-	-	-	48.7	**87.8**
MT-LSTM (F2S) (Liu et al., 2015)	-	-	-	49.1	87.2

Reverse DR-AGG	61.6	62.5	44.5	49.3	87.2

Table 3: Experimental result comparison on five datasets. For the document-level datasets, hierarchical aggregation is used for both self-attention and DR-AGGs.

(1) so relentlessly wholesome it made me want to swipe something .
(2) so relentlessly wholesome it made me want to swipe something .
(3) so relentlessly wholesome it made me want to swipe something .

Table 4: A visualization to show the perspective of a sentence from 3 different upper level capsule. A deeper color indicates more information of the associated word is routed to the corresponding capsule.

classification, such as SST-1 SST-2, our model also achieves better results. Compared to max pooling, average pooling and self-attention, which are closely related to our model, DR-AGGs significantly improves the performance. For example the standard DR-AGG outperforms the max pooling approach by 1%, 1.8%, 4%,2.5% and 0.4% on Yelp 2013,Yelp 2014, IMDB, SST-1 and SST-2. It empirically shows that our proposed dynamic routing policy is the most effective method on aggregating information.

It is worth to note the reversed DR-AGG is inferior to the standard DR-AGG by a small margin, although it has also achieved better results than the other aggregation methods and SOTA approaches. As discussion before, the reversed DR-AGG have much resemblance with the attention using output capsule as query vector. Not all of the input capsules would be selected by the reversed DR-AGG, while in the standard DR-AGG, the information of all the input capsules need be sent to the output capsules.

Effects of Iterative Routing We also study how the iteration number affect the performance of aggregation on the SST-2 dataset. Figure 2 shows the comparison of 1 - 5 iterations in the standard DR-AGG. The capsule number is set to 1, 2, 3 and 4 for each comparison respectively. We found that the performances on several different capsule number setting reach the best when iteration is set to 3. The results indicate the dynamic routing is contributing to improve the performance.

Visualization Additionally, we visualize how much information each input capsule sends to the output capsules. As shown in Table 4, the visualization experiment was conducted with the setting on three output capsules. The i-th column represents the i-th input capsule, while the j-th row is the j-th output capsule. The color density of each word denotes the proportion c_{ij} in equation 15. A deeper color indicates more information of the concerned word is routed to the output capsule.

Intuitively, the different part of the sentence is routed to three different capsules. In another word, each capsule has a different perspective or focus of the sequence. Therefore, DR-AGG can avoid the problem of information redundancy and information missing.

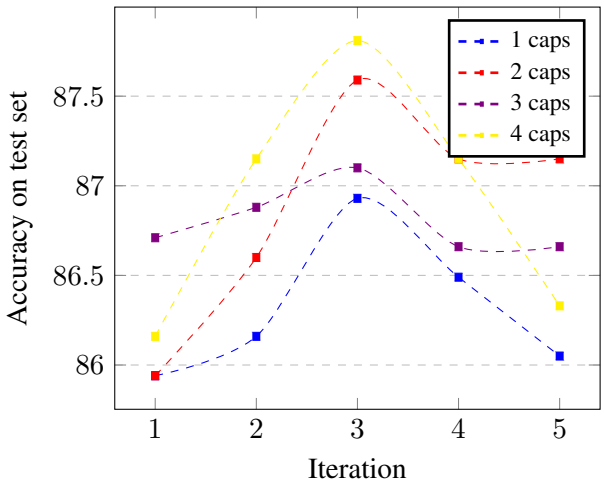

Figure 2: Relationship between test accuracy and routing iteration, where the vertical axis denotes test accuracy and the horizontal axis denotes routing iteration. When the iteration is set to 3 performance peaks on several different capsule number setting

6 Related Work

Currently, much attention has been paid to how developing a sophisticated encoding models to capture the long and short term dependency information in a sequence. Specific to text classification task, most of the models cannot deal with the texts of several sentences (paragraphs, documents), such as MV-RNN (Socher et al., 2012), RNTN (Socher et al., 2013), CNN (Kim, 2014), AdaSent (Zhao et al., 2015), and so on. The simple neural bag-of-words model can deal with long texts, but it loses the word order information. PV (Le and Mikolov, 2014) works in an unsupervised way, and the learned vector cannot be fine-tuned on the specific task. There are also many works (Liu et al., 2015; Xu et al., 2016; Cheng et al., 2016) to improve LSTM's ability to carrying information for a long distance.

A line of orthogonal researches (Lin et al., 2017; Yang et al., 2016; Shen et al., 2018a; Shen et al., 2018b) is to introduce attention mechanism (Vaswani et al., 2017) to weighted average the outputs of CNN/RNN layer. The attention mechanism can effectively reduce the burden of CNN/RNN. The CNN/RNN encoding layer is only expected to extract local context information for each word, while the global semantics of text sequence can be aggregated from the local encoding vectors.

The attention based aggregation collects information in a bottom-up way, without considering the state of the final encoding. It is hard to avoid the problems of information redundancy or information lost. An improved idea is to use multi-hop attention, like memory network (Sukhbaatar et al., 2015; Kumar et al., 2015), to iterative aggregate information. This idea is equivalent to our proposed reversed dynamic routing mechanism.

Different from the attention based aggregation methods, aggregation via dynamic routing is iteratively deciding that *what* and *how much* information need be transfer to the final encoding of each word.

7 Conclusion

In this paper, we focus on how to obtain a fixed-size encoding of text sequence by aggregating the encodings of each word. Although we use LSTM hidden states as word encoding in this paper, the other word encodings, such as convolved n-gram, could be alternatively used. We introduced a fixed-size encoding of text sequence with dynamic routing mechanism. Experimental results of five text classification tasks show that the model outperforms other encoding models by a significant margin.

In the future, we would like to investigate more sophisticated routing policy for better encoding the text sequence. Besides, dynamic routing should also be useful to improve the encoder in the sequence-to-sequence tasks (Sutskever et al., 2014).

Abstract

Semantic role labeling (SRL) is to recognize the predicate-argument structure of a sentence, including subtasks of predicate disambiguation and argument labeling. Previous studies usually formulate the entire SRL problem into two or more subtasks. For the first time, this paper introduces an end-to-end neural model which unifiedly tackles the predicate disambiguation and the argument labeling in one shot. Using a biaffine scorer, our model directly predicts all semantic role labels for all given word pairs in the sentence without relying on any syntactic parse information. Specifically, we augment the BiLSTM encoder with a non-linear transformation to further distinguish the predicate and the argument in a given sentence, and model the semantic role labeling process as a word pair classification task by employing the biaffine attentional mechanism. Though the proposed model is syntax-agnostic with local decoder, it outperforms the state-of-the-art syntax-aware SRL systems on the CoNLL-2008, 2009 benchmarks for both English and Chinese. To our best knowledge, we report the first syntax-agnostic SRL model that surpasses all known syntax-aware models.

1 Introduction

Semantic role labeling (SRL) is a shallow semantic parsing, which is dedicated to identifying the semantic arguments of a predicate and labeling them with their semantic roles. SRL is considered as one of the core tasks in the natural language processing (NLP), which has been successfully applied to various downstream tasks, such as information extraction (Bastianelli et al., 2013), question answering (Shen and Lapata, 2007; Berant et al., 2013), machine translation (Xiong et al., 2012; Shi et al., 2016).

Typically, SRL task can be put into two categories: constituent-based (i.e., phrase or span) SRL and dependency-based SRL. This paper will focus on the latter one popularized by CoNLL-2008 and 2009 shared tasks (Surdeanu et al., 2008; Hajič et al., 2009). Most conventional SRL systems relied on sophisticated handcraft features or some declarative constraints (Pradhan et al., 2005; Zhao et al., 2009a), which suffers from poor efficiency and generalization ability. A recently tendency for SRL is adopting neural networks methods attributed to their significant success in a wide range of applications (Bai and Zhao, 2018; Zhang and Zhao, 2018). However, most of those works still heavily resort to syntactic features. Since the syntactic parsing task is equally hard as SRL and comes with its own errors, it is better to get rid of such prerequisite as in other NLP tasks. Accordingly, Marcheggiani et al. (2017) presented a neural model putting syntax aside for dependency-based SRL and obtain favorable results, which overturns the inherent belief that syntax is indispensable in SRL task (Punyakanok et al., 2008).

Besides, SRL task is generally formulated as multi-step classification subtasks in pipeline systems, consisting of predicate identification, predicate disambiguation, argument identification and argument classification. Most previous SRL approaches adopt a pipeline framework to handle these subtasks one

after another. Until recently, some works (Zhou and Xu, 2015; He et al., 2017) introduce end-to-end models for span-based SRL, which motivates us to explore integrative model for dependency SRL.

In this work, we propose a syntactic-agnostic end-to-end system, dealing with predicate disambiguation and argument labeling in one model, unlike previous systems that treat the predicate disambiguation as a subtask and handle it separately. In detail, our model contains (1) a deep BiLSTM encoder, which is able to distinguish the predicates and arguments by mapping them into two different vector spaces, and (2) a biaffine attentional (Dozat and Manning, 2017) scorer, which unifiedly predicts the semantic role for argument and the sense for predicate.

We experimentally show that though our biaffine attentional model remains simple and does not rely on any syntactic feature, it achieves the best result on the benchmark for both Chinese and English even compared to syntax-aware systems. In summary, our major contributions are shown as follows:

- We propose an accurate syntax-agnostic model for neural SRL, which outperforms the best reported syntax-aware model, breaking the long-held belief that syntax is a prerequisite for SRL.
- Our model gives state-of-the-art results on the CoNLL-2008, CoNLL-2009 English and Chinese benchmarks, scoring 85.0% F_1, 89.6% F_1 and 84.4% F_1, respectively.
- Our work is the first attempt to apply end-to-end model for dependency-based SRL, which tackles the predicate disambiguation and the argument labeling subtasks in one shot.

2 Semantic Structure Decomposition

SRL includes two subtasks: predicate identification/disambiguation and argument identification/labeling. Since the CoNLL-2009 dataset provides the gold predicates, most previous neural SRL systems use a default model to perform predicate disambiguation and focus on argument identification/labeling. Despite nearly all SRL work adopted the pipeline model with two or more components, Zhao and Kit (2008) and Zhao et al. (2013) presented an end-to-end solution for the entire SRL task with a word pair classifier. Following the same formulization, we propose the first neural SRL system that uniformly handles the tasks of predicate disambiguation and argument identification/labeling.

In semantic dependency parsing, we can always identify two types of words, semantic head (predicate) and semantic dependent (argument). To build the needed predicate-argument structure, the model only needs to predict the role of any word pair from the given sentence. For the purpose, an additional role label *None* and virtual root node $<VR>$ are introduced. The *None* label indicates that there is no semantic role relationship inside the word pair. We insert a virtual root $<VR>$ in the head of the sentence, and set it as the semantic head of all the predicates. By introducing the *None* label and the $<VR>$ node, we construct a semantic tree rooted at the $<VR>$ node with several virtual arcs labeled with *None*. Thus, the predicate disambiguation and argument identification/labeling tasks can be naturally regarded as the labeling process over all the word pairs. Figure 1 shows an example of the semantic graph augmented with a virtual root and virtual arc, and Table 1 lists all the corresponding word pair examples, in which two types of word pairs are included, $<VR>$ followed by predicate candidates[1] and a known predicate collocated with every words in the sentence as argument candidates. Note that since the nominal predicate sometimes takes itself as its argument, the predicate itself is also included in the argument candidate list.

3 Model

Our model contains two main components: (1) a deep BiLSTM encoder that takes each word embedding $\boldsymbol{e}$ of the given sentence as input and generates dense vectors for both words in the to-be-classified word pair respectively, (2) a biaffine attentional scorer which takes the hidden vectors for the given word pair as input and predict a label score vector. Figure 2 provides an overview of our model.

[1]Note that there is a key difference between CoNLL 2008 and 2009 shared task for English, the latter has specified the predicate in the data so that here we have only one sample for $<VR>$-predicate pair to make predicate disambiguation. For the former, predicate candidates should be every words in the given sentence. More details are seen in Section 4.4.

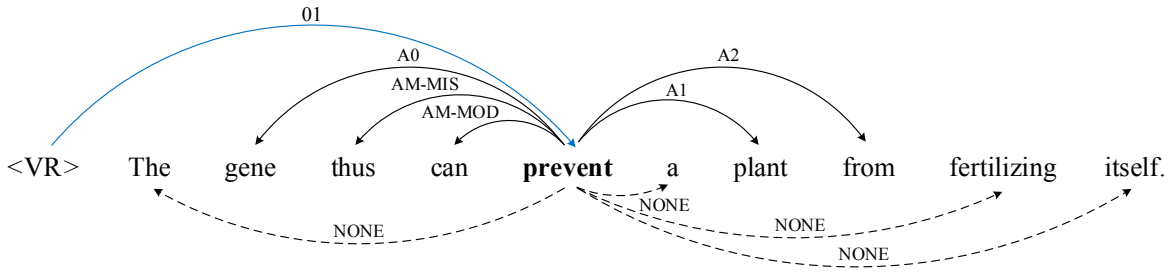

Figure 1: The dependency graph with a virtual node <VR> and virtual arcs with *None* label.

Head	dependent (word pair)	Label	Head	dependent (word pair)	Label

...	...	...	...	...	...
prevent	itself	None	fertilizing	itself	A1

Table 1: Word pairs for semantic role label classification.

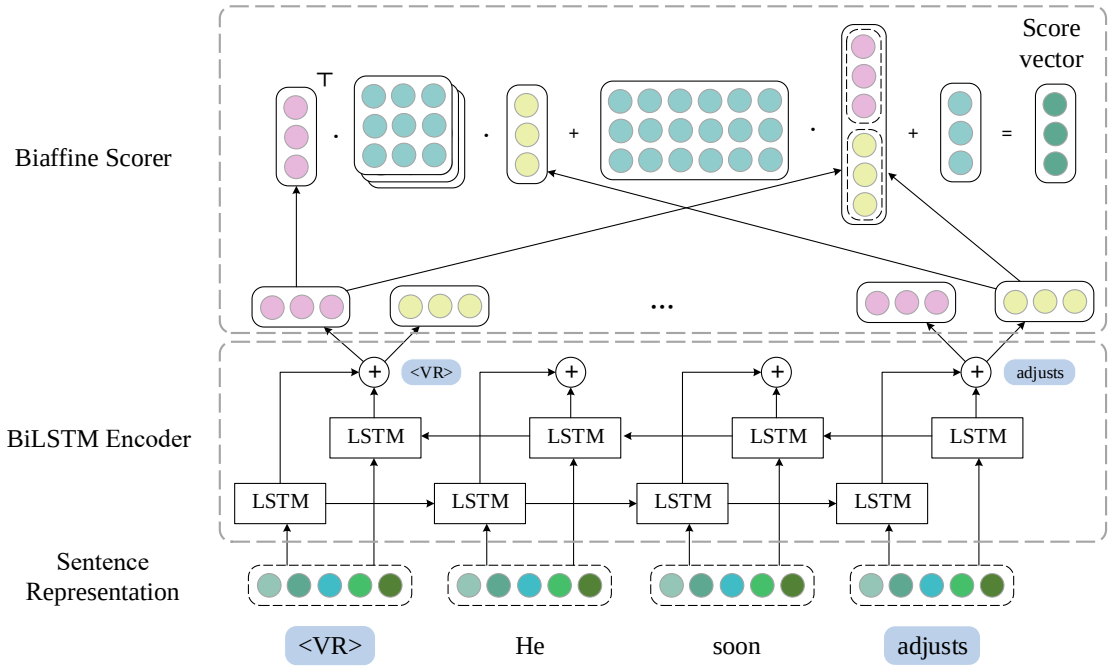

Figure 2: An overview of our model.

3.1 Bidirectional LSTM Encoder

Word Representation The word representation of our model is the concatenation of several vectors: a randomly initialized word embedding $\boldsymbol{e}^{(r)}$, a pre-trained word embedding $\boldsymbol{e}^{(p)}$, a randomly initialized part-of-speech (POS) tag embedding $\boldsymbol{e}^{(pos)}$, a randomly initialized lemma embedding $\boldsymbol{e}^{(l)}$. Besides, since previous work (He et al., 2018) demonstrated that the predicate-specific feature is helpful in promoting the role labeling process, we employ an indicator embedding $\boldsymbol{e}^{(i)}$ to indicate whether a word is a predicate when predicting and labeling the arguments for each given predicate. The final word representation is given by $\boldsymbol{e} = \boldsymbol{e}^{(r)} \oplus \boldsymbol{e}^{(p)} \oplus \boldsymbol{e}^{(l)} \oplus \boldsymbol{e}^{(pos)} \oplus \boldsymbol{e}^{(i)}$, where $\oplus$ is the concatenation operator.

Encoder As commonly used to model the sequential input in most NLP tasks (Wang et al., 2016; He et al., 2018), BiLSTM is adopted for our sentence encoder. By incorporating a stack of two distinct LSTMs, BiLSTM processes an input sequence in both forward and backward directions. In this way, the BiLSTM encoder provides the ability to incorporate the contextual information for each word.

Given a sequence of word representation $S = \{\boldsymbol{e}_1, \boldsymbol{e}_2, \cdots, \boldsymbol{e}_N\}$ as input, the i-th hidden state $\boldsymbol{g}_i$ is encoded as follows:

$$\boldsymbol{g}_i^f = LSTM^{\mathcal{F}}\left(\boldsymbol{e}_i, \boldsymbol{g}_{i-1}^f\right), \quad \boldsymbol{g}_i^b = LSTM^{\mathcal{B}}\left(\boldsymbol{e}_i, \boldsymbol{g}_{i+1}^b\right), \quad \boldsymbol{g}_i = \boldsymbol{g}_i^f \oplus \boldsymbol{g}_i^b,$$

where $LSTM^{\mathcal{F}}$ denotes the forward LSTM transformation and $LSTM^{\mathcal{B}}$ denotes the backward LSTM transformation. $\boldsymbol{g}_i^f$ and $\boldsymbol{g}_i^b$ are the hidden state vectors of the forward LSTM and backward LSTM respectively.

3.2 Biaffine Attentional Role Scorer

Typically, to predict and label arguments for a given predicate, a role classifier is employed on top of the BiLSTM encoder. Some work like (Marcheggiani et al., 2017) shows that incorporating the predicate's hidden state in their role classifier enhances the model performance, while we argue that a more natural way to incorporate the syntactic information carried by the predicate is to employ the attentional mechanism. Our model adopts the recently introduced biaffine attention (Dozat and Manning, 2017) to enhance our role scorer. Biaffine attention is a natural extension of bilinear attention (Luong et al., 2015) which is widely used in neural machine translation (NMT).

Nonlinear Affine Transformation Usually, a BiLSTM decoder takes the concatenation $\boldsymbol{g}_i$ of the hidden state vectors as output for each hidden state. However, in the SRL context, the encoder is supposed to distinguish the currently considered predicate from its candidate arguments. To this end, we perform two distinct affine transformations with a nonlinear activation on the hidden state $\boldsymbol{g}_i$, mapping it to vectors with smaller dimensionality:

$$\boldsymbol{h}_i^{(pred)} = ReLU\left(\boldsymbol{W}^{(pred)}\boldsymbol{g}_i + \boldsymbol{b}^{(pred)}\right), \quad \boldsymbol{h}_i^{(arg)} = ReLU\left(\boldsymbol{W}^{(arg)}\boldsymbol{g}_i + \boldsymbol{b}^{(arg)}\right),$$

where $ReLU$ is the rectilinear activation function, $\boldsymbol{h}_i^{(pred)}$ is the hidden representation for the predicate and $\boldsymbol{h}_i^{(arg)}$ is the hidden representation for the candidate arguments.

By performing such transformations over the encoder output to feed the scorer, the latter may benefit from deeper feature extraction. First, ideally, instead of keeping both features learned by the two distinct LSTMs, the scorer is now enabled to learn features composed from both recurrent states together with reduced dimensionality. Second, it provides the ability to map the predicates and the arguments into two distinct vector spaces, which is essential for our tasks since some words can be labeled as predicate and argument simultaneously. Mapping a word into two different vectors can help the model disambiguate the role that it plays in different context.

Biaffine Scoring In the standard NMT context, given a target recurrent output vector $h_i^{(t)}$ and a source recurrent output vector $h_j^{(s)}$, a bilinear transformation calculates a score s_{ij} for the alignment:

$$s_{ij} = \boldsymbol{h}_i^{\top(t)}\boldsymbol{W}\boldsymbol{h}_j^{(s)},$$

However, considering that in a traditional classification task, the distribution of classes is often uneven, and that the output layer of the model normally includes a bias term designed to capture the prior probability $P(y_i = c)$ of each class, with the rest of the model focusing on learning the likelihood of each class given the data $P(y_i = c|x_i)$, (Dozat and Manning, 2017) introduced the bias terms into the bilinear attention to address such uneven problem, resulting in a biaffine transformation. The biaffine transformation is a natural extension of the bilinear transformation and the affine transformation. In SRL task, the distribution of the role labels is similarly uneven and the problem comes worse after we introduce the additional <*VR*> node and *None* label, directly applying the primitive form of bilinear attention would fail to capture the prior probability $P(y_i = c_k)$ for each class. Thus, the biaffine attention introduced in our model would be extremely helpful for semantic role prediction.

It is worth noting that in our model, the scorer aims to assign a score for each specific semantic role. Besides learning the prior distribution for each label, we wish to further capture the preferences for the label that a specific predicate-argument pair can take. Thus, our biaffine attention contains two distinguish bias terms:

$$\boldsymbol{s}_{ij} = \boldsymbol{h}_i^{\top(arg)} \boldsymbol{W}^{(role)} \boldsymbol{h}_j^{(pred)} \tag{1}$$

$$+ \boldsymbol{U}^{(role)} \left(\boldsymbol{h}_i^{(arg)} \oplus \boldsymbol{h}_j^{(pred)} \right) \tag{2}$$

$$+ \boldsymbol{b}^{(role)}, \tag{3}$$

where $\boldsymbol{W}^{(role)}$, $\boldsymbol{U}^{(role)}$ and $\boldsymbol{b}^{(role)}$ are parameters that will be updated by some gradient descent methods in the learning process. There are several points that should be paid attention to in the above biaffine transformation. First, since our goal is to predict the label for each pair of $\boldsymbol{h}_i^{(arg)}$, $\boldsymbol{h}_j^{(pred)}$, the output of our biaffine transformation should be a vector of dimensionality N_r instead of a real value, where N_r is the number of all the candidate semantic labels. Thus, the bilinear transformation in Eq. (1) maps two input vectors into another vector. This can be accomplished by setting $\boldsymbol{W}^{(role)}$ as a $(d_h \times N_r \times d_h)$ matrix, where d_h is the dimensionality of the hidden state vector. Similarly, the output of the linear transformation in Eq. (2) is also a vector by setting $\boldsymbol{U}^{(role)}$ as a $(N_r \times 2d_h)$ matrix. Second, Eq. (2) captures the preference of each role (or sense) label condition on taking the j-th word as predicate and the i-th word as argument. Third, the last term $\boldsymbol{b}^{(role)}$ captures the prior probability of each class $P(y_i = c_k)$. Notice that Eq. (2) and (3) capture different kinds of bias for the latent distribution of the label set.

Given a sentence of length L (including the <*VR*> node), for one of its predicates w_j, the scorer outputs a score vector $\{\boldsymbol{s}_{1j}, \boldsymbol{s}_{2j}, \cdots, \boldsymbol{s}_{Lj}\}$. Then our model picks as its output the label with the highest score from each score vector: $y_{ij} = \arg\max_{1 \le k \le N_r} (\boldsymbol{s}_{ij}[k])$, where $\boldsymbol{s}_{ij}[k]$ denotes the score of the k-th candidate semantic label.

4 Experiments

4.1 Dataset and Training Detail

We evaluate our model[2] on English and Chinese CoNLL-2009 datasets with the standard split into training, test and development sets. The pre-trained embedding for English is trained on Wikipedia and Gigaword using the GloVe (Pennington et al., 2014), while those for Chinese is trained on Wikipedia. Our implementation uses the DyNet[3] library for building the dynamic computation graph of the network.

When not otherwise specified, our model uses: 100-dimensional word, lemma, pre-trained and POS tag embeddings and 16-dimensional predicate-specific indicator embedding; and a 20% chance of dropping on the whole word representation; 3-layer BiLSTMs with 400-dimensional forward and backward LSTMs, using the form of recurrent dropout suggested by (Gal and Ghahramani, 2016) with an 80% keep probability between time-steps and layers; two 300-dimensional affine transformation with the ReLU non-linear activation on the output of BiLSTM, also with an 80% keep probability.

The parameters in our model are optimized with Adam (Kingma and Ba, 2015), which keeps a moving average of the L2 norm of the gradient for each parameter throughout training and divides the gradient for each parameter by this moving average, ensuring that the magnitude of the gradients will on average be close to one. For the parameters of optimizer, we follow the settings in (Dozat and Manning, 2017), with $\beta_1 = \beta_2 = 0.9$ and learning rate 0.002, annealed continuously at a rate of 0.75 every $5,000$ iterations, with batches of approximately $5,000$ tokens. The maximum number of epochs of training is set to 50.

4.2 Results

Tables 2 and 3 report the comparison of performance between our model and previous dependency-based SRL model on both English and Chinese. Note that the predicate disambiguation subtask is unifiedly tackled with arguments labeling in our model with precisions of 95.0% and 95.6% respectively on English and Chinese test sets in our experiments[4]. The proposed model accordingly outperforms all the SRL systems so far on both languages, even including those syntax-aware and ensemble ones. The improvement grows even larger when comparing only with the single syntax-agnostic models.

For English, our syntax-agnostic model even slightly outperforms the best reported syntax-aware model (He et al., 2018) with a margin of 0.1% F_1. Compared to syntax-agnostic models, our model overwhelmingly outperforms (with an improvement of 0.9% F_1) the previous work (He et al., 2018).

Although we used the same parameters as for English, our model substantially outperforms the state-of-art models on Chinese, demonstrating that our model is robust and less sensitive to the parameter selection. For Chinese, the proposed model outperforms the best previous model (He et al., 2018) with a considerable improvement of 1.5% F_1, and surpasses the best single syntax-agnostic model (He et al., 2018) with a margin of 2.5% F_1.

Table 4 compares the results on English out-of-the-domain (Brown) test set, from which our model still remains strong. The proposed model gives a comparable result with the highest score from syntax-aware model of (He et al., 2018), which affirms that our model does well learn and generalize the latent semantic preference of the data.

Results on both in-domain and out-of-the-domain test sets demonstrate the effectiveness and the robustness of the proposed model structure—the non-linear transformation after the BiLSTM serves to distinguish the predicate from argument while the biaffine attention tells what to attend for each candidate argument. In Section 4.3.2, we will get an insight into our model and explore how each individual

[4]Note that we give comparable predicate disambiguation results with He et al. (2018), with 95.01% and 95.58% F_1 on development and test sets, respectively.

component impacts the model performance.

4.3 Ablation Analysis

4.3.1 Word Representation

To learn how the input word representation choice impacts our model performance, we conduct an ablation study on the English test set whose results are shown in Table 5. Since we deal with the two subtasks in a single model, the choice of word representation will simultaneously influence the results of both of them. Besides the results of argument labeling, we also report the precision of predicate disambiguation.

The results demonstrate that the multiple dimensional indicator embedding proposed by (He et al., 2018) contributes the most to the final performance of our model. It is consistent with the conclusion in (Marcheggiani et al., 2017) which argue that encoding predicate information promotes the SRL model. It is interesting that the impact of POS tag embedding (about 0.3% F_1) is less compared to the previous works, which possibly allows us to build an accuracy model even when the POS tag label is unavailable.

4.3.2 Into the Model

In this section, we get insight into the proposed model, exploring how the deep BiLSTM encoder and the biaffine attention affect the labeling results respectively. Specifically, we present two groups of results on the CoNLL-2009 English test set. 1) Shallow biaffine attentive (SBA) labeler. Instead of mapping the output of the BiLSTM into two distinct vector spaces, we apply a single non-linear affine transformation on the output. The single transformation just serves to reduce the dimensionality and does not differ the predicates from the arguments. 2) Deep bilinear attentive (DBA) labeler. We apply the primitive form of bilinear attention in the scorer by removing the two bias terms of the biaffine transformation. By this means, we learn to what extent can the bias terms fit the prior distribution of the data. Results of the two experiments are shown in Table 6.

The results show that the bias terms in biaffine attention play an important role in promoting the model performance. Removal of the bias terms dramatically declines the performance by 1.7% F_1. Thus we can draw a conclusion that the bias term does well in fitting the prior distribution and global preference

System	AL			PD

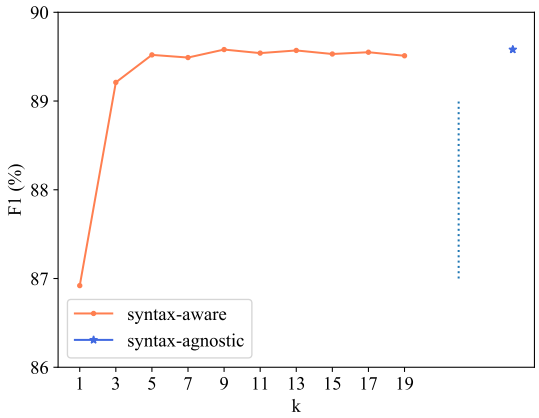

Figure 4: F1 scores against the pruning order k on English test set.

of the data. The bilinear attentional model behaves more poorly since it struggles to learn the likelihood of each class on an uneven data set without knowledge about the prior distribution. Though the deep encoder contributes less to the performance, it also brings an improvement of 0.5% F_1. Note that the only difference of SBA-labeler of our standard model is whether the hidden representations of the arguments and the predicates lay in different vector spaces. Such a result confirms that distinguishing the predicates from the arguments in encoding process indeed enhances the model to some extent.

4.3.3 Syntax-aware and Syntax-agnostic

Noting that the work (Zhao and Kit, 2008) and (Zhao et al., 2013) are similar to ours in modeling the dependency-based SRL tasks as word pair classification, and that they successfully incorporate the syntactic information by applying argument candidate pruning, we further perform empirical study to explore whether employing such pruning method enhance or hinder our model. Specifically, we use the automatically predicted parse with moderate performance provided by CoNLL-2009 shared task, with the LAS score about 86%.

The pruning method is supposed to work since it can alleviate the imbalanced label distribution caused by introducing the *None* label. However, as shown in Table 7, the result is far from satisfying. The main reason might be the pruning algorithm is so strict that too many true arguments are falsely pruned. To address this problem, He et al. (2018) introduced an extended k-order argument pruning algorithm. Figure 3 shows the curves of coverage and reduction rate against the pruning order k on the English training set following (He et al., 2018). Following this work, we further perform different orders of pruning and obtain the F_1 scores curve shown in Figure 4. However, the k-order pruning does not boost the performance of our model. Table 8 presents the performance gap between syntax-agnostic and syntax-aware settings of the same models. Unlike the other two works, the introduction of syntax information fails to bring about bonus for our model. Nevertheless, it is worth noting that even when running without the syntax information, our mode still show a promising result compared to the other syntax-aware models.

System	syntax-agnostic	syntax-aware	Δ F_1
Marcheggiani and Titov (2017)	87.7	88.0	0.3

This work (CoNLL-2009 predicted)	89.6	89.6	$\approx$0

Table 8: The absolute performance gaps between syntax-agnostic and syntax-aware settings. Both (He et al., 2018) and our models use 10-order pruning according to syntactic parse tree.

4.4 CoNLL 2008: Augment the Model with Predicate Identification

Though CoNLL-2009 provided the gold predicate beforehand, the predicate identification subtask is still indispensable for a real world SRL task. Thus, we further augment our model with the predicate identification ability.

Specifically, we first attach all the words in the sentence to the virtual root $<VR>$ and label the word which is not a predicate with the *None* role label. It should be noting that, in CoNLL-2009 settings, we just attach the predicates to the virtual root, since we do not need to distinguish the predicate from other word. The training scheme still keeps the same as that in CoNLL-2009 settings, while in testing phase, an additional procedure is performed to find out all the predicates of a given sentence.

First, our model is fed the representations of the virtual root and each word of the input sentence, identifying and disambiguating all the predicates of the sentence. Second, it picks each predicate predicted by the model with each word of the sentence to identify and label the semantic role in between, which remains the same as the model does on CoNLL-2009. The second phase is repeated until all the predicates have got its arguments being identified and labeled. We evaluate our model on CoNLL-2008 benchmark using the same hyperparameters settings mentioned in Section 4.1 except that we remove the predicate-specific indicator feature.

The F_1 scores on predicates identification and labeling of our model is 89.43%, which remain comparable with the most recent work (He et al., 2018) (90.53% F_1). As shown in Table 9, though tackling all the subtasks of CoNLL-2008 SRL unifiedly in a full end-to-end manner, our model outperforms the best reported results with a large margin of about 1.7% semantic F_1.

5 Related Work

Semantic role labeling was pioneered by Gildea and Jurafsky (2002). Most traditional SRL models heavily rely on complex feature engineering (Pradhan et al., 2005; Zhao et al., 2009a; Björkelund et al., 2009). Among those early works, Pradhan et al. (2005) combined features derived from different syntactic parses based on SVM classifier, while Zhao et al. (2009a) exploited the abundant set of language-specific features that were carefully designed for SRL task.

In recent years, applying neural networks in SRL task has gained a lot of attention due to the impressive success of deep neural networks in various NLP tasks (Zhang et al., 2016; Cai et al., 2017; Qin et al., 2017; Cai and Zhao, 2017). Collobert et al. (2011) initially introduced neural networks into the SRL task. They developed a feed-forward network that employed a convolutional network as sentence encoder and a conditional random field as a role classifier. Foland and Martin (2015) extended their model to further use syntactic information by including binary indicator features. FitzGerald et al. (2015) exploited a neural network to unifiedly embed arguments and semantic roles, similar to the work (Lei et al., 2015) which induced a compact feature representation applying tensor-based approach. Roth and Lapata (2016) introduced the dependency path embedding to incorporate syntax and exhibited a notable success, while Marcheggiani and Titov (2017) employed the graph convolutional network to integrate syntactic information into their neural model.

Besides the above-mentioned works who relied on syntactic information, several works attempted to build SRL systems without or with little syntactic information. Zhou and Xu (2015) came up with an end-to-end model for span-based SRL and obtained surprising performance putting syntax aside. He et al. (2017) further extended their work with the highway network. Simultaneously, Marcheggiani et al. (2017) proposed a syntax-agnostic model with effective word representation for dependency-based SRL.

However, almost all of previous works treated the predicate disambiguation as individual subtasks, apart from (Zhao and Kit, 2008; Zhao et al., 2009a; Zhao et al., 2009c; Zhao et al., 2013), who presented the first end-to-end system for dependency SRL. For the neural models of dependency SRL, we have presented the first end-to-end solution that handles both semantic labeling subtasks in one single model. At the same time, our model enjoys the advantage that does not rely any syntactic information.

This work is also closely related to the attentional mechanism. The traditional attention mechanism was proposed by Bahdanau et al. (2015) in the NMT literature. Following the work (Luong et al., 2015) that encouraged substituting the MLP in the attentional mechanism with a single bilinear transformation, Dozat and Manning (2017) introduced the bias terms into the primitive form of bilinear attention and applied it for dependency parsing. They demonstrate that the bias terms help their model to capture the uneven prior distribution of the data, which is again verified by our practice on SRL in this paper.

Different from the latest strong syntax-agnostic models in (Marcheggiani and Titov, 2017) and (He et al., 2018) which both adopted sequence labeling formulization for the SRL task, this work adopts word pair classification scheme implemented by LSTM encoder and biaffine scorer. Compared to the previous state-of-the-art syntax-agnostic model in (He et al., 2018) whose performance boosting (more than 1% absolute gain) is mostly due to introducing the enhanced representation, namely, the CNN-BiLSTM character embedding from (Peters et al., 2018), our performance promotion mainly roots from model architecture improvement, which results in quite different syntax-aware enhanced impacts. Using the same latest syntax-aware k-order pruning, the syntax-agnostic backbone in (He et al., 2018) may receive about 1% performance gain, while our model is furthermore enhanced little. This comparison also suggests the possibility that maybe our model can be further improved by incorporating with the same character embedding as (He et al., 2018) does[5].

6 Conclusion and Future Work

This paper presents a full end-to-end neural model for dependency-based SRL. It is the first time that a SRL model shows its ability to unifiedly handle the predicate disambiguation and the argument labeling subtasks. Our model is effective while remains simple. Experiments show that it achieves the best scores on CoNLL benchmark both for English and Chinese, outperforming the previous state-of-the-art models even with syntax-aware features. Our further investigation by incorporating the latest syntax-aware pruning algorithm shows that the proposed model is insensitive to the input syntactic information, demonstrating an interesting performance style for the SRL task. Of course, we cannot exclude the possibility that the proposed model can be furthermore improved by other syntactic information integration ways, which is left for the future work.

[5]Such an attempt may be hindered by too luxurious computational resource requirement, as there comes extremely high graphic memory prerequisite when integrating both biaffine scorer and the ELMo character embedding.

Abstract

Most existing research on authorship attribution uses various lexical, syntactic and semantic features. In this paper we demonstrate an effective template-based approach for combining various syntactic features of a document for authorship analysis. The parse-tree based features that we propose are independent of the topic of a document and reflect the innate writing styles of authors. We show that the use of templates including sub-trees of parse trees in conjunction with other syntactic features result in improved author attribution rates. Another contribution is the demonstration that Dempster's rule based combination of evidence from syntactic features performs better than other evidence-combination methods. We also demonstrate that our methodology works well for the case where actual author is not included in the candidate author set.

1 Introduction

In the past decade authorship analysis has become a significant need due to its various application areas such as identification of authors of anonymous posts in blogs (Koppel et al., 2011; Koppel and Yeron, 2014), of emails (Patchala et al., 2015), for copyright issues, plagiarism detection, and authentication of electronic documents (Abbasi and Chen, 2005; Chaski, 2005). Typically we encounter two types of author attribution problems. The first kind is the *closed author set problem* where the test-document is written by someone within the set of candidate authors being examined. The second kind is the *semi-closed authorship problem* where the test-document may or may not be written by someone in the set of candidate authors.

The main hypothesis underlying authorship attribution methods is that the grammatical style of an author remains the same across topics and is fairly unique to each author. This uniqueness of an author is easily identifiable when considering small sets of authors, and it expectedly dilutes as the author set becomes large. It is, therefore, desirable to discover from texts more such features that are unique to an author and help increase the discriminability of authors based on their writings. The focus of this paper is on identification and integration of features to enable improved authorship attribution.

We use template based classification and an evidence combination method for exploiting information embedded in different types of syntactic features of documents. We build templates using the frequencies of sub-trees of various heights derived from the parse trees of sentences in documents. Our intuitive basis for using these new features is that they capture the grammatical style very well. We consider the frequencies of sub-trees of heights two, three, and four, as

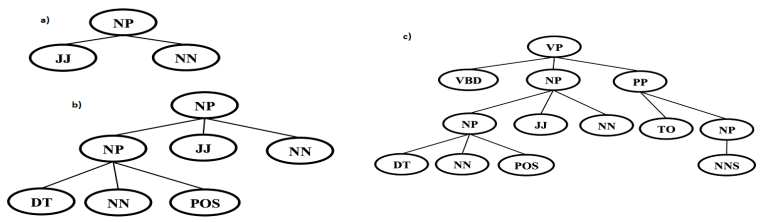

Figure 1: Height two, height three and height four sub-trees of a parse tree.

Proceedings of the 27th International Conference on Computational Linguistics, pages 2766–2777
Santa Fe, New Mexico, USA, August 20-26, 2018.

possible features to describe an author's writings. Examples of sub-trees of various heights derived from a syntactic parse tree are shown in Figure 1. In addition to these we also include three other feature types, namely, character n-grams, function words, and Part-of-Speech (POS) tags' n-grams.

We evaluate the effectiveness of each individual feature type for author attribution and then show that combining the evidence from multiple feature types enhances the performance. We show that the consensus formation approach of Dempster-Shafer (DS) framework (Dempster, 1967; Shafer, 1976) performs better than other evidence combination methods. We have used the consensus formation rule of the Dempster-Shafer theory because the six feature types that we use capture very similar and overlapping underlying information about the syntax of the text. Each feature type also has some unique insights that are not provided by the other features. We cannot combine the six features as independent pieces of evidence, and therefore seek only the consensus among individual inferences based on them. Such consensus among sources of evidence is highlighted by the Dempster's rule of combination.

Using the example in Figure 2, we illustrate the intuitive differences between the DS consensus approach, voting, and aggregation (combination) approaches. Figure 2 shows three features (columns) and three authors 'a', 'b', and 'c' (rows). Given a test document the $mass\ values$ assigned to the three authors by each feature type are shown in their respective columns.

	Height two sub-trees	Height three sub-trees	Height four sub-trees	
NULL	0	0	0	
Author 'a'	0.34	0.3	0.3	Dempster rule
Author 'b'	0.2	0.27	0.5	Combined
Author 'c'	0.36	0.33	0.1	Voting
'a', 'b', 'c'	0.1	0.1	0.1	

Figure 2: An example of Dempster's rule.

The fourth row, including all the authors, captures the uncertainty of the evidence source and this much mass is not assigned to any individual author. When an author is selected based on voting, author 'c' is elected because two out of three feature types declare author 'c' as the winner. When we use a combination approach ($0.2 + 0.27 + 0.5 = 0.97$), author 'b' is selected. When Dempster's rule is used, author 'a' is selected because the extent to which all the different features "agree" on an author is highest for author 'a'.

2 Related work

Any framework for authorship attribution has two main tasks: 1) Feature selection, and 2) A classification technique to do authorship attribution using the selected features.

2.1 Feature Selection

The crux of the authorship attribution problem is the selection of a set of features that remain stable across a large number of writings created by an author. A large variety of features built from lexical, syntactic, semantic, content, and structural properties of the texts have been used as style markers in the past (Juola, 2006; Stamatatos, 2009).

The work published in Kjell et al. (1994) is the first to use the character bigrams and trigrams for authorship analysis of $Federalist$ papers. Later, the work in (Keelj et al., 2003; Houvardas and Stamatatos, 2006; Stamatatos, 2007; Stamatatos, 2012) used character n-grams of different sizes and reported an accuracy of up to 72% with 50 authors.

Syntactic features explain the grammatical structure of sentences and are considered to be reliable style markers as they are not under the conscious control of the author (Bayyen et al., 1996). There are many studies (Argamon and Levitan, 2005; Garcia and Martin, 2007; Kestemont, 2014) that showed the effectiveness of function words as features in authorship attribution tasks. Using rewrite rules as features - Gamon (2004) reported an accuracy of 86% (author set size 3), and Patchala et al. (2015) reported 74% accuracy (30 authors). The work in Eder (2013) studied the effectiveness of POS trigrams with a set of 21 authors and reported an accuracy of 65%. The problem with POS n-grams is that, they don't provide much information about how an author forms the phrases in sentences. The features generated with partial parsing (Luyckx and Dalemens, 2005) capture only the dependency between phrases but not how each phrase is formed. Our intuition is that considering various levels of sub-trees will capture dependency between phrases and also how a phrase is formed. The authors of Kim et al. (2011) identified

- For each author
  1. Combine all the articles in training text set for each author.
  2. Generate the character trigrams from raw text and compute their frequencies.
  3. Tokenize the text into sentences.
  4. Using a parser (Klein and Manning, 2003), parse the sentences and extract the POS trigrams, function words, and height two, three, four level sub-trees, and compute the frequencies for each feature type.
  5. Sort the features within each feature type by decreasing frequencies.
  6. Choose the top n discriminating features using the entropy metric for each feature.

Figure 3: Steps to generate the features

the most discriminating sub-trees in syntactic parse-trees and reported an accuracy of 84% (for 7 authors). Even though the sub-trees we derived from syntactic trees are in the same spirit as in Kim et al. (2011), we use them in building author templates, and combine the information of these features with other syntactic feature types in a completely different and novel way.

2.2 Attribution Techniques

There are two types of classifiers used in authorship attribution: 1) Template-matching classifiers, and 2) Machine-learning based classifiers (such as SVMs).

In template-matching approaches, all the training documents by an author are merged to form a single text collection and is used to generate a feature template for each author's writing style. A test document's signature is then compared with each author's template and authorship is assigned to the author with the closest match. Using character n-grams as features and entropy as similarity measure, the work in Peng et al. (2003) has reported an accuracy of 90% (for 8 authors). Instead of using a single template for each author, the work in (Jankowska et al., 2013; Layton, 2014; Koppel et al., 2011) created multiple templates for each author by selecting subsets of features and the result from each template is combined to find the best match using voting. The work in Koppel et al. (2011) has reported precision and recall values of 90% and 43% for 1000 authors and proved that this template based approach works well even in the case of large author sets.

In machine learning based approaches each document is treated as a representative data point of an author's style in a feature space and a classifier is trained. The work in Abbasi and Chen (2005) uses a combination of lexical, structural and syntactic features, employs Decision Trees as model, and reports an accuracy of 90% (for 20 authors). A number of studies in authorship analysis (Gamon, 2004; Zheng et al., 2006; Stamatatos, 2007; Luyckx and Daelemans, 2008; Luyckx, 2011; Silva et al., 2011) have used various Support Vector Machine (SVM) based classifiers. The work in Luyckx and Daelemans (2008) uses SVM and POS n-grams to assign authorship of essays written by 145 students and reported an accuracy of 55%. Work in (Stamatatos, 2007; Stamatatos, 2012) reported an accuracy of 75% (50 authors) by using character n-grams and SVM.

3 Methodology

We address the authorship attribution problem using the template-based methodology. The main reasons for this choice include stability in the face of changing sets of authors, ability to handle semi-closed authorship problems, and ability to more effectively combine different types of syntactic feature sets.

Each syntactic feature type captures a different mix of properties of the text in a document. This necessitates inclusion of a number of different feature types to design a robust classification system. We consider six types of features: character trigrams, function words, POS trigrams, and sub-trees of height two, three and four.

The steps to generate author's template are summarized in Figure 3. Instead of including thousands of feature values into an author template, we find the most frequent and then within them the most

informative feature values of each feature type. That is, we may include some character trigrams by first selecting the most frequent ones and then within those the most informative ones as measured by their informational entropy across all the authors. Typically 800 to 1500 of each feature's values and their frequencies are included in a template. The most frequent feature items used by an author are likely to persist in their higher relative frequencies across their multiple writings. One such template for each of the six feature types is created for each author. Let us say the resulting six templates for an author are: T_1, T_2, T_3, T_4, T_5, and T_6. Each template contains the relative frequencies of occurrence of individual feature items of a feature type for an author. For example, a template may contain relative frequencies of selected 1000 character trigrams, or 1000 POS trigrams, or 1000 height two sub-trees of parse trees.

Given a test document, six signatures referred to as: S_1, S_2, S_3, S_4, S_5, and S_6, which are similar in structure to the six templates generated for authors are generated. We use the Kullback-Leibler (KL) divergence (Kullback and Leibler, 1951) to compute the dissimilarity values between a test document's six signatures and the corresponding six templates for an author. This gives us six different divergence values for each document-author pair.

We now consider the decision rules for assigning an author to a test document. We examine the cases of making a decision for: (i) the closed author set using only one feature type (ii) the semi-closed author set using only one feature type; (iii) the closed author set using all the six feature types; and (iv) the semi-closed author set using all the six feature types. Our decision making strategies for these four cases are as follows.

Case-1: Compute the divergence value between the test document's selected feature signature, S_m, and each author's template for the m^{th} feature type, T_m. Let us say, D(S_m , T_m(i)) is the divergence value for the m^{th} feature type for the i^{th} author's template. We find the k^{th} author for whom this divergence value is the smallest and assign him/her the authorship.

Case-2: We use the intuitive idea that if the k^{th} author is the true author then the value D(S_m , T_m(k)) must be significantly smaller than the average of D(S_m , T_m(i)) values for all the authors in the pool. We capture this notion by requiring that the k^{th} author is assigned to a document only when the z-score of D(S_m , T_m(k)) is -2.0 or smaller when compared to the values D(S_m , T_m(i)), for all authors else we announce that the true author is not in the candidate set.

Case-3: In this case we seek to combine information obtained from all six feature types and obtain consensus among the inferences arrived by each of them individually. We use Dempster's rule from Theory of Evidence to combine the evidences. Let us say there are k authors in the pool of known authors and for the m^{th} feature type we compute the k divergence values as Div(m,i) = D(S_m , T_m(i)) where i takes the value from 1 to k. Now such a divergence vector is generated for each of the six feature types.

To apply the Dempster's Rule we need to convert these divergence values for authors (for a fixed feature type) to a $mass\ assignment$. As part of this conversion process we have to group all those authors who have very similar divergence values for a feature type into a single group. Given a vector of k divergence values (one feature type), we first normalize the divergence values by scaling them as follows:

$$NormDiv(i,j) = \frac{(max_j(Div(i,j)) - Div(i,j))}{(max_j(Div(i,j)) - (min_j(Div(i,j)))}. \quad (1)$$

Here, i represents the author number, j represents the feature type and $Div(i,j)$ denotes the divergence value of i^{th} author for j^{th} feature type. These scaled values are such that the author with the template closest to the document signature gets a value of 1 and the author with the template farthest from the document gets a value of 0. If two or more authors have very similar scaled scores (say 1.0 and 0.98) then they are equally likely to be the authors of the document (as per the feature type under consideration).

Therefore, as the next step of this process we form groups of authors from the perspective of this feature type. For each author in the candidate set, we identify the authors whose scaled scores are within the threshold δ and include all these authors to form an author set. The score of the author group is set equal to the average of the scaled values of the authors contained in the group. We then remove the duplicate author groups, if any are formed, and normalize all the group scores (for the author sets,

for each feature type) so that all the scores (for each feature type) add up to 1.0 as per the DS theory requirement of a mass assignment. We call these scores as mass values. Now, we have generated one mass assignment function for each feature type.

For example, say, for eight authors (a, b, c, d, e, f, g, h) the scaled values are: (1, 0.97, 0.94, 0.92, 0.87, 0.81, 0.73, 0). The mass assignment for these eight authors is shown in Table 1.

Author groups	Scaled scores	Average	mass values
<a,b >	<1, 0.97 >	0.985	0.157
<a, b, c, d >	<1, 0.97, 0.94, 0.92 >	0.957	0.153
<b, c, d >	<0.97, 0.94, 0.92 >	0.943	0.151
<b, c, d, e >	<0.97, 0.94, 0.92, 0.87 >	0.925	0.148
<d, e >	<0.92, 0.87 >	0.895	0.143
<f >	<0.81 >	0.81	0.129
<g >	<0.73 >	0.73	0.116
<h >	<0 >	0	0

Table 1: Mass assignment process using eight authors and δ value 0.05

We repeat this process for the divergence vector of each feature type and generate mass assignments for groups of authors. Then, the mass assignments for each feature type are combined using Dempster's rule of combination. Given two mass assignments m_1, m_2, the combined mass assignment m_{12} is computed as follows:

$$m_{12}(A) = \frac{1}{1-K} \sum_{B \cap C = A \neq \emptyset} m_1(B) m_2(C), \quad K = \sum_{B \cap C = \emptyset} m_1(B) m_2(C) \tag{2}$$

Here, K is the measure of the amount of conflict between two mass assignments and A, B, C represent subsets of authors.

After computing the consensus mass assignment from six feature types we compute the *plausibility* values of each candidate author being the true author of the test document.

The plausibility pl(A) is the sum of all the masses of sets 'B' that intersect the set of interest-'A' and is defined as follows:

$$pl(A) = \sum_{B | B \cap A \neq \emptyset} m(B) \tag{3}$$

We then select the author with the highest plausibility value as the true author of the test document.

Case-4: For this situation we follow the same process as in case-3 and then determine if the author with the highest plausibility has a plausibility value greater than 0.5, and its z-score among plausibility values for all authors is larger than 2.0. If not, we say that the true author is not in the given author set.

4 Dataset Description

News Articles' Dataset: We selected 7 columnists from the New York Times newspaper and 3 from the Guardian newspaper and extracted 50 articles for each author. To make each author's writings topic independent we selected the topics of sports, education, immigration, elections, health and politics and made sure that each author has written articles on at least 4 of these topics in our collection. These articles consists of, on an average, 800 words per document.

Reuter_50_50 Dataset: *Reuter_50_50* dataset (Houvardas and Stamatatos, 2006; Stamatatos, 2007; Bache and Lichman, 2013) has 50 authors and 5,000 documents. The training corpus has 2,500 documents and test corpus has 2,500 documents (50 documents for each author in train and test) with an average of 500 words per document.

Blogs Dataset: We used the *blogs* dataset (Schler et al., 2006; Koppel et al., 2011) and selected the top 100 authors based on the number of posts. We selected 10 posts for each author as test documents and rest as training documents. Each posting has around 200 words on average.

5 Results and Analysis

We have used the traditional metrics - accuracy, precision, and recall for measuring the performance of our author attribution study.

We have used the Naïve Bayes, Support Vector Machine (SVM), Voting, and the method proposed in Koppel et al. (2011) which we call as 'Koppel 2011' to compare the performance of proposed features types and methodology. Matlab's Naïve Bayes classifier with multinomial distribution and LIBSVM one-vs-one classifier with RBF kernel are used for Naïve Bayes and SVM based classification, and parameters are optimized in each case.

In case of attributing an author based on all six feature types, the method labeled 'Combined (C)' is performed by concatenating all the six feature templates of an author into one large template and then making the decisions using the divergence of similarly concatenated test signatures. The voting method labeled 'Voting' is executed by assigning the authorship to the author selected by maximum number of feature types. The method with label 'Koppel 2011' uses the approach discussed in Koppel et al. (2011). The purpose of these methods is to contrast their result with proposed Dempster's combination rule based method (DS combined).

5.1 Closed author set using only one feature type

The main reason to assign authorship considering each feature type (section 3: case-1) separately is to compare and contrast their individual performances. For each feature type, we kept the number of features - 'n' to be constant at 1,500 and reported the accuracies in Figure 4. This figure shows the accuracy of author attribution using four different classifiers: our proposed method KL-Divergence, Naïve Bayes, SVM, and Koppel 2011.

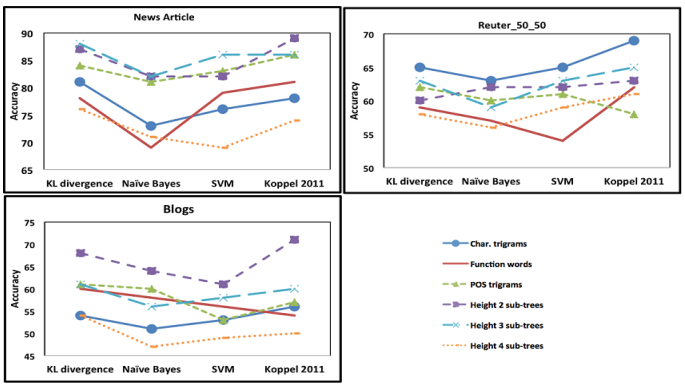

Figure 4: Accuracy values for closed-author set using one feature type.

Here, we can see that the frequencies of sub-trees of height two, and three, and POS trigrams - yielded greater accuracy in *news articles* and *blogs* datasets irrespective of the classification algorithm used. In *Reuter_50_50* dataset, character trigrams gave a slightly better accuracy compared to other features. A common intuition with character n-grams is that they capture the thematic information along with the author style (Stamatatos, 2012). Many authors in *Reuter_50_50* dataset have written articles on a particular subtopic with a high occurrence of a set of words specific to the topic. This makes it easy for character trigrams to distinguish different authors. Parse trees frequencies work better for the News Articles dataset because each author has written articles on different topics and the feature is topic independent.

5.1.1 Effect of feature set size

For this analysis (Figure 5), we kept the training and test document sets fixed, and gradually increased the number of best feature items (number of best character 3-grams, or height 2 sub-trees etc.) included in each template. Most of the feature types attained maximum accuracy when 1000 to 2000 feature items are included and are stable in performance when few hundred feature items are added.

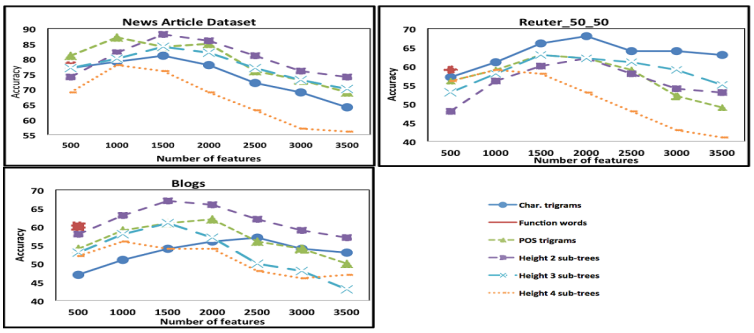

Figure 5: Effect of feature set size.

Afterward, the performance decreased as more feature items are added. The results presented in (Stamatatos, 2007; Stamatatos, 2012) suggest considering at least a feature set size of 3000 - 5000 for character trigrams in *Reuter_50_50* dataset. In their formulation they include the 5000 most frequent character trigrams in the feature set whereas in our formulation we select the top '*n*' discriminating features based on informational entropy. From Figure 5, we can observe that there is no overall consensus on ideal size for feature sets. However, one can achieve a reasonable accuracy by considering the most discriminating features numbering between 1000 and 2000. This is a very wide range. For larger numbers it seems the curse of dimensionality sets in and the extra feature items, that are less discriminating, add noise to the author attribution process. Fewer feature items have lower accuracy because they may not have enough information in them to make best decisions.

5.1.2 Effect of training data size

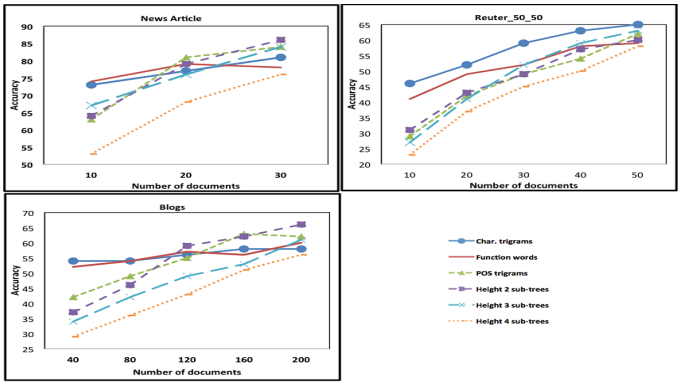

Figure 6: Effect of training data size.

To analyze the effect of limited training data, we started with ten documents and increased the number of documents in multiples of ten for *news article* and *Reuter_50_50* dataset. In *blogs* dataset, we started with 40 documents and increased the size in multiples of 40. Each document in *news article* dataset is approximately twice the size of the document in *Reuter_50_50* and *blogs* dataset. The test set is kept constant for each author and the attribution accuracy results are shown in Figure 6. There is a large difference in accuracy between the character trigrams and other syntactic features especially with limited training data and this difference narrows once we start increasing the number of training documents. The function words and character 3-grams templates have the best performance when the training dataset is very small. So, these features are very effective even with very small training set sizes. We also notice that, expectedly, as the number of training documents increases the performance for each feature type improves consistently. At the higher end of the number of training documents, subtrees of height two became the best feature types for the News Articles and the Blogs datasets and kept improving their performance even for the Reuters dataset.

5.2 Semi-closed author set using only one feature type

Here, we use the approach described in Case-2 of the methodology section (Section 3). In addition to the test documents in the *news articles* dataset, we added 200 randomly selected documents from the *Reuter_50_50* dataset to the *news article* test set. Similarly, we added 200 test documents from *news article* dataset to *Reuter_50_50* dataset. For *blogs* dataset, we randomly selected 500 documents written by the authors who are not in the selected sample dataset and added them to the test set. The feature set size '*n*' is kept constant at 1500 items and z-score threshold for making a decision is selected as -1.5 for all the datasets.

In Table 2, we show the precision and recall values, measured individually for each feature type. We can observe the similar behavior as in the closed author set case. That is, grammar based features gave better performance in *news article* and *blogs* datasets and character trigrams gave higher performance in *Reuter_50_50* dataset. We observe that as the number of authors increases the precision and recall values decline. They are the highest for the News articles dataset (10 authors), followed by Reuters (50 authors) and then the lowest for the Blogs dataset (100 authors). Also, the recall is consistently smaller than the precision because for the semi-closed case an author is announced only if he/she stands significantly apart compared to other authors.

		Character trigrams	Function words	POS trigrams	Height 2 sub-trees	Height 3 sub-trees	Height 4 sub-trees

Table 3: Precision and Recall values using all feature types (Case-3)

5.3 Closed author set using all the six feature types

We consider feature item set sizes between 500 - 3000, in multiples of 500, and the average values for precision and recall along with their standard deviations are show in Table 3. Here, the threshold δ for forming the groups of authors for the Dempster's rule combination method, is kept constant at 0.05. We observed that for δ values between 0.025 and 0.075 there is negligible change in performance in all the datasets. To show that the sub-tree features derived from the parse trees capture some additional author discriminating information that is not captured by the char. trigrams, func. words, and POS trigrams, we performed the following experiment. First we used the three feature types (func. words, char. trigrams, POS trigrams) and calculated the precision and recall values using our DS combined approach (*DS combined(3)*). Then we considered all six feature types, and calculated the precision and recall values (*DS combined(6)*). There is a significant increase in precision and recall values when we include the sub-tree features for consensus formation compared to only combining the three non-tree feature types. This validates our hypothesis that the sub-tree feature types capture some additional information that is not captured by the other three feature types. We also can see that the performance improves significantly when inferences from multiple features types are combined using various aggregation methods; and the best performance for all datasets is obtained when Dempster's rule is used.

Robustness Analysis:

The main aim of our test described in this section is to analyze how our *DS combined* method performs when small changes are introduced in the test documents. For each test document in an author's test set we

		Original	Adding 50 words	Adding 100 words
News Article	prec.	88±3.0	86±4.3	83±3.8
	rec.	82±2.1	80±3.9	77±5.7
Reuter_50_50	prec.	73±3.7	71±2.8	65±2.7
	rec.	66±5.0	64±3.7	60±3.6
Blogs	prec.	68±2.4	61±2.1	54±2.4
	rec.	65±1.1	58±2.4	51±2.3

Table 4: Precision and Recall values with slight changes to test documents

added 50 random words of text taken from a different author within the same dataset. We repeated this in all the three datasets and used feature set sizes between 500 - 3000, in multiples of 500. The results obtained are shown in Table 4. The δ value is kept constant at 0.05 for all the datasets. The *Blogs* dataset is very sensitive to changes in test documents as the test document size is very small (200 words). There is very small drop in precision and recall values in other datasets when we added 50 random words to a test document. However, when we added 100 random words to each test document, performance decreased more in *Reuter_50_50* dataset but not that much in *news article* dataset. This is because the average test document size is small (500 words) in the former dataset and the average size in *news article* dataset is 800 words.

To study the effect of candidate author set size on *DS combined* approach, we kept the feature set size constant at 1500 items and analyzed the performance by gradually increasing the author set size. For each author set size, we repeated the experiment ten times by randomly selecting the authors and the average precision and recall values are reported in Figure 7. As expected, both the precision and recall values slowly decrease with an increase in the author set size.

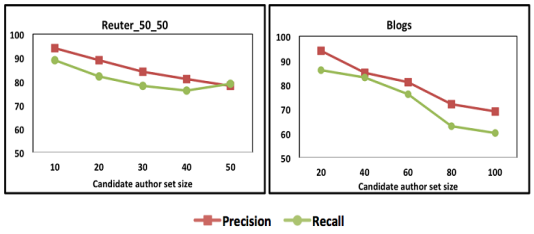

Figure 7: Precision and recall values for different candidate author set sizes.

5.4 Semi-closed author set using all the six feature types

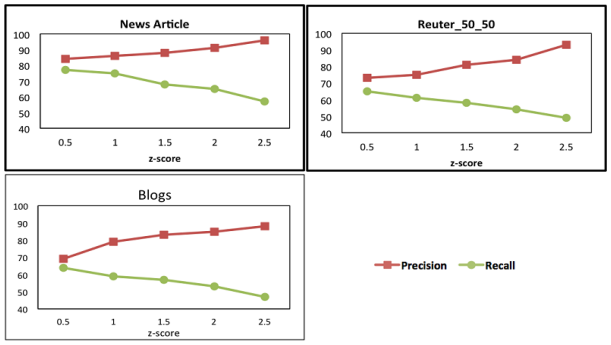

Figure 8: Precision and recall values for different z-score cutoff values.

For this test, we have used the same datasets as described in Section 5.2 and used the approach described in case-4 of the methodology section. The precision and recall values for various z-score cut off values are shown in Figure 8. In all datasets the precision values do not decline, but rise slightly, as the z-score cutoff goes up to 2.5. This is because a larger z-score cutoff means that the winning author must have a significantly higher plausibility value compared to all the other authors. Therefore, an author is announced for a document only if he/she is the clear winner compared to all the others. The recall values reduce somewhat with increasing z-score cutoff and this is because the authors who do not stand out very strongly compared to the other authors do not get attributed to the documents.

6 Conclusion

In the above discussion we have shown two main contributions of our proposed methodology for author attribution of documents. The first is that templates formed from the sub-tree frequencies in the parse tree of an author's text provide very valuable insights about one's writing style. The second main contribution is the demonstration that information embedded in different types of syntactic features is best combined using Dempster's rule compared to some other methods of information fusion. We have also shown successfully that our proposed approach works well for both - 'closed' and 'semi-closed' cases. We have shown the robustness of our proposed approach from various perspectives and the best results obtained using Dempster's Rule based combination of all six features are of significantly high quality.

Abstract

Dealing with 'open-vocabulary' slots has been among the challenges in the natural language area. While recent studies on attention-based recurrent neural network (RNN) models have performed well in completing several language related tasks such as spoken language understanding and dialogue systems, there has been a lack of attempts to address filling slots that take on values from a virtually unlimited set. In this paper, we propose a new RNN model that can capture the vital concept: Understanding the role of a word may vary according to how long a reader focuses on a particular part of a sentence. The proposed model utilizes a long-term aware attention structure, positional encoding primarily considering the relative distance between words, and multi-task learning of a character-based language model and an intent detection model. We show that the model outperforms the existing RNN models with respect to discovering 'open-vocabulary' slots without any external information, such as a named entity database or knowledge base. In particular, we confirm that it performs better with a greater number of slots in a dataset, including unknown words, by evaluating the models on a dataset of several domains. In addition, the proposed model also demonstrates superior performance with regard to intent detection.

1 Introduction

In spoken dialogue systems and goal-oriented dialogue systems, slot filling and intent detection are primarily involved in a process of understanding user utterances based on pre-designed semantic frames. Slot filling is to identify a sequence of tokens and extract semantic constituents from the utterances, and intent detection is to classify the intent of the utterances. Two examples relevant to these problems are shown in Figure 1 for the domains of flight and message.

In recent years, a significant amount of interest has built up around slot filling and intent detection due in part to the competition among commercial artificial intelligence assistants, such as Samsung Bixby, Apple Siri, Google Assistant, Microsoft Cortana, and Amazon Alexa. As a result, a multitude of studies regarding recurrent neural network (RNN) models for slot filling and intent detection has been completed and has resulted in outcomes that generally outperform most other past approaches. In particular, there have been various attempts to improve the performance of RNNs for spoken dialogue systems such as label sampling (Liu and Lane, 2015), the hybrid type of Elman and Jordan (Mesnil et al., 2015), Deep LSTM (Yao et al., 2014), external memory (Peng et al., 2015), bidirectional LSTM (Hakkani-Tur et al., 2016), encoder-labeler and Deep LSTM (Kurata et al., 2016), attention (Liu and Lane, 2016), bidirectional LSTM and CRF (Huang et al., 2015), word hashing (Ravuri and Stolcke, 2015a; Ravuri and Stolcke, 2015b) CNN and bidirectional LSTM (Chiu and Nichols, 2015), external word embeddings (Kim et al., 2016), multi-task learning of a word-based language model (Shi et al., 2015), and multi-task learning of intent and domains (Shi et al., 2015; Hakkani-Tur et al., 2016; Bapna et al., 2017).

Proceedings of the 27th International Conference on Computational Linguistics, pages 2778–2790

Sentence	find	flights	to	new	york	tomorrow
Slots	O	O	O	B-toloc	I-toloc	B-date
Intent	find_flight					

Sentence	text	to	mary	that	sad	puppy	Noise
Slots	O	O	B-recipient	O	B-text	I-text	I-text
Intent	send_message						

Figure 1: Two examples of a flight domain and a message domain with intent and slot annotation, following the IOB (in-out-begin) slot representation

Although most previous studies that exploited RNN and attention methods (Liu and Lane, 2016; Vaswani et al., 2017) were able to achieve state-of-the-art performance across a wide range of natural language research areas, they failed to deal with 'open-vocabulary' slots, which is one of the most important problems in the context of end-user experience using voice assistant. 'Open-vocabulary' slots signify a slot type that can take on values from a virtually unlimited set, such as file name, album name, text body, or schedule title. Therefore, words that are not seen in the training set or are employed differently from the meaning inherent in them can be included in sentences because of the fact that they have no constraints on the length and specific patterns of content. For slot filling of 'open-vocabulary' slots with such characteristics, the goal of this study was to capture the vital concept in which the meaning or role of words could vary according to how long a reader focuses on a particular part of a sentence. For example, in the utterance "Send how about dinner tonight to him" in the message domain, if a reader focuses on 'how about dinner tonight,' the word 'tonight' signifies time. However, it should rather focus on the entire utterance that starts with "Send how …" and recognize the word 'tonight' as a part of the text body. Thus, it is necessary to understand the holistic semantics at the level of the whole sentence, not only the vicinity of a word.

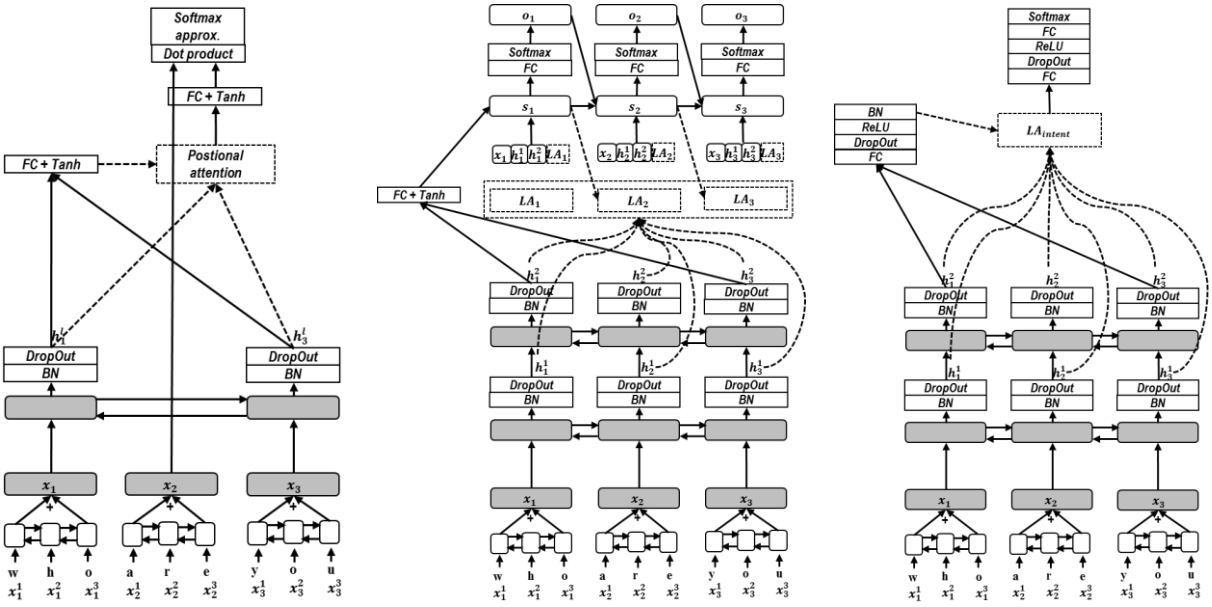
Our model embodies the above concept by introducing a long-term aware attention structure and positional encoding primarily intended for the relative distance between words. Long-term aware attention structure utilizes and stacks two layers of an RNN and treats them as a pair of short-term and long-term meanings. The lower layer denotes short-term or relatively local information corresponding to the vicinity of a word, and the upper layer denotes long-term or relatively global information corresponding to the whole sentence. A novel positional encoding, called the light-house encoding, considers the relative distance between current word and the word being compared in relation to the current word. In addition, it is completely based on characters rather than words, which is adequate for unknown words of 'open-vocabulary' slots. It is also trained with multi-task learning of a character-based language model and an intent detection model to improve the stability and utility of character-based representation and to obtain additional sentence-level information. The language model serves as a regularizer, and the intent detection model is beneficial in the presence of 'open-vocabulary' slots because it allows the proposed model to refer to the global information of a sentence. Lastly, to focus on the effectiveness of modeling, this study only uses the lexical input of language without the help of any external information, such as a named-entity or knowledge base.

We evaluated our model on slot filling and intent detection with the ATIS corpus (Hemphill et al., 1990) and five in-house domains. For the ATIS corpus, the proposed model achieved a state-of-the-art result on intent detection and a result comparable to the state-of-the-art result on slot filling. The proposed model also outperformed the existing RNN models for both tasks on the dataset of five domains. In particular, we demonstrate that our model has outstanding performance on 'open-vocabulary' slots and its efficacy is increased as more data in a domain contain 'open-vocabulary' slots including unknown words.

The main contribution of this study is a new RNN-based model that captures global information of words for discovering 'open-vocabulary' slots. To achieve this, we propose a long-term aware attention structure and a novel positional encoding with help from character-based modeling and multi-task learning.

2 Slot Filling and Intent Detection

Slot filling is a sequence labeling problem and intent detection can be treated as a classification problem that has multiple output labels. In the example in Figure 1, the flight domain may contain *find_flight*, *find_airfare*, and *find_distance* as intent list and *toloc*, *fromloc*, *date*, and *flight_number* as



(a) (b) (c)

Figure 2. Structures of our proposed model (a) Structure of our language model (b) Structure of our slot filling model (c) Structure of our intent detection model

the slot list. The task of slot filling is to find an explicit alignment between slots and a given user query, and the task of intent detection is to instantiate one or more intents from the intent list for a given user query.

More formally, we want to learn two functions for the $f_{\text{slot}} : \mathrm{X} \rightarrow \Upsilon$ and $f_{\text{intent}} : \mathrm{X} \rightarrow \Upsilon'$ that maps an input sequence $\mathrm{X} = x_1, x_2, \ldots, x_{T_x}$ to the corresponding label sequence $\Upsilon = y_1, y_2, \ldots, y_{T_x}$ and intent labels $\Upsilon' = y'_1, \ldots, y'_n$ where T_x is the length of the input sequence and n is the number of intents. The sequence of slots is in the form of IOB labels that have three outputs corresponding to 'B' as the beginning of a slot, 'I' as the continuation of a slot, and 'O' as the absence of a slot.

3 Model Description

The structure of our proposed model is shown in Figure 2. The input of the network is a sequence of characters x_i^j where i is a word index and j is a character index inside a word. Our model includes task models that include both the slot filling model (SFM) in (b) of Figure 2 and the intent detection model (IDM) in (c) of Figure 2, as well as language model (LM) in (a) of Figure 2. All three models share character embedding and a word-related layer to build word representation x_i, and task models (SFM and IDM) share two encoding layers as well to build sentence-level representations which are h_i^1 as the output of the 1st encoding layer and h_i^2 as the output of the 2nd encoding layer. The encoding layer of LM is defined separately as h_i^l because it is an independent encoding layer only for LM, which is unlike h_i^1 and h_i^2 which are shared between SFM and IDM. In addition, the slot filling model utilizes sequential outputs as input of the next decoder in the shape of a slot label embedding o_i.

Basically, we use a bi-directional GRU (bGRU) as the RNN of the encoder and decoder in all models (Chung et al., 2014). The locations of dropout (Srivastava et al., 2014) and batch normalization (Ioffe and Szegedy, 2015), selection of the activation function, connection between representations of the encoder and inputs of the decoder, and choices of summation and concatenation are obtained from extensive experiments.

3.1 Character-based Word Representation

A layer of bGRU to build word representation x_i, depicted in the bottommost layer of Figure 2, encodes word information into hidden representations from character inputs. Word representation x_i is the sum of two final hidden states of the bGRU. The first one is a vector concatenating forward pass and backward pass at the first time step of characters. The other one is the same type vector at the last time step of characters. All parameters including character embeddings in the bGRU are shared in SFM, IDM, and LM.

We chose character-based embeddings without word-based embeddings for two reasons. Firstly, for large vocabulary tasks, the size of the word embeddings overwhelms the number of other parameters if word embedding is used. Secondly, the character-based approach could give us better robustness in terms of unknown and rare words than the word-based approach, which is an important aspect for 'open-vocabulary' slots. The larger the number of words we model, the more the sparseness problem is exacerbated. Furthermore, Kim et al., (2015) said that word representation based on character embedding is able to better detect orthographic forms and semantic features and better learn to differentiate between morphemes, such as prefixes and suffixes, than word embedding. Moreover, Verwimp et al. (2017) claimed that it is possible to reveal structural similarities between words and be used when a word is out-of-vocabulary, unknown and infrequent.

3.2 Long-term Aware Attention Structure

Basically, the existing attention mechanism in alignment-based RNN models has the following form (Mnih et al., 2014; Bahdanau et al., 2015; Firat et al., 2016).

$$c_i = \sum_{j=1}^{T_x} \alpha_{ij} h_j \tag{1}$$

$$\alpha_{ij} = \frac{\exp(e_{ij})}{\sum_{k=1}^{T_x} \exp(e_{ik})} \tag{2}$$

$$e_{ij} = f(s_{i-1}, h_j) \tag{3}$$

where j is the sequential index of a word, s_{i-1} is the decoder state at step $i-1$, c_i is a corresponding attention vector, α_{ij} is position-wise weights related to s_{i-1} which is obtained by the function f.

In this formula, the query of attention is the previous decoder state s_{i-1}, and the keys and values of attention are each encoding information h_j. An attention weight α_{ij} is obtained from some operations including softmax and neural network f based on query and keys, and final attention vector c_i is made by weighted sum of attention weights and values.

To address the challenge presented at the beginning of the paper, we took two ideas which embody the concept where the meaning or role of words can vary according to how long a reader focuses on a particular part of a sentence. The first idea is to build multiple RNNs hierarchically and each upper layer uses final forward and backward hidden states of a layer right below it as initial hidden states in opposite directions. For example, SFM and IDM in our model share two layers of the bGRU as a sentence-level encoder as follows:

$$\overrightarrow{h_i^1} = \mathrm{GRU}_1\left(\overrightarrow{h_{i-1}^1}, x_i\right), \overleftarrow{h_{i-1}^1} = \mathrm{GRU}_1\left(\overleftarrow{h_i^1}, x_i\right), i = 1, \ldots, T_x \tag{4}$$

$$\overrightarrow{h_0^1} = 0_d, \overleftarrow{h_{T_x+1}^1} = 0_d \tag{5}$$

$$h_i^1 = \left[\overrightarrow{h_i^1}; \overleftarrow{h_i^1}\right] \tag{6}$$

$$\overrightarrow{h_i^2} = \mathrm{GRU}_2\left(\overrightarrow{h_{i-1}^2}, h_i^1\right), \overleftarrow{h_{i-1}^2} = \mathrm{GRU}_2\left(\overleftarrow{h_i^2}, h_i^1\right), i = 1, \ldots, T_x \tag{7}$$

$$\overrightarrow{h_0^2} = \overleftarrow{h_1^1}, \overleftarrow{h_{T_x+1}^2} = h_{T_x}^1 \tag{8}$$

$$h_i^2 = \left[\overrightarrow{h_i^2}; \overleftarrow{h_i^2}\right] \tag{9}$$

where $\overrightarrow{\ }$ and $\overleftarrow{\ }$ are the forward pass and backward pass of the bGRU, $\overrightarrow{h_0^1}$ and $\overrightarrow{h_0^2}$ are the initial hidden states of the forward pass for the 1st layer and the 2nd layer, $\overleftarrow{h_{T_x+1}^1}$ and $\overleftarrow{h_{T_x+1}^2}$ are the initial hidden states of the backward pass for the 1st layer and the 2nd layer, and [;] is the concatenation operator.

The intuition behind equation (8) is that each pass in an upper bGRU layer provides more global information than a lower one and updates the states of each word time step to redeem correlations between distant words with the help of sentence-level information in the opposite direction of lower bGRU layer. In other words, we stack two layers of the bGRU and treat them as a pair of short-term and long-term meanings. The first layer output h_i^1 of two bGRU layers denotes short-term or relatively local information and the second layer output h_i^2 denotes long-term or relatively global information.

The second idea is that, in the attention mechanism of the decoder, the output h_i^1 of the lower layer is used as both a value and a key and output h_i^2 of the upper layer is used only as a key. We intended that the model would keep short-term information for the concrete meaning of a word, and combine it

using additional sentence-level information for actual meaning or role in a sentence learned from training data. More formally,

$$LA_i = \sum_{j=1}^{T_x} \alpha_{ij} h_j^1 \tag{10}$$

$$\alpha_{ij} = \frac{\exp(e_{ij})}{\sum_{k=1}^{T_x} \exp(e_{ik})} \tag{11}$$

$$e_{ij} = f\left(s_{i-1}, h_j^1, h_j^2\right) \tag{12}$$

where LA_i is an attention vector at each decoding step i, h_j^1 is a hidden state of the 1st bGRU layer at word index j, h_j^2 is the hidden states of the 2nd bGRU layer at word index j.

We expect these simple changes allow the model to compensate for missing points or defects at the level of the whole sentence, and also disentangle the local and global requisite information as appropriate for the tasks. The key features of the ideas above are the ability to avoid insufficient tackling of long range dependencies and the ability to offer assistance in learning the actual meaning or role within a sentence. Although the LSTM (Gers and Schmidhuber, 2000) and GRU are well designed to solve the problem of long range dependencies that results in the model becoming unable to capture correlations between words separated by many time steps as a distance between the current word and the relevant word grows, the long range dependencies may still be a lingering issue, especially for 'open-vocabulary' slots, from an approximated learning method like truncated backpropagation through time (truncated BPTT), noisy and meaningless interim inputs, and ambiguity.

In practice, we constitute the function f in (12) used for computing weights by fully connected neural networks.

$$f\left(s_{i-1}, h_j^1, h_j^2\right) = v_a^T \left(Tanh\left(FC(s_{i-1})\right) + Tanh\left(FC\left(h_j^1\right)\right) + Tanh\left(FC\left(h_j^2\right)\right)\right) \tag{13}$$

where FC is a fully connected neural network with a linear matrix and a bias vector to be projected into attention dimension d_a and $v_a \in R^{d_a}$ is a vector to compute one scalar weight logit for each decoding step i in the decoder and word index j of hidden states in the encoder.

3.3 Light-house Positional Encoding

Positional encoding conveys positional information in a form of vectors, which is related to where words are located within a sentence. To appropriately impose the second idea of the long-term aware attention structure on our model, positional encoding in the attention mechanism of the decoder is necessary because the encoder is able to focus more on the meaning in a sentence as intended by the fact that applying it to the attention mechanism separately conveys interactions depending on the distance between words to the decoder.

We introduce a novel positional encoding, called light-house positional encoding, which considers the relative distance between the current word and the word being compared in relation to the current word. Our scheme has two differences from the previous positional encodings (Sukhbaatar et al., 2015; Vaswani et al., 2017; Gehring et al., 2016; Gehring et al., 2017). One is that it defines only one trained embedding, which is unlike position-wise encoding and fixed encoding, and the other is that it is not placed in the inputs of the encoder and decoder but on the inside of attention computation. The formula is as follows:

$$p_i^b = \beta * |b - i| * D \tag{14}$$

where i is a word index, b is the current word index as a basis, $D \in R^d$ is the distance embedding which has positional dimension d, β is a parameter which controls the norm of the encoding increased by the distance.

The existing positional encodings are mostly fixed encoding like sinusoid type or learned position-wise encoding which is set up per each word independently. However, light-house positional encoding defines only one distance embedding D with respect to one time step between words. It configures positional encodings p_i^b for each word index i according to time step distance $|b - i|$ from the current word index b multiplied by a parameter β. Thus, it has fewer position-related parameters than the position-wise encoding. Additionally, the further the distance between words being compared, the larger the norm of positional encoding it has, which makes deeper layers easily notice distance-related information from positive and negative values of encoding and weights. In our experiments, the distance embeddings of models for several domains have positive and negative values in a 50/50 ratio on aver-

age. In practice, although we are able to deal with β as a learned parameter, we treat it as a hyper-parameter, which is closely connected to the average length of sentences. $\beta = 1$ showed stable results in our experiments.

As for placement, we place it only inside of the attention computation function f of (13) as follows:

$$f(s_{i-1}, h_j^1, h_j^2) = v_a^T \left(Tanh(FC(s_{i-1})) + Tanh\left(FC([h_j^1; p_j^i])\right) + Tanh\left(FC([h_j^2; p_j^i])\right)\right) \quad (15)$$

where [;] is concatenation operator and p_j^i is the positional encodings for each word index j of hidden states in the encoder based on each decoding step i in the decoder.

The reason for this placement is also for the sake of using positional encoding only where it is absolutely necessary because the other layers are composed of the bGRU and it exhibits dynamic temporal behavior.

3.4 Configuration for Models and Multi-task Learning

The SFM in (b) of Figure 2 is composed of a layer of the bGRU to build word representation x_i, two layers of the bGRU in the encoder, and a layer of the bGRU including the attention mechanism in decoder. The encoder and decoder of the SFM are based on the long-term attention structure and light-house positional encoding that we explained above. In addition, we utilize both ends of the hidden states of the 2nd encoder layer, h_1^2 and $h_{T_x}^2$, to make an initial state of decoder s_0 by concatenating them and using a layer of the fully connected neural network with a hyperbolic tangent 'tanh'. That means that the initial state of the decoder is built from states with the broadest information in the encoder.

The IDM in (c) of Figure 2 is composed of encoder layers shared with the SFM and two layers of the fully connected neural network in the decoder. It is also based on the long-term attention structure and light-house positional encoding. The difference with the STM in relation to using two ideas is that there is only one attention vector LA_{intent}, its positional encoding is computed by treating the last word time step as the current word index b in (14), and a query of attention is made by a layer of the fully connected neural network with a rectified linear unit 'ReLU', not 'tanh'.

The LM in (a) of Figure 2 is composed of a layer of the bGRU for word representation x_i shared with the SFM and IDM, a separate layer of the bGRU in the encoder, and a layer of the fully connected neural network in the decoder. It adopts a conventional attention structure like (1) to (3) and light-house positional encoding, and it also has only one attention vector called 'Positional attention' like the IDM. The LM was trained by randomly removing a word in a sentence, inserting other words within window 10 ($\pm$5) of the removed word as an input, and using the removed word as an output. Thus, positional encoding in the LM treats the index of the removed word as the current word index b = 5 in (14), and its 10 indexes of input are 0, …,4,6, …,10. Finally, the formula of the decoder is as follows:

$$Positional\ attention = \sum_j \alpha_j h_j^l, j = 0, \ldots, 4, 6, \ldots, 10 \quad (16)$$

$$\alpha_j = \frac{\exp(e_j)}{\sum_k \exp(e_k)}, k = 0, \ldots, 4, 6, \ldots, 10 \quad (17)$$

$$e_j = f(s, h_j^l) \quad (18)$$

$$f(s, h_j^l) = v_a^T \left(Tanh(FC(s)) + Tanh\left(FC([h_j^l; p_j^5])\right)\right) \quad (19)$$

$$\mathrm{s} = Tanh\left(FC([h_0^l; h_{10}^l])\right) \quad (20)$$

where h_j^l is the outputs of a separate encoding layer for $j = 0, \ldots, 4, 6, \ldots, 10$, s is a query of attention, FC is a fully connected neural network with a linear matrix and a bias vector to be projected into attention dimension d_a and $v_a \in R^{d_a}$ is a vector to compute one scalar weight logit for each word index j of hidden states in the encoder, p_j^b is a positional encoding for each word index j of the hidden states in the encoder based on the word index 5 corresponding to the removed word.

In the LM, the decoder formulates one representation from 'Positional attention' via a layer of the fully connected neural network with 'tanh' and we use the dot product between the word representation for each word candidate and the final output to compute the final probability, which indicates how well each word fits into the position of the removed word. In addition, the LM utilizes infrequent normalization softmax approximation, combining the strengths of Noise Contrastive Estimation (NCE) and self-normalization, which results in a higher speed-up factor (Andreas and Klein, 2015).

Domains	# of train	# of test	# of slot labels	# of intent types
Calculator	3401	680	10	2
Calendar	9062	1812	70	24
Camera	9425	1885	63	61
Gallery	61885	12377	54	197
Message	18571	3714	49	74

Table 1. The number of training sets, test sets, slot labels, and intent types in 5 Samsung Bixby domains

	ATIS	Gallery	Calendar	Message
Ratio of "open vocabulary slots" to "close vocabulary slots" in the test set	59.58% (1689/2835)	15.13% (5305/35045)	34.56% (1064/3079)	79.44% (3655/4601)
Ratio of "open vocabulary slots including unknown words" to "the other open vocabulary slots" in the test set	2.42% (41/1689)	4.79% (254/5305)	13.82% (147/1064)	45.42% (1660/3655)

Table 2. Percentages of 'open-vocabulary' slots, including unknown words in the test set for each domain

In practice, all words existing in a training batch are treated as a result of down-sampling for approximating the normalization term.

We institute multi-task learning for the above three models with two types called 'Slot only' and 'Joint'. The first one is a combination of the SFM and the LM and the other is a combination of all three models. It also follows that joint learning of intent detection has a positive effect on performance of slot filling as in Liu and Lane (2016). A final cost function to be maximized is as follows:

$$\mathcal{L} = \log\big(p(\mathrm{Y}|\mathrm{X})\big) + \log\big(p(Y'|X)\big) + \lambda\Big(\log\big(p(x_b|X \setminus x_b)\big) + \textstyle\sum_{w_i \setminus embeddings} \| w_i \|_2^2\Big) \quad (21)$$

$$p(\mathrm{Y}|\mathrm{X}) = \textstyle\prod_{t=1}^{T_x} p\big(y_t \big| x_1, \dots, x_{T_x}, y_1, \dots, y_{t-1}\big) \quad (22)$$

$$p(Y'|X) = \textstyle\prod_{k=1}^{n} p\big(y'_k \big| x_1, \dots, x_{T_x}\big) \quad (23)$$

where λ is a weight-decay hyper-parameter for the LM and l2-norm, T_x is the length of the input sequence, n is the number of intents, and w_i is all the parameters learned from training data. Thus, the LM is used for stability and utility of character-based word representation and can be construed as a regularizer for the SFM and IDM.

4 Experiments

4.1 Data

The ATIS corpus (Hemphill et al., 1990) is the most commonly used dataset for the research on spoken language understanding. In this study, we used the ATIS corpus from Hakkani-Tur et al. (2016).[1]

The dataset consists of sentences of people making flight reservations. The training set contains 4978 utterances from the ATIS-2 and ATIS-3 corpora, and the test set contains 893 utterances from the ATIS-3 NOV93 and DEC94 datasets. There are in total 127 distinct slot labels and 18 different intent types.

For this study we collected English in-house real data of five different Bixby domains. We adopted domains and corresponding intent types to show the performance of our model in terms of various levels of difficulty. Table 1 describes the number of training sets, test sets, slot labels, and intent types in the five domains. The calculator and camera domains have no 'open-vocabulary' slots, and 'open-vocabulary' slots of the others, including the ATIS corpus, are shown in Table 5 of Appendix B. We did not utilize any external information, such as a named entity database or knowledge base with entities like city, airport, person, etc., to focus on the performance only using the lexical input of language. Thus, we treated named entity slots as 'open-vocabulary' slots. Additionally, we defined the difficulty of each domain associated with 'open-vocabulary' slots on the basis of how many values of 'open-vocabulary' slots in each domain included unknown words in the test set. Table 2 shows that ATIS, gallery, calendar, and message had a high level of difficulty in an increasing order.

For the five Bixby domains, we compared our model to three previous models: the hybrid RNN (Mesnil et al., 2015), the encoder-labeler deep LSTM (Kurata et al., 2016), and the attention biRNN for both 'Slot only' and 'Joint' (Liu and Lane, 2016).

Table 4. Best F1-score of slot filling and best error rate of intent detection for five Bixby domains in comparison with previous approaches

4.2 Training details

For the training of our model, we used a mini-batch stochastic descent method named Adadelta (Zeiler, 2012), a method with a relatively simple configuration, and set its momentum related parameter to a value of 0.95, but we used default settings and methods specified in published codes and papers for the comparison models.[2] We also utilized l2-norm regularization for parameters and gradient clipping for stable training.

For tuning hyper-parameters, we split the training set into 90% training and 10% development. After choosing the hyper-parameters, we re-trained the model with all of the training data. For evaluation, we evaluated the performance on slot filling using an F1 score and the performance on intent detection using the classification error rate, and each result was recorded from the best one among 10 different initializations.

We did not utilize any kind of pre-training or external data for any of the experiments. Details of the preprocessing procedures and the finally determined model parameters are given in Appendix A.

4.3 Results

For the ATIS corpus, Table 3 shows that our models for both 'Joint' and 'Slot only' achieved comparable results to the state-of-the-art result of slot filling. In particular, our 'Slot only' model provided improvement from 95.78 to 95.93 in comparison to the previous best 'Slot only' model. For intent detection, Table 3 also shows that we provided the state-of-the-art performance with a 1.46 error rate using the 'Joint' model. In addition, learning with additional intent information in our model had no positive effect on the performance of slot filling.

On the other five domains of Bixby, we compared our model with three previous methods for slot filling and also compared it with only one previous method for intent detection. The Hybrid RNN

[2] Attention BiRNN : https://github.com/HadoopIt/rnn-nlu and Hybrid RNN : https://github.com/mesnilgr/is13

(Mesnil et al., 2015) applied the RNN to slot filling for the first time, the Encoder-labeler Deep LSTM (Kurata et al., 2016) applied the encoder-decoder concept to slot filling, and the Attention BiRNN (Liu and Lane, 2016) applied attention and multi-task learning to slot filling and intent detection and achieved the state-of-the-art performance among the previous approaches for both. Thus, for slot filling, we intended to check change of the performance as additional ideas are introduced such as the RNN, encoder-decoder, attention, and long-term aware attention and light-house positional encoding. Not to our surprise, adding ideas improved the performance and our model demonstrated the best performance for both slot filling and intent detection. In particular, as the difficulty of domains associated with 'open-vocabulary' slots increased, like calendar and message, a larger gap in performance emerged to the amount of about a 5% absolute gain for slot filling and about a 1% error rate for intent detection. However, multi-task learning with the intent detection model did not have much effect on the performance of slot filling. The results are summarized in Table 4.

To see more detailed results in terms of 'open-vocabulary' slots, we divided the results of slot filling into an F1 score on 'closed-vocabulary' slots and an F1 score on 'open-vocabulary' slots as shown in Table 6 of Appendix C. We highlight some observations.

First, results from our models of both 'Joint' and 'Slot only' had better F1 scores over the previous best model with respect to 'open-vocabulary' slots for domains having them. In accordance with the results of all the slots, our model experienced more benefit in the performance of 'open-vocabulary' slots as the difficulty of the domains we defined increased. Furthermore, the first three samples of Table 7 in Appendix D and all the samples of Table 8 in Appendix D confirm that our model tends to draw conclusions by referring to the whole sentence as we intended.

Second, there was a trade-off to some degree between 'closed-vocabulary' slots and 'open-vocabulary' slots as was revealed in the ATIS corpus case. That is why the performance of our model could not exceed the state-of-the-art result in Table 3. If the distinction or boundary between slots is not clear like 'Boston late night' in a sentence "ground transportation that I could get in Boston late night", the whole can be treated as an 'open-vocabulary' slot due to a shortage of training data about the '*period_of_day*' slot corresponding to 'late night'. We have to recognize it depending only on the content of the sentence without any information about the city name, and moreover, 'boston late night' may be construed as one of city names. In addition, our model tends to open up more possibilities for various conclusions. For an example of "flight ## from jfk to lax", our model considers 'lax' as a '*city_name*' slot despite the fact that '*airport_code*' slot consists of three letters. Samples of slot filling results for the ATIS corpus are in Table 7 of Appendix D.

Third, multi-task learning of our 'Joint' model generally had a higher performance than our 'Slot only' model regarding 'open-vocabulary' slots on all datasets, including the ATIS corpus. Therefore, it is safe to say that the performance of 'open-vocabulary' slots in our approach benefits more from the joint training with intent detection and the help of sentence-level information. On the contrary, unlike the result of Liu and Lane (2016) the 'Joint' model of them had a lower performance than the 'Slot only' model of them for 'closed-vocabulary' slots as well as for 'open-vocabulary' slots.

5 Conclusion and Future Work

In this study, we presented a new modeling with RNNs and successfully dealt with 'open-vocabulary' slots. It focuses more on relatively global information within a sentence using a long-term aware attention structure and light-house positional encoding with the help of multi-task learning of a character-based language model and intent detection model. Compelling experimental results on several domains demonstrated the advantages of our model, especially for 'open-vocabulary' slots.

In this study, we did not utilize additional methods for generalization, such as variational dropout (Gal and Ghahramani, 2016), attention weights dropout, label smoothing, and dropout in decoder (Vaswani et al., 2017; Merity et al., 2017; Melis et al., 2017), and we did not search extensively hyper-parameter space and choices of optimizers extensively as in Merity et al. (2017) and Melis et al. (2017). These could enhance the performance of our RNN model. Furthermore, we will conduct not only a delicate analysis of weights of the long-term aware attention structure but also experiments using models based on architectures other than RNN and hierarchically deeper structures.

Appendix A. Experimental Details

We preprocessed the datasets as follows for all datasets. To deal with unseen or unknown inputs in the test set, we replaced all 'words' with at most three occurrences in the training data by <UNK> for comparison models and all 'characters' with at most ten occurrences in the training data also by <UNK> for our model. We also changed all sequences of numbers to sequences of '#', for example, '2017' is converted to '####'. For comparison models, we applied basic tokenizer before training, which is related to apostrophe and a combination of number and word.

For the training of our model, we used the Adadelta with 0.95 momentum related parameter and 5 gradient clipping. Parameters related to batch normalization are initialized by 1, parameters related to the hidden of RNN are initialized by orthogonal values obtained from the singular vector decomposition and the standard normal distribution with scale 1, bias parameters are initialized by zeros, and all other parameters are initialized by the standard normal distribution with scale 0.01. All dimension settings are simply 100 except 50 dimension of a slot label embedding o_i.

Hyper-parameters are 0.5 dropout, $\beta = 1$ hyper-parameter of the light-house positional encoding, 0.02 noise probability of character replacement for each characters in the inputs, 0.1 weight decay for the l2-norm of parameters learned from the training data and the language model cost, and 5 to 12 batch size according to the domains.

Appendix B. Lists of 'Open-vocabulary' Slots

Domains	'Open-vocabulary' slots
ATIS	{*airport_name, airline_name, city_name, state_name, fromloc.airport_name, fromloc.city_name, fromloc.state_name, stoploc.airport_name, stoploc.city_name, toloc.airport_name, toloc.city_name, toloc.country_name, toloc.state_name*}
Gallery	{*album_name, app_name, recipient, contact, file_name, location, poi, recipient, story_name, tag_name, title*}
Calendar	{*app_name, recipient, save_invitee, save_location, save_notes, save_title, search_keyword*}
Message	{*appname, blocked_phrase, search_keyword, text_body, recipient, contact*}

Abstract

The Business Process Management (BPM) field focuses in the coordination of labor so that organizational processes are smoothly executed in a way that products and services are properly delivered. At the same time, NLP has reached a maturity level that enables its widespread application in many contexts, thanks to publicly available frameworks. In this position paper, we show how NLP has potential in raising the benefits of BPM practices at different levels. Instead of being exhaustive, we show selected key challenges were a successful application of NLP techniques would facilitate the automation of particular tasks that nowadays require a significant effort to accomplish. Finally, we report on applications that consider both the process perspective and its enhancement through NLP.

1 Introduction

In the last decade, the maturity achieved by Natural Language Processing (NLP) technologies, together with the explosion of *big data* and *deep learning* techniques, have turned the spotlight to the possibilities offered by NLP approaches for a variety of novel applications. Many of these applications are situated in a business setting where documents and textual data is extensively used to manage production, logistics, accounting, and procurement, to give just a few examples. These application areas have in common that they relate to various business processes that are executed inside a company and beyond.

Organizing business processes in an efficient and effective manner is the overarching objective of business process management. Classically, business process management has been many concerned with the quantitative analysis of key performance dimensions such as time, cost, quality, and flexibility (Dumas et al., 2013) without taking the automatic processing of textual data too much into account. Recent research highlights the potential of NLP-based analysis techniques (Leopold, 2013; Mendling et al., 2015; Mendling et al., 2017) to support many business process management tasks in a scalable fashion.

In this paper, we describe the application of NLP techniques to BPM, where the focus rests on the processes that an organization must carry out on its daily activities, and on how are they modeled, updated, optimized, and shared with the relevant stakeholders. We believe that the NLP community has much to offer to BPM, as well as many interesting challenges to address, and we aim to display the most relevant in this paper.

The rest of the paper is structured as follows. Section 2 describes the background of our research. Section 3 provides an outline how NLP could inform business process management tasks in the future. Section 4 highlights the potential impact of NLP-supported business process management in various domains. Finally, Section 5 concludes the paper.

2 Background

In this section, we describe the essential ideas of business process management and its major design and analysis artifacts, which are process representations and event logs. Likewise, we provide a current

Proceedings of the 27th International Conference on Computational Linguistics, pages 2791–2801
Santa Fe, New Mexico, USA, August 20-26, 2018.

perspective on NLP and how it can be oriented towards improving BPM in a general setting.

2.1 Requirements of Business Process Management

Business process management is concerned with various management activities that are related to business processes (Dumas et al., 2013). In line with Mendling et al. (2017), we describe three levels of business process management as illustrated in Figure 1. The top level called multi process management is concerned with the identification of the major processes of an organization and the prioritization of these. The middle level is concerned with the management of a single process along the classical BPM lifecycle (Dumas et al., 2013) including the steps of discovery, analysis, redesign, implementation and controlling. The level of process instance management deals with planning the tasks of a process, executing them, monitoring them, and potentially adapting the instance if required. All the three layers make use of business process models and event data.

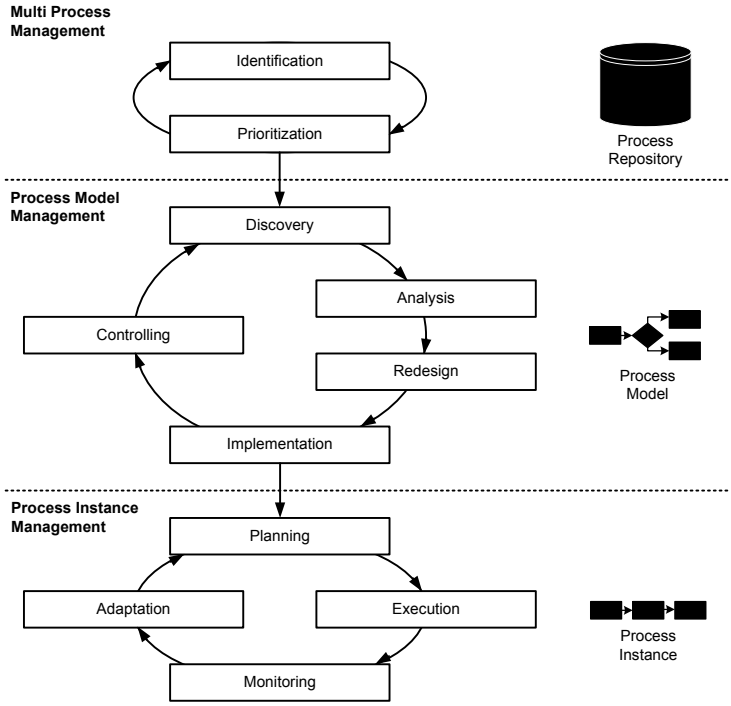

Figure 1: Three Levels of Business Process Management (taken from (Mendling et al., 2017)).

2.2 Process Representations

A variety of representation formats can be used to capture process information in informational artifacts (Wolter and Meinel, 2010), including process models (Davies et al., 2006), natural language descriptions (Phalp et al., 2007), spreadsheets (Krumnow and Decker, 2010), and checklists (Reijers et al., 2017). The representation format used to provide process information to users should be well-suited for its particular purpose, in two ways: A format should convey its informational content in a useful manner and the intended users should be able to appropriately understand the received format (van der Aa, 2018).

Representation formats emphasize different aspects of business processes. This means that the choice for a certain representation format depends on the intended focus of an informational artifact. For instance, *natural language text* can be very useful to provide process participants with detailed insights on how to perform complex tasks (Baier and Mendling, 2013). However, for a process participant who needs to be sure that all necessary steps are performed, a *checklist* might be more useful. This later format could be more suitable because it emphasizes the information that is of primary importance for that purpose. Furthermore, process models have been found to be better suited to express complex execution logic of a process in a more comprehensive manner than natural language (Mendling, 2008, p.23).

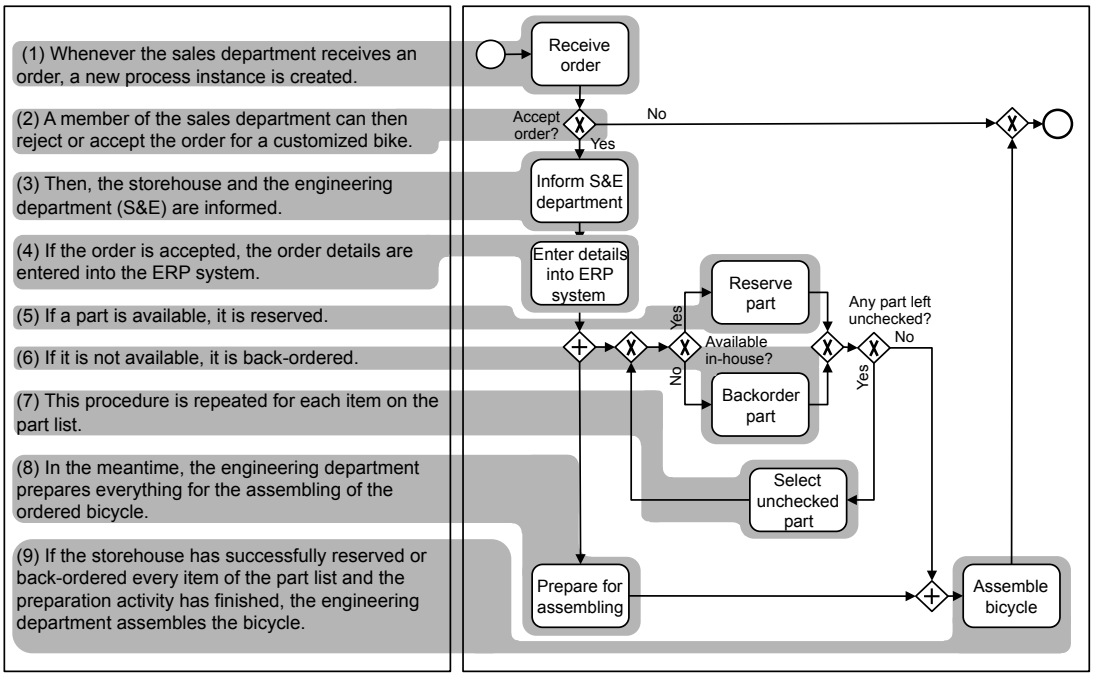

Figure 2: A textual and a model-based description of a bicycle manufacturing process.

It is also important that users of an informational artifact are able to work well with the employed representation format. The ability of users to do so can depend on their familiarity and preferences with respect to different formats. Research by Figl and Recker (2016) shows that people prefer different process representation formats depending on the application purpose and on the *cognitive style* of the user. For example, some participants were found to prefer textual descriptions over process models, whereas others preferred models over text for the same purpose. The influence of user preferences on the choice for model or text-based process representations is also recognized by Recker et al. (2012) and Chakraborty et al. (2010).

Figure 2 shows an example of two different process representations, namely a process model and a textual process description. On the left- hand side, we observe a textual description, which comprises nine sentences. On the right-hand side, a corresponding model-based description can be seen, modeled using the Business Process Model and Notation (BPMN). The model contains eight activities, which are depicted using boxes with rounded edges. The diamond shapes that contain a plus symbol indicate concurrent streams of action; the diamond shapes containing a cross represent decision points. The gray shades suggest correspondences between the sentences and the activities of the process model.

2.3 Event Data for the Footprints of Process Executions

Information systems supporting processes in organizations enable the persistent storage of process executions, in large log files denoted *event logs*. Event logs can be seen as a tabular representation of all the necessary events for a process execution (denoted as *case*) to be accomplished. Table 1 provides an excerpt of an event log for the bicycle manufacturing process used in this paper. Three important elements (columns in the table) that identify an event (row) in an event log are: i) the case ID (to identify the process instance or case executed), ii) the timestamp (to identify when the event was executed), and iii) the activity name (to identify the task performed). Extra information in form of additional columns may exist, to provide contextual information to the execution of events. For instance, in the table three cases appear: case 1 denotes an order that was rejected, case 2 denotes an order that was completely executed till the bicycle assembly, and case 3 is ongoing.

In contrast to the process representations described in the previous section, event logs describe the reality, i.e., the recorded events witnessing all process instances stored in the information system. We will refer to event logs in this paper in particular parts, to highlight the importance to relate observed and

Event	Case ID	Activity	Timestamp	Dept.	Add. Data
1	1	`Receive Order`	10-04-2015 9:08am	Sales	Reject
2	2	`Receive Order`	10-04-2015 10:03am	Sales	Accept
3	2	`Inform S&E dept.`	10-04-2015 10:05am	Sales	–
4	2	`Enter details ERP`	10-04-2015 10:09am	Sales	–
5	2	`Prepare for assemb.`	10-04-2015 10:10am	Eng.	–

8	2	`Backorder part`	10-04-2015 12:06am	Storeh.	Breaks
9	3	`Receive Order`	10-04-2015 13:18am	Sales	Accept
10	2	`Assemble bycicle`	11-04-2015 10:03am	Eng.	–

Table 1: Part of an event log for the bicycle manufacturing process.

modeled behavior.

2.4 NLP Capabilities and Frameworks

There are several existing NLP technologies that can be more or less straightforwardly applied to BPM. As illustrated in Fig. 2, a textual description of a bussiness process is a text where several actors are mentioned, and their actions and interactions described. Thus, out-of-the-box analyzers can be used to structure the content of the text. Tools such as Stanford Core (Manning et al., 2014), FreeLing (Padró and Stanilovsky, 2012), Apache OpenNLP[1], or NLTK (Bird et al., 2009) can be used to extract predicates and involved actors via SRL, perform WSD to identify domain objects that may be mentioned using different words, solve coreferences to decide which of the mentioned actors correspond to the same entity, decide which order the described actions must follow or whether there are choices or loops, etc.

However, existing analysis pipelines are still below optimal performance, specially in the more semantic tasks (WSD, coreference, SRL, temporal relation extraction, etc.) and on an unrestricted domain (process descriptions may report organization processes in a huge range of sectors –health, education, banking, manufacturing, etc).

So, several challenges for NLP researchers can be found in the application to BPM:

- Improvement of the performance of individual analyzers, specially at the semantic/pragmatic level (e.g. in Figure 2, the mentions *the sales department* in sentence (1), and *a member of the sales department* in sentence (2) are actually referring to the same actor in the process, but a coreference system would consider them two different entities).
- Domain adaptation methods to tune generic NLP processors to deal with process descriptions in a specific organization or sector. This may require the creation/acquisition of tailored ontologies that help specifying with the right terms important parts of the process and relations among these relevant domain concepts.
- Definition of new tasks, such as the detection of exclusivity, parallelism/concurrency, decision points, or iteration of tasks described in the text (e.g. the phrase *this procedure* or the marker *in the meantime* in sentences (7) and (8) in Figure 2 are ambiguous with respect their antecedent, and each interpretation leads to different formal models).
- Use of world knowledge to improve the results (often some steps or relations among tasks are omitted because the reader is assumed to be able to understand it using common sense or domain knowledge, such as that a payment happens always after an invoice is emitted, or that a bicycle can not be assembled until all required parts have been obtained).

[1] `https://opennlp.apache.org`

- Information extraction from event logs. Among others, interesting directions is the elicitation through NLP techniques of process steps for loosely specified processes, projecting event logs for events at a given granularity level, etc.

3 Expanding BPM Capabilities through NLP

In this section, we provide interesting research directions based on incorporating/extending NLP capabilities in the three levels described in Fig. 1.

3.1 Multi-Process Management

Multi process management is concerned with the identification of the major business processes of a company and the prioritization of these processes. The overall landscape of business processes is often represented as a process architecture, which is stored in a business process repository. Large multinational corporations often maintain several thousand process models in such repositories.

Prior research on multi process management has focused on repository management, building on techniques for determining process similarity (Dijkman et al., 2011), automatically matching business process models (Weidlich et al., 2010), and other querying techniques (Leopold et al., 2017). Several concepts have been proposed on top including automatic refactoring (Weber et al., 2011) including harmonization of terminology (Pittke et al., 2015), automatic service derivation (Leopold et al., 2015), semantic search (Thomas and Fellmann, 2009) and merging business process models (Rosa et al., 2013).

Several challenges remain in this area including the following (Mendling et al., 2015). First, the availability of a business process repository bears the potential to discover an overarching formal ontology that captures the full spectrum of operations of a company. Second, content captured in the repository might be automatically categorized, for example with respect to documentation standards such as ISO:9001. Such tasks require the application and adaptation of existing NLP techniques in this specific context.

3.2 Process Management

Several important challenges need to be tackled so that tasks in the process model management stage of Fig. 1 such as discovery, analysis, redesigning and controlling of processes are excelled at organizations. In this section we focus on providing examples of key enablers for tackling these challenges.

The discovery of processes concerns the identification of the main processes in an organization, and the corresponding elicitation into a (graphical) notation such as BPMN, which facilitates the communication between the stakeholders involved in a process. In practice, this phase is often implemented using workshop meetings, requiring quite significant efforts to materialize a process model from the conversations arising in these meetings. An alternative is the use of process mining techniques, which enable, for instance, the automatic discovery of process models from event logs (van der Aalst, 2016).

NLP techniques can be applied at very different granularities to boost the discovery of precise process model descriptions of a process. Among the available techniques, we highlight the most disruptive ones:

- *Transform textual descriptions into process models*: The creation of process models consumes up to 60% of the time spent on process management projects. This is a paradox, because there are often extensive textual process documentations available in organizations. Therefore, automatically transforming textual process descriptions to process models represents a particularly attractive use case. Several techniques have been developed for this purpose (Friedrich et al., 2011). These use tailored NLP techniques in order to identify actions, e.g. "*The sales department receives an order*", and their inter-relations, e.g. "*If the order is accepted, the order details are entered into the system*. These extracted components represent the foundation for the generation of a process model from a text. However, a number of challenges still remain for this endeavor. For instance, techniques must be able to identify sentences that provide contextual information, rather than describe process steps. Furthermore, the inherent ambiguity of natural language can lead to different interpretations regarding the process that is described (Van der Aa et al., 2016).

- *Translate process models*: Sometimes the same process (e.g., the admission process to enroll in a university) is defined multiple times (e.g., several universities in several countries, or a worldwide

company that applies a given process across several countries). In these contexts, it is crucial to have multilingual support for translating a given process model description (in any form) into a target language. For the case of process model graphical descriptions (e.g., BPMN), translation of individual model elements may be sufficient to obtain a translated description with a certain quality, since the structure of the process is retained. In contrast, translating textual descriptions of a process may become more challenging, due to the particularities each language has in describing certain constructs.

- *Text Annotation and Inference*: In the scope of the two previous use cases (from text to process models, process model translation), the difficulty of generating the output would be significantly alleviated if the text was correctly annotated, reducing the noise introduced by automatic NLP tools. One can envision that, in the narrow scope of the description of a process one could define a limited set of template annotations that address particular perspectives (control-flow, roles, data, among others) which can help a user to (partially) annotate a textual description of a process. Nowadays, there exist advanced tools for text annotation such as Brat (Stenetorp et al., 2012). From annotated textual descriptions of a process model (e.g., control-flow annotations establishing relations between two sentences), inferences can elicit new relations that can be used to have a more precise and refined descriptions (e.g., transitive closure of the relations). The same annotations could be used as training data to improve or adapt automatic languages analyzers tuned to this particular tasks.

The analysis phase is oriented towards finding weakness of current process model candidates. This phase can also be significantly improved by a tailored used of NLP techniques in particular situations. We describe here some examples of challenges to face in order to materialize such improvements:

- *Verify semantic correctness and completeness*: The semantic quality of process models is crucial to the proper understanding of business processes. A number of techniques aim to verify this quality in an automated manner. These techniques achieve this, for example, by detecting and/or correcting inconsistent use of terminology (Koschmider and Blanchard, 2007) or violations of labeling conventions (Becker et al., 2009; Leopold et al., 2013a; Van der Vos et al., 1997). Others aim to improve modeling quality by detecting common modeling errors (Gruhn and Laue, 2011) or ambiguously labeled activities (Pittke et al., 2015; Pittke et al., 2014).

- *Calculate consistency between process model and text*: As mentioned before, keeping different process descriptions helps improving the knowledge about processes across an organization. However, as processes evolve continuously, it is necessary to detect inconsistencies between process descriptions in order to ensure the expectations for process outcomes are the same for every actor (van der Aa et al., 2017). The challenge here is to find correspondences between sentences in the text and elements in the process model, and warn in case important parts are not mapped. This requires a respective NLP analysis in both process descriptions and computation of similarities while considering the different discourse level, ambiguities, anaphora/coreference in the text, among others. Fig. 2 shows an example of a possible mapping between the textual and the model description of the process.

In the redesign phase, issues detected in the previous phase are amended by a refactoring of the process model, so that the to-be model is produced. NLP-based techniques can also be oriented towards this goal:

- *Fine-tuning of semantic abstraction levels*: Larger sets of process models, so-called, process model collections, are typically hierarchically organized. This means, that process models on higher level provide a rather course-grained view of a process, while process model on a lower level provide a more detailed view. One of the major challenges in this context is to make sure that process models on the same level in the hierarchy also have a comparable level of abstraction. First works that addressed this problem have used rather simple linguistic measures, such as the specificity of individual words, to determine whether two process models provide a comparable level of abstraction (Leopold et al., 2013b). However, a solution that assesses the abstraction level based on the conveyed semantics is still missing.

- *Process description semantic auto-completion*: Process descriptions may be semantically incomplete. Ideally, a process description should be semantically complete before it is used. There are different situations where a process description could be auto-completed. For instance, imagine that the second sentence in the process description of Fig. 2 is: *A member of the sales department must check the order for a customized bike and decide its acceptance*. Semantically, this sentence suggests that there is also the possibility to reject the order of a bike. However, it is not explicit in the textual description what to do if the result of the check is negative. Warning about this incompleteness of the textual description may help improving it, by reducing its ambiguity. A similar situation may occur in the graphical description in the right, i.e., if the arc labeled *No* (and the target gateway) are missing in the process model description in Fig. 2. Some techniques are available for this task (Hornung et al., 2007), but there are still several challenges, mainly on the automation of the problem.

In the controlling phase, apart from the traditional monitoring techniques that focus on checking the performance and conformance requirements, Natural Language Generation techniques can be applied to keep different descriptions of the process available:

- *Transform process model to textual descriptions*: Not all stakeholders are able to understand a process model descriptions like the one shown at the right of Fig. 2. However, virtually everyone can understand the textual description shown at the left. Recent studies on process understandability advocate for the use of several descriptions in order to boost the understanding (Ottensooser et al., 2012). Hence, generating textual descriptions of processes that complement formal ones helps ensuring different stakeholders will have the same expectations for a certain process (Leopold et al., 2014), and NLG is a good fit for this task. There are two main challenges associated with this task. First, we need to properly infer which words from the short process model labels refer to verbs and which words refer to nouns, and due to the shortness of the labels and the lack of a proper sentences structure (e.g., consider the label *Order reservation*) this is a non-trivial task which may require domain knowledge. Second, parallel behavior as well as choices from the process model have to be communicated using a sequence of sentences, without compromising the ability of the reader to comprehend the process semantics.

3.3 Instance Management

Managing the execution of a single process instance (e.g., a particular order for manufacturing a bicycle in the process of Fig. 2, e.g., case 2 of Table 1) is the primary objective of the bottom level of BPM.

There exists a significant amount of research from the last years about *conversational systems* (Mott et al., 2004), ultimately implemented as conversational bots or chatbots. Now let us assume that conversational systems are trained to support the execution of business processes. The ultimate goal would be to allow stakeholders of the process to navigate through it by means of querying a dialog system. For instance, for the process described in Fig. 2, a new worker may have doubts on what to do after a new order is received. A tailored conversation system may come into rescue, by first describing her what are the formal requirements for an order to be accepted. Then, when these requirements have been evaluated by the worker, it will communicate back to the dialogue system the outcome of the evaluation (accepted or not), and the dialogue system will provide the next step correspondingly (in case of the order being accepted, to inform the engineering department; in case of the order being rejected, finish the process). The challenge here is how to build useful conversational systems when a description of the process is available.

In general, BPM tailored conversational systems may incorporate important NLP features like semantic understanding, context resolution, NLG, among others.

4 Applications

4.1 Education

The possibility of transforming a formal process description (e.g., a BPMN like the one on the right in Fig. 2) into a text (Leopold et al., 2014), or vice-versa, as well as the ability to align a textual and a formal

description of a process (Sànchez-Ferreres et al., 2017) opens the door to a range of educational applications for modeling students (e.g. Computer Science or Business students that need to learn to formalize a process): For instance, the model created by a student can be automatically compared to the text given as statement, not only for automatic grading, but also to provide feedback regarding missing/redundant tasks or inconsistent paths in the control flow. Also, an initial model automatically generated from text can be given to the student to complete or correct.

4.2 Troubleshooting

An important application domain for ensuring the correct execution of a process in a organization is through tailored dialogue systems. An example of this is chatbot-aided troubleshooting (Acomb et al., 2007), where artificial agents are used to complement human operators in contact centers. So far, knowledge representation in such chatbots comprises several components like natural language understanding and/or generation, together with a planner that encompasses the possible reactions to provide (Thorne, 2017). The incorporation of process descriptions may help into attaining a more precise dialogue system, so that the planning of the dialogue is done under the constraints of the process, and that the agent can better assist the human in following the appropriate steps.

4.3 Regulations

Non-compliance represents a risk for many organizations. According to a recent study by Thomson Reuters, non-compliance may even represent a possible cause of bankruptcy, also for the so-called "behemoths" in the financial sector (English and Hammond, 2014). Recognizing the risk that is associated with non-compliance, organizations in a wide range of domains are stepping up their spending in order to ensure their compliance with laws, regulations, and procedures. In this context, automated compliance checking techniques that consider the process model and the event log play a crucial role thanks to their ability to automatically identify compliance violations (Accorsi and Stocker, 2012; Van der Aalst et al., 2010). For this reason, numerous approaches have been developed to perform this task (Van der Aalst et al., 2012; Weidlich et al., 2011; Awad et al., 2008). While the majority of such techniques require the allowed process behavior to be specified in formal models, such as process models or business rules, recent advances of NLP in the context of BPM overcome this restriction. In particular, a technique (van der Aa et al., 2018) has been developed that can perform compliance checks on the basis of textual process documentation. This technique employs probabilistic methods in order to deal with the inherent ambiguity of natural language, which can cause uncertainty about the truly allowed process behavior specified in a text.

4.4 Healthcare

Electronic health records (ERHs) contain detailed information of patients. They can and have been used for monitoring adherence to clinical guidelines. There has been several studies on how using these ERHs can lead to improving the management of patients in the healthcare domain. NLP tooling related to ERH processing can also provide a significant step towards improving the efficiency in the treatment of certain diseases (Garvin et al., 2018).

Both clinical guidelines and ERHs can be the source for elicitating formal process descriptions, using a combination of the techniques listed in the Sect. 3.2. Moreover, recent techniques for comparing process models with event logs stored in Healthcare Information Systems (HIS) have proven to be successful in improving the analysis of patients (Mans et al., 2015). We therefore envision the connection of both disciplines: on the one hand, NLP-based techniques to formalize into models ERHs or clinical guidelines, that can be then used to accurately analyze patients with the event data stored in a HIS.

5 Conclusions

In this paper, we have highlighted research directions and prospective applications for NLP in the area of business process management. A more intensive exchange between the two fields has the potential to significantly enhance the tool set of business process management and to fruitfully provide both practical challenges and industrial application scenarios to the NLP community.

Abstract

The rapid growth of documents across the web has necessitated finding means of discarding redundant documents and retaining novel ones. Capturing redundancy is challenging as it may involve investigating at a deep semantic level. Techniques for detecting such semantic redundancy at the document level are scarce. In this work we propose a deep Convolutional Neural Network (CNN) based model to classify a document as novel or redundant with respect to a set of relevant documents already seen by the system. The system is simple and does not require manual feature engineering. Our novel scheme encodes relevant and relative information from both source and target texts to generate an intermediate representation for which we coin the name Relative Document Vector (RDV). The proposed method outperforms the existing benchmark on two document-level novelty detection datasets by a margin of $\sim$5% in terms of accuracy. We further demonstrate the effectiveness of our approach on a standard paraphrase detection dataset where the paraphrased passages closely resembles semantically redundant documents.

1 Introduction

Document-level novelty detection implies the categorization of a document as *novel* if it contains sufficient *new* information with respect to whatever *relevant* is previously known or seen. Existing literature on novelty detection from texts mostly followed the detection of novelty at the sentence level, i.e., to extract the sentences that carry new information with respect to some relevant source texts (c.f. Section 2). *The current work is aimed at automatically classifying an incoming document as* ***novel*** *or* ***non-novel*** *on the basis of documents already seen by the system*. We view the problem as a two-class classification problem in machine learning with the judgment that whether an incoming document bears sufficiently new information to be labeled as novel with respect to a set of source documents. The source document set could be seen as the memory of the reader which stores known information. Document-level novelty detection is a crucial problem and finds application in diverse domains of language processing such as information retrieval, document summarization, predicting impact of scholarly articles, etc. It is a complex problem that comprehends *lexical, syntactic, semantic and pragmatic* levels of texts in conjunction with certain characteristics like *relevance, diversity, relativity, and temporality* (Ghosal et al., 2018). Literature methods for novelty detection based on lexical similarity, divergence features, and information retrieval measures, although proved effective for sentence level but could not address the document-level comprehension needs. Our understanding of the problem led us to an assertion that a deep neural network might be able to extract the text subtleties involved in understanding a document's *novelty*. To the best of our knowledge this is the very first attempt to address document-level novelty detection without the involvement of any hand-crafted features. Our approach achieves significant performance improvement over the existing measures on novelty detection from texts on three different datasets, thus establishing our contention.

Proceedings of the 27th International Conference on Computational Linguistics, pages 2802–2813
Santa Fe, New Mexico, USA, August 20-26, 2018.

1.1 Motivation

Motivation behind the current work stems from *the eternal quest of the inquisitive mind* : **new information**.

- The exponential dump of redundant information in documents across the web, which does not add anything new to the knowledge, yet consumes valuable space and time (of readers) accentuates identifying novel documents and discarding non-novel documents in the current context.
- Plagiarism detection in scholarly articles at the semantic level is another ambitious vision that demands research attention. Methods for document-level novelty detection can aid in the investigation.
- Our survey reveals that in spite of having potential in various applications, document-level novelty detection has not garnered deserved attention from the community. Also it was intriguing to investigate how deep neural architectures could distinguish between novel and non-novel texts.

1.2 Contributions

The principal offerings of the present work could be outlined as :

1. *Proposing an effective deep learning strategy for document-level novelty detection: a first of its kind*
2. *Presenting an effective semantic vector representation to model information from both source and target documents.*

2 Related Works

Research in novelty mining could be traced back to the Topic Detection and Tracking (TDT) (Wayne, 1997) evaluation campaigns where the concern was to detect new events or First Story Detection (FSD) with respect to online news streams. Techniques mostly involved grouping the news stories into clusters and then measuring the belongingness of an incoming story to any of the clusters based on some preset similarity threshold. Some notable contributions from TDT are (Allan et al., 1998; Yang et al., 2002; Allan et al., 2000; Yang et al., 1998).

The task gained prominence in the novelty tracks of Text Retrieval Conferences (TREC) from 2002 to 2004 (Soboroff and Harman, 2005; Harman, 2002; Soboroff and Harman, 2003; Clarke et al., 2004) although the focus was sentence-level novelty detection. The goal of these tracks was to highlight the relevant sentences that contain novel information, given a topic and an ordered list of relevant documents. Some interesting works in TREC were based on the sets of terms (Zhang et al., 2003a; Zhang et al., 2003b), term translations (Collins-Thompson et al., 2002), Principal Component Analysis (PCA) vectors (Ru et al., 2004), Support Vector Machine (SVM) classification (Tomiyama et al., 2004) etc. Similar works relied on named entities (Gabrilovich et al., 2004; Li and Croft, 2005; Zhang and Tsai, 2009), language models (Zhang et al., 2002; Allan et al., 2003), contexts (Schiffman and McKeown, 2005), etc. Next came the novelty sub tracks of Recognizing Textual Entailment-Text Analytics Conference (RTE-TAC) 6 and 7 (Bentivogli et al., 2011) where Textual Entailment was viewed as one close neighbor to sentence level novelty detection.

At the document level an interesting work was carried out by (Yang et al., 2002) via topical classification of on-line document streams and then detecting novelty of documents in each topic exploiting the named entities. Another work by (Zhang et al., 2002) viewed novelty as an opposite characteristic to redundancy and proposed a set of five redundancy measures ranging from the set difference, geometric mean, distributional similarity in order to calculate the novelty of an incoming document with respect to a set of memorized documents. They also presented the first publicly available Associated Press-Wall Street Journal (APWSJ) news dataset for document level novelty detection. (Tsai and Zhang, 2011) applied a document to sentence level framework to calculate the novelty of each sentence of a document which aggregates to detect novelty of the entire document. (Karkali et al., 2013) computed novelty score based on the inverse document frequency scoring function. Another work by (Verheij et al., 2012) presents a comparison study of different novelty detection methods evaluated on news articles

where language model based methods perform better than the cosine similarity based ones. More recently (Dasgupta and Dey, 2016) conducted experiments with information entropy measure to calculate innovativeness of a document. Each of these works evaluated their methods on separate datasets and to the best of our knowledge except APWSJ none of these is publicly available.

Novelty detection is also studied in works related to diversity in information retrieval literature. Idea is to retrieve relevant yet diverse documents in response to user query. The work on Maximal Marginal Relevance (Carbonell and Goldstein, 1998) was the first to explore diversity and relevance for novelty. Some other notable works along this line are (Chandar and Carterette, 2013; Clarke et al., 2011; Clarke et al., 2008).

The work that we present here significantly differs from the existing literature as we provide a deep neural network solution to the problem which does not depend on hand crafted features, and learns the notion of novelty and non-novelty from the data itself.

3 Document Novelty : Challenges and Observations

Deciding the novelty of an entire document or what amount of new information makes a document appear novel are very challenging tasks. Even more challenging since the task inherently exhibits several text characteristics (*relevance, diversity, relativity, temporality*) to be addressed simultaneously. A novel document should be *relevant* to context, should exhibit *diversity* in information content, should have *relatively* more new relevant yet diverse information and is usually deemed as a *temporal* update over the existing knowledge. The difficulty associated with the task is further exaggerated when there are a large number of history documents against which a target document is to be judged for novelty. We propose a possible solution that could address most of these challenges and also reduce the need of manual feature engineering to an extent. We analyze the available benchmark sentence-level novelty detection datasets like TREC/RTE-TAC and come up with certain observations :
(1) Named Entities (NEs) play a vital role in adjudging the *relevance* of a test document against its source document(s).
(2) Semantic features play a crucial role in identifying *redundancy* or *non-novelty*. Lexical level features (such as *n-gram* match) do well when there is a word-by-word match or when two texts share a fair amount of tokens. But it fails in cases where surface form is very different yet conveys the same meaning (*paraphrases*).
(3) Lexical features are sometimes efficient to detect document level new information content. For e.g., if the source document(s) consists of information regarding the facts of a certain accident and the target document reports the police investigation carried out afterwards-although the two documents would share a fair amount of NEs, yet would differ in contextual information content which could be captured to a large extent via lexical level features.

4 Dataset Description

Since our focus is on document-level novelty detection we consider only document level datasets. Existing benchmark datasets on sentence-level novelty detection are not suited to our experimental framework. We also evaluate our approach on the standard Webis Crowd Paraphrase Corpus (Webis CPC) (Burrows et al., 2013) whose inherent semantic richness sets a competitive benchmark for our method.

4.1 APWSJ Corpus

The APWSJ data consists of news articles from Associated Press (AP) and Wall Street Journal (WSJ) corpus covering the same time period (1988 to 1990) and many on the same topics, guaranteeing some redundancy in the document stream. Similar to (Zhang et al., 2002) we use the documents within the designated 33 topics[1] with redundancy judgments by the assessors. The dataset was meant to filter superfluous documents in a retrieval scenario and deliver only the documents having *redundancy score* below a calculated threshold. Documents for each topic were delivered in a chronological manner and

[1] http://www.cs.cmu.edu/ yiz/research/NoveltyData/

the assessors provided two degrees of judgments on the non-novel documents: *absolute redundant* or *somewhat redundant* based on prior documents. The unmarked documents were treated as *novel.*

4.2 Webis CPC

The Webis Crowd Paraphrase Corpus 2011 (Webis-CPC-11) contains 7,859 candidate paraphrases obtained from the Mechanical Turk crowdsourcing. The corpus[2] is made up of 4,067 accepted paraphrases, 3,792 rejected non-paraphrases, and the original texts. For our experiment we assume the original texts as the source document and the corresponding candidate paraphrase/non-paraphrase as the target document. We hypothesize that a paraphrased document would not contain any new information and hence could be treated as *non-novel* whereas a non-paraphrased candidate could be taken as *novel*. Basically we seek to investigate the viability of our proposed method to discover the semantically redundant documents (paraphrases) from this dataset.

4.3 TAP-DLND 1.0

We experiment with this recent benchmark resource for document-level novelty detection (DLND) (Ghosal et al., 2018). The dataset[3] is balanced and consists of 2,736 novel documents and 2,704 non-novel documents. For each novel/non-novel document there are three source documents against which the target document is annotated. The state of *novelty* for each target document is to be measured against those source documents i.e. once the system has already seen the designated source documents for a particular event, it is to judge whether an incoming on-topic document is novel or not. The semantic nature of the dataset makes it an ideal candidate for our experiments.

5 Proposed Model

Having an acceptable benchmark dataset avaialable at our end, instead of handcrafting the similarity/divergence based features,we try to learn feature representations from a target document with respect to the source document(s) using a Convolutional Neural Network (CNN). Our proposed model is based on a recent sentence embedding paradigm proposed by (Conneau et al., 2017). We leverage their idea and create a representation of the *relevant* target document *relative* to the designated source document(s) and call it as the *Relative Document Vector (RDV)*[4]. We then train a Convolutional Neural Network (CNN) with the RDV of the target documents in the similar line of (Kim, 2014), and finally classify a document as *novel* or *non-novel* with respect to its source documents (Figure 1). Although there are document embedding models available, our method is specifically tailored to address the *relativity* and *diversity* criteria which is fundamental to the definition of *novelty*. Here T_1 is the *target* document whose state of *novelty* is to be determined against the source document(s) $S_1, S_2, ...S_M$ i.e. to say the objective is to automatically figure out whether T_1 is *novel* or not once the machine has already seen/scanned $S_1, S_2, ...S_M$. Our model assumes that the documents are relevant to a context. We reserve *Temporality* to be explored in a later work.

5.1 Embedding and Sentence Encoder

The task of *Novelty Detection* requires high-level understanding and reasoning about semantic relationships within texts. Textual Entailment or Natural Language Inference is one such task which exhibits such complex semantic interactions. Following from (Conneau et al., 2017) we therefore employ a sentence encoder based on a bi-directional Long Short Term Memory (LSTM) architecture with max pooling, trained on the large-scale Stanford Natural Language Inference (SNLI) dataset (Bowman et al., 2015). SNLI entries supposedly captures rich semantic associations between the text pairs (entailment/inference relationships between premise and hypothesis). The output of our sentence encoder is

[2]https://www.uni-weimar.de/en/media/chairs/computer-science-department/webis/data/corpus

[3]http://www.iitp.ac.in/ ai-nlp-ml/resources.html

[4]We call our document vector *relative*, as we desire to encode the relative *new* information of a target document w.r.t. its relevant source document(s)

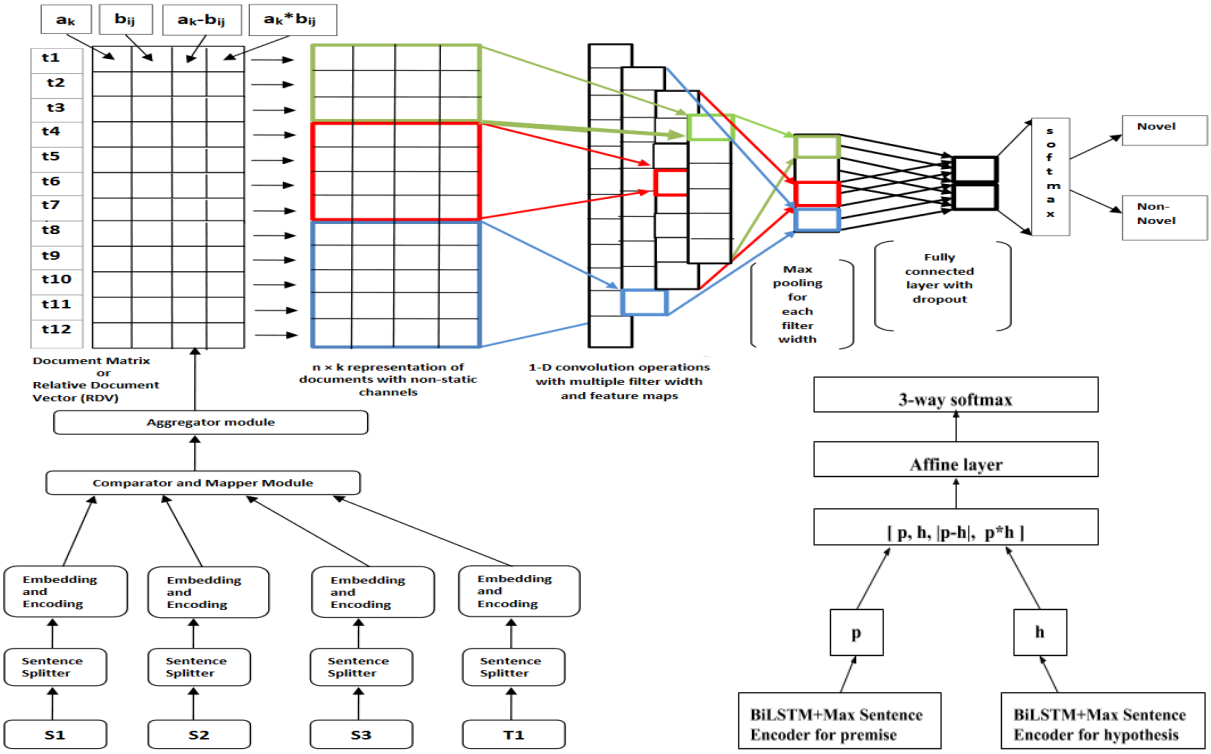

Figure 1: RDV-CNN framework for Novelty Detection. Generic SNLI Training (Conneau et al., 2017). The sentence encoder is trained on SNLI. The RDV-CNN is trained with the respective novelty datasets.

a fixed sized (2048 dimension) sentence embedding of each of the sentences[5] of the input document (source or target).

5.1.1 BiLSTM with max pooling

For a sequence of T words $\{w_t\}_{t-1,...,T}$, a bidirectional LSTM computes a set of T vectors $\{h_t\}_t$. For $t \in [1, ..., T]$, h_t, is the concatenation of a forward LSTM and a backward LSTM that read the sentences in two opposite directions. We combine the varying number of $\{h_t\}_t$ to form a fixed-size vector by selecting the maximum value over each dimension of the hidden units (max pooling).

$$\overrightarrow{h_t} = \overrightarrow{LSTM}_t(w_1, ..., w_T)$$

$$\overleftarrow{h_t} = \overleftarrow{LSTM}_t(w_1, ..., w_T)$$

$$h_t = [\overrightarrow{h_t}, \overleftarrow{h_t}]$$

5.1.2 Training the sentence encoder

We follow the generic SNLI training scheme of (Conneau et al., 2017). The semantic nature of SNLI corpus makes it a good candidate for learning universal sentence embeddings in a supervised way to capture universally useful features. The training[6] on SNLI is done using the shared sentence encoder that outputs a representation for the premise p and hypothesis h (Figure 1). The representations are further concatenated as:

$$[p, h, |p - h|, p * h]$$

to form a resulting vector, which captures information from both the premise and hypothesis, and is fed into a 3-class classifier[7] (multi-layer perceptron with 1 hidden layer of 512 units) consisting of multiple fully-connected layers culminating into a softmax layer.

[5] split using NLTK

[6] SGD with a learning rate of 0.1 and a weight decay of 0.99 are used. At each epoch, the learning rate is divided by 5 if the development accuracy decreases. Training is done with a mini-batch size of 64. GloVe vectors trained on Common Crawl 840B (https://nlp.stanford.edu/projects/glove/) with 300 dimensions are used as fixed word embeddings.

[7] SNLI has 3 classes of sentence-pair judgments: neutral, contradiction, entailment

5.2 Comparator Module

This module finds the closest sentence in the source document(s) with respect to each of the target sentences. Thus each sentence (t_k) in a target document (T) is mapped to its nearest source sentence (s_{ij}) where i denotes the source document and j signifies the sentence position within that document. The encoder module outputs a fixed-length vector representation a_k for the target sentence t_k and b_{ij} for any source sentence s_{ij}. We define closeness as the maximum of cosine similarity between the vectors a_k and b_{ij}.

$$s_{cosine}(\overrightarrow{a_k}, \overrightarrow{b_{ij}}) = \frac{\overrightarrow{a_k}.\overrightarrow{b_{ij}}}{|\overrightarrow{a_k}||\overrightarrow{b_{ij}}|}$$

Thus we have a mapping relationship for each sentence in the target document with one of the source sentences.

$$b_{ij} \rightarrow a_k$$

where a_k has the max. cosine similarity with b_{ij}.

5.3 Aggregator module

This module aggregates the mappings produced in the comparator module to generate a document matrix. The mapping of a target sentence t_k to its closest source sentence s_{ij} is rendered by constructing a feature vector that captures the relation between the source and the target. This feature vector consists of the concatenation of the two sentence embeddings corresponding to t_k and s_{ij}, their absolute element-wise difference, and their element-wise product (Mou et al., 2016). The first heuristic follows the most standard procedure of the Siamese architecture, while the latter two are certain measures of "similarity" or "closeness". Thus, the *Relative Sentence Vector* (RSV) corresponding to a target sentence t_k is represented as :

$$RSV_k = [a_k, b_{ij}, |a_k - b_{ij}|, a_k * b_{ij}]$$

where comma (,) refers to the column vector concatenation. This representation is inspired from the word embedding studies (Mikolov et al., 2013) where the linear offset of vectors is seen to capture semantic relationships between the two words. (Mou et al., 2016) successfully leveraged this idea for modeling sentence-pair relationships which we alleviate to model documents. Thus for each target sentence t_k we compute the RSV and aggregate them to form the *Relative Document Vector* (RDV) of target document T_j with respect to the source documents(s) S_i. Aggregation is realized as a *slot filling task* to shape the document matrix[8] or RDV of dimension N X $4D$ where N is the number of sentences in a target document (padded when necessary) and D is the sentence embedding dimension produced by the encoder module. *Our rationale behind the RDV-CNN is: The operators:* ***absolute element-wise difference*** *and* ***product*** *would result in such a vector composition for* ***non-novel*** *sentences which would manifest '****closeness****' whereas for* ***novel*** *sentences would manifest '****diversity****'; the aggregation of which would aid in the interpretation of document level* ***novelty*** *or* ***redundancy*** *by a deep neural network. We chose CNN due to its inherent ability to automatically extract features from distinct representations.*

5.4 CNN module

The document matrix or the RDV now becomes the input to a CNN[9] for training and subsequent classification of a target document as *novel* or *non-novel* with respect to its source document(s). The CNN component is similar to the one as used in (Kim, 2014) for sentence classification. The notable difference is in the usage of word embedding. Instead of *word2vec* embeddings we use here the relative sentence embeddings of dimension $4D$ (k^{th} sentence in the document is represented by an embedding vector $RSV_k \in \mathbb{R}^D$). We experiment with the NON-STATICTEXT channel variant (embeddings gets updated during training) of the CNN.

For each possible input channel, a given document is transformed into a tensor of fixed length N (padded

[8] each row in the document matrix is one *relative sentence vector* corresponding to each target sentence t_k

[9] *tanh* as the activation function, filter windows (h) of 3,4,5 with 100 feature maps each, dropout rate (p) of 0.5 on the penultimate layer with a constraint on l_2-norms of the weight vectors. $ADADELTA$ (Zeiler, 2012) optimizer with a learning rate set to 0.1. Training via Stochastic Gradient Descent (SGD). Input batch size : 50, number of training iterations (epochs): 250. 10% of the training data for validation.

with *zero-tensors* wherever necessary to tackle variable sentence lengths) by concatenating the relative sentence embeddings.

$$RSV_{1:N} = RSV_1 \oplus RSV_2 \oplus RSV_3 \oplus ..... \oplus RSV_N$$

where $\oplus$ is the concatenation operator. To extract *local features*[10], convolution operation is applied. Convolution operation involves a *filter*, $W \in \mathbb{R}^{HD}$, which is convolved with a window of H embeddings to produce a local feature for the H target sentences. A local feature, c_k is generated from a window of embeddings $RSV_{k:k+H-1}$ by applying a non-linear function (such as hyperbolic tangent) over the convoluted output. Mathematically,

$$c_k = f(W.RSV_{k:k+H-1} + b)$$

where $b \in \mathbb{R}$ is the *bias* and f is the non-linear function. This operation is applied to each possible window of H target sentences to produce a feature map (c) for the window size H.

$$c = [c_1, c_2, c_3, ..., c_{N-H+1}]$$

A global feature is then obtained by applying *max-pooling* operation (Collobert et al., 2011) over the feature map. The idea behind *max-pooling* is to capture the most important feature-one with the highest value -for each feature map. We describe the process by which one feature is extracted from one filter (red bordered portions in Figure 1 illustrate the case of $H = 4$). The model uses multiple filters for each filter size to obtain multiple features representing the text. These features form the penultimate layer and are passed to a fully connected feed forward layer (with number of hidden units set to 100) followed by a *SoftMax* layer whose output is the probability distribution over the labels (*novel* or *non-novel*).

6 Results and Discussion

We proceed with the intuition: *redundancy* recognition would eventually lead us to *novelty* detection. The three datasets we use represent the most comprehensive resources that are publicly available and could be effectively used for document-level novelty detection.

6.1 On APWSJ: a document-level novelty detection dataset

We take upon the results reported by (Zhang et al., 2002) on APWSJ and use similar metrics to report the performance of our approach. Table 1 exhibits the effect of different redundancy measures (taken from (Zhang et al., 2002)) on APWSJ considering both *absolutely redundant* and *somewhat redundant* documents as redundant or non-novel. Our RDV-CNN approach delivers comparable performance in a 10-*fold* cross-validation classification setting. Although the system suffers in identifying the *redundant* documents but succeeds to minimize the errors committed. It signifies the affinity of our architecture towards detecting *novel* documents. It is to be noted here that (Zhang et al., 2002) conducted their experiments in an information filtering scenario using some thresholding scheme, where the **redundant or non-novel** documents were to be filtered from being delivered (*Not Delivered*). Only the *novel* documents were to be *Delivered* by the retrieval system. No learning was involved. Even APWSJ corpus was developed to support this Information Retrieval (IR) perspective of retrieving novel documents. Hence, there is a huge class imbalance. The presence of a relatively less number of *non-novel* documents in APWSJ (only 9.07%) and also that *somewhat redundant* documents are considered as *redundant*[11] in our experiment may have hindered the learning of *redundant* patterns by our system. However, the superiority of our approach is established when we experiment with two other balanced datasets that closely approximates the semantic level redundancy we aim to capture.

6.2 On Webis-CPC-11: a corpus for paraphrase detection (simulating non-novelty)

As stated earlier, we deem paraphrase detection as one close simulation of semantic level redundancy (non-novelty) detection. With this view we subject our model to detect passage-level paraphrase pairs

[10] features specific to a region in case of images or window of target sentences

[11] as originally considered in (Zhang et al., 2002). We replicate the same experimental conditions for fair comparison.

Measure	Recall	Precision	Mistake
Set Distance	0.52	0.44	43.5%
Cosine Distance	0.62	0.63	28.1%
LM:Shrinkage	0.80	0.45	44.3%
LM:Dirichlet Prior	0.76	0.47	42.4%
LM:Mixture Model	0.56	0.67	27.4%
Proposed Approach (RDV-CNN)	0.58	**0.76**	**22.9%**

Table 1: Results for Redundant class on APWSJ, $LM \rightarrow$ Language Model, $Mistake \rightarrow$100-Accuracy. Except for RDV-CNN, all other numbers are taken from (Zhang et al., 2002)

from Webis-CPC-11. We investigate similar evaluation systems for novelty detection as carried out in (Ghosal et al., 2018). The three novelty detection measures (Set Difference, Geometric Distance, Language Model), originally formulated by (Zhang et al., 2002) and another based on *Inverse Document Frequency (IDF)* by (Karkali et al., 2013) are our benchmarks for evaluation. Instead of setting a fixed threshold[12] as in these works we train a Logistic Regression (LR) classifier based on those measures to automatically determine the decision boundary.

Baseline 1: As a baseline we take *state-of-the-art* document embedding (*Paragraph Vector*) technique by (Le and Mikolov, 2014) for document representation; concatenate the source and target document vectors and pass it to LR.

Baseline 2: Both the target and source sentence encodings[13] are passed to separate BiLSTM layers; the two resultant vectors are concatenated and passed to a Multi Layered Perceptron (MLP) with hidden dim of 2048 followed by classification via softmax.

Table 2 clearly shows that our RDV-CNN outperforms all the measures and baselines and maintains a significant supremacy to detect semantic-level redundant passages.

Evaluation System	Description	P	R	F_1	A
Baseline 1	Paragraph Vector+LR	0.72	0.58	0.64	66.94%
Baseline 2	BiLSTM+MLP	0.71	0.73	0.72	70.91%
Novelty Measure 1(Zhang et al., 2002)	Set Difference + LR	0.71	0.52	0.60	64.75%
Novelty Measure 2(Zhang et al., 2002)	Geometric Distance + LR	0.69	0.75	0.71	70.23%
Novelty Measure 3(Zhang et al., 2002)	LM: Dirichlet Prior + LR	0.74	0.77	0.75	74.34%
Novelty Measure 4(Karkali et al., 2013)	IDF + LR	0.65	0.55	0.59	61.72%
Proposed Approach	**RDV-CNN**	**0.75**	**0.84**	**0.80**	78.02%

Table 2: Results for Paraphrase class on Webis-CPC (in %), IDF$\rightarrow$ Inverse Document Frequency, LR$\rightarrow$ Logistic Regression

6.3 On TAP-DLND 1.0: a corpus for document-level novelty detection

We experiment with the recently published TAP-DLND 1.0 corpus for our *document level novelty detection* experiments. TAP-DLND 1.0 is well balanced and consists of a fair share of different levels (lexical as well as semantic) of textual views for both novel and non-novel documents. Since our objective here is to identify both novel and non-novel documents we report results for each class. We take the same baseline as we use for Webis-CPC in the previous section. Our approach outperforms the popular semantic document embedding technique *Paragraph Vector* and another deep neural baseline (BiLSTM+MLP) by a considerable margin(12% and 6% in terms of accuracy, respectively). We also re-execute the other novelty detection measures by (Zhang et al., 2002) (Set Difference, Geometric Distance, Language Model) and (Karkali et al., 2013) (IDF) on TAP-DLND 1.0 and report the results. Our RDV-CNN even surpasses

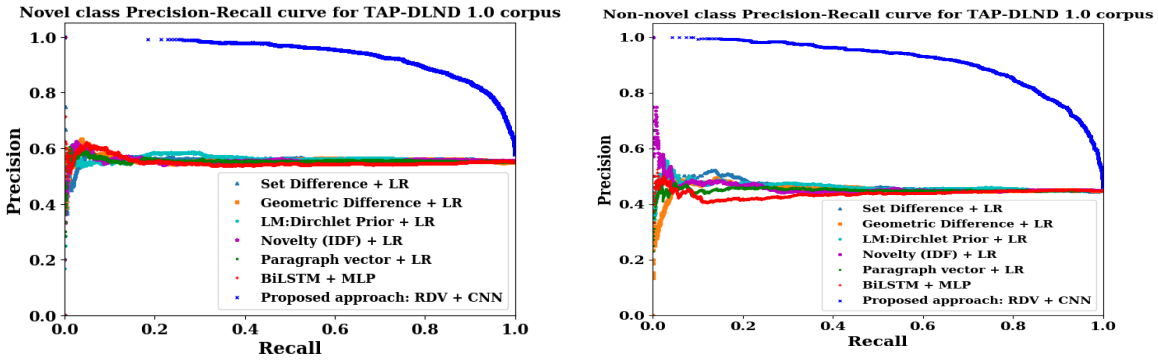
[12] the weak thresholding algorithm reported in these works yield poor results

[13] trained on SNLI as in section 5.1.2

Evaluation System	Description	P(N)	R(N)	F_1(N)	P(NN)	R(NN)	F_1(NN)	A
Baseline 1	Paragraph Vector+LR	0.75	0.75	0.75	0.69	0.69	0.69	72.81%
Baseline 2	BiLSTM+MLP	0.78	0.84	0.80	0.78	0.71	0.74	78.57%
Novelty Measure 1 (Zhang et al., 2002)	Set Difference+LR	0.74	0.71	0.72	0.72	0.74	0.73	73.21%
Novelty Measure 2 (Zhang et al., 2002)	Geometric Distance+LR	0.65	0.84	0.73	0.84	0.55	0.66	69.84%
Novelty Measure 3 (Zhang et al., 2002)	LM:Dirichlet Prior+LR	0.73	0.74	0.74	0.74	0.72	0.73	73.62%
Novelty Measure 4 (Karkali et al., 2013)	Novelty (IDF)+LR	0.52	0.92	0.66	0.66	0.16	0.25	54.26%
(Ghosal et al., 2018)	Supervised features	0.77	0.82	0.79	0.80	0.76	0.78	79.27%
Proposed Approach	**RDV-CNN**	**0.86**	0.87	**0.86**	**0.84**	**0.83**	**0.83**	**84.53%**

Table 3: Results on TAP-DLND 1.0 , P→ Precision, R→ Recall, A→ Accuracy, R→ Recall, MLP→ Multi Layer Perceptron, N→ Novel, NN→ Non-Novel, IDF→ Inverse Document Frequency

the current benchmark (Ghosal et al., 2018) on TAP-DLND 1.0 by a considerable margin in identifying both novel and non-novel documents. Figure 2 shows the consistency and edge of our approach over other measures. This behavior we attribute to our customized architecture of mapping each target sen-



(a) PRC for Novel class

(b) PRC for Non-Novel Class

Figure 2: Precision-Recall Curve for TAP-DLND 1.0

tence to the nearest source sentence to produce a *relative* document representation being input to a CNN. The CNN then extracts the features from the *relative* document representation and finally classifies the incoming document. Results signify that our network is able to learn the complex semantic interactions between source and target information necessary to conclude upon the state of novelty of a document. It is to be noted that except (Ghosal et al., 2018) and our baselines, all other measures that we consider for comparison were developed with an information retrieval perspective. The *p-values* for F_1 score produced by 20 runs of our system against the baseline are less than 0.05 and hence the improvement is statistically significant and unlikely to be observed by chance in 95% confidence interval.

6.4 Observations and Analysis

We scrutinize the results and arrive to the following observations:
(1) The RDV-CNN customized architecture of mapping each target sentence to the nearest source sentence for producing a *relative* document representation tackles the *relativity* criterion required for the problem. It facilitates CNN to extract the relevant features from the *relative* document representation which accounts for the better performance across the two datasets.
(2) Lexical approaches perform closer to our approach in detecting paraphrase pairs. This is due to the higher number of Named Entities (NEs) shared between those literary texts in Webis-CPC-11.
(3) Poor recall for non-novel class by IDF measure (Karkali et al., 2013) is due to the existence of many

The associated codes of this paper is available at: https://github.com/edithal-14/A-Deep-Neural-Solution-To-Document-Level-Novelty-Detection-COLING-2018-

new entity terms in the target documents for TAP-DLND 1.0.
(4) Lexical overlap based measures performs poorly in identifying *non-novel* documents in TAP-DLND 1.0. This behavior approves our discussion in Section 3 that we need semantic flair to address *non-novelty*. RDV-CNN bridges the gap.
(5) The deep baselines did not appear as promising to capture the semantic interactions between source and target sentences as did RDV-CNN (Section 5.3).
(6) We thoroughly examined our gold and predicted class labels. Errors committed by our system are mostly due to presence of multiple source premise sentence for a target sentence. Our RDV-CNN could capture only one premise for a target sentence and map them. We intend to accommodate multiple premises in RDV definition in our future work.
(7) The universal sentence encoding generated by BiLSTM trained on SNLI are sometimes unable to capture the complex semantic interactions between source and target sentences. This mostly occurred for new NEs and out-of-vocabulary (OOV) words.

7 Conclusion and Future work

In this work we put forward a deep learning solution for document-level novelty detection. Our deep neural network succeeds in extracting the text subtleties essential for this complex task. The system displays comparable potential on an existing resource, significant performance gain over the high-level *paraphrase detection* task and outperforms the state-of-the-art on an apt dataset. Analysis of results validates our claim that semantic features play a vital role in identifying *semantic level redundancy* aka *non-novelty* whereas relevant lexical divergence is a good indicator of *novelty*. However, we agree that given a large number of documents as source our architecture would be computationally expensive which we intend to mitigate. Also we desire to incorporate *relevance* judgment as an essential component our architecture. Our future agenda includes investigating the role of attention mechanism in creating the *Relative Document Vector* as an intermediate representation of target documents for document-level novelty detection.

Abstract

Authorship attribution typically uses all information representing both content and style whereas attribution based only on stylistic aspects may be robust in cross-domain settings. This paper analyzes different linguistic aspects that may help represent style. Specifically, we study the role of syntax and lexical words (nouns, verbs, adjectives and adverbs) in representing style. We use a purely syntactic language model to study the significance of sentence structures in both single-domain and cross-domain attribution, *i.e.* cross-topic and cross-genre attribution. We show that syntax may be helpful for cross-genre attribution while cross-topic attribution and single-domain may benefit from additional lexical information. Further, pure syntactic models may not be effective by themselves and need to be used in combination with other robust models. To study the role of word choice, we perform attribution by masking all words or specific topic words corresponding to nouns, verbs, adjectives and adverbs. Using a single-domain dataset, IMDB1M reviews, we demonstrate the heavy influence of common nouns and proper nouns in attribution, thereby highlighting topic interference. Using cross-domain Guardian10 dataset, we show that some common nouns, verbs, adjectives and adverbs may help with stylometric attribution as demonstrated by masking topic words corresponding to these parts-of-speech. As expected, it was observed that proper nouns are heavily influenced by content and cross-domain attribution will benefit from completely masking them.

1 Introduction

Authorship attribution attributes a text sample to a person based on either content or their writing style. On the other hand, stylometry involves authorship attribution only based on writing style and needs to be independent of topic or genre. Though authorship attribution has various applications, some important ones are security-related. eg. cybercrime investigation, digital forensics, countering identity deception in social networks, etc. In today's connected world, most of our cyber-interactions are text-based on various platforms like messages, emails, blogs, tweets, forum posts etc. With rampant cybercrime attacks, it is important to perform robust authorship attribution or verification across these platforms. This calls for stylometric attribution approaches that model style and work well in cross-domain scenarios. Cross-domain scenarios include both cross-topic (same genre but different topics) and cross-genre (different genres) scenarios.

Various authorship attribution approaches have been surveyed in literature (Juola and others, 2008; Stamatatos, 2009; Neal et al., 2017). However, only some of these approaches focus specifically on cross-domain attribution. Function words have been touted as content-independent and hence reliable as a style marker (Juola and others, 2008). Syntactic information, both shallow (Luyckx and Daelemans, 2008) and deep (Baayen et al., 1996; Raghavan et al., 2010; Feng et al., 2012; Fuller et al., 2014; Björklund and Zechner, 2017), have also been proposed for ensuring topic or genre independence. Few other approaches, perform preprocessing to prevent topic/genre dependency when using lexical or character features (Stamatatos, 2012; Sapkota et al., 2014; Markov et al., 2017; Stamatatos, 2018).

Proceedings of the 27th International Conference on Computational Linguistics, pages 2814–2822
Santa Fe, New Mexico, USA, August 20-26, 2018.

In this paper, we study the role of different linguistic aspects on style, specifically sentence syntax and word choice. We use a language model to represent syntax and words as against using vector representations with machine learning approaches. We do so for two reasons: i) Vector representation of syntax has not been effective in past efforts (Stamatatos, 2009), ii) Vector representation of words or character n-grams mostly consist of function words and may not be helpful to study the role of lexical parts-of-speech (POS).

To study the role of syntax, we perform authorship attribution using a purely syntactic language model. The syntactic model is constructed using the Probabilistic Context-free grammars (PCFG) obtained from an author's training data. While the approach is similar to other syntactic approaches (Raghavan et al., 2010), we keep our model purely syntactic by removing any lexical information. We also add context to the rewrite rules by vertical and horizontal Markovization. To handle previously unseen rules, we also incorporate smoothing where the language model can back-off to lower order models.

To study the role of word choice, we perform attribution by masking out all words or specific topic words corresponding to different lexical POS. We do so because character n-gram based approaches have largely outperformed function word based approaches (Kestemont, 2014) indicating that lexical words may also help with authorship attribution. This analysis would help understand which of these lexical words may help represent style. Other approaches (Stamatatos, 2018) also mask out infrequent words (mostly lexical words) but we perform an in-depth analysis as to which of these lexical words are useful for representing style.

In this paper, we attempt to answer the following questions:

- Does sentence structure or syntax help with stylometric attribution in cross-domain settings?
- What are effects of words corresponding to different lexical POS on cross-domain attribution?
- Does masking topic words corresponding to various lexical POS help with stylometric attribution in cross-domain settings?

2 Methodology

In this section, we explain the approaches taken to answer the above questions pertaining to stylometric attribution. This could help us come up with better style representations that would work well in cross-domain scenarios.

2.1 Role of syntax

We use a purely syntactic language model to study the role of sentence structure or syntax in cross-domain stylometric attribution. A syntactic language model is obtained by constructing the probabilistic context-free grammar (PCFG) for each author using the constituency parse trees of sentences in their training posts. While some approaches (Raghavan et al., 2010) use the rewrite rules directly to construct PCFGs, we apply both vertical and horizontal Markovization (Klein and Manning, 2003) to the parse trees before constructing PCFGs. This helps to incorporate some context into the rewrite rules and improves parsing accuracy. To keep the approach purely syntactic, we remove the leaf nodes which contain the sentence words (Fuller et al., 2014; Björklund and Zechner, 2017). A test sample is attributed to the author whose PCFG yields the highest likelihood score. In order to account for unseen rules during test time, we also incorporate smoothing that allows the model to backoff to lower order syntactic language models. The rewrite rules of a sample sentence corresponding to different Markovization orders used in our model are shown in Figure 1.

We compare the syntactic language model with an analogous character language model (Teahan and Harper, 2003). This approach uses a lossless text compression method called Prediction by Partial Matching (PPM) (Cleary and Witten, 1984). With PPM, individual characters are encoded using the context provided by the preceding characters thus representing each author A using a separate language model p_A. To attribute an unknown sample $\mathbf{u}$ of length L, we compute its cross-entropy with respect to an

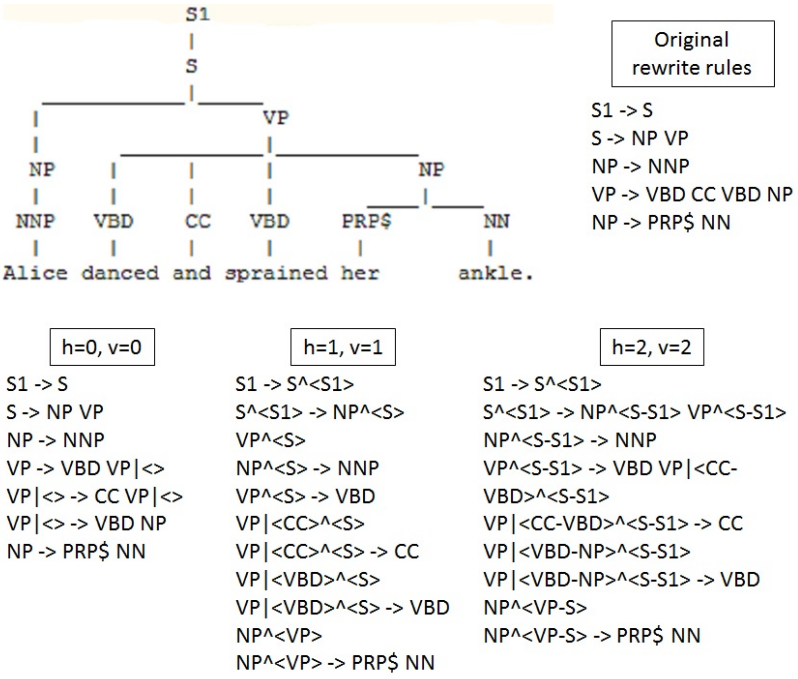

Figure 1: Parse tree of a sample sentence and rewrite rules under different orders of vertical (v) and horizontal (h) Markovization. The leaf nodes are excluded from the rewrite rules.

author model p_A as

$$H(p_A, u) = -\frac{1}{L}\, log_2\, p_A(u)$$
$$= -\frac{1}{L}\sum_{i=1}^{L} log_2\, p_A(x_i|context_i)$$

where $context_i$ of character x_i is $x_1, x_2, ..., x_{i-1}$. The unknown sample is attributed to the author whose model yields least cross-entropy. For computational efficiency, the context is typically truncated to preceding n-1 characters i.e. $x_{i-n}, ..x_{i-1}$.

2.2 Role of word choice

Besides syntax, the choice of words used by a person also plays an important role in stylometric attribution. These words may have a primary purpose of being lexical or grammatical. Lexical words have meaning by themselves and are mostly content-specific. Such words typically include nouns, verbs, adjectives and adverbs. On the other hand, grammatical words do not have any meaning by themselves and specify the relationships between lexical words. Hence, they are independent of content and typically include determiners, prepositions, pronouns, etc. Conventionally, grammatical words, especially function words, have been proposed for stylometric authorship attribution since they are independent of content. However, character n-gram based approaches have largely outperformed function word based approaches (Kestemont, 2014) indicating that some lexical words may also help with authorship attribution. In order to understand which lexical words may help with stylometric attribution, we study the effects of masking all lexical words and certain topic words corresponding to different POS on authorship attribution.

2.2.1 Role of lexical POS

To analyze the effects of different lexical POS on stylometric attribution, we preprocess the posts to replace words corresponding to different POS with a predefined string $<T>$. We use the set of Penn TreeBank POS tags in our experiments. The following effects are analyzed using a character language model (Teahan and Harper, 2003) for both single-domain and cross-domain datasets:

- **orig:** This utilizes the original posts and are used for benchmarking.
- **no_NNP:** This utilizes posts in which all proper nouns (NNP, NNPS) are replaced by $<T>$.
- **no_NN:** This utilizes posts in which all common nouns (NN, NNS) are replaced by $<T>$.
- **no_VB:** This utilizes posts in which all verbs (VB, VBD, VBG, VBN, VBP, VBZ) except function words are replaced by $<T>$.
- **no_ADJ:** This utilizes posts in which all adjectives (JJ, JJR, JJS) are replaced by $<T>$.
- **no_ADV:** This utilizes posts in which all adverbs (RB, RBR, RBS) are replaced by $<T>$.

2.2.2 Role of topic words

The approach in Section 2.2.1 assumes that all words corresponding to a lexical POS may be content-specific. This may not be the case as some of these words may actually help with stylometric attribution. Hence, in this section, we analyze the effects of masking only the topic words corresponding to different lexical POS on attribution. We use Latent Dirichlet Allocation (LDA) (Blei et al., 2003) to obtain the topic words for each lexical POS. Since each author may focus on different topics, we perform LDA for each author using their training posts. The topic words of all authors are then collated and used for masking. We analyze the same effects as Section 2.2.1 - *orig, no_topic_NNP, no_topic_NN, no_topic_VB, no_topic_ADJ* and *no_topic_ADV*.

3 Datasets

We use two datasets for our experiments as follows:

- **IMDB1M reviews** (Seroussi et al., 2011): This single-domain dataset consists of 204,809 posts and 66,816 reviews written by 22,116 users. For our experiments, we use only a subset of 674 users with more than 50 posts per person. The chosen data subset contains 160,482 posts across 674 users. On an average, the dataset consists of 238 posts/author, 347 characters/post, 73 words/post and 4 sentences/post.
- **Guardian10 corpus** (Stamatatos, 2012): This cross-domain dataset consists of opinion articles and book reviews written by 13 authors and up to 10 posts per topic/genre. On an average, this dataset consists of 34 posts/author, 6234 characters/post, 1202 words/post and 52 sentences/post. Cross-topic experiments are performed only using the opinion articles which are on four different topics - Politics, UK, World and Society. Cross-genre experiments involve training author models using opinion articles on all four topics and evaluating authorship attribution performance on book reviews.

4 Results

In this section, we report the results of our analysis detailed in Section 2.

4.1 Role of syntax

We use the BLLIP parser (Charniak and Johnson, 2005) trained on Wall Street Journal (WSJ) corpus to treebank an author's training data. We use vertical and horizontal Markovization order of two *(h=2, v=2)* since higher orders did not seem to improve performance. The leaf nodes are removed from the parse trees to keep the analysis purely syntactic. To test stylometric attribution, we evaluate the syntactic language model (Syntactic LM) on both single-domain IMDB1M and cross-domain Guardian10 datasets. We repeat these experiments using the syntactic language model with lexical information in its leaf nodes (Syntactic LM + Lexical) and also using the character language model (Character LM) (Teahan and Harper, 2003) for comparison. The single-domain and cross-domain attribution performances are reported in Tables 1 and 2 respectively.

Table 1: Single-domain performance on IMDB1M using syntactic language model

Scenarios	Precision(%)	Recall(%)	F-score(%)	Accuracy(%)
Syntactic LM	30.96	27.71	28.28	27.71
Syntactic LM + Lexical	44.31	43.52	42.26	43.53
Character LM	64.41	64.77	63.42	64.77

Table 2: Cross-domain performance on Guardian10 using syntactic language model

Domain	Scenarios	Precision(%)	Recall(%)	F-score(%)	Accuracy(%)
Cross-topic	Syntactic LM	21.85	22.22	18.40	24.14
	Syntactic LM + Lexical	27.30	25.15	21.27	26.56
	Character LM	76.89	67.41	67.02	70.41
Cross-genre	Syntactic LM	20.44	26.96	21.90	33.33
	Syntactic LM + Lexical	18.92	23.15	18.99	28.57
	Character LM	72.32	56.90	59.79	69.84

4.1.1 Discussion

We studied the role of sentence structure or syntax in stylometric attribution using a purely syntactic language model. For single-domain IMDB1M dataset, it can be inferred from Table 1 that using a purely syntactic model (*Syntactic LM*) seems to be ineffective as compared to using both syntax and lexical information (*Syntactic LM + Lexical*). This reaffirms the fact that single-domain attribution benefits largely from lexical information some of which may be topic-dependent. For cross-domain settings, it can be inferred from Table 2 that purely syntactic attribution (*Syntactic LM*) may be more helpful for cross-genre data than cross-topic data. Adding lexical information to purely syntactic model (*Syntactic LM + Lexical*) seems to improve cross-topic attribution while it deteriorates cross-genre attribution.

Nevertheless, purely syntactic models seem to perform poorly compared to character language models as is evident from in Tables 1 and 2. Character n-gram based approaches have been highly successful in authorship attribution because they represent character, lexical and syntactic information to varying extents (Luyckx, 2011; Kestemont, 2014) and are robust to morphological variations in language use (Sapkota et al., 2015). However, from a purely quantitative perspective, their success can be attributed to the fact that character n-grams have much more data points than function words or syntactic rules thereby yielding superior performance (Kestemont, 2014). Character n-grams span the same word or word combinations multiple times depending on the n-gram order and hence amplify the presence of possibly unique word/phrase choices by an author. PCFG-based syntactic language models do not have this advantage as the set of all possible syntactic rewrite rules is much lesser than the set of all possible character n-grams. Hence, the low performance of purely syntactic models does not necessarily imply that they are not useful in representing style. One can use these in combination with character language models to improve cross-domain performance.

4.2 Role of word choice

To analyze the role of word choice in stylometric attribution, we perform experiments on both single-domain and cross-domain datasets by masking out all lexical words and topic words corresponding to different POS.

4.2.1 Role of lexical POS

To study the effects of lexical words on authorship attribution, we mask all words corresponding to specific lexical POS as described in Section 2.2.1. We use *NLTK* toolkit (Bird and Loper, 2004) for POS tagging. We perform author identification on both single-domain and cross-domain datasets using the character language model (Teahan and Harper, 2003). We perform 4-fold cross-validation and report the average precision, recall, F-score and accuracy across all cross-validation folds.

For single domain IMDB1M dataset, the performance measures reflecting the effects of masking different lexical POS are reported in Table 3. Similarly, the performance measures for cross-topic and cross-genre experiments on Guardian10 dataset are reported in Table 4.

Table 3: Effect of lexical POS on single-domain authorship attribution using IMDB1M

Scenarios	Precision(%)	Recall(%)	F-score(%)	Accuracy(%)
orig	64.41	64.77	63.42	64.77

	no_ADV	78.71	73.02	72.42	73.02
	no_topic_ADV	80.89	74.60	73.93	74.60

4.2.2 Role of topic words

In this section, we hypothesize that not all words corresponding to lexical POS are content-specific. Hence, we experiment with masking certain topic words corresponding to different lexical POS. The topic words are chosen using the LDA implementation in *gensim* Python toolkit. Only words corresponding to specific lexical POS are input to LDA. We experiment by varying the number of topics (t = 2,10,50) and number of words per topic (w=10,100). The topic words obtained from each author's training data are collated and used for masking. We perform 4-fold cross-validation experiments on both single-domain and cross-domain datasets. We report the performance measures for the best performing configuration using both IMDB1M (t=50, w=10) and Guardian datasets (t=10, w=10) in Tables 3 and 4.

4.2.3 Discussion

It is known that function words are independent of content and are useful for representing style. However, the success of character n-gram approaches in authorship attribution indicate that some lexical words may also be useful for authorship attribution. Besides, character n-gram approaches do not necessarily decouple style and content and using these approaches as such may deteriorate attribution in cross-domain settings. Hence, we studied the effect of masking all words or topic words corresponding to different lexical POS on both single-domain and cross-domain attribution as explained in Sections 2.2.1

and 2.2.2. For all experiments, attribution with the character language model without masking any lexical POS ($orig$) is considered as the baseline.

For single-domain IMDB1M dataset, it can be observed from Table 3 that excluding all common nouns (no_NN) and proper nouns (no_NNP) affects the attribution performance drastically. In contrast, masking only topic words corresponding to common nouns (no_topic_NN) and proper nouns (no_topic_NNP) seems to improve attribution performance compared to masking them completely (no_NNP, no_NN). Nevertheless, this performance is lesser than that of $orig$. This shows the heavy influence of nouns and proper nouns in single-domain attribution. Masking all words or topic words corresponding to other lexical POS like verbs, adjectives or adverbs do not seem to impact the performance even though POS like verbs do contribute significantly to attribution as seen in Figure 2a. This could possibly be due to the heavy dependence on common nouns and proper nouns for attribution under those scenarios.

In contrast, for cross-domain Guardian10 dataset, it can be observed from Table 4 that excluding proper nouns (no_NNP) completely yields a marked improvement in performance for both cross-topic and cross-genre experiments. In fact, excluding only topic words corresponding to proper nouns (no_topic_NNP) performs poorly compared to no_NNP though it performs marginally better than $orig$. Hence, while performing cross-domain attribution, it would be wise to exclude proper nouns from style representations. With respect to common nouns, masking topic words (no_topic_NN) improves performance as compared to completely masking them (no_NN) for both cross-topic and cross-genre scenarios. This implies that some common nouns also help represent style as shown by their distribution in Figures 2b,2c,2d,2e and 2f. With respect to verbs, in cross-topic settings, masking topic words (no_topic_VB) marginally improves performance while completely masking them (no_VB) reduces performance. In cross-genre settings, masking all verbs completely (no_VB) improves performance significantly while masking only topic verbs (no_topic_VB) improves performance marginally compared to $orig$. This implies that choice of verbs have a significant influence in cross-genre settings as compared to cross-topic settings. For both adjectives and adverbs, masking certain topic words (no_topic_ADJ and no_topic_ADV) improves attribution performance as against completely masking them (no_ADJ and no_ADV) for both cross-topic and cross-genre settings. This suggests that some of these adverbs and adjectives may help represent style. The top 20 non-topic words corresponding to different lexical POS for both datasets are shown in Table 5.

Table 5: Top 20 non-topic lexical POS

Figure 2: POS distribution on single-domain and cross-domain datasets. POS with $<1\%$ contribution have been suppressed

One of the most pressing problems in this line of research is that there seems to be a dearth for publicly available large-scale cross-domain datasets. Authorship attribution approaches in literature largely demonstrate their results using either small datasets or large-scale single-domain datasets. This does not provide a clear picture of the factors that contribute to style which may be robust in cross-domain settings. The role of syntax or word choice or other aspects in representing style can be better ascertained with experiments on large-scale cross-domain datasets.

5 Conclusion

Authorship attribution approaches in literature focus mostly on single-domain attribution where content and style are highly entangled. This does not provide a clear picture of linguistic aspects that are robust to cross-domain settings. In this paper, we studied the role of sentence structure and word choice in representing style. We evaluated the role of syntax using a purely syntactic language model and show that syntax may be useful with cross-genre attribution while cross-topic attribution and single-domain attribution may be benefit from both syntax and lexical information. However, syntactic language models are not discriminative by themselves and need to be used in conjunction with more successful character n-gram models. We evaluated the role of word choice by masking off all words or certain topic words corresponding to different lexical POS. For common nouns, verbs, adjectives and adverbs, masking off certain topic words yield better performance suggesting that the remaining words corresponding to these lexical POS may help represent style. However, proper nouns seem to be heavily influenced by topic and cross-domain attribution may benefit from completely masking them.

Abstract

Texts from the Internet serve as important data sources for financial market modeling. Early statistical approaches rely on manually defined features to capture lexical, sentiment and event information, which suffers from feature sparsity. Recent work has considered learning dense representations for news titles and abstracts. Compared to news titles, full documents can contain more potentially helpful information, but also noise compared to events and sentences, which has been less investigated in previous work. To fill this gap, we propose a novel target-specific abstract-guided news document representation model. The model uses a target-sensitive representation of the news abstract to weigh sentences in the news content, so as to select and combine the most informative sentences for market modeling. Results show that document representations can give better performance for estimating cumulative abnormal returns of companies when compared to titles and abstracts. Our model is especially effective when it used to combine information from multiple document sources compared to the sentence-level baselines.

1 Introduction

Texts from the Internet was shown to be statistically correlated with stock market trends (Antweiler and Frank, 2004). Natural language processing (NLP) techniques have been applied to extract information from company filings (Lee et al., 2014), financial news articles (Xie et al., 2013) and social media texts (Bollen et al., 2011) in order to gain understandings of financial markets. In particular, traditional methods exploited statistical signals, such as lexical and syntactic features (Wang and Hua, 2014; Schumaker and Chen, 2009), sentiment (Bollen et al., 2011) and event structures (Ding et al., 2014; Ding et al., 2015; Ding et al., 2016) from these text sources, which suffers from feature sparsity problems.

With the recent trends in deep learning for NLP, neural networks have also been leveraged to learn dense representations for text elements, which can address the sparsity of discrete features in statistical models. Such representations can implicitly represent sentiment, event and factual information, which can be extremely challenging for sparse indicator features. In particular, Ding et al. (2015) show that deep learning representations of event structures yield better accuracies for stock market prediction compared to discrete event features. Chang et al. (2016), Duan et al. (2018) use neural networks to directly learn representations of news abstracts, showing that it is effective for predicting the cumulative abnormal returns of public companies.

One limitation of Ding et al. (2015) and Chang et al. (2016), however, is that these methods only model news titles and abstract texts, which are typically single sentences. Ding et al. (2015) show that a model that uses only news content gives inferior results compared to one trained using news titles only, and that adding news content information to a title-driven model does not significantly improve the results. Intuitively, news content can contain richer information that is not directly relevant to the title message, or the most important event, and hence can lead to noise in predictive modeling. On the other hand, news

Proceedings of the 27th International Conference on Computational Linguistics, pages 2823–2833
Santa Fe, New Mexico, USA, August 20-26, 2018.

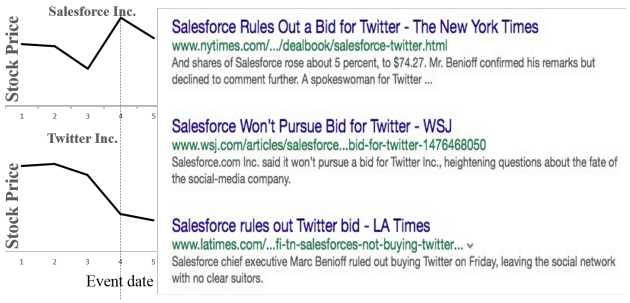

Figure 1: Event "Salesforce rules out Twitter bid" showing different impacts to differnt firms. Twitter fell 5.12%, while Salesforce rose 5.15% on the event day.

content can also contain useful information for making informed decisions. For example, given the news abstract passage *"Amicus Inc (arcs.o), a provider of health-care IT services, said it agreed to be bought by an affiliate of private firm them bravo llc for $217 million in an all-crash deal."*, it would be difficult to tell whether the acquisition is beneficial to investors. However, a sentence in the news content states that *"the deal offers Amicus Inc shareholders $5.35 for each share, a premium of 21 percent over the stock's close on December 24 on NASDAQ"*, which explicitly indicates a positive return.

We aim to exploit such useful information from the news content for making more informed decisions in stock market prediction. A main challenge is how to automatically identify the most useful parts of the news content, while disregarding noise, which prevents naive utilization of news contexts (aka Ding et al. (2015)). Another challenge, as Chang et al. (2016) suggest, is that information must be selected with regard to a certain stock of interest. As shown in Figure 1, the same event "*Salesforce rules out Twitter bid*" can lead to different influences on different stocks, with Salesforce benefiting from it yet Twitter suffering from it.

To address the above challenges, we build a neural model that selects and represents relevant sentences from a full news document with respect to a specific firm of interest. In particular, we leverage conditional encoding (Rocktäschel et al., 2015) to encode information of a given stock into the dense representation of the news abstract. Using this target-specific news abstract representation, we apply neural attention (Bahdanau et al., 2014) over each sentence in the news content to automatically learn its relative importance with regard to the target company. The attention weights are learned automatically towards a final predictive goal. The model is full data-driven, which do not rely on an external syntactic parser as the first step to obtain its target-specific linguistic structures.

In addition to Chang et al. (2016) model, which uses only abstract information, we also compare with several state-of-the-art baselines for learning document representations, such as paragraph vector (Le and Mikolov, 2014) and hierarchical attention network (Yang et al., 2016), giving the best reported performances. The advantage of our approach over sentence-level baseline is especially obvious when it is used to combine information from multiple news document sources. In addition, a case study shows that our model can select the sentences that most intuitively help predict stock returns from a full news document. Our contributions can be summarized as follows:

- We propose a target-specific document representation model, which leverages the abstracts as evidences to select informative sentences from the documents while disregarding noise.
- We are the first, to our knowledge, to build a neural model that can effectively leverage full news document for stock market prediction.

2 Problem Definition

Cumulative Abnormal Return The task that we attack in this paper is *Cumulative Abnormal Return Prediction (**CAR**)*. Formally, the abnormal return AR_{jt} of a firm j on a date t is the difference between its actual return R_{jt} and the expected return $\hat{\mathrm{R}}_{jt}$, $\mathrm{AR}_{jt} = \mathrm{R}_{jt} - \hat{\mathrm{R}}_{jt}$. The expected return $\hat{\mathrm{R}}_{jt}$ can be

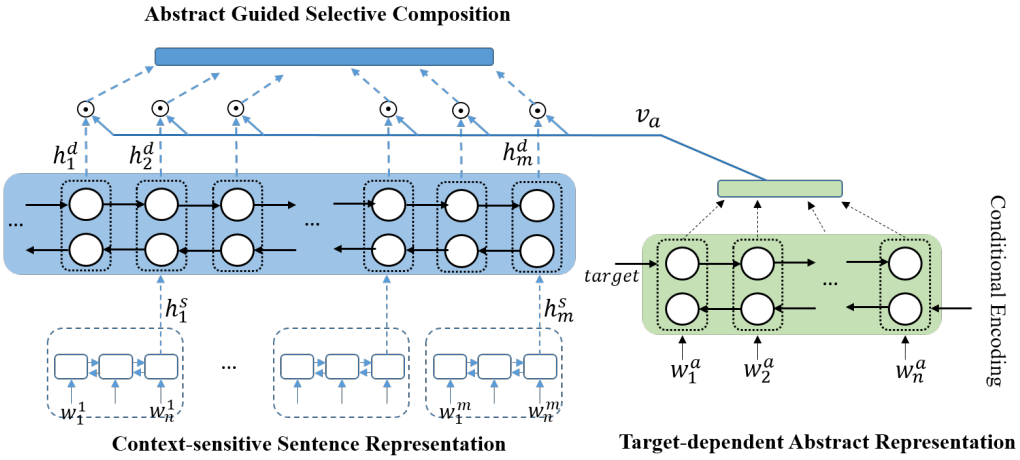

Figure 2: The architecture of proposed method

estimated by an asset price model based on historical prices, or approximated by the market return in a short-term event window (Kothari and Warner, 2004). The cumulative abnormal return CAR_j of the firm j in an n-day time window is calculated by summing up the daily abnormal returns in the period (Eq 1). In this paper, we adopt the commonly used three-day window (-1,0,1), which we denote as CAR_3 and day 0 is the day when the current news documents are released.

$$\text{CAR}_j = \sum_{t=1}^{n} \text{AR}_{jt} \tag{1}$$

Cumulative Abnormal Return Prediction The ultimate goal is to build a model that predicts the cumulative abnormal return CAR_3 of a public company based on a set of related news documents released on day 0. Given a document D and associated firm f, we learn a representation d_f for D that is specified to firm f based on our proposed approach (introduced in Section 3). With the firm-specific document representation d_f, we predict the CAR_3 direction $y \in \{-1, 1\}$ using a parameterized softmax function (Eq 2).

$$p(y|d_f) = \text{softmax}(W \cdot d_f + b), y \in \{-1, 1\}, \tag{2}$$

where $p(y = -1|d_f)$ and $p(y = 1|d_f)$ indicate the probability of CAR_3 being negative and positive, respectively. In the next section, we describe our method for learning d_f.

3 Model

The challenges for learning a target-sensitive document representation are two-fold. On the one hand, we must encode firm-specific information into the dense document representations so as to make them different across targets. On the other hand, we must identify the most informative sentences while disregarding noise for the prediction. To remedy this, we propose to first learn a target-specific representation for the abstract, which is most relevant to the market movement among all the sentences and then leverage the abstract to guide the sentence selection. The architecture of our proposed approach is illustrated in Figure 2, which consists of three key modules. We give details of each module in this section.

3.1 Target-dependent Abstract Representation

As the first step, we learn a target-dependent representation for the abstract of a news document by encoding target information into it. We use a bidirectional Long-short memory network as the basic model. In order to allow information of a target company to influence the semantic representation, we apply conditional encoding (Rocktäschel et al., 2015), using an embedding vector of the target firm of concern $e^t(c)$ as the initial state vector for the sentence-level Bi-LSTMs. We average the hidden states of each word in the sentence to obtain the target-dependent news abstract representation v_a. The vector

$e^t(c)$ for the company of interest is initialized by averaging the words of its constituents and are fine-tuned during training.

3.2 Context-sensitive Sentence Representation

To preserve the semantic structures of documents and make the sentence representations aware of their contexts, we leverage a hierarchical structure (Li et al., 2015) to encode sentences (the abstracts are not considered) in a document. A sentence-level LSTM is first used to encode words into hidden state vectors, and then a document-level LSTM is applied to encode sentences into hidden state vectors.

At the sentence level, given a sentence $\{w_1, w_2, \cdots, w_n\}$, we obtain their embedding forms $\{\vec{e}(w_1), \vec{e}(w_2), \cdots, \vec{e}(w_n)\}$ via a lookup table. A Bi-LSTM is used to capture sentence-level context from $\{\vec{e}(w_1), \vec{e}(w_2), \cdots, \vec{e}(w_n)\}$, yielding two sequences of hidden states $\{\overrightarrow{h_1^w}, \overrightarrow{h_2^w}, \cdots, \overrightarrow{h_n^w}\}$ and $\{\overleftarrow{h_1^w}, \overleftarrow{h_2^w}, \cdots, \overleftarrow{h_n^w}\}$, respectively. We average $\overleftarrow{h_i^w}$ and $\overrightarrow{h_i^w}$ into a single vector h_i^w for the word w_i, and use average pooling over the sentence to obtain a single sentence embedding vector h^s.

In the document level, given the sentence embedding $\{h_1^s, h_2^s, \cdots, h_m^s\}$ for sentences $\{s_1, s_2, \cdots, s_m\}$ in a document D, respectively, the same Bi-LSTM structure (with a different set of model parameters) is applied to obtain hidden states $\{\overrightarrow{h_1^d}, \overrightarrow{h_2^d}, \cdots, \overrightarrow{h_m^d}\}$ and $\{\overleftarrow{h_1^d}, \overleftarrow{h_2^d}, \cdots, \overleftarrow{h_m^d}\}$, respectively. For each sentence s_i, the forward and backward hidden vectors are averaged to give a single hidden state embedding h_i^d. h_i^d contains both internal information from the sentence by semantic composition of words, and document level context by bi-directional recurrent composition.

We use this vector form of each sentence as their representation for abstract and sentence composition. We apply the same conditional encoding to sentence-level and document-level Bi-LSTMs in context-sensitive sentence representation.

3.3 Abstract Guided Selective Composition

As mentioned in Section 1, some sentences can give background information that can support decision making, which is too lengthy to include in the abstract. To address the challenge of informative sentence selection, we consider the target-specific representation obtained as well as the sentence relevances to the abstract in our model.

To compose context-sensitive sentence representations into a final document representation, we use the attention mechanism (Bahdanau et al., 2014), taking the embedding of the abstract to guide calculation of attention weights. Another benefit of using the attention mechanism is the prediction is made interpretable, since interpretability is crucial in financial prediction, as investors have to verify the underlying basis for the decisions.

Formally, given the target-specific representation of the abstract v_a from Section 3.1 and the context-sensitive sentence representations $\{h_1^d, h_2^d, \cdots, h_m^d\}$ from Section 3.2, we concatenate v_a and h_i^d and feed it to a single-layer, feed-forward neural network (Eq 3) to get the score for each sentence h_i^d in the document,

$$u_i = v^\top \tanh(W_a[v_a, d_i] + b), \tag{3}$$

where W_a is the weight matrix, b is the bias, v is a projection vector that maps the output to a scalar and u_i is the weight score showing how much attention should be put on current sentence s_i in the composition of the whole document. The attention score α_i are computed from u_i by Eq 4.

$$\alpha_i = \frac{\exp(u_i)}{\sum_i \exp(u_i)}, \tag{4}$$

$$d = \sum_i \alpha_i h_i^d. \tag{5}$$

Here α_i is the normalized weight score, where $\sum_i \alpha_i = 1$. The final output d is a weighted sum of all the hidden states h_i^d (Eq 5). We concatenate the vector of the abstract v_a and d as the final representation for the document $d' = [v_a, d]$.

	Training	Development	Test
+CAR$_3$	9,674	493	995
-CAR$_3$	9,643	507	1,005

Table 1: Number of CAR$_3$ in the datasets

3.4 Multi-Document Composition

There can be more than one news document mentioning a firm of interest in a certain event window. We adopt a self-attentive neural network (Bahdanau et al., 2014) to assign different weights to the news documents $\{d'_1, d'_2, \cdots, d'_n\}$ (Eq 6) with respect to our prediction goal.

$$u_i = v^\top \tanh(W^{(s)} d'_i + b^{(s)}), \tag{6}$$

where $W^{(s)}$ is a weight matrix and $b^{(s)}$ is a bias, u_i is a scalar showing how much attention should be put on document d_i. The normalization process is the same with Eq 5 but with different parameters. We denote the final representation as $\hat{d}$, and use it as d_f for CAR$_3$ prediction in Section 2.

4 Training

Given a set of training instances T with documents and their corresponding CAR$_{\mathcal{3}}$ as discussed in Section 2, the overall training objective is to minimize the cross-entropy loss with `L2` regularization (Eq 7),

$$\min_{\Theta} - \sum_{T} \sum_{j} t_j \log p(y_j|d_f) + \sum_{\theta \in \Theta} \lambda_\Theta ||\theta_2^2||, \tag{7}$$

where $p(y_j|d_f)$ is the predicted distribution for class j and t_j is the ground-truth distribution. Θ represents all the parameters and the λ_Θ are the regularization parameters.

We pre-train continuous bag-of-word (CBOW) word embeddings with dimension 100 on a collection of Reuters and Bloomberg financial news articles, which is released by Ding et al. (2014). The overall document size is over 400K. The open source toolkit *word2vec*[1] is used to train the word embeddings, which are then fine tuned during the training of the prediction model to help boost the model performance. Out-of-vocabulary (OOV) words are replaced by a `UNK` token. We adopt `Adam` (Kingma and Ba, 2014) as our optimization algorithm, with the initial learning rate being set to 0.0005, `L2` regularization at the strength of 10^{-6}. We use mini-batch size of 32, the model that achieved the best micro-F1 performance on the development set is kept for final test.

5 Experiments

5.1 Data

We collect publicly available financial news articles from Reuters from October 2006 to December 2015. In our preliminary experiments, we find that a news document is more likely to be relevant to a firm only if it is mentioned in the news abstract. Thus, we only include news documents mentioned at least one public listed firm in the U.S. security market. We group the news documents per firm per event date. If the news is released during a trading hour, day 0 is the current day, otherwise day 0 is the next trading day. We compute the expected return $\hat{\mathrm{R}}_{jt}$ by the return of equally-weighted market index including all the stocks on NYSE, Amex, NASDAQ.

We follow Chang et al. (2016) and split the dataset into training, development and test sets, with 1000 instances for development, 2000 instances for testing and the rest for training. The numbers of positive and negative CAR$_{\mathcal{3}}$ in the dataset are listed in Table 1, in which the positive and negative cases are fairly balanced.

[1] https://code.google.com/archive/p/word2vec/

5.2 Evaluation Metrics

Our model is designed for stock recommendation, where companies with high absolute cumulative abnormal return expectations can be given to traders for their information. As a result, it can be useful to have a confidence threshold $beta$ in the model, so that only companies with $p(y = 1|d_f) > \beta$ or $p(y = -1|d_f) > \beta$ are recommended. With increasing β values, the number of recommended stocks is expected to decrease, while the precision to increase. As a result, the model performance is evaluated by the area under the precision-recall curve (AUC). The precision and recall are calculated on both the positive class and negative class. This metric offers a trade-off between precision and recall when varying the prediction confidence threshold. Following Chang et al. (2016), we also evaluate the model on test instances with $|\text{CAR}_3| > 2\%$, namely the event windows with high impacts.

5.3 Baselines

We compare our method with a set of baseline representation learning methods for d_f learning including *target-dependent abstract* representation method of Chang et al. (2016), and state-of-the-art *target-independent document* representations.

Target-dependent News Abstract representation (TGT-CTX-LSTM) Chang et al. (2016) give the current state-of-the-art accuracies for CAR prediction by using the abstract only. They used a syntactic parser to analyze the dependency structure of the abstract (as a sentence), and then transform it to a target-specific dependency tree form. They leverage a tree structured LSTM (Tai et al., 2015) to learn abstract representation according to the target-specific tree form.

Paragraph Vector We take the paragraph vector embedding of Le and Mikolov (2014) as an unsupervised full document representation baseline. This method gives remarkable performances on tasks such as document classification (Yang et al., 2016) and sentiment analysis (Tang et al., 2015).

Target-dependent sentence combination (TD-AVG) This model first learns a context-sensitive representation for all sentences using Bi-LSTM and conditional encoding (Rocktäschel et al., 2015). Average pooling is then applied on the sentence representations to obtain the final document representation. This baseline is equivalent to a conditionally encoded version of the target-specific model of Li et al. (2015), but with a different training objective (i.e., classification instead of auto-encoder). We refer to it as TD-AVG. We use conditional encoding (Rocktäschel et al., 2015) on the sentence-level and document-level Bi-LSTMs.

Target-dependent hierarchical neural network (TD-HAN) This model is similar to TD-AVG except that it adopts an attention model (Bahdanau et al., 2014) over the context-sensitive sentence representations. Intuitively, similar to abstract, some parts of the document are more related to CAR compared to others. Such sentences should be given more weights in composition for document representations. This baseline is adapted from Yang et al. (2016), who applied attention on both the word level and the sentence level in a hierarchical LSTM network for document representation. In the implementation, it is slightly different in not using attention on the word level. We refer to it as TD-HAN.

5.4 Results

Table 2 summarizes the AUCs of both positive and negative classes of different embedding models on the test dataset. As shown in Table 2, our model gives AUCs of 0.65 for both positive and negative classes on the test dataset, outperforming all the baselines. Following Chang et al. (2016), we also make comparisons on cases that give higher CAR, with threshold $|\text{CAR}_3| > 2\%$. This subset covers a total of 1021 cases. Our model gives AUCs of 0.75 and 0.73 on $+\text{CAR}_3$ and $-\text{CAR}_3$, respectively. The improvement is statistically significant at a 1% significance level using T-test. Figure 3 presents the precision-recall curve of *Paragraph Vector*, *TGT-CTX-LSTM* (Chang et al., 2016) and our proposed method. We make more detailed analysis of our approach and relevant models.

	+CAR$_3$	-CAR$_3$	+CAR$_3$ $> 2\%$	-CAR$_3$ $< -2\%$
Paragraph Vector (Le and Mikolov, 2014)	0.51	0.53	0.54	0.55
TGT-CTX-LSTM (Chang et al., 2016)	0.63	0.62	0.70	0.68
TD-AVG (Tang et al., 2015)	0.61	0.61	0.71	0.68
TD-HAN (Yang et al., 2016)	0.63	0.63	0.72	0.71
Our Approach (without target)	0.64	0.63	0.73	0.72
Our Approach	**0.65****	**0.65****	**0.75****	**0.73****

Table 2: Final *AUC* on the test set, ** means that the result is better than the best baseline at 1% significance level.

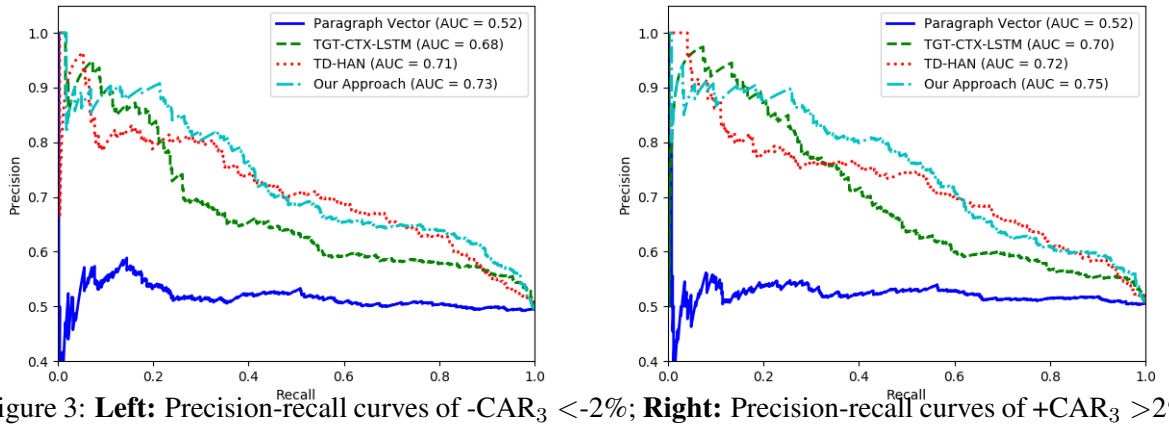

Figure 3: **Left:** Precision-recall curves of -CAR$_3$ $<$-2%; **Right:** Precision-recall curves of +CAR$_3$ $>$2%

The Usefulness of Supervision The performance of *Paragraph Vector* falls far behind other approaches. The primary cause is that its document representation is both target-independent and unsupervised, which neither benefit from the end task nor information from specific targets. This demonstrates the importance of supervisions in capturing the deep semantic meaning of documents for our prediction task.

The Usefulness of Modeling Full Document As shown in Table 2, simple averaging schema TD-AVG gives inferior performances compared to the target-specific abstract representation TGT-CTX-LSTM. This indicates the informativeness of abstract for predicting the stock market movements. However, when the simple average pooling of TD-AVG is replaced by a simple feed-forward attention over the context-sensitive sentence representation, i.e., TD-HAN, the model achieves comparable performance with state-of-the-art model TGT-CTX-LSTM. The results indicate the importance of choosing the right strategy to compose the sentences in document-level compositions, since a document is more sparse and contains noise. It also implies that if the document-level background information is properly modeled, document-level models have obvious advantages over sentence-level model, since short text and simple structure may not fully represent the information conveyed in the document.

Our proposed method, which incorporates firm-specific information as well as the hierarchical structures of news documents, achieves the best performances, showing that target-specific supervisions and fine-grained information from the main contents of news can help gain understanding about the market fluctuations.

The Impact of Target The performances of our model with and without target information are also compared in Table 2. Our model without target information achieves 0.64 and 0.63 AUC on positive and negative classes, respectively, which is comparable with the best baselines. Encoding the target information into the representation did not bring a significant improvement to the model performance. An explanation for the relatively small difference between our method with and without target-specific

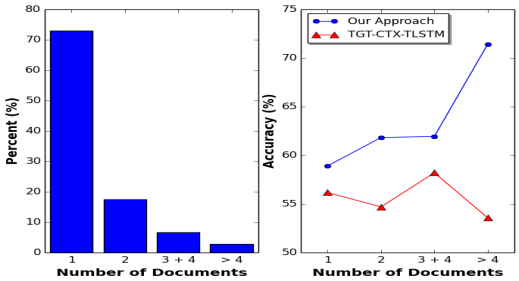

Figure 4: **Left**: The proportion of instances with different number of financial news documents in our test dataset. For example, over 70 percent of instances in our test dataset have information collected from one document in the event window; **Right**: The accuracy of our approach and baseline TGT-CTX-TLSTM against the number of news documents in the event window.

encoding is that there is a relatively low ratio (10.2%) of news abstracts in our dataset mentioning more than one company.

Accuracy with Respect to the Number of Documents As mentioned in the previous section, there can be more than one news documents associated with a firm of interest in a particular event window. More than 25 percent of CAR_3 instances in our dataset have information gathered from more than one documents. Extra documents can provide richer background information about the firm of interest, but may also bring more noise. Figure 4 (Right) shows the accuracies of our model and the baseline TGT-CTX-LSTM with respect to the number of news documents. It is worth noting that our model and TGT-CTX-LSTM use the same attention strategy to combine information from multiple documents. The performance of our approach improves as the number of documents to model grows, showing its effectiveness in utilizing more non-overlapping information sources. Compared to sentence-level baseline TGT-CTX-LSTM, our model can better capture information from multiple document sources.

5.5 Case Study

To illustrate the attention mechanism for weighing sentences in the news documents, Table 3 shows the details of three news documents. The target firm, the actual CAR_3 and the prediction probability of our method and the baseline method TGT-CTX-LSTM are shown in the first rows of each news. The first line of each document is the abstract. The automatically learned weights are shown in the front of each sentence. For case 1, since the most informative parts of the document are not in the abstract, TGT-CTX-LSTM, which only exploits the abstract, yields the incorrect prediction. Our model puts more weights on the last two sentences, which suggest the value of the acquired properties and the voting rights for the target Lennar Corp.. This meets human expectation, since they have shown the potential of the future prospect of the firm.

For case 2, though the ground-truth CAR_3 outperforms the market by a large margin, the baseline TGT-CTX-LSTM shows less confidence for the prediction compared with our method. The abstract gives little knowledge about the purchase event, which make the system that rely on the abstract difficult to make a decision. The second sentence in the news explicitly state the impact of the news to the shareholders, the target firm stock price rose by more than 20 percent. We observed similar patterns in other cases, where the model prefer to put more weights on the sentences which explicitly mention the stock returns. An explanation is that the market follows the trends and it takes time for the market to absorb all information.

For case 3, both methods present similar confidence for the prediction. However, our model puts more weight on the third sentence instead of the abstract. The two sentences can be treated as paraphrases, because they are very close in the meaning, both mentioning future profit expectations of the firm and a quarterly profit decline. It is worth noting that, for documents with a large number of long sentences, our model tends to give evenly-distributed weights for all the sentences in such documents. This is a limitation of our attention model, which we leave for future work. Above all, the result demonstrates that our model is able to automatically capture the most informative parts in the documents.

6 Related Work

Our work falls into the area of mining financial text for stock market prediction. Rich linguistic features in financial text have been studied. Wang and Hua (2014) and Schumaker and Chen (2009) exploit shallow lexical and syntactic features, such as n-grams, noun-phrases and named entities. Such representations ignore the word orders and the important semantic relations between sentences, which thus can not fully represent the information conveyed in a document. With the rise of open information extraction techniques, Xie et al. (2013) exploit semantic frames and Ding et al. (2014) use event tuples to represent the news events. Such representation suffers from the problem of discreteness and data sparsity, which makes it difficult to generalize. The main difference between our method and this line of work is that they use discrete representations of the title or abstract of the financial news. Instead, we propose a fixed-length, continuous representations for the entire documents.

Our work also aligns with recent work on using deep neural models to learn embedding vectors for sentences and documents. Le and Mikilov (2014) extend the skip-gram algorithm (Mikolov et al., 2013) by regarding documents as contexts, training their embeddings together with training word embeddings. Kingma and Ba (2014) train sentence embeddings by using LSTMs to compose word vectors in sentences, leveraging neighbor sentences. Kenter et al. (2016) take a similar basis by using neighbor sentences to guide sentence vector training, but use a simpler network structure by calculating sentence embeddings as the sum of its word embeddings. Li et al. (2015) use a hierarchical auto-encoder structure to learn sentence and document embeddings. Yang et al. (2016) extends the hierarchical LSTM network of Li et al. (2015), applying attention for weighting different words and sentences, giving state-of-the-art accuracies for document classification. In contrast to the existing methods, we propose learning a target-specific representation of documents for a specific end task, namely news-driven market prediction.

7 Conclusion

We investigated target-specific document representations of financial news for cumulative abnormal return prediction in this paper, comparing a set of document embedding models. Empirical studies showed that a combination of target-specific news abstract representation and contextual sentence representation via the attention mechanism can give better results compared to several alternative sentence-level and document-level methods. Our final model demonstrated the usefulness of modeling a full document, as compared to only titles and abstracts, for obtaining more accurate results.

Abstract

Word composition is a promising technique for representation learning of large linguistic units (e.g., phrases, sentences and documents). However, most of the current composition models do not take the ambiguity of words and the context outside of a linguistic unit into consideration for learning representations, and consequently suffer from the inaccurate representation of semantics. To address this issue, we propose a model-free context-aware word composition model, which employs the latent semantic information as global context for learning representations. The proposed model attempts to resolve the word sense disambiguation and word composition in a unified framework. Extensive evaluation shows consistent improvements over various strong word representation/composition models at different granularities (including word, phrase and sentence), demonstrating the effectiveness of our proposed method.

1 Introduction

Recent development in natural language processing (NLP) has seen a rise of continuous representation learning of linguistic units, which has been successfully applied to various tasks such as contextual word similarity (Iacobacci et al., 2015; Huang et al., 2012), machine translation (Devlin et al., 2014), paraphrase detection (Socher et al., 2011a) and sentiment classification (Tang et al., 2015). The continuous representation of linguistic units bring many benefits. For example, we can easily calculate the semantic relatedness between two words *'dog'* and *'cat'* using cosine distance of their continuous representations. Specifically, a representation learning method aims at mapping a linguistic unit with k words $S = [w_1, w_2, ..., w_k]$ into a continuous vector in a low dimensional feature space.

Currently, most of the representation learning methods focus on learning word embeddings, mostly based on the distributional hypothesis (Harris, 1954), i.e., *words in similar contexts tend to have similar meanings*. In most cases, a word is represented by summarizing all its contexts in a large text corpus, either by dimension reduction from co-occurrence matrix (Levy and Goldberg, 2014), or by neural network models (Collobert and Weston, 2008; Mikolov et al., 2013; Huang et al., 2012).

Intuitively, a word may express distinct meanings in different contexts, so its representations may be distinct in various linguistic units. For example, the word *'bank'* should have different representations in *'commercial bank'* and in *'river bank'*, because they correspond with two distinct senses of *'bank'*: the former with the meaning of *'financial institution'*, and the latter with *'riverside'* meanings. To address this issue, some multi-prototype word embeddings models are proposed to learn multiple representations for individual words. For instance, MSSG (Neelakantan et al., 2015) utilizes local context to infer the accurate semantic of a word, and the global context is incorporated by TWE (Liu et al., 2015) to learn accurate representations of a word.

The representations of linguistic units larger than words (e.g., phrases, sentences), unfortunately, usually cannot be learned using the method as word representations. The main reason is the context sparsity problem, i.e., most of the large linguistic units will not occur frequently even in a large text corpus, which leads to insufficient context statistics for accurate representations learning.

Proceedings of the 27th International Conference on Computational Linguistics, pages 2834–2845
Santa Fe, New Mexico, USA, August 20-26, 2018.

To effectively learn the representations of large linguistic units, a promising approach is word composition, which is based on the Frege's principle of composition: (Pelletier, 2001) – *the meaning of a complex expression is determined by the meanings of their constituent expressions and the rules used to combine them*. Specifically, given a linguistic unit S with $[w_1, w_2, ..., w_k]$ words, a composition method first infers the vectors of all words in S based on embedding matrix. After that, a composition model is utilized to transform the word vectors into a single representation of unit *S*. For example, to represent the phrase *'the dog outside'*, a composition method will first infer the representations of *'the'*, *'dog'* and *'outside'*, and then feed those word vectors into a composition model, e.g., element-wise addition, element-wise multiplication (Mikolov et al., 2013), recursive neural network (Socher et al., 2012), gated recurrent neural network, Long-Short Term Memory network (Le and Zuidema, 2015) or convolutional neural network (Xu et al., 2015). There are also approaches that jointly learn the representations of words and larger units, e.g Le and Mikolov (2014).

However, the meaning of a large linguistic unit not only depends on its constituent words but also affected by the context around it. For example, the meaning of word *'going'* in sentence *'I am going to the bank.'* can be disambiguated based on the local context (the other words in the sentence). But the meaning of word *'bank'* in this sentence can not be inferred without context outside this sentence. Unfortunately, deriving contextual information outside of a given sentence is not trivial due to the data sparsity problem. What's worse, in some practical NLP applications, there is no context for a given sentence, such as question answering or information retrieval.

To address this issue, this paper proposes a model-free context-aware word composition model to learn proper representations for linguistic units at different granularity levels by incorporating latent semantic information. The proposed model attempts to address the word sense disambiguation and word composition in a unified architecture. Specifically, inspired by TWE (Liu et al., 2015), this paper utilizes topic distribution as the global context of a linguistic unit. Each topic is utilized to derive accurate meanings for all the word occurrences in the linguistic unit and to learn the topic-specific representation of the unit. After that, the context-aware representation of the linguistic unit is inferred by summarizing all its representations under different topics based on the topic distribution. In this way, our method can make use of the topic information of a word to learn its accurate topic-specific representation, and the topic distribution of the a unit is employed as a cue to guide the process of word composition to learn meaningful representation.

Note that, our context-aware composition framework is model-free in that it can employ any existing composition model as the base composition model. We assess our method on multiple text similarity tasks based on various base composition models. Experimental results verify the effectiveness of our model on learning the representations of linguistic units at different granularity level, and show consistently improvements over various base composition models. The main contribution are threefold: (1) It regards the linguistic unit as a whole, and utilizes the latent semantic information to learn the accurate representations for both the linguistic unit and the word occurrences in it; (2) This paper verifies that the topic information is benefit for both the accurate word representation and word composition. (3) We proposed a model-free framework that can enhance various kinds of methods.

2 Related Work

This section briefly reviews related work, including context representation models, word/phrase embeddings leanings methods and word composition methods.

2.1 Context Representation Model

How to represent contextual information is a key topic in natural language processing research area. Currently, a main trend is to represent context via latent variable models (Szpektor and Dagan, 2008), e.g., the Latent Dirichlet Allocation (LDA) (Blei et al., 2003). Using LDA models, a context will be represented as a topic distribution. Frank et al. (2014) used topic models to provide context for a vowel categorisation task in child directed speech.

2.2 Word/Phrase Embeddings

Currently, most of the word embeddings methods use either neural network or co-occurrence matrix. Several well-known models include C&W (Collobert and Weston, 2008), word2vec (Mikolov et al., 2013) and GloVe (Pennington et al., 2014). The main drawback of these methods is that they represent a word using a single vector, such a uniform representation method cannot accurately represent polysemy.

There are also various methods which try to learn multi-prototype word embeddings to solve the polysemy problem, with each vector corresponding to a sense instead of word, such as the Multi-Prototype model (Huang et al., 2012), the MSSG (Neelakantan et al., 2015), the EHModel (Tian et al., 2014), the SenseEmb (Guo et al., 2014) and the SAMS model (Cheng and Kartsaklis, 2015). The main drawback of these models is that they need to induce the senses of a word, which is a very challenging task.

Salant and Berant (2017) verified the importance of the contextual information for word representation. Recently, a number of methods are proposed to learn contextual word representations based on neural network (Melamud et al., 2016; Peters et al., 2018) without considering word composition.

(Liu et al., 2015) proposed a TWE model which employs the topic assignments to produce topic-specific word embeddings to avoid the challenging task of word sense induction, and generates the representation of a larger unit by adding the vectors of topical word embeddings weighted by TFIDF of them. Fadaee et al. (2017) labels a word with topic distribution in both hard and soft ways, and learns topic-specific representations and general representation for a word simultaneously. Shi et al. (2017) introduces a method to enhance the word representation and topic model with each other. By contrast, our proposed model aims at utilizing topic distribution to enhance the word composition models for learning representations of linguistic units of different granularity levels, including word, phrase and sentence.

2.3 Word Composition

Due to the context sparsity problem, word composition is a promising technique to learn representations of linguistic units larger than words. A lot of models have been developed for word composition, e.g., simple models such as element-wise addition/multiplication (Mitchell and Lapata, 2010; Mikolov et al., 2013) and neural network based models such as recurrent neural network (Paulus et al., 2014), gated recurrent neural network, Long-Short Term Memory network (Le and Zuidema, 2015), convolution neural network (Xu et al., 2015) and attention-based model (Ling et al., 2015). These composition models could be used as the base composition model in our model-free framework.

Skip-Thought (Kiros et al., 2015) learns word and sentence representations based on sentences around it simultaneously. Doc2vec (Le and Mikolov, 2014) jointly trains the word sentence vectors by predicting the words in it. Recently, (Mao et al., 2017) introduced a topic-aware model to enhance the word composition model based on topic embeddings, which verifies the benefit of topic information for word composition. But despite its apparent success, there remains a major drawback: this method suffers from the limitations that learning topic embeddings and the uniform representation of words. By contrast, our method generates different vectors for a word in various context and only depends on the topic distributions of linguistic units.

3 Model-Free Context-Aware Word Composition Framework

In this section, we present our model-free context-aware word composition framework, which contains two main components: context-aware word representation and context-aware word composition. We first describe the method of learning a context-aware word embeddings. After that, we propose a model-free context-aware word composition framework to learn contextual representation of a linguistic unit.

3.1 Context-Aware Word Embeddings

This section describes how to learn the context-aware word representation of a contextual word based on contextual Information.

Contextual Information. In this paper, we represent contextual information using the most prevalent topic model (Blei et al., 2003), i.e., the context of a linguistic unit is represented as a topic distribution $C = \{p(Topic_1), p(Topic_2), ..., p(Topic_K)\}$. For example, the phrase context

'river bank' of the word *'bank'* may be represented as $\{Geography^{0.8}, Financial^{0.01}, ..., Sport^{0.1}\}$, by contrast the phrase context *'commercial bank'* of the word *'bank'* may be represented as $\{Geography^{0.02}, Financial^{0.85}, ..., Sport^{0.03}\}$. Note that, the proposed method can also use other context representation model, such as Melamud et al. (2016; Peters et al. (2018).

Using the above context representation model, we estimate the context-aware representation as follows: (1) We train a topic model on a large-scale text corpus using topic model; (2) Given the context of a word occurrence $S = [w_1, w_2, ..., w_k]$, where w_i represents a word, we employ collapsed Gibbs sampling algorithm (Griffiths and Steyvers, 2004) to infer the topic assignments for all words in S, and the topic distribution of S is utilized as contextual information.

Context-Aware Word Embedding Learning: Based on the above contextual information, a word can express distinct meanings under different topic assignments, and the unit representation can be learned separately for each individual topic, before being combined to constitute the final context-aware unit representation. For example, the word *'bank'* with topic assignments *'Geography'* and *'Financial'* respectively express two distinct senses of *'bank'*: *'riverside'* and *'financial institution'*. We employ the topic assignment as the contextual cue of a word in a specific context. In this way, we need to learn the embeddings of all $\langle word : topic \rangle$ pairs – we refer them topic-specific word embeddings. Formally, we learn a set of vectors for each word, with each vector corresponding to a specific topic. For instance, the word *'bank'* will be represented as:

$$\vec{V}_{Geo}(bank) = [0.628, 0.093, 0.051, ..], \vec{V}_{Fin}(bank) = [0.034, 0.016, 0.320, ..]$$

where $\vec{V}_{Geo}(bank)$ and $\vec{V}_{Fin}(bank)$ correspond to two distinct senses of *'bank'* under topics of *'Geography'* and *'Financial'*, respectively.

To learn the above topic-specific word embeddings from a text corpus, we first assign each word in the text corpus with a topic using the topic models; secondly we treat each $\langle word : topic \rangle$ pair as an individual unit; finally we learn the embeddings of all $\langle word : topic \rangle$ pairs using word embedding model, such as Word2Vec and Glove.

3.2 Context-aware Word Composition

In this section, we propose a model-free context-aware word composition framework, which represents a linguistic unit based on contextual information and context-aware word representation. Our method employs topic distribution of a linguistic unit as its contextual information. Specifically, given a linguistic unit $S = [w_1, w_2, ..., w_n]$, its topic distribution $C = \{p(topic_1|S), p(topic_2|S), ...\}$ and the topic-specific embeddings of all words, we construct the representation of S as follows:

1) We calculate the topic-biased representation of S under topic t by composing the topic-specific word embeddings as follows:

$$\vec{V}_{TopicBiased}(S, t) = f(\vec{V}_t(w_1), ..., \vec{V}_t(w_n)) \quad (1)$$

where f is a base composition model, which composes a sequence of vectors into a single representation. Notice that we can utilize any context-unaware word composition model as our base composition model, such as recurrent neural network, convolutional neural network, element-wise addition/multiplication, etc. For example, given the sentence *'we run along the bank'*, the topic-biased representation of the sentence under topic *'Geography'* is learned as:

$$\vec{V}_{TopicBiased}(S, Geo) = f(\vec{V}_{Geo}(we), ..., \vec{V}_{Geo}(bank))$$

2) We construct the context-aware representation of S by the weighted average of all topic-biased representations of S based on its topic distribution:

$$\vec{V}_{Contextual}(S) = \sum_{t \in T} p(t|S) \cdot \vec{V}_{TopicBiased}(S, t) \quad (2)$$

where $p(t|S)$ is the topic probability of topic t of S. For instance, using the inferred topic distribution of the sentence S as $\{Geography^{0.03}, Financial^{0.01}, .., Sport^{0.73}\}$, we generate the context-aware representation of S by averaging all the topic-biased vectors of S according to its topic distribution as:

$$\vec{V}_{Contextual}(S) = 0.03 \cdot \vec{V}_{TopicBiased}(S, Geo) + ... + 0.73 \cdot \vec{V}_{TopicBiased}(S, Sport)$$

To learn the context-aware representation for a word in a specific sentence,the latent topic distribution of the sentence and the topic-specific word embeddings are needed. Specifically, a word in a specific context can be learned by averaging the topic-specific word embeddings based on the topic distribution:

$$\vec{V}_{Contextual}(w|S) = \sum_{t \in T} p(t|S) \cdot \vec{V}_t(w) \tag{3}$$

where $\vec{V}_{contextual}(w|S)$ represents the context-aware representation of word w in context S, $p(t|S)$ is the topic probability of S under topic t, $\vec{V}_t(w)$ represents the topic-specific embedding of word w and T represents the set of topics. For example, given a sentence *S='Bank is a financial institution that accepts deposits'*, we first infer its topic distribution of the sentence as $C = \{Geography^{0.01}, Financial^{0.8}, ..., Sport^{0.03}\}$. Secondly we learn the context-aware representation of *'bank'* as follows:

$$\vec{V}_{Contextual}(bank|S) = 0.01 \cdot \vec{V}_{Geo}(bank) + 0.8 \cdot \vec{V}_{Fin}(bank) + 0.03 \cdot \vec{V}_{Sport}(bank) \tag{4}$$

where $\vec{V}_{sport}(bank)$ represents the topic-specific representation of *'bank'* under topic *'Sport'*.

4 Experiments

In this section, we assess our method on text similarity tasks at different granularities. And we conduct experiments on paraphrase detection task to evaluate the improvements of our method over various base word composition models.

4.1 Model Pre-training

In our experiments, we employ two different corpora for a comprehensive comparison to the various baseline models. We train the LDA model and the topic-specific word embeddings on the British National Corpus (BNC) (Consortium and others, 2007), which contains more than 93 million terms, and a bigger corpus – a snapshot of the English Wikipedia corpus[1] with about 990 million tokens.

Specifically, we use GibbsLDA++ (Phan and Nguyen, 2007) to estimate the topic distribution and infer the topic assignment for each word in the corpus. The parameters of GibbsLDA++ are empirically tuned as follows: $\alpha = 0.5, \beta = 0.1$, the number of topics 50, the number of iterations 400. For the topic-specific word embeddings, we use the SkipGram algorithm, with the dimension of word vector 300, the windows size 5, the number of iterations 5 and 10 negative samples per occurrence.

4.2 Overall Results

The proposed model focuses on learning the context-aware representations of large linguistic units. To evaluate the learned representations of linguistic units, we conduct experiments on text semantic similarity tasks at different granularities, including contextual word similarity, phrase similarity and sentence similarity. In this section, we calculate the similarity of two linguistic units based on cosine similarity of their representations, and we assess different systems using the Spearman's correlation between system outputs and gold standards manually labelled.

Contextual Word Similarity Results

To assess the quality of our context-aware word representations, we conduct experiments on the Stanford Contextual Word Similarity (SCWS) dataset (Huang et al., 2012), which contains 2003 manually labelled word pair similarities, with each word is paired with a sentence context.

We compare our context-aware word representation model with several baseline word embeddings models, including C&W (Collobert and Weston, 2008), CBOW and SkipGram (SG) (Mikolov et al., 2013). We also compare with two multi-prototype word embeddings models, including MSSG model (Neelakantan et al., 2015) and SAMS model (Cheng and Kartsaklis, 2015), both of which predict the

[1] https://www.wikipedia.org/

sense of a word based on its local context. All of the above models are trained on BNC. In addition, we compare with CBOW and SkipGram (SG) (Mikolov et al., 2013), Huang (Huang et al., 2012), Tian (Tian et al., 2014), TWE (Liu et al., 2015), STD-dif (Shi et al., 2017) and HTLE (Fadaee et al., 2017) models based on Wikipedia corpus for fair comparison, which have achieved state-of-the-art performances. And we report their best published result. The overall results are presented in Table 1.

Corpus	CBOW	SK	C&W	MSSG	SAMS	Tian	Huang	TWE(best)	STE-Dif	HTLE	Our
BNC	59.0	61.0	55.0	56.0	58.0	-	-	-	-	-	**63.2**
Wikipedia	65.3	65.7	-	-	-	65.4	65.3	68.1	68.0	63.0	**68.3**

Table 1: The Spearman's correlation ρ of different methods on SCWS dataset.

From Table 1, we can see that: (1) Our context-aware word representation had achieved the best performance on both the BNC and Wikipedia corpora. Compared with the three context-unaware word representation baselines CBOW, SkipGram and C&W, our method correspondingly achieves 6.8%, 3.3% and 14.5% ρ improvements. (2) The latent topic model based context representation can effectively capture the proper meanings of a contextual word. Compared with the multi-prototyped word embeddings baselines MSSG and SAMS, our method achieved 12.5% and 8.6% ρ improvements, respectively. We believe the topic distribution of the entire sentence is a beneficial cue for accurately representing polysemy words. (3) The results verify that the context-aware way of learning word representation as Formula (3) may provide a better way of utilizing topic distribution than hard label schema as in TWE, because both of the models implemented on the dataset.

Phrase Similarity Results

To assess the performance of our method on phrase representation learning, we conduct phrase similarity experiments on the ML2010 dataset (Mitchell and Lapata, 2010), which contains 108 pairs of phrases for adjective-noun (AN), verb-object (VO) and compound-noun (NN) respectively.

In our experiments, we employ the element-wise addition as base composition model, which turns out to be both robust and effective in many tasks. We compare our system with two baselines: the element-wise addition models correspondingly using the context-unaware word embeddings learned by CBOW and SkipGram. We also compare our system with state-of-the-art results from ML Original (Mitchell and Lapata, 2010), PAS(Hashimoto et al., 2014), PARAGRAM (Wieting et al., 2015b), DeepCCA (Lu et al., 2015) and vecDCS (Tian et al., 2016). The results of the models are taken from the original papers. The overall results are shown in Table 2.

	ML Original	PAS	PARAGRAM	DeepCCA	vecDCS	SkipGram	CBOW	Our
AN	0.46	0.46	0.50	0.45	0.41	0.47	0.45	**0.60**
NN	0.37	0.49	0.51	0.45	0.51	0.51	0.49	**0.54**
VO	0.45	0.45	0.40	0.47	0.49	0.39	0.40	**0.47**
ALL	0.44	0.47	0.47	0.46	0.47	0.41	0.43	**0.54**

Table 2: The Spearman's correlation ρ of different methods on ML2010 datasets.

From Table 2, we can see that: (1) By incorporating the topic distributions of phrases, our context-aware word composition model achieves the best results on all three types of phrases: compared with SkipGram and CBOW baselines, our method achieves 22.2% and 20.8% ρ improvements on average. (2) Compared with state-of-the-art systems, our method achieves the best performances on all types of phrases. The result verified the effectiveness of contextual information in phrase representation.

Sentence Similarity Results

To assess our method on sentence representations, we conduct experiments on the semantic textual similarity dataset (STS2015) from SemEval 2015, which contains five datasets of different genres: answers-students, answers-forums, belief, headlines and images.

In our experiments, the element-wise addition method is employed as the base composition model for our context-aware word composition model. We compare our method with two baselines: the element-

wise addition composition model using word embeddings learned from CBOW and SkipGram. All of the models in this experiment is trained based on Wikipedia corpus. We also compare to several strong baselines: skip-thought vector (ST) (Kiros et al., 2015) and average Glove vector (Pennington et al., 2014). Because our proposed model aims at improving word composition model based on topic distribution, we don't compare with the methods which incorporate syntax information or other resources (Wieting et al., 2015a). The overall results are showed in Table 3.

From Table 3, we can note that: our context-aware word composition method significantly improved the performances on all of the datasets by incorporating the topic distribution information. Compared with the baselines CBOW and SkipGram, our method achieved 35.5% and 19.2% ρ improvements on average. And the topic distribution is a beneficial resource for modelling the context of a sentence for learning better representation of the sentence.

Model	Answers students	Answers forums	Beliefs	Headlines	Images	Overall
ST	0.361	0.330	0.246	0.436	0.177	0.310
GloVe	0.305	0.630	0.405	0.618	0.675	0.527
SkipGram	0.413	0.475	0.392	0.581	0.621	0.496
CBOW	0.477	0.620	0.467	0.573	0.684	0.564
Our	**0.632**	**0.631**	**0.657**	**0.681**	**0.761**	**0.672**

Table 3: The Spearson's correlation ρ for different methods on STS2015 datasets.

All of the previous experiments have verified that the context-aware combination model is effective and can achieve better results than the baseline models. Furthermore, the proposed context-aware model achieved the greatest improvements over base models at sentence level, and made the least progress on word level. We suspect that because the local contextual information is utilized in learning word representation, which weakens the value of global context. By contrast, the contextual information is rarely taken into consideration by word composition models. As a result, we believe the global contextual information is beneficial for learning representations of larger linguistic units, such as sentence.

4.3 The Effect of Using Different Base Composition Models

Our method is model free that it can employ any context-unware composition models as its base word composition models. In this section, we intend to clarify whether the context-aware method could enhance the representations on different base composition models. Concretely, we conduct experiments on four of the most commonly used word composition models as base models: element-wise addition (Mikolov et al., 2013), recurrent neural network (RNN) (Mikolov et al., 2010; Socher et al., 2011b), gated recurrent neural network (GNN) (Tang et al., 2015) and Long-Short-Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997; Le and Zuidema, 2015; Ghosh et al., 2016) on paraphrase detection task.

Paraphrase Detection

Paraphrase detection is a binary classification task which is used to decide whether two sentences express the same meanings, which is an appropriate task for evaluating our method. In this paper, we employ MSRPC datasets (Dolan et al., 2004).

Model	**C-unware**		**C-aware**	
	Acc	F	Acc	F
Addition	0.658	0.765	0.699	0.801
RNN	0.682	0.80	0.732	0.822
GNN	0.735	0.832	0.763	0.841
LSTM	0.739	0.838	**0.776**	**0.852**
ST	0.642	0.739	-	-
MSSG	-	-	0.692	0.793
SAMS	-	-	**0.786**	**0.853**

Table 4: Accuracies and F-Scores of paraphrase detection on MSRPC datasets.

For each base composition model, we compare our method with its context-unaware version. In addition, we compare with Skip-Thought (ST) vector as a strong baseline, MSSG and SAMS are used

Topic	Top 4 Frequent Words of Topic
Financial	money, million, cost, tax
Geography	river, lake, mountain, island
Information	user, systems, ibm, software
Sport	play, team, season, ball

Table 5: Top 4 topics of the word *'bank'*.

⟨ word:topic ⟩	Neighbors
bank:Geography	longitude:Geography, inland:Geography, coasts:Geography, southward:Geography
bank:Financial	bankers: Financial, debt: Financial, loans: Financial, finance: Financial

Table 6: The top 4 nearest neighbors of word *'bank'* with topics *'Geography'* and *'Financial'*.

as the multi-prototype word embeddings models for comparison. In this experiment, we implement a two layers RNN/GNN/LSTM with a max pooling layer as base word composition model. We randomly select 500 sentence pairs in training data as validation data to find the best parameters. We learn the best hyper-parameters based on validation data as follows: the hidden units for RNN/GNN/LSTM is 300, the mini-batch size as 100, the dropout rate is 0.4, the learning rate of SGD is 0.01. All of the word embeddings are trained on BNC (Consortium and others, 2007) for fair composition with SAMS. Accuracy and F-Score are used as the metrics. The results are shown in Table 4.

From Table 4, we can see that:(1) The context-aware representation consistently improved the performances on all the base word composition models. (2) Compared with Skip-thought vector model and MSSG model, our proposed model had achieved better performance, we believe the latent semantic information of a sentence may be the main reason that leads to the results. (3) SAMS achieved better results than our model, however, it utilized external knowledge resource (PPDB), which is a larger dataset for enhancing the performance on paraphrase detection task. The paraphrase detection results demonstrate that our context-aware representation brings beneficial information for different base word composition models and improves the performances on this task. The proposed model may achieve better results by utilizing more advanced base word composition models, we leave it for future work.

5 Detailed Analysis

To better understand the way of the proposed method works, this section provides detailed analysis on the quality of the topic-specific word embeddings and context-aware representations.

5.1 The Quality of Topic-Specific Word Representations

Topic-specific word representations are essential to our method, which is the basic unit for composing representations of larger linguistic units. In this section, we analyze the quality of topic distributions and topic-specific word embeddings.

For the reason that the proposed context-aware model is based on an assumption that a word can express distinct meanings with different topic assignments, so it is important to estimate whether topics can distinguish different senses of a word. Table 5 shows the top 4 topics of word *'bank'* and the most frequent words of these topics. From Table 5, we can infer that, *'bank'* with topic of *'Financial'* associates with the meanings of *'money'* or *'tax'*, and *'bank'* with *'Geography'* topic associates with the meanings of *'river'* or *'lake'*. In addition, We list the top 4 $\langle word : topic \rangle$ neighbors for *'bank:Geography'* and *'bank:Financial'* in Table 6. The conclusion can be drawn that the topic information can effectively distinguish distinct senses of a word.

5.2 The Quality of Context-Sensitive Word Composition

We analyze the quality of linguistic unit representations using the *'river bank'* and *'commercial bank'* as examples. We first present the top 3 most frequent topics of their words in Table 7.

Word	Topic Probabilities
bank	Financial(62.7%), Geography(23.4%), Information(7.3%)
river	Geography(89.7%), Information(0.07%) , Sport(0.01%)
commercial	Financial(86.3%), Information (6.5%), Law(5.0%)

Table 7: The top 3 most frequent topics of *'river'*, *'bank'* and *'commercial'*.

From Table 7, we can see that, both the word *'commercial'* and *'bank'* have high probability on topic *'Financial'*, so *'commercial bank'* will have a high probability belonging to topic *'Financial'*. In this way, the representation of *'commercial bank'* will mainly depend on the topic-biased representation under *'Financial'* topic, which is composed from topic-specific embeddings of *'commercial:Finanial'* and *'bank:Financial'*. By contrast, the representation of *'river bank'* will mainly depend on the embeddings of *'river:Geography'* and *'bank:Geography'*. In a word, the proposed model is capable of correctly identifying the important topics for a specific phrase, and generate proper representation for it.

In addition, we list top 5 nearest $\langle word : topic \rangle$ pairs of the phrases in Table 8. As shown in Table 8, all of the nearest neighbors of *'river bank'* are labelled with *'Geography'* topic and all of the nearest neighbors of *'commercial bank'* are related to its *'Financial'* topic. This result demonstrates the effectiveness of our method on learning accurate representations of phrases.

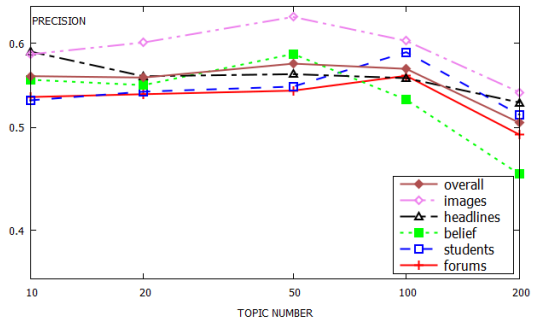

Figure 1: The precisions on STS2015 datasets with different numbers of topics in LDA model.

Phrase	$\langle word : topic \rangle$ **neighbors**
river bank	river:Geography, valley:Geography, park:Geography, north:Geography, boat: Geography
commercial bank	bank:Financial, leasing:Financial, merchandising: Financial, retailing: Financial, financing: Financial

Table 8: The top 5 nearest $\langle word : topic \rangle$ pairs for *'river bank'* and *'commercial bank'*.

The experimental results reveal that the topic distribution information could be used as the cue for learning proper representations of a linguistic unit in different contexts. And the proposed context-aware model can generate accurate representations for phrases.

5.3 The Number of Topics

One important parameter of our method is the number of topics of the LDA model. In order to detect the impact of the number of topics on our model, we conduct experiments using different topic numbers (including 10, 20, 50, 100 and 200) on STS2015 datasets with element-wise addition as base composition model, the results are shown in Figure 1.

From Figure 1, we can see that: (1) Our method is not very sensitive to the topic number, which achieved stable performances when using topic numbers range from 10 to 100. But the precision drops quickly when the number of topics is set as 200, we believe such large number of topics inevitably causes insufficient occurrences for learning topic-specific word embeddings, which is crucial basic units for our compositional method. (2) Our method achieved the best precision when the topic number is 50. We believe this is actually a trade-off between distinguishability and data sparsity.

6 Conclusions

In this paper, we have proposed a model-free context-aware word composition framework for text representation learning, which can effectively utilize the latent semantic information of the whole linguistic unit for learning context-aware representations for linguistic units. The proposed model is model-free in that our method can employ various context-unaware word composition models as the base model within our proposed framework. Experimental results demonstrated the effectiveness of our method on text representation learning at different granularities, including word, phrase and sentence, and the improvements on various base word composition models. In future work, to further improve the learned representations of linguistic units, we want to also take the non-compositional units into consideration, i.e., to solve the representations of multiword expressions like idioms or name entities, whose meanings

cannot be composed from the meanings of its constituent parts, such as *kill the goose that lays the golden eggs* and *speak of the devil*.

Learning Features from Co-occurrences: A Theoretical Analysis

Yanpeng Li
IBM T. J. Watson Research Center
Yorktown Heights, New York 10598, USA
liyanpeng.lyp@gmail.com

Abstract

Representing a word by its co-occurrences with other words in context is an effective way to capture the meaning of the word. However, the theory behind remains a challenge. In this work, taking the example of a word classification task, we give a theoretical analysis of the approaches that represent a word X by a function $f(P(C|X))$, where C is a context feature, $P(C|X)$ is the conditional probability estimated from a text corpus, and the function f maps the co-occurrence measure to a prediction score. We investigate the impact of context feature C and the function f. We also explain the reasons why using the co-occurrences with multiple context features may be better than just using a single one. In addition, based on the analysis, we propose a hypothesis about the conditional probability on zero probability events.

1 Introduction

In natural language processing (NLP) and information retrieval (IR), representing a word by its co-occurrences with contexts is an effective way to learn the meaning of the word and lead to significant improvement in many tasks (Deerwester et al., 1990; Brown et al., 1992; Mikolov et al., 2013). The underlying intuition known as distributional hypothesis (Harris, 1954) can be summarized as: "a word is characterized by the company it keeps" (Firth, 1957). However, there is a lack of theory to justify why it works, even for a simple task such as word classification or clustering. For example, to determine if the word "phycoerythrin" is a gene name, we found it was effective to use the ratio of the count of "phycoerythrin gene" to the count of "phycoerythrin" as features (Li et al., 2009), denoted by

$$\hat{P}(\text{“}Xgene\text{”}|X = phycoerythrin) = \frac{Count(phycoerythrin\ gene)}{Count(phycoerythrin)}$$

The ratio is equivalent to the estimation of the conditional probability $P(\text{“}Xgene\text{”}|X = phycoerythrin)$ from a large text corpus. The pattern "$Xgene$" is a context feature that indicates if the word "gene" appears right next to the word X. Assuming $Y \in \{0, 1\}$ is the gold standard label such as "being a gene name" and $C \in \{0, 1\}$ is a binary context feature such as "$Xgene$". The nature of the approach is to predict $P(Y = 1|X)$ by $P(C = 1|X)$ based on the intuition that there could be correlation between these two functions of X. Also $P(Y = 1|X)$ tends to be more difficult to estimate than $P(C = 1|X)$, since the gold standard labels are more expensive to obtain than the context patterns. We need to know why and when $P(C = 1|X)$ is effective to predict $P(Y = 1|X)$. Obviously, this study is beyond computational linguistics only but of general interest of probability and statistical theory.

In this work, we first show that in a word classification task, simple co-occurrence with a single context feature can achieve perfect performance under some assumptions. Then we investigate the impact of context features and different co-occurrence measures without the assumptions. We also explain the reasons why using co-occurrences with multiple context features, e.g., vector representation can be better than just using a single one. In addition, we give a further analysis of the first theorem for the case of continuous random variables and discuss some hypothesis that may open the door to a new area in probability theory.

Santa Fe, New Mexico, USA, August 20-26, 2018.

2 Notions

We consider a word classification task that assigns each word in a text corpus one or more class labels by the co-occurrences of the word with one or more context patterns. By going through the occurrence of each word in the corpus, we define each example as a tuple $(word, context, labels)$ denoted by $(X, \mathbf{c}, \mathbf{y})$. The component *X* is a discrete random variable taking the values from the set $\{x_1, ..., x_m\}$, where each element refers to a different word. The component $\mathbf{c} = (C_1, ..., C_n)$ is a vector of features, where each component C_k(*k* is from 1 to *n*) is a random variable that takes the value 1 or 0, indicating if a word or pattern appears in the context. Similarly we define $\mathbf{y} = (Y_1, ..., Y_t)$ as a vector of binary labels such as concepts. We aim to investigate how well we can assign each example a set of labels **y** by the co-occurrence information of *X* and C_k with insufficient or without **y** at training stage.

Note that for a label variable Y, there are two cases. It may depend on both *X* and **c** or depend on *X* only. In the tasks such as word sense disambiguation or part-of-speech tagging, the same word can be assigned to different labels in different contexts. In some tasks that investigate the meaning of words independently of contexts, e.g., building WordNet (Miller, 1995) or calculating word-word similarity, the same word X can only be assigned to an unique label 0 or 1 for each *Y*. In other words, *Y* is function of *X*, that is, for each *X*, $P(Y|X)$ equals 0 or 1. We consider both cases in our analysis, but we find that we can get much simpler results for the second case. Moreover, the word classification task for the second case can be generalized to the task of annotating everything with words. For example, describing an image with several words or a sentence is closely related to the task of classifying words into the class of description for the given image.

In the following sections, when we aim to investigate the impact of a single context feature C_k or a single task Y_t, for simplicity, we use a random variable C or Y to denote C_k or Y_t respectively. So the tuple $(X, \mathbf{c}, \mathbf{y})$ can be simplified as (X, C, Y) in the setting of single context feature and single task. To avoid "dividing by zero", we assume that $P(X) \neq 0$, $P(Y) \neq 0$ and $P(C) \neq 0$ in all the sections except Section 6 where we discuss some open problems about the conditional probability on zero probability events.

3 Conditional independence assumption

We show that in a special case if a context feature C is conditionally independent with the word feature X on label Y, the Pearson correlation coefficient between $P(Y = 1|X)$ and $P(C = 1|X)$ equals 1 or -1.

Theorem 1. *Given random variables* $X \in \{x_1, ..., x_m\}$, $C \in \{0, 1\}$ *and* $Y \in \{0, 1\}$, *if*

1. $P(C = 1, Y = 1) \neq P(C = 1)P(Y = 1)$
2. $P(C = 1, X = x_i|Y = 1) = P(C = 1|Y = 1)P(X = x_i|Y = 1)$ *and* $P(C = 1, X = x_i|Y = 0) = P(C = 1|Y = 0)P(X = x_i|Y = 0)$ *for every i from 1 to m*

, we have:

$$Corr(P(Y = 1|X), P(C = 1|X))^2 = 1$$

Proof.

$$\begin{aligned}
P(C = 1|X) &= \frac{1}{P(X)}(P(C = 1, X|Y = 1)P(Y = 1) + P(C = 1, X|Y = 0)P(Y = 0)) \\
&= \frac{1}{P(X)}(P(C = 1|Y = 1)P(X|Y = 1)P(Y = 1) \\
&+ P(C = 1|Y = 0)P(X|Y = 0)P(Y = 0)) \\
&\qquad \text{(using the conditional independence assumption)} \\
&= \frac{1}{P(X)}(\frac{P(C = 1, Y = 1)P(X, Y = 1)}{P(Y = 1)} + \frac{P(C = 1, Y = 0)P(X, Y = 0)}{P(Y = 0)})
\end{aligned}$$

$$
\begin{aligned}
&= \frac{1}{P(X)}\left(\frac{P(C=1,Y=1)P(X,Y=1)}{P(Y=1)}\right. \\
&\left.+ \frac{(P(C=1)-P(C=1,Y=1))(P(X)-P(X,Y=1))}{P(Y=0)}\right) \\
&= \left(\frac{P(C=1,Y=1)}{P(Y=1)} - \frac{P(C=1)-P(C=1,Y=1))}{P(Y=0)}\right)P(Y=1|X) \\
&+ \frac{P(C=1)-P(C=1,Y=1)}{P(Y=0)} \\
&= \frac{P(C=1,Y=1)-P(C=1)P(Y=1)}{P(Y=1)P(Y=0)}P(Y=1|X) + P(C=1|Y=0)
\end{aligned}
$$

Since $P(C=1,Y=1) \neq P(C=1)P(Y=1)$, $P(C=1|X)$is a linear function of $P(Y=1|X)$, so we have $Corr(P(Y=1|X), P(C=1|X))^2 = 1$ □

This theorem indicates that a perfect context feature for a given task is not necessarily the class label itself. Therefore, even if we have little information about Y, we still have the chance to know the information of $P(Y|X)$ by $P(C|X)$. Some previous works also reported similar findings in different tasks (Blum and Mitchell, 1998; Abney, 2002; Veeramachaneni and Kondadadi, 2009; Li, 2013). However, in practice it is almost impossible to get the case with exact conditional independence in different tasks. Even if it exists, it is difficult to find it because in order to calculate the conditional dependence we still need to know the joint probability $P(X,C,Y)$. Therefore, we need a theory to describe the performance in the situation with certain degree of conditional dependence. We also need to know the impact of different functions that convert simple co-occurrence measures e.g., $P(C=1|X)$ to feature values or prediction scores. In the following sections, we will show the results for the cases.

4 Co-occurrences with a single context feature

In this section, we study the case of co-occurrence with a single context feature for a single task. Although it seems simple, there is still no systematic theoretical framework for it. Based on the theory about the function of discrete random variables, we analyze the impact of context features and the functions that convert co-occurrence measures to prediction scores. Note that the cases discussed in this section are not under the conditional independence assumption introduced in Section 3.

4.1 Function of a discrete random variable

Since the co-occurrence based learning actually converts the word variable $X \in \{x_1, ..., x_m\}$ to another variable $S \in \{s_1, ..., s_u\}$ by certain co-occurrence measure such as $P(X, C=1)$ or $P(C=1|X)$, or equivalently, we can say S is a function of X. Our goal is to find the function that can achieve the best performance. Therefore, we investigate some general principles about the function of a discrete variable. In this work, we use Pearson correlation coefficient of conditional probabilities as the measure of performance, because it tends to make the complicated analysis simpler.

Lemma 1. *Let g be a function that maps $X \in \{x_1, ..., x_m\}$ to another random variable $S \in \{s_1, ..., s_u\}$. For any binary random variable $Y \in \{0,1\}$ and any function f that assigns S a real number, we have the following results:*

(1) $Cov(P(Y=1|X), f(S)) = Cov(P(Y=1|S), f(S))$

(2) $Cov(P(Y=1|X), P(Y=1|S)) = Var(P(Y=1|S))$

(3) $Corr(P(Y=1|X), P(Y=1|S)) = \frac{\sqrt{Var(P(Y=1|S))}}{\sqrt{Var(P(Y=1|X))}}$

(4) $Corr(P(Y=1|X), f(S)) = Corr(P(Y=1|S), f(S))Corr(P(Y=1|X), P(Y=1|S))$

Proof. (1).

$$E(P(Y=1|X)) = \sum_{i=1}^{m} \frac{P(X=x_i)P(Y=1,X=x_i)}{P(X=x_i)} = \sum_{i=1}^{m} P(Y=1,X=x_i) = P(Y=1)$$

Similarly, we can prove $E(P(Y=1|S)) = P(Y=1) = E(P(Y=1|X))$

$$Cov(P(Y=1|X), f(S)) = Cov(P(Y=1|X), f(g(X))) \qquad \text{(the definition of } g\text{)}$$
$$= \sum_{i=1}^{m} P(X=x_i)(P(Y=1|X=x_i) - E(P(Y=1|X)))(f(g(x_i)) - E(f(g(X))))$$
$$= \sum_{j=1}^{u} (f(s_j) - E(f(S))) \sum_{i\in\{i|g(x_i)=s_j\}} P(X=x_i)(P(Y=1|X=x_i) - E(P(Y=1|X)))$$
$$= \sum_{j=1}^{u} (f(s_j) - E(f(S)))P(S=s_j)(P(Y=1|S=s_j) - E(P(Y=1|X)))$$
$$= \sum_{j=1}^{u} P(S=s_j)(f(s_j) - E(f(S)))(P(Y=1|S=s_j) - E(P(Y=1|S)))$$
$$\text{(by } E(P(Y=1|X) = E(P(Y=1|S))\text{)}$$
$$= Cov(P(Y=1|S), f(S))$$

(2). Since $P(Y=1|S)$ is a function of S, let $f(S)$ be $P(Y=1|S)$ and using (1), and we have $Cov(P(Y=1|X), P(Y=1|S)) = Cov(P(Y=1|S), P(Y=1|S)) = Var(P(Y=1|S))$

(3). Based on (2), we have

$$Corr(P(Y=1|X), P(Y=1|S)) = \frac{Cov(P(Y=1|X), P(Y=1|S)))}{\sqrt{Var(P(Y=1|X))}\sqrt{Var(P(Y=1|S))}}$$
$$= \frac{Var(P(Y=1|S)))}{\sqrt{Var(P(Y=1|X))}\sqrt{Var(P(Y=1|S))}} = \frac{\sqrt{Var(P(Y=1|S)))}}{\sqrt{Var(P(Y=1|X))}}$$

(4). By combining (1) and (3), we have

$$Corr(P(Y=1|X), f(S)) = \frac{Cov(P(Y=1|X), f(S)))}{\sqrt{Var(P(Y=1|X))}\sqrt{Var(f(S))}}$$
$$= \frac{Cov(P(Y=1|S), f(S)))}{\sqrt{Var(P(Y=1|X))}\sqrt{Var(f(S))}} = \frac{Cov(P(Y=1|S), f(S)))}{\sqrt{Var(P(Y=1|S))}\sqrt{Var(f(S))}} \frac{\sqrt{Var(P(Y=1|S))}}{\sqrt{Var(P(Y=1|X))}}$$
$$= Corr(P(Y=1|S), f(S))Corr(P(Y=1|X), P(Y=1|S))$$

□

The first equation plays a fundamental role, which indicates that if S is function of X, to calculate the covariance between $P(Y=1|X)$ and $f(S)$, we don't need the appearance of X but just S, as if X is safely hidden. It simplifies the analysis by avoiding explicit analysis of the divergence between $P(Y=1|X)$ and $f(S)$ such as $|P(Y=1|X) - f(S)|$ or $P(Y=1|X)f(S)$. Therefore, the correlation coefficient can also be written in a much simpler form. In the word classification task, the term $f(S)$ can be viewed as a classifier based on the new features S. The $Corr(P(Y=1|X), f(S))$ measures its correlation with the best possible classifier $P(Y=1|X)$ based on the word features X (single view) only. If Y is a function of X (the second case discussed in Section 2), we have $Corr(P(Y=1|X), f(S)) = Corr(Y, f(S))$, which measures almost exactly the performance of the word classification task. Based on these results, we are able to analyze the performance of the new features generated by co-occurrences.

4.2 An upper bound of any function

Theorem 2. *Given random variables $X \in \{x_1, ..., x_m\}$, $C \in \{0, 1\}$ and $Y \in \{0, 1\}$, for any function f that maps $P(C = 1|X)$ to a real number, there is:*

$$Corr(P(Y = 1|X), f(P(C = 1|X)))^2$$
$$= Corr(P(Y = 1|P(C = 1|X)), f(P(C = 1|X)))^2 Corr(P(Y = 1|X), P(Y = 1|P(C = 1|X)))^2$$

Proof. Since $P(C = 1|X)$ is a function of X, let S be the random variable that takes the value $P(C = 1|X)$ and based on Lemma 1 (4), we have:

$$Corr(P(Y = 1|X), f(S))^2 = Corr(P(Y = 1|S), f(S))^2 Corr(P(Y = 1|X), P(Y = 1|S))^2$$

Equivalently, we can write the equation as:

$$Corr(P(Y = 1|X), f(P(C = 1|X)))^2$$
$$= Corr(P(Y = 1|P(C = 1|X)), f(P(C = 1|X)))^2 Corr(P(Y = 1|X), P(Y = 1|P(C = 1|X)))^2$$

□

It shows that the performance of the classifier $f(P(C = 1|X))$ is determined by the product of two parts. The first part depends on both the context feature C and the function f. The second depends on the context feature only but not on f. Therefore, if we fix the context feature C to select the function f, using $Corr(P(Y = 1|X), f(P(C = 1|X)))^2$ (correlation with the gold standard $P(Y = 1|X)$) and $Corr(P(Y = 1|P(C = 1|X)), f(P(C = 1|X)))^2$ (correlation with the "silver" standard $P(Y = 1|P(C = 1|X))$) produce the same result. Similar to Lemma 1(1), we don't need the appearance of $P(Y = 1|X)$ for function selection. In addition, since any correlation coefficient ranges from -1 to 1, we have:

$$Corr(P(Y = 1|X), f(P(C = 1|X)))^2 \leq Corr(P(Y = 1|X), P(Y = 1|P(C = 1|X)))^2$$

It indicates that if we want to improve the performance by fixing a certain context feature C and changing different functions f , e.g., from $P(C = 1|X)$ to $log(P(C = 1, X)/(P(C = 1)P(X)))$ (the point wise mutual information), the performance cannot be arbitrarily high but upper bounded by the squared correlation coefficient between $P(Y = 1|X)$ and $P(Y = 1|P(C = 1|X))$. Given fixed word feature set X and label Y, the upper bound is determined only by the context feature C but not relevant to the function f. Actually, the upper bound is a special case of maximal correlation coefficient (Rényi, 1959; Hall, 1967). In order to build a high performing classifier $f(P(C = 1|X))$, we must find a way to improve the upper bound $Corr(P(Y = 1|X), P(Y = 1|P(C = 1|X)))^2$, in other words, to select a good context feature C. However, it is not easy to do it from this formula directly. Therefore, we relate the upper bound to the special case introduced in Section 3. Since $P(C = 1|X)$ is a function of itself, based on Theorem 2, we have:

$$Corr(P(Y = 1|X), P(C = 1|X))^2 \leq Corr(P(Y = 1|X), P(Y = 1|P(C = 1|X)))^2$$

The squared correlation coefficient $Corr(P(Y = 1|X), P(C = 1|X))^2$ not only reflects the performance of a special co-occurrence measure $P(C = 1|X)$, but also provide a way to improve the upper bound (for other co-occurrence measures). Based on Theorem 1, under the conditional independence assumption, $Corr(P(Y = 1|X), P(C = 1|X))^2$ equals 1, so that $Corr(P(Y = 1|X), P(Y = 1|P(C = 1|X)))^2$ equals 1 as well. As what we discussed in Section 3, it is important to know more about the cases out of the conditional independence assumptions, but it is difficult to analyze $Corr(P(Y = 1|X), P(C = 1|X))^2$ based on the conditional dependence directly without any other assumptions. In the following section, we show that we are able to obtain much simpler results under the assumption that the label variable $Y \in \{0, 1\}$ is a function of X.

4.3 Assuming that *Y* is a function of *X*

In Section 2, we have pointed out that there are many cases in practice that assume *Y* is a function of *X*. In addition, if we can explain everything about this simple task, we may naturally find the cues to move to more advanced tasks such as sentence classification.

Theorem 3. *If* $Y \in \{0,1\}$ *is a function of* $X \in \{x_1, ..., x_m\}$*, for a context feature* $C \in \{0,1\}$ *we have:*

$$Corr(P(Y=1|X), P(C=1|X))^2$$
$$= Corr(P(Y=1|Y), P(C=1|Y))^2 Corr(P(C=1|X), P(C=1|Y))^2$$

Proof. Since *Y* and *C* are both binary random variables, by Lemma 1 (4) we replace Y by C without loss of generality, and we have:

$$Corr(C=1|X), f(S))^2 = Corr(P(C=1|S), f(S))^2 Corr(P(C=1|X), P(C=1|S))^2$$

Since *Y* is a function of *X* and $P(Y=1|Y)$is a function of Y, in the above equation replace *S* by *Y* and $f(S)$ by $P(Y=1|Y)$, and we have:

$$Corr(C=1|X), P(Y=1|Y))^2 = Corr(P(C=1|Y), P(Y=1|Y))^2 Corr(P(C=1|X), P(C=1|Y))^2$$

Since *Y* is a function of *X*, for any X, there is $P(Y=1|X) = P(Y=1|Y) = Y$. So, we have:

$$Corr(C=1|X), P(Y=1|X))^2 = Corr(C=1|X), P(Y=1|Y))^2$$
$$= Corr(P(Y=1|Y), P(C=1|Y))^2 Corr(P(C=1|X), P(C=1|Y))^2$$

□

This result describes what a good context feature is and can give guidance for the selection of context features for a particular task. It is much simpler and more practical than what we can get by the direct analysis of the conditional dependence, since we just need to know the joint distribution of (X, C) and (C, Y) rather than (X, C, Y). This result can also be written as a simpler form as follows.

Corollary 1. *If* $Y \in \{0,1\}$ *is a function of* $X \in \{x_1, ..., x_m\}$*, for a context feature* $C \in \{0,1\}$ *we have:*

$$Corr(P(Y=1|X), P(C=1|X))^2 = \frac{(P(C=1, Y=1) - P(C=1)P(Y=1))^2}{P(Y=1)(P(Y=0))Var(P(C=1|X))}$$

Proof.

$$\begin{aligned}
&Corr(P(Y=1|X), P(C=1|X))^2 \\
&= Corr(P(Y=1|Y), P(C=1|Y))^2 Corr(P(C=1|X), P(C=1|Y))^2 && \text{(Theorem 3)} \\
&= \frac{Cov(P(Y=1|Y), P(C=1|Y))^2}{Var(P(Y=1|Y))Var(P(C=1|Y))} \frac{Var(P(C=1|Y))}{Var(P(C=1|X)} && \text{(Lemma 1 (3))} \\
&= \frac{(E(P(Y=1|Y)P(C=1|Y)) - E(P(Y=1|Y))E(P(C=1|Y)))^2}{Var(P(Y=1|Y))} \frac{1}{Var(P(C=1|X)} \\
&= \frac{(P(C=1, Y=1) - P(C=1)P(Y=1))^2}{P(Y=1)(P(Y=0))Var(P(C=1|X))}
\end{aligned}$$

□

In the equation, the term $(P(C=1, Y=1) - P(C=1)P(Y=1))^2$ describes the dependency between context feature C and the class label Y. The term $Var(P(C=1|X))$ addresses the dependency between context feature C and each word feature X. We can see more clearly in another equivalent form:

$$Corr(P(Y=1|X), P(C=1|X))^2 = \frac{P(Y=1)}{P(Y=0)} \frac{(\frac{P(C=1,Y=1)}{P(C=1)P(Y=1)} - 1)^2}{E((\frac{P(C=1,X)}{P(C=1)P(X)} - 1)^2)}$$

From this mutual information style form, we can conclude that a good context feature for a particular task should be a trade-off between high dependence with label Y and low dependence with every word feature X. The conclusion is similar to our prevsious work (Li, 2013), but the result here is more general, under weaker assumptions, and more accurate (e.g., equations rather than inequalities). During the engineering work of context feature selection, intuitively, people tend to emphasize the numerator (tight connection with the label Y), but ignore the denominator (loose connection with each word X). However, the theory indicates that we should consider both factors to make a good co-occurrence. For example, some experiments showed that the co-occurrences with simply high frequency words such as "the" and "of" chould be used as good features (Li and Yu, 2014). Obviously, for these function words, in the equation both numerator and denominator tend to be smaller than the class-indicative words such as "$Xgene$" mentioned in Section 1, but the ratio of them may be larger. Therefore, it will be interesting to investigate what happen if both numerator and denominator approach to zero. Actually, the scope of candidates of context features is far beyond context words, since any binary pattern such as letters or sound that appears in the context can be a context feature.

5 Co-occurrences with multiple context features

So far, we have investigated the co-occurrences with a single context feature only. In practice, we usually find representing a word by a vector of co-occurrences with multiple context features tends to perform better. In the following theorem, we show part of the reason by analyzing the performance of the vector from multiple context features.

Theorem 4. *If we represent each X by a r-dimensional vector* $\mathbf{x} = (P(C_1 = 1|X), ..., P(C_r = 1|X))$*, where* $C_1, ..., C_r$ *are r context features (*$r \leq n$*), for the label* $Y \in \{0, 1\}$ *and any funcation f that maps each veoctor* $\mathbf{x}$ *to a real number, we have:*

(1) $Corr(P(Y=1|X), f(\mathbf{x}))^2 = Corr(P(Y=1|\mathbf{x}), f(\mathbf{x}))^2 Corr(P(Y=1|X), P(Y=1|\mathbf{x}))^2$

(2) $Corr(P(Y=1|X), P(Y=1|\mathbf{x}))^2 = \frac{Corr(P(Y=1|X), P(Y=1|P(C_k=1|X)))^2}{Corr(P(Y=1|\mathbf{x}), P(Y=1|P(C_k=1|X)))^2}$ *for every k from 1 to n*

Proof. (1) Since X is a discrete random variable and $\mathbf{x} = (P(C_1 = 1|X), ..., P(C_r = 1|X))$, we know that $\mathbf{x}$ is a discrete random variable and a function of X as well. Therefore, based on Lemma 1 (4), we come to the conclusion directly:

$$Corr(P(Y=1|X), f(\mathbf{x}))^2 = Corr(P(Y=1|\mathbf{x}), f(\mathbf{x}))^2 Corr(P(Y=1|X), P(Y=1|\mathbf{x}))^2$$

(2) Since for each $\mathbf{x} = (P(C_1 = 1|X), \ldots, P(C_r = 1|X))$ with the a different value, the value of $P(C_k = 1|X)$is unique, the discrete random variable $P(C_k = 1|X)$ is a function of $\mathbf{x}$. In Lemma 1 (3), replace X by $\mathbf{x}$, and S by $P(C_k = 1|X)$ without loss of generality, and we have

$$Corr(P(Y=1|\mathbf{x}), P(Y=1|P(C_k=1|X)))^2 = \frac{Var(P(Y=1|P(C_k=1|X)))}{Var(P(Y=1|\mathbf{x}))}$$

Since $\mathbf{x}$ is a function of X and $P(C_k = 1|X)$ is a function of X, according to Lemma 1 (3), we have

$$Corr(P(Y=1|X), P(Y=1|\mathbf{x}))^2 = \frac{Var(P(Y=1|\mathbf{x}))}{Var(P(Y=1|X))}$$

$$Corr(P(Y=1|X), P(Y=1|P(C_k=1|X)))^2 = \frac{Var(P(Y=1|P(C_k=1|X)))}{Var(P(Y=1|X))}$$

By combining the three equations above, we have:

$$Corr(P(Y=1|X), P(Y=1|\mathbf{x})) = \frac{Corr(P(Y=1|X), P(Y=1|P(C_k=1|X)))}{Corr(P(Y=1|\mathbf{x}), P(Y=1|P(C_k=1|X))^2}$$

□

Similar to Theorem 2, the performance of the vector-style representation can also be written as the products of two parts. The second part $Corr(P(Y=1|X), P(Y=1|\mathbf{x}))^2$ is an upper bound of the performance of any function, which is determined only by the set of context features $C_1, ..., C_r$. The result (2) shows that the upper bound from the vector is always better than the performance from any individual context feature, since we can prove $Corr(P(Y=1|X), P(Y=1|\mathbf{x})) \geq Corr(P(Y=1|X), P(Y=1|P(C_k|X)))^2$. Similar to the proof of (2), it can be proved that $Corr(P(Y=1|X), P(Y=1|\mathbf{x}))^2$ always increases when more context features are introduced. However, $Corr(P(Y=1|\mathbf{x}), f(\mathbf{x}))^2$ may decrease when the vector become longer, so its real performance $Corr(P(Y=1|X), f(\mathbf{x}))^2$ may increase or decrease depending on the first term. Therefore, we need to find the factors that determine the combined performance of the two terms in the future.

6 Assuming that the probability of *X* is zero

In the previous sections, we discussed the impact of context feature C. In addition, we should also consider the impact of the content feature X. We found an interesting case that satisfies exactly the conditional independence assumption in Theorem 1, although it is beyond the word classification task. If we assume that X is a continuous random variable such as $X \in \mathbb{R}$, we have $P(X=x)=0$, $P(X=x, C|Y)=0$, and $P(X=x|Y)=0$ for every real number $x \in \mathbb{R}$, which fits exactly the conditional independence assumption. The trouble is that we have the conditional probability $P(C=1|X)$ and $P(Y=1|X)$ in the format of $0/0$. It is well known that the conditional probability on an event with zero probability is undefined in the current probability theory, but there is no proof that it cannot be defined logically. If we assume that in some condition $P(C=1|X)$ and $P(Y=1|X)$ exist and are between 0 and 1, for example, as if we may define $f(x)=\frac{sin(x)}{x}$ when $x=0$ as $f(0)=\lim_{x\to 0}\frac{sin(x)}{x}$, the open question is: does the following equation (from Section 3) still hold?

$$P(C=1|X) = \frac{P(C=1,Y=1)-P(C=1)P(Y=1)}{P(Y=1)P(Y=0)}P(Y=1|X) + P(C=1|Y=0)$$

If the answer is "Yes", it suggests that given every specific point $X=x$, the possibility of appearance of any two non-independent events (e.g., $C=1$ and $Y=1$) has a linear relationship. One underlying philosophy is that two things with low dependence (e.g., low semantic similarity) could have strong correlation in some case, since $Corr(P(C=1|X), P(Y=1|X))$ is always 1 or -1 even if $|\frac{P(C=1,Y=1)-P(C=1)P(Y=1)}{P(Y=1)P(Y=0)}|$ is very small but not zero. Based on it we may have even more interesting findings. If the answer is "No", we would have a more complicated result, e.g., two or more different equations: one for $P(X)\neq 0$ and one or more for $P(X)=0$. An interesting fact is that for Bayes' theorem the answer of the similar question is "Yes", since if we assume $P(X)=0$ and $P(C=1|X)\in[0,1]$, we will have $P(X|C=1)=P(C=1|X)P(X)/P(C=1)=0$.

We also believe that such probability is more useful in practice because it gives to more exact knowledge and prediction. For example, assuming that $X=x$ is a specific time or position represented by a real number, $P(Y=1|X=x)$ (where $P(X=x)=0$) could mean the possibility of the occurrence of Y at the point of time or position x, which is more exact than the probability $P(Y=1|X\in[x1,x2])$, where $P(X\in[x1,x2])\neq 0$. Interestingly, such model is closely related to physics, and we will give a further analysis in the future.

7 Conclusions and future works

In this paper, we give a theoretical study of the approaches that learn the representation of word by the approaches like $f(P(C=1|X))$ or $f(P(C_1=1|X), ..., P(C_r=1|X))$. The theoretical framework is able to explain a set of approaches based on distributional semantics and give guidance for algorithm

design such as the selection of context feature and the co-occurrence metrics. In the next steps, we are going to give a deeper analysis of each formula that determines the performance, such as the diversity between multiple context features, find more principles that are constructive to algorithm design in practice and extend the theory to analyze other advanced tasks such as sentence classification and semantic similarity. Moreover, it will be interesting to see if we can verify the hypothesis in Section 6 and get inspiration from it.

Abstract

Extracting a bilingual terminology for multi-word terms from comparable corpora has not been widely researched. In this work we propose a unified framework for aligning bilingual terms independently of the term lengths. We also introduce some enhancements to the context-based and the neural network based approaches. Our experiments show the effectiveness of our enhancements over previous works and that the system can be adapted in specialized domains.

Title and Abstract in French

Vers un système unifié pour l'extraction terminologique bilingue de termes simples et complexes

L'extraction d'une terminologie bilingue pour les termes complexes à partir de corpus comparables n'a pas été beaucoup étudiée. Dans ce travail, nous proposons un système unifié pour l'alignement des termes bilingues indépendamment de la longueur des termes. De plus nous introduisons également des améliorations aux approches basées sur l'alignement de contexte et sur un réseau neuronal. Nos expériences montrent l'efficacité de nos améliorations sur les travaux antérieurs, et le fait que le système peut être adapté en domaines de spécialité.

1 Introduction

Bilingual terminology extraction from comparable corpora has aroused a lot of attention since the 1990s (Fung, 1995; Rapp, 1999). Two classes of approach have been developed depending on the nature of the term to be aligned. The first class concerns the alignment of single-word terms using context-based or neural network approaches while the second attempts to align multi-word terms relying on compositional approaches. Few studies have focused on providing a unified framework for aligning single-word and multi-word terms, apart from Delpech et al. (2012) and Taslimipoor et al. (2016). The first requires some specific linguistic information like the morpheme translation table, which makes it difficult to employ for two languages from different linguistic families such as English and Chinese. The second incorporates word embeddings into their collocation alignment system but it is limited to several types of mapping that must match a set of pre-defined syntactic patterns. Our objective is to provide such a unified framework for aligning terms of variable length in specialized domains without specific linguistic knowledge of the source or target language.

Large size comparable corpora in specialized domains are not always available. Consequently, many data driven systems cannot learn from enough information. A possible solution to this problem is to associate external data such as general domain corpora (Hazem and Morin, 2016) to the specialized corpora. Our work adapts this method in order to improve the system performance.

Besides the enrichment of the data, our work focuses on studying and improving different state-of-the-art approaches both for single-word term and multi-word term alignments, which are finally unified into a single framework for alignment of terms of any length. We first describe the context-based projection

Proceedings of the 27th International Conference on Computational Linguistics, pages 2855–2866
Santa Fe, New Mexico, USA, August 20-26, 2018.

approach, and based on discussions in previous works, we introduce two enhancements which improve our final results. Secondly, we cover the bilingual word embedding approach which depends on vector representations of words that can be learned on large text collections using different neural networks (Bengio et al., 2003; Mnih and Hinton, 2008; Collobert and Weston, 2008; Mikolov et al., 2013b), then we also propose an enhancement that re-normalizes the word embedding vector length in order to improve the results.

After studying the approaches for single-word terms which are our fundamental components for processing multi-word terms, following the idea in Morin and Daille (2012), we propose a new system called Compositional Approach with Word Embedding Projection (CMWEP) to combine the advantages of the traditional compositional approach and the bilingual word embedding approach. Our final results show considerable improvements over the state-of-the-art approach for bilingual multi-word term extraction. Moreover, the proposed method is able to align variable length terms in a single process.

2 Single-Word Term Alignment

In this section, we describe the two principal state-of-the-art approaches used for bilingual lexicon extraction from comparable corpora. Furthermore we introduce our enhancements in order to overcome various limitations of these approaches. The reason why we want to study these approaches for single-word terms (SWTs) is that they are fundamental low-level elements in our approaches for multi-word terms (MWTs).

The two approaches for SWTs are known as distributional and distributed semantics (Hermann and Blunsom, 2014). Both use word vector representations. The vectors in the first approach are sparse, high dimensional and explicit (Levy and Goldberg, 2014). The vectors in the second one are dense, low dimensional and generalized. They both rely on the distributional hypothesis (Harris, 1968) which assumes that a word and its translation tend to appear in the same lexical contexts.

2.1 Context-Based Projection Approach

The historical context-based projection approach, also known as the standard approach (SA) has been studied in a variety of works (Fung, 1995; Rapp, 1999; Chiao and Zweigenbaum, 2002; Bouamor et al., 2013; Hazem and Morin, 2016; Jakubina and Langlais, 2017). To implement this approach, we first build a co-occurrence matrix for the source and target languages, where each line represents a context vector in an n-word window. These vectors are then normalized using the Mutual Information (MI (Fano, 1961)) for instance. Then we get the word in the target language vector space by projecting each element in the context vector via a bilingual seed lexicon. Finally, the candidate translations are ranked by calculating the similarity of the projected context vector with all the context vectors into the target language. We use the Cosine similarity measure as it is the one most used in previous works. In addition it enables us to parallelize the process of similarity comparison.

Due to the small size of specialized domain corpora, occurrences of words are not always statistically reliable. In order to improve word co-occurrence counts, Hazem and Morin (2016) show that using a general language corpus can significantly improve the standard approach results. They suggest two methods for exploiting external resources. The first adaptation called Global Standard Approach (GSA) consists in building the context vectors from a comparable corpus composed of the specialized and the general comparable corpora. We implement the second adaptation called Selective Standard Approach (SSA) which gives the best results in their experiments. Elements of this adaptation are defined as follows: Let S be the vocabulary of the specialized corpus, G the vocabulary of the general corpus, w the word to represent and c a context word that appears in the window around w such that :

$$\forall w \in S \cap G, \forall c \in S \cap G,\ cooc(w,c) = cooc_S(w,c) + cooc_G(w,c) \quad (1)$$

Distance-Sensitive Co-occurrence

In the standard approach, we note that some context words in the window are not effectively related to the central word. Usually the further the latter is away from a context word, the less they are semantically related. This effect is more obvious especially after stop word filtering. A word originally far from the

central word can appear in the context window. This makes the context vector less relevant as a representation for the central word. To reduce this effect, we propose a weighted co-occurrence depending on the distance between the two words, denoted by Distance-Sensitive Co-occurrence (DSC):

$$DSC(w,c) = g(c|w) \times cooc(w,c) \quad \text{where} \quad g(c|w) = \Delta(w,c)^{-\lambda}, \;\; \lambda \in [0,1] \tag{2}$$

where w and c respectively denote the central word and the context word, $g(c|w)$ the weight that is distributed to c as the context of w, Δ is the distance between the two words and λ a hyper-parameter that determines the degree of penalization for distant word pairs. Note that λ = 0 is equivalent to a uniform distribution.

Weighted Mutual Information

Another limitation in the standard approach with MI is that MI overestimates low counts and underestimates high counts. In order to overcome this drawback, we propose the Weighted Mutual Information (WMI) inspired by the work of Pennington et al. (2014) where they introduce a function to smooth word co-occurrences. The original function is a weight function which prevents the overestimation of word co-occurrences. We also use it as a weight function for MI:

$$WMI(w,c) = f(cooc(w,c)) \times MI(w,c) \tag{3}$$

$$f(x) = \begin{cases} (x/x_{max})^{\alpha}, \alpha = 3/4, x_{max} = 20, \text{ if } x < x_{max} \\ 1 \text{ otherwise} \end{cases} \tag{4}$$

We have kept the same value for the hyper-parameter α. Concerning the x_{max}, since our corpora size is much smaller than the one in their work, we decide to make it correspondingly smaller (20). By adding the weight function, the output value for low co-occurrence counts is in fact reduced and the high co-occurrence counts are not impacted because their weight coefficient is always 1.

2.2 Neural Network-Based Approach

The neural network based approach uses neural network models to obtain word representation in low dimensional and dense vectors. These word vectors are also called word embeddings (Mikolov et al., 2013b). In the case of bilingual word embedding, Mikolov et al. (2013a) propose a method to learn a linear transformation from the source language to the target language for the task of lexicon extraction from bilingual corpora. Much research has been focused on this area since then. Faruqui and Dyer (2014) introduce canonical correlation analysis (CCA) to project the embeddings in both languages to a shared vector space. Xing et al. (2015) propose the orthogonal transformation and the vector length normalization during the learning phase. Artetxe et al. (2016) generalize these works and explain the equivalence of different objective functions under orthogonality and different normalization procedures. They show that combining these models effectively improves the results for both monolingual and bilingual tasks. Finally Smith et al. (2017) point out that the mapping should be orthogonal in order to be self-consistent.

Normalization, Mean Centering and Orthogonal Mapping

The method of Artetxe et al. (2016)[1] combines several related studies in this particular order:

1. Normalizing each word vector to unit length.
2. Dimension-wise mean centering for source and target matrices.
3. Learning the transformation matrix by mathematical analysis while constraining the orthogonality of the transformation matrix. In the original work of Mikolov et al. (2013a), the matrix is learned by gradient descent which is an on-line method.

Renormalization After Mean Centering

We observe in the implementation above that once the dimension-wise averages are subtracted, each word vector is no longer unit normalized. As a consequence, this could lead to a violation against the

[1] https://github.com/artetxem/vecmap

initial intuition that each word should have the same importance for learning the transformation matrix. Therefore we propose a second normalization after the mean centering. Although this would make the expected random product of any dimension not strictly zero, our experiment results show that it is still more beneficial for the bilingual task. Intuition could be that the mean centering was more in consideration of monolingual tasks, whereas in bilingual tasks, the length normalization of each word vector outweighs the mean centering.

Concatenation for Usage of External Data

Word embedding systems usually need a large amount of data in order to obtain reliable word vectors. However the size of domain-specialized comparable corpora is generally very modest (fewer than one million words). The word embedding models trained on our small size specialized corpora are not capable of generalizing meaningful features. To overcome this problem, the idea exploited in Hazem and Morin (2016) which seeks external general data to enrich the training phase can be useful, but it occasionally makes the specialized word representation biased by the general corpus. This is especially the case when the specialized corpus contains some infrequent or ambiguous words that have different meanings in different corpora. Considering these factors, we propose to use a concatenated vector of the one trained on the specialized corpora and on the general corpora as our new word vector. More specifically, we want to concatenate a relatively small size word vector from the specialized corpora and a relatively large size one from the general corpora. In our experiment, the word vector size for the word embedding model trained on the specialized corpus is set to be 100 and the size for the model trained on the general corpus is set to be 300. Hence we preserve the specialized corpus features albeit with less corresponding weight features in the transformation matrix. Consequently the new concatenated word vector carries self-contained information from both corpora (Figure 2). Another advantage is that by doing the concatenation, it is not necessary to retrain our word embedding models over large corpora because we can use existing pre-trained models available. This could save a great deal of time in practice while improving efficiency.

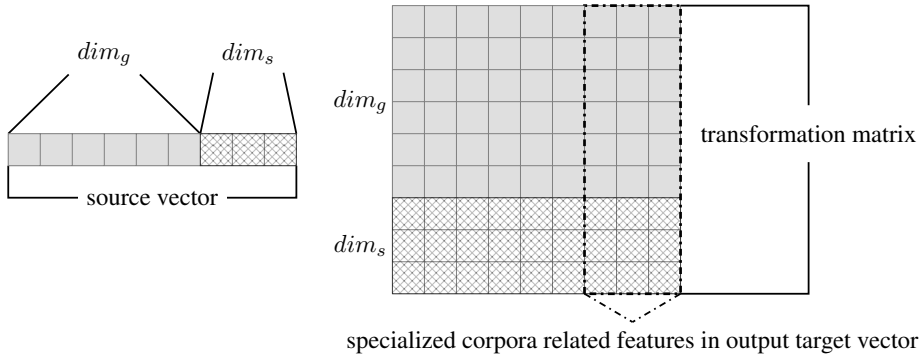

Figure 1: Let dim_g be the dimension size of the word vector from general corpora, and dim_s the size from specialized corpora. The transformation matrix will have a total number of $(dim_g + dim_s)^2$ weight features. Among these, $dim_g \times (dim_g + dim_s)$ will be source or target general corpora related features and only $dim_s \times (dim_g + dim_s)$ source or target specialized corpora related ones.

3 Multi-Word Term Alignment

Regarding MWTs, we first describe the compositional approach and an adapted version which combines the traditional compositional approach and the context-based projection approach. We also introduce a unified representation for MWTs which enables the mapping of variable length terms. Finally we propose a new approach in this family which combines the traditional compositional approach and the neural network approach. To the best of our knowledge, this is the first time that word embedding vectors are used in a compositional approach.

3.1 Compositional Approach

The compositional approach (CA) (Grefenstette, 1999; Tanaka, 2002; Robitaille et al., 2006) is a simple and direct approach that consists in translating each element of an MWT via a dictionary and generating all possible combinations and permutations. The ranking of the candidates is done by their frequency in the target corpora.

Compositional Approach with Context-Based Projection

The main limitation of the traditional compositional approach is the inability to translate a term when one of its composing words is not in the dictionary. To solve this problem, Morin and Daille (2012) propose the Compositional Approach with Context-Based Projection (CMCBP), where the objective is to combine the advantages of the standard and compositional approaches by substituting non-dictionary words with their context vectors obtained by the standard approach. The CMCBP begins by building the co-occurrence matrix as in the standard approach. Then it applies a direct translation reinforced by context alignment. If a word of a term to be translated is not present in the dictionary, it uses the context vector obtained by the standard approach and projects it into the target language, otherwise it takes the context vector of the target language directly. The next step is the generation of all combinations of possible translation representations for a source language term. Finally, the candidate terms are ranked according to their similarity with terms of the same length in the target language, and the final score for each possible translation is defined by the arithmetic or geometric mean of each similarity score.

MWT Representation

CMCBP does not, however, take the mapping of MWTs of variable lengths into account. For example, the English term "*wind vane*" can be translated as "*girouette*" in French and the English term "*wind energy*" by "*Windenergie*" in German. In order to take these cases into account, we propose to modify the representation of the MWTs, inspired by the works of Blacoe and Lapata (2012) in which the representation of a sentence is the sum of the distributional representations of each composing word:

$$vector(term) = \frac{1}{n}\sum_{i}^{n}\frac{vector(w_i)}{||vector(w_i)||}, \quad \text{where } n \text{ is the term length} \tag{5}$$

Notice that this is different from the mean vector introduced in the original work, here the mean vector is calculated from the normalized vectors because we want each component word to have the same impact rather than having the whole meaning influenced by the random vector length which could lead to some unpredictable bias. The MWT representation is then stored in a single vector, giving the ability to handle translations of different lengths while reducing the calculation time. In fact, in CMCBP, aligning an MWT requires calculating all possible permutations, so we must compare a factorial number of vectors for sorting candidates against a single vector with this new representation.

Compositional Approach with Word Embedding Projection

Following the idea of CMCBP, we propose a new method called Compositional Approach with Word Embedding Projection (CMWEP). It can be implemented by applying the following steps:

1. Prepare two word embedding models for the source and the target language with the same vector size.
2. Learn the transformation matrix using the approach we mentioned in 2.2.
3. Translate each word in an MWT via a bilingual seed lexicon. If a word is not in the dictionary, we return the embedding vector projected by the transformation matrix, and if the word is in the lexicon, we return the averaged vector of a list of embedding vectors for each possible translation. Giving an MWT "ABC" for instance, if "A" and "B" are in the lexicon and have their respective translations: {"a_1", "a_2", "a_3"}, {"b_1", "b_2"} and "C" is not in the lexicon, then for "A" and "B", we return the averaged vector of the word embeddings list of {"a_1", "a_2", "a_3"} and {"b_1", "b_2"} directly by the lookup table of the target language word embedding system, for "C" we return its projected embedding vector using the learned transformation matrix. In this way each word in the MWT in the source language is represented by a single vector in the target language space.

4. Generate the representation vector for the whole MWT by applying the method in the section above since each composing word has been represented by one vector.
5. Compare the translated vector to each candidate in the target language using a similarity measure such as Cosine. The candidate translations are ranked according to the scores of the similarity measure.

Here we show an overview which illustrates how the CMWEP turns a MWT into a vector. In addition, as it shares the same idea as in CMCBP, this diagram also represents the process in CMCBP.

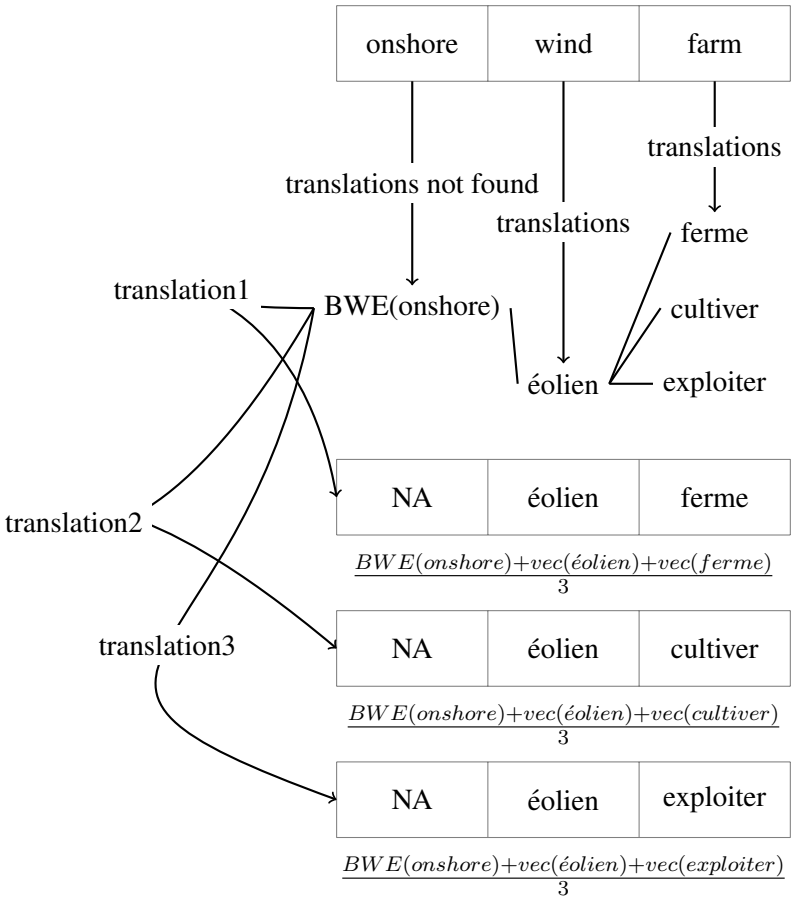

Figure 2: An example for translating the MWT *onshore wind farm* into French. The translations for each composing word are limited to those that exist in the comparable corpus and the bilingual dictionary. The final similarity between the MWT and a candidate is the maximum of the three similarities between each of the three possible representation vectors and the candidate vector.

4 Experiment Data and Resources

In this section, we outline the different textual resources used for our experiments: the comparable corpora, the reference lists, the bilingual seed lexicon and the pre-trained word embedding models.

4.1 Comparable Corpora

For our experiments, we used two specialized comparable corpora that have been used in previous works for bilingual terminology extraction in technical domains:

Breast Cancer Corpus (BC) is composed of documents collected from the Elsevier website[2]. The documents were taken from the medical domain within the subdomain of breast cancer.

[2] http://www.elsevier.com

Wind Energy Corpus (WE) has been released by the TTC project. The corpus has been crawled using the Babouk crawler (Groc, 2011) based on several keywords such as "*wind*", "*energy*", "*rotor*" in English and their translations in French.[3].

News Commentary (NC) consists of political and economic commentaries crawled from the web[4]. We use this corpus as our external data.

4.2 Gold Standard

Our reference lists for SWTs in BC and WE corpora are the same as used in Hazem and Morin (2016) which consist of 248 SWTs for BC and 139 for WE. The reference list for MWTs in WE is built based on the term list provided. Finally this list contains 73 MWT pairs but each pair has multiple variant translations and in our settings, we consider them to be also the gold translations[5]. If we deploy the 73 MWTs to a list where each pair contains only one translation, the list would have a size of 277 pairs. Because some MWTs have far more possible translations than others, we decide not to use the deployed version list to prevent the result from being biased by these MWTs. The reference list for the Italian/English task is the same as in Artetxe et al. (2016) which contains 1,500 entries. We would like to mention that the candidate list for one MWT includes all the words in the vocabulary plus all the MWTs extracted by a symbolic terminology extraction system, which generally extracts three times as many MWTs as words in the vocabulary. The terms are extracted following some pre-defined syntactic patterns, for example the pattern *NOUN NOUN* could lead to the extraction of *shop assistant*. So the one-to-many or many-to-one mapping is theoretically findable. Moreover, our reference list for the MWT task contains only out-of-dictionary MWTs. Table 1 presents the principal characteristics of the data.

Corpus	**# distinct words**		**# content words**		**Reference List**
	FR	EN	FR	EN	
BC	521,262	525,934	6,630	8,821	SWT: 248
WE	314,549	313,943	6,038	7,134	MWT: 73, SWT: 139
NC	5.7 M	4.7 M	23,597	29,489	

Table 1: Characteristics of comparable corpora in our experiments

4.3 Bilingual Lexicon

For our French/English experiments, we use the French/English dictionary ELRA-M00337[6] (243,539 entries). From this dictionary we select a subset of 3,007 entries from the BC corpora and a subset of 2,745 entries from the WE corpora based on a word frequency threshold of 5. These two subsets are used as the training data in our word embedding mapping experiments. For our Italian/English experiments, we only use the same seed lexicon[7] as used in Artetxe et al. (2016) where 5,000 entries are manually selected.

4.4 Pre-trained Word Embedding Models

To be fully comparable, in the Italian/English experiments we use the same model as in Artetxe et al. (2016). This could be retrieved by following the instructions they provide. The English embeddings were trained on a 2.8 billion word general corpus (UKWAC + WIKIPEDIA + BNC)[8], while a 1.6 billion word general corpus ITWAC was employed to train the Italian embeddings. As for the French/English embeddings, the vectors in dimension 300 were obtained using the skip-gram model described in Bojanowski et al. (2016) with default parameters[9].

5 Experiment Settings and Results

We conducted two sets of experiments. The first one aims at validating our enhancements to the state-of-the-art approaches by comparing the results of the bilingual SWT extraction in general and specialized domains. The second experiment aims at studying the application of the proposed approaches of the bilingual MWT extraction focusing on a specialized domain which is our main interest. This kind of task often lacks specialized data. As pointed out in Mikolov et al. (2013a), applications to low resource domains is a very interesting topic with much to be explored.

5.1 Standard Approach

In the standard approach, the window size is 3 (a total of 7 words are considered), which is the same as in Hazem and Morin (2016). The distance weight parameter λ in distance-sensitive co-occurrence is empirically set to be 0.25.

5.2 Word Embedding on Specialized Corpora

We use the implementation of *word2vec* from *deeplearning4j*[10] to train the word embedding model on our specialized corpora. Considering the relative low frequency of some words in specialized corpora, we apply the skip-gram algorithm which is supposed to work better with infrequent words[11]. We set the negative sample to 20, the window size to 5 and the training epoch to 20.

5.3 Results on SWT Task

Table 2 shows the results of the bilingual SWT extraction using the standard approach (SA) and its variant, the Selective Standard Approach (SSA) for the breast cancer corpus (BC) and the wind energy corpus (WE). It also includes the results of our two enhancements: Weighted Mutual Information (WMI) and Distance-Sensitive Co-occurrence (DSC).

Standard Approach	**BC**	**WE**
Hazem and Morin (2016)†	25.9	15.6
SA + WMI	28.9	21.4
SA + DSC	27.4	15.8
SA + WMI + DSC	**29.5**	**21.8**

(a) Result (MAP%) of standard approaches for the bilingual SWT extraction

Selective Standard Approach	**BC**	**WE**
Hazem and Morin (2016)†	56.5	44.4
SSA + WMI	55.0	33.9
SSA + DSC	**57.3**	**45.3**
SSA + WMI + DSC	55.8	35.7

(b) Result (MAP%) of selective standard approaches with NC corpus as the external data for the bilingual SWT extraction

Table 2: Context-Based Projection approaches results for bilingual SWT extraction. † indicates results obtained by our implementation of the approach.

We observe in Table 2a that WMI alone improves the results compared to those obtained by Hazem and Morin (2016) with MI but also compared to those when using the *Discounted Odds Ratio* (Evert, 2005) as the normalization method, where the MAP is 0.270 for BC and 19.4 for WE. This shows the interest of penalizing small occurrences to compensate the overestimation of the original MI. The second observation is that DSC alone also improves the results. This confirms our intuition that the further a context word is from its central word, the less relevant it is. Finally, we see that combining both enhancements gives the best result. So we could consider that the two enhancements are not mutually exclusive. Another observation is that the improvement of DSC for WE is indeed poorer than for BC, but the tendency is always improving. So we think our hypothesis above holds true for the WE data. Again we can see the same tendency when combining WMI. Note that, despite the difference in improvement between the two datasets, the enhancement that our approach offers is still relevant.

The results in Table 2b shows that WMI is less efficient when the data is enriched because the overestimation of small occurrences is smoothed by the addition of the enlarged overall data as discussed in

[10] http://deeplearning4j.org/

[11] https://code.google.com/archive/p/word2vec/

Hazem and Morin (2016). Moreover, since some term elements to be translated are quite infrequent or even non-existent in the general corpus, it is possible that penalizing all the small occurrences reduces discriminative features in the general corpus. Besides, although the results of SSA are different the two corpora share again the same tendency: they both reach their best when using DSC without WMI. However DSC always improves the results whether it is applied alone or combined with WMI. Again, it shows that the two enhancements are not mutually exclusive with external data.

Bilingual Word Embedding	**Accuracy**
Mikolov et al. (2013a)‡	34.93
Artetxe et al. (2016)‡	39.27
Our method (Renorm.)	**39.60**

(a) Accuracy % (p@1) of bilingual word embedding approaches for the Italian/English general word mapping task. The word embedding vectors are trained on wiki corpora mentioned in 4.4.

Bilingual Word Embedding	**BC**	**WE**
Hazem and Morin (2017)‡	82.3	-
L^2 + MC + Orth.	27.4	21.8
Concat + L^2 + MC + Orth.	82.4	**83.1**
Concat + L^2 + MC + Orth. + Renorm.	**83.2**	**83.1**

(b) Result (MAP%) of bilingual word embedding approaches for bilingual SWT extraction

Table 3: Bilingual Word Embedding approaches results for bilingual SWT extraction. ‡ indicates results reported by the authors.

Table 3 shows the results of the bilingual word embedding approaches on SWTs of the specialized BC and WE corpora along with the general WIKIPEDIA corpus. Our final proposed method is in the last line in each table. We can see that without external data, the results are not better than the traditional approach.

In Table 3a the three factors (denoted by L^2*, MC, Orth.*) resumed in Artetxe et al. (2016) improve the original results of Mikolov et al. (2013a). By adding an additional operation between the mean centering and the orthogonal mapping, our method brings a small but consistent improvement that can also be found in the special domain task in Table 3b. Other than that, the external data information stored in the pre-trained word embeddings significantly improves the results when carefully concatenated to those trained on special corpora.

5.4 Results on MWT Task

Model	**Accuracy**	**MAP**
CA	59.0	61.5
CMCBP	49.3	61.4
CMCBP + WMI + DSC	46.6	63.2
CMCBP + SSA	50.7	66.0
CMCBP + SSA + WMI + DSC	53.4	66.3
CMWEP + L^2 + MC + Orth.	52.1	67.8
CMWEP + L^2 + MC + Orth. + Concat.	**61.6**	73.3
CMWEP + L^2 + MC + Orth. + Concat. + Renorm.	**61.6**	**73.4**

Table 4: Accuracy (p@1) and MAP % of different approaches for MWTs in the WE corpus

Table 4 shows results with different approaches on MWTs in the special domain WE corpus. The traditional compositional approach (CA) has better accuracy than CMCBP because the candidates are ranked by their frequency in the target language corpus while the candidates in CMCBP are ranked by the similarity measure, so theoretically those translated by CA are also translated by CMCBP but with the same similarity score (1.0). Therefore, the final rank in CMCBP is to some degree randomized as multiple top candidates have the same score. Nevertheless, when using external data (+SSA), the MAP is considerably improved by CMCBP, this shows that the CMCBP can effectively find many out-of-dictionary translations that can not be found by CA. The same problem also exists in CMWEP.

Another remarkable point is that unlike the SWT bilingual extraction with SSA, combining WMI and DSC improves the results in MAP with or without external data.

Our word embedding methods (CMWEP) notably improve the results when using information carried by external data (+ *concat*) by almost 12 points in MAP and 2.6 points in accuracy. Combining the usage of external data and the renormalization gives the best result. The characteristics of the WE corpus determine the fact that for most MWTs, each component word are included in the dictionary. So CA already provides a high result especially for the accuracy, if we took a less academic or less cleaned corpus for example the Amazon Reviews where there are more out-of-vocabulary words because of spelling mistakes and web languages, we expect the result of CA to be much lower while the result of other approaches would be less impacted. This is also why the renormalization improves the result very slightly, since most of the translations are projected by a CA-like process.

5.5 Error analysis

The error analysis is made by manual observation: we first extract the 28 MWTs for which no translation has been found in the in the top@1 of our best performing model (the last line in Table 4), then we study these MWTs one by one. Among the 28 MWTs, we observe three categories:

1. **Weak compositionality**. The translation of the whole is not a combination of all the translations for each element (Melamed, 2001). 10 MWTs (35.7%) belong to this type. For example "*pitch angle*" is translated as "*angle d'inclinaison* (lit. *angle of tilt*)" by the system while the gold one should be "*angle de calage* (lit. *angle of sitting*)" where the word "*calage*" is not the translation of any word in the bilingual dictionary. Similarly, the gold translation for "*rotor shaft*" is a single word "*arbre*" which is basically the translation of one composing word "*shaft*". This problem could be even worse between two further languages, Baldwin and Tanaka (2004) report that at least 50% of the Japanese *NN* compounds are not translated through a compositional strategy into English.
2. **Ambiguous translations**. Multiple possible translations have the same similarity at the top@n list because each composing word has multiple translations in the dictionary and some combinations exist in the terminology candidate list. 12 MWTs (42.9%) belong to this type. For example, "*low frequency*" is translated by "*rotation inférieure* (lit. *inferior rotation*)" while it should be "*basse fréquence* (lit. *low frequency*)". Both "*inférieure*" and "*basse*" are translation of "*low*", and "*rotation*" and "*fréquence*" are translation of "*frequency*". This problem also relates to the monolingual word disambiguation.
3. **Different orders with same words**. Since our method ignores the word order, two sequences of the same set of words have the same representation vector. 6 MWTs (21.4%) belong to this type. For example, "*power installation*" is translated as "*puissance d'installation* (lit. *power of installation*)" while it should be "*installation de puissance* (lit. *installation of power*)". We could have taken the word order into consideration but it would increase a huge amount of calculation time. Moreover, the alignment of variable length terms would not be manageable.

6 Conclusion and future work

This work proposes a unified framework for bilingual terminology extraction of multi-word terms, improving on several previous works. Our experiments demonstrate the effectiveness of our enhancements of previous works. Generally speaking, the bilingual word embedding method with external data information plus the three factors resumed in Artetxe et al. (2016) and the renormalization outperforms previous works and brings us the best result. Moreover we observe that without external information, the traditional approach with our proposed enhancements still has very competitive results. For future work, we would like to restructure the representation of MWTs which is now based on a naive hypothesis that all the notional words contribute equally to the whole meaning of an MWT. In addition, as we mentioned in section 5.5, the performance for two further languages would be interesting to see and the disambiguation for words with multiple possible translations could be very useful.

Abstract

Neural activation models that have been proposed in the literature use a set of example words for which fMRI measurements are available in order to find a mapping between word semantics and localized neural activations. Successful mappings let us expand to the full lexicon of concrete nouns using the assumption that similarity of meaning implies similar neural activation patterns. In this paper, we propose a computational model that estimates semantic similarity in the neural activation space and investigates the relative performance of this model for various natural language processing tasks. Despite the simplicity of the proposed model and the very small number of example words used to bootstrap it, the neural activation semantic model performs surprisingly well compared to state-of-the-art word embeddings. Specifically, the neural activation semantic model performs better than the state-of-the-art for the task of semantic similarity estimation between very similar or very dissimilar words, while performing well on other tasks such as entailment and word categorization. These are strong indications that neural activation semantic models can not only shed some light into human cognition but also contribute to computation models for certain tasks.

1 Introduction

The human ability of translating concepts into words and back depends on the ability of mind to decode and encode meaning. This mental process, which is not currently completely understood, has captivated the interest of both neuroscientists and computational linguists (Haxby et al., 2001; Ishai et al., 1999; Cree and McRae, 2003; G. Kanwisher et al., 1997; Just et al., 2010). Specifically, when a person experiences a visual stimulus of a concept, reads, speaks or writes a word, particular neuronal regions in the brain are activated (Pulvermller, 2001).

Various studies have been carried out to explore brain encoding and decoding mechanisms when a stimulus is present, as detailed next. For visual stimuli, studies have shown that is feasible to discriminate and reconstruct images using patterns of neural activity, mainly found in the visual cortex (Kay et al., 2008; Thirion et al., 2006; Nishimoto et al., 2011; Naselaris et al., 2009; Miyawaki et al., 2008), the part of brain responsible for visual information processing. Other works have demonstrated the relationship between cognitive perception and speech (Benson et al., 2001; Formisano et al., 2008). Regarding textual stimuli, researchers have shown distributed semantic maps of words are present in our brains (Huth et al., 2012; Sudre et al., 2012).

Lexical semantics are based on the assumption that similar words appear in similar contexts (Harris, 1954). Based on that assumption, two different approaches for building semantic models have been proposed. The first approach is to encode word semantics, by applying dimensionality reduction of context-word occurrence matrix which was computed using large corpora (Deerwester et al., 1990; Bullinaria and Levy, 2012). The second approach replaces thse "counting" by predictive models (Baroni et al., 2014) based on neural networks (Bengio et al., 2000; Mnih and Hinton, 2007; Mikolov et al., 2013;

*The research was performed when the author was a postdoctoral researcher at School of ECE, NTUA in Athens, Greece.

Proceedings of the 27th International Conference on Computational Linguistics, pages 2867–2878
Santa Fe, New Mexico, USA, August 20-26, 2018.

Turian et al., 2010; Collobert and Weston, 2008). Counting models calculate and weight context vectors, while predictive models learn word vectors by guessing the context in which these words tend to appear.

In pursuance of enriching such lexical semantic models with cognitive information, as well as discovering the cognitive representation of word semantics, a number of studies have attempted to examine the mapping between semantic representation of computational and cognitive models. In prior work, it has been shown that semantic of words are related to activation potentials in regions of the brain and that decoding between neural activations and semantic content (Mitchell et al., 2008; Palatucci et al., 2009; Sudre et al., 2012; Murphy et al., 2012; Pulvermller, 2001) is possible. Furthermore, neural activations are shown to have predictive power with respect to semantics at the word (Mitchell et al., 2008; Jelodar et al., 2010) and sentence (Jing et al., 2017; Anderson et al., 2017) level. Computational studies that aim to explore the influence of neural activations in word representations have shown that by incorporating neural activations when training lexical semantic models can improve their generalization ability despite the small amount of neural activation data used (Fyshe et al., 2014; Ruan et al., 2016). These works show that a strong relationship exists between computational semantic models and neural representations. However, it remains to be seen how cognitive semantic representations, including localized neural activation patterns can help improve the performance of computational semantic models, especially for complicated classification and recognition tasks.

Motivated by the aforementioned studies that show correlation between localized neural activations and word semantics, we propose a computational model for semantic similarity that utilizes predicted neural activations learned from a small set of concrete nouns. The proposed model is applied to a variety of natural language processing tasks. The neural activation prediction model used here for lexical expansion is that proposed in (Mitchell et al., 2008). In our list of experiments, we first compare the performance of the proposed neural activation model for a concrete noun semantic similarity task and show that for certain word pairs it outperforms the state-of-the-art. Then we evaluate the performance of neural activation vectors for a word classification, sensory modality (sense) classification and textual entailment task. The fusion of neural and traditional word embedding vectors are shown to outperform the state-of-the-art. To our knowledge, this is the first time brain imaging data are successfully used for the aforementioned tasks.

2 Related Work

A significant body of literature investigates neural activations by mapping word semantics to fMRI data. Most of them have in common a basic idea published in (Mitchell et al., 2008). In this work, a model is introduced that maps low dimensional word coocurence vectors to neural activations. The approach is validated in a neural activation-based word classification task. This work shows that the mapping between lexical semantic spaces constructed via computational lexical semantic algorithms and 3D neural activations representations measured via fMRIs is possible.

A first variant of the aforementioned model was introduced in (Jelodar et al., 2010), where the use of WordNet features was investigated for constructing the lexical semantic space. Word classification results reported showed similar performance to (Mitchell et al., 2008), however, by fusion of the two lexical semantic models improved classification results where achieved.

A second approach, introduced in (Levy and Bullinaria, 2012), extends the work in (2008) by increasing the number of fMRI voxels used in the neural activation vectors and the number of featurs (dimension) of the lexical semantic model showing additional performance improvement.

Algorithms that count word coocurences and utilize hand-crafted features for constructing lexical semantic models can be found in (Bullinaria and Levy, 2012; Baroni and Lenci, 2010).Moreover, various lexical semantic models that predict a word based on its context have also elaborated (Bengio et al., 2000; Mikolov et al., 2013; Collobert and Weston, 2008). Word prediction models tend to perform better in natural language processing tasks such as analogy, similarity, synonym detection, concept taxonomy (Baroni et al., 2014) and sentiment analysis (Socher et al., 2011; Socher et al., 2013). However, their relationship with cognitive lexical representation is not yet well understood, at least to a degree that would allow us to improve current computation lexical semantic models. Along these lines, there have

been two main lines of work. In (Fyshe et al., 2014), neural activations were integrated in the training procedure of lexical semantic models in order to learn word embeddings that include latent neural information. Although a small number of words was used to bootstrap the neural activation representations, it have been shown that their model can predict unseen words and generalizes well across different topics. Ruan et al. (2016), have shown that neural activations for different parts of the brain are correlated with word embeddings especially skip-grams. A semantic model was also proposed for training word embeddings as a first step towards including cognitive information in a word vector representation.

3 Approach

3.1 Neural activations prediction

The neural activation prediction model used here is that proposed in Mitchell (2008)[1] First activation potentials are measured from fMRI images. We consider voxels to be 3D pixels created by MRI scanning software depicting brain state. Every voxel v is associated with a $TN \times V'$ array, M, of neural activation values (blood flow), where V' is the number of voxels, T is the number of trials, N is the number of stimuli, in our case different nouns. The first step is to select the most stable (salient) voxels, V to include in the neural activation model. The stability score s_v for voxel v is computed as the average pairwise Pearson correlation ϱ for all the different row combinations of M, as follows:

$$s_v = \frac{2}{TN(TN-1)} \sum_{i=1}^{TN} \sum_{j=i+1}^{TN} \varrho(M_{i,:}, M_{j,:}), \quad \forall\, v = 1 \cdots V' \tag{1}$$

where $M_{i,:}$ is the ith row of matrix M. High stability scores, s_v, as described in Eq. 1, indicate that corresponding voxels have consistent representations across different trials and nouns.

Next, the neural activation predictive model proposed in (Mitchell et al., 2008) is defined.

For this purpose we identify a set of m seed words s_1, s_2, ..., s_m, and a function $f_i(w)$ that estimates the association between seed word s_i and word w. The core assumption of the model is that words that are closely associated have similar neural activation patterns, thus the mapping from the associative (semantic) space to the neural activation (voxel) space is estimated as follows:

$$y_v(w) = \sum_{i=1}^{m} c_{v,i}\, f_i(w), \quad \forall\, v = 1 \cdots V, \tag{2}$$

where $y_v(w)$ is the activation of voxel v for word w, $f_i(w)$ is a scalar value that reflects the association between the i^{th} seed word s_i and the word w, m is the number of seed words (semantic features), V is the total number of voxels, and $c_{v,i}$ is a learned weight ranging between 0 and 1. A set of 25 verbs (seed words) was identified in (Mitchell et al., 2008) as semantic features s_i; seed words were manually selected according to psycholinguistic criteria. The similarity function $f_i(w)$ was set to the (normalized) co-occurrence frequency of the i^{th} seed word and w, estimated on a corpus. The weights $c_{v,i}$ were estimated using the fMRI data on words w using linear or ridge regression estimation. Once $c_{v,i}$ have been estimated, Eq. 2 can be used to predict the neural activation of unseen words[2].

3.2 From neural activations to similarity

Based on the hypothesis that similar words have similar neural activations, we propose a model to estimate word similarities based on neural activations predicted using Eq. 2. We evaluated various metrics for computing semantic similarity from neural activations. We present only a top performing metric

[1]The features in (2008) are attractive because of their simplicity and low-dimensionality, and generalize well for lexical expansion to a large lexicon compared to other works described in Section 2 that potentially perform slightly better.

[2]Although Eq. 3 can be used to perform lexical expansion an any token w for which $f_i(w)$ can be computed, the proposed framework (choice of $f()$ and associated fMRI data) is meant for concrete words and typically only neural activations for concrete words are reported in the literature.

formulated as the weighted square distance, namely:

$$S(w_1, w_2) = \sum_{v=1}^{V} b_v \ (y_v(w_1) - y_v(w_2))^2, \tag{3}$$

where $S(w_1, w_2)$ is the semantic similarity between words w_1 and w_2, V represents the number of voxels used in the predicted neural image, $y_v(w)$ is the activation of a voxel for word w, and b_v is a learned weight of the contribution of a particular voxel to the similarity metric. In Figure 1 the predictions

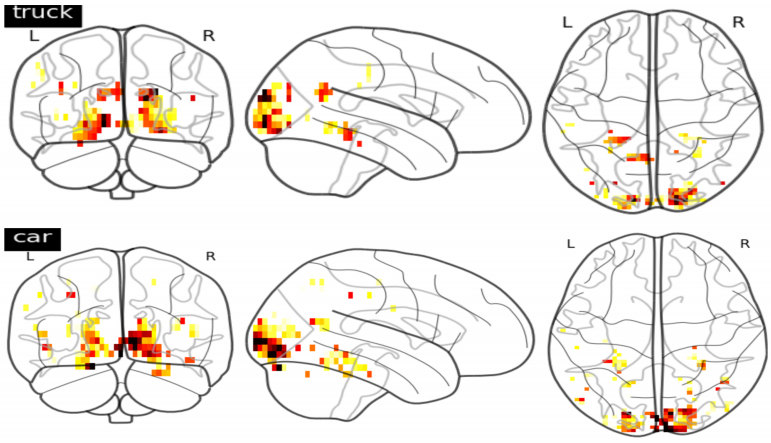

Figure 1: Neural activation images for two similar concrete nouns including the 500 most stable voxels (participant P1). This figure shows just one horizontal slice in Montreal Neurological Institute (MNI) space of the three-dimensional image.

of neural activations for two highly similar nouns in fMRI dataset are presented. Visualizations were created from 500 voxels to gather insight for our computational model. Observe that both brain images have similar neural activations both in terms of which parts of the brain are activated and the activation values. Although, we don't utilize localization information, our weighting schema implicitly detects activation patterns by variations in b_i coefficients.

4 Experimental Data and Preprocessing

We built the neural activations prediction model as in (Mitchell et al., 2008) using fMRI data for 60 concrete nouns. We calculate the semantic features $f_i(w)$ for each concrete noun, w, by counting its co-occurences with 25 manually selected verbs in a large corpus created in (Iosif et al., 2016) by aggregating results of web queries to Yahoo. The fMRI data used in our experiments were collected and processed by (Mitchell et al., 2008) and are publicly available. In this dataset, each one of the participants was presented 60 concrete nouns (for 6 times each) through a line drawing which was labeled with the corresponding noun. Each out of nine subjects, was asked to think about properties of the presented noun during scanning procedure. Finally, a vector representation of the whole cortex neural activation was extracted. Further details about the dataset can be found in (Mitchell et al., 2008) and its supplementary website[3]. Prior to training both training and test data are averaged across trials and the final neural activations of each noun are mean normalized. The following datasets have been used for semantic similarity, taxonomy creation, sense classification and entailment tasks. The code of the present work is publicly available[4].

MEN: For the semantic similarity task we train and evaluate our model on the MEN dataset (Bruni et al., 2014) which consists of 3000 word pairs (2000 for training set and 1000 pairs for test set). Each word pair is associated with a similarity score. This score was computed by averaging the similarities

[3] http://www.cs.cmu.edu/~tom/science2008/
[4] https://github.com/athn-nik/neural_asm

that provided by human annotators. We hand-labeled the dataset to keep only concrete nouns because the neural activation prediction model is trained only on concrete nouns. This resulted in 1114 pairs (562 unique words) in the training set and 524 pairs (438 unique words) in the test set. The similarity scores were normalized between zero and one. We also created 2 subsets of MEN of 39 highly similar and 79 highly dissimilar word pairs using a thresholding technique, where pairs with similarity score over 0.85 and under 0.1 belong in the first and second subset respectively.

ESSLLI: For the taxonomy creation task, we evaluate our model on the ESSLLI dataset (Baroni et al., 2008). It consists of a three-level hierarchy (2-3-6 classes). The lowest level of hierarchy contains 6 classes of concrete nouns (birds, land animals, fruit, greens, vehicles, tools), the middle 3 classes (vegetables, artifacts, animals) while the upper class is distinguished between living beings and objects.

Sensicon: For sense classification, we use the Sensicon (Tekiroglu et al., 2014) dataset. Sensicon is a dictionary which contains 22684 English words and associates each word with 5 numerical scores and a part of speech annotation. The scores correspond to the relevance of the word to each of the 5 senses, namely vision, hearing, taste, smell and touch. In order to use these scores for the sense classification task we selected nouns who have non-zero scores in only one sense results in 1011 words.

SNLI dataset: For the entailment task, we used the Stanford Natural Language Inference (SNLI) dataset (Bowman et al., 2015) which contains around 570K sentence pairs with three labels: entailment, contradiction and neutral. We preprocessed the initial dataset to keep only training and testing examples that have at least two or three concrete nouns that are also in the MEN dataset for both premise and hypothesis. This resulted in 30,498 training and 592 test samples for the case of at least three common words and 171,528 training and 3201 test samples for the case of at least two common words with MEN.

5 Experiments on Semantic Similarity

In this section we present baseline results on the neural activation prediction model of (Mitchell et al., 2008) and investigate the performance of the proposed neural activation semantic model of Eq. 3 for a semantic similarity task on the MEN dataset. Our goal here is first to reproduce the results in (Mitchell et al., 2008) and then to investigate the properties of neural activation embeddings semantic models compared to traditional embedding models, e.g., word2vec in (Mikolov et al., 2013).

5.1 Neural activations prediction

As proposed in (Levy and Bullinaria, 2012), we choose the 500 most stable voxels from the fMRI images. Then, $c_{v,i}$ is estimated as in Eq. 2 by applying linear regression per voxel across different words with regularization. To evaluate the neural activation prediction model we used cosine similarity in order to evaluate if our prediction for the possible pair of test words is correct or not. Correct prediction means that sum of the cosine similarities of the correct matched pairs is greater than the false matched pair as shown next:

$$cos(\vec{i_1}, \vec{p_1}) + cos(\vec{i_2}, \vec{p_2}) > cos(\vec{i_2}, \vec{p_1}) + cos(\vec{i_1}, \vec{p_2}), \tag{4}$$

where $\vec{i}$ is the actual image and $\vec{p}$ is the predicted image of 500 voxels. The dataset, which consists of 60 nouns, is split in train set (the rest 58 nouns) and test set (2 nouns) for all possible 1770 combinations using cross-validation.That process is followed for every one of 9 participants. The results are shown reported in Table 1 when using linear and ridge regression to estimate $c_{v,i}$ in Eq. 2. Results in Table 1 are on average consistent with the baseline results reported in (Mitchell et al., 2008). We achieved higher performance for some participants and lower for others. This can be attributed to the different tools we used to implement the system (as we used scikit-learn (Pedregosa et al., 2011) and (Mitchell et al., 2008) used Matlab). Moreover, we experimented with the number of voxels and our results agree with the findings reported in (Levy and Bullinaria, 2012).

Participant ID	Linear Regression	Ridge Regression	Mitchell et. al
1	0.79	0.84	0.83
2	0.75	0.82	0.76
3	0.63	0.76	0.78
4	0.63	0.79	0.72
5	0.61	0.78	0.78
6	0.58	0.65	0.85
7	0.58	0.75	0.73
8	0.65	0.68	0.68
9	0.57	0.68	0.82
Mean	0.64	0.75	0.77

Table 1: Baseline Model Results

5.2 Similarity task

For the semantic similarity task, we applied Eq. 3 for the word pairs of the MEN dataset. The $y_v(.)$s of Eq. 3 were computed using Eq. 2 utilizing up to 250 voxels. We exploited the training subset of MEN for learning the b weights of Eq. 3 using linear regression. Those weights were used for computing the similarities for the test subset of MEN. The Spearman correlation coefficient between the human similarity scores (ground truth) and the similarity scores computed by Eq. 3 was used as evaluation metric. The results are presented in Table 2, where we compare the performance of the proposed neural model (averaged across participants) against the performance yielded by the w2vec word embeddings (Mikolov et al., 2013) trained on the GoogleNews corpus.

Subset	**Number of voxels**	**Neural model**	**w2vec**
All Concrete nouns	50	0.43	0.76
	100	0.47	0.76
	150	0.48	0.76
	200	0.48	**0.76**
Most & Least similar	50	0.58	0.73
	100	0.82	0.73
	150	0.82	0.73
	200	**0.88**	0.73
Least similar	50	0.43	0.43
	100	0.44	0.43
	150	0.47	0.43
	200	**0.63**	0.43
Most similar	50	0.28	0.14
	100	0.63	0.14
	150	0.68	0.14
	200	**0.83**	0.14

Table 2: Evaluation results on the concrete nouns subset of the MEN test set, and on most and least similar concrete word subsets.

Overall, the w2vec model outperforms the neural model achieving 0.76 correlation on all concrete nouns. For the neural model, performance increases as more voxels are exploited reaching 0.48 correlation is obtained for at least 150 voxels. In Table 2, the performance is also shown for three subsets of the MEN test set, namely, "Most & Least similar", "Least similar" and "Most similar" concrete nouns.

For all three subsets, the performance achieved by the neural model exceeds[5] the performance of w2vec when at least 100 voxels are used. The performance improvement becomes more pronounced as the number of voxels increases. The best correlation score achieved is 0.88 for the case of the "Most & Least similar" subset for 200 voxels, outperforming the w2vec model (0.73 correlation). Especially for the case of the "Most similar" evaluation subset, we observe a remarkable difference between the two models, i.e., 0.83 vs. 0.14 for the neural and the w2vec model, respectively.

6 Classification and Entailment Experiments

Next we present the performance of the neural activation semantic model for a taxonomy creation (semantic class classification), sensory modality (sense) classification, and lexical entailment task. Neural vectors are averaged across participants and evaluated both standalone and in combination (early or late fusion) with traditional word embedding models.

6.1 Taxonomy Creation

The performance of similarities computed by Eq. 3 were also evaluated on a taxonomy creation task on the ESSLLI dataset (Baroni et al., 2008). Taxonomy creation is performed using the neural activation vectors $\vec{y}(w)$ estimated from Eq. 2 and the coefficient vectors $\vec{b}$ defined in Eq. 3 trained using linear regression on the whole of the MEN dataset. Then, the similarity matrix $S(w_i, w_j)$ is estimated for all pairs in the dataset using Eq. 3 and then the spectral clustering algorithm proposed in (Ng et al., 2001) is applied to obtain the lexical classes. In this work, neural fusion refers to early fusion (vector concatenation) of word vectors and neural activation vectors. We used a purity-based metric for evaluating the quality of the automatically created clusters. The purity P of the taxonomy is defined as in (Baroni and Lenci, 2010):

$$P = \frac{1}{d} \sum_{i=1}^{k} \max_{j}(e_{ij}), \tag{5}$$

where e_{ij} is the number of nouns assigned to the ith cluster that belong to the jth groundtruth class, k is the number of clusters, and d is the total number of concrete nouns included in the dataset. Purity expresses the fraction of nouns that belong to the true class, which is most represented in the cluster, taking values in the range [0,1].

Dataset	Neural Model	w2vec	Neural Fusion
ESSLI (6 classes)	0.61	0.70	**0.71**
ESSLI (3 classes)	0.77	0.95	**0.95**
ESSLI (2 classes)	0.66	**0.77**	0.72

Table 3: Evaluation results for taxonomy creation.

The evaluation results are presented in Table 3 for the neural activation model, the w2vec word embeddings (Mikolov et al., 2013) trained on the GoogleNews corpus and the late fusion of the two models (denoted as neural fusion) with equal weighting of their similarity matrices S. All results shown are computed on $V = 250$ voxels. The neural model performs worse that the w2vec model in all three subtasks (6, 3 or 2 classes), however, the proposed neural fusion achieves the best purity scores for 6 and 3 classes, at 0.71 and 0.95 purity, respectively.

6.2 Sense Classification

For the sensory modality (sense) classification task we use the Sensicon dataset to evaluate the performance of our model regarding sense discrimination. By definition all nouns in Sensicon are concrete nouns since they are associated with a real-world sensory stimulus. Sense classification is performed as

[5]The differences between the similarity scores estimated by our model and the baseline (i.e., w2vec) were found to be statistically significant at 99% level according to paired-sample t-test.

described in the previous section, i.e., the similarity matrix in Eq. 3 is calculated using the weight vector $\vec{b}$ trained on the MEN dataset and then the spectral clustering (Ng et al., 2001) is applied for the five sense categories. The resulting clusters are used for sense classification either between two senses, one versus all or among all five senses.

Classes	Neural Model	w2vec	Neural Fusion
Vision, Audition	0.55	0.55	**0.57**
Vision, Touch	0.68	0.66	**0.69**
Vision, Taste	0.60	0.60	**0.61**
Audition, Touch	0.59	0.58	**0.59**
Audition, Taste	0.57	0.55	**0.57**
Taste, Touch	0.54	0.54	0.54
Vision, Other	0.68	0.68	0.68
Audition, Other	0.74	0.74	0.74
Touch, Other	0.81	0.81	0.81
Taste, Other	0.78	0.78	**0.79**
Audition, Vision, Smell, Touch, Taste	0.37	0.33	**0.39**

Table 4: Evaluation results for two-way, one-vs-all, and five-way sense classification.

The evaluation results[6] are presented in Table 4 for the neural model, the w2vec model (same as the one used in the previous section) and the late fusion of the two (neural fusion) using equal weighting on the similarity matrices S. The evaluation metric used is the purity of clusters defined in Eq. 5. All results shown are computed on $V = 250$ voxels.

The neural and w2vec models achieve very similar results for two-way classification tasks, with the neural model performing better 0.37 vs 0.33 for five-way sense classification. The neural fusion model outperforms both neural and w2vec models for the majority of the two-way classification tasks and also achieves top performance for the five-way classification task reaching 0.39 purity score. Overall, the neural and neural fusion models show strong performance for this task, which is reasonable given the localization of sensory representations in the human cortex.

These results are also consistent with neuroscientific research (Heed, 2010; Marieb and Hoehn, 2007; Kobayashi, 2006; Ungerleider, 1982; Pickles, 1988; Buck and Axel, 1991).

6.3 Entailment Task

Next, we applied the neural activations to an entailment classification task. We used a Bi-LSTM model proposed in (Rocktäschel et al., 2015) featuring contextual attention (see Figure 2) as our baseline model. Word embeddings for concrete nouns were estimated using GloVe as detailed in (Pennington et al., 2014) and used as input to the Bi-LSTM network. The neural activations vectors were then combined via early fusion (vector concatenation) with GloVe embeddings (Pennington et al., 2014). Evaluation results for GloVe vectors and neural fusion are shown in Table 5 in terms of prediction accuracy. The results are

Dataset(SNLI)	Dimensions (GloVe, neural)	GloVe	Neural Fusion
3-common	(300,250)	68.2	**68.7**
2-common	(300,250)	76.6	**77.7**

Table 5: Entailment task accuracy for GloVe and neural fusion vector input to the Bi-LSTM.

reported for two subsets of the SNLI dataset, namely, 3-common and 2-common (see section 4).

We observe that the top accuracy is achieved by the fusion scheme for both the 3-common and 2-common subsets ($68.7 \pm 0.9\%$ and $77.7 \pm 0.9\%$).

[6]Note that the sense smell is not always present in Table 4 because smell has only four nouns compared in to other senses that contain more than 100 nouns each.

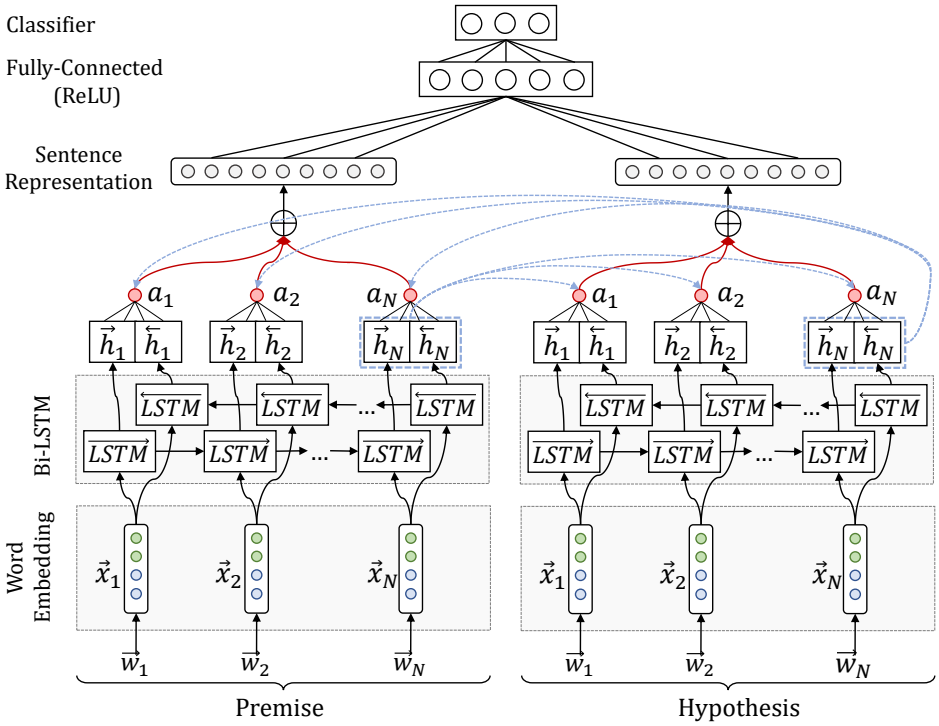

Figure 2: Bi-LSTM with context attention used in our experiments. Words' representations are either pretrained word embeddings or fusion of neural activations and word embeddings.

7 Conclusion

We proposed a simple neural activation semantic model extending the work of (Mitchell et al., 2008). The performance of the neural model was investigated for the tasks of word semantic similarity, taxonomy creation, sensory modality classification and concept entailment.

The analysis of the neural model word performance showed that the proposed model can differentiate between very similar and very dissimilar concrete nouns better than state-of-the-art word embeddings semantic models, while it performs worse overall for the word semantic similarity task. This is a strong indication that the semantic discriminability of neural activation vectors is of a different flavor than that of traditional word embedding vectors, and thus neural vectors can be used to augment state-of-the-art semantic representations. Results on the taxonomy classification, sense classification and entailment task indeed verify the different flavor of neural embeddings. For certain tasks, e.g., sense classification, neural models provide state-of-the-art performance. For other tasks, the fusion of neural and word2vec embeddings provides significant improvement. Overall (predicted) localized neural activation vectors can also be used in conjunction with other semantic representations and deep architectures to improve the results in challenging tasks, like concept entailment.

Although the collection of neuroimaging data has many limitations such as variation across participants, high signal-to-noise ratio and the need of expensive equipment for data capture, it provides an alternative view of how lexical and sensory information in localized in the human brain. Despite the very small dataset used in our experiments, results are encouraging about the value of neural activations patterns for computational tasks. In future work, we will investigate the relative performance of neural activations for a variety of natural language processing tasks, how to build neural vector predictors for the whole dictionary via lexical expansion, as well as more efficient fusion algorithms of neural and traditional word embedding models.

Folksonomication: Predicting Tags for Movies from Plot Synopses Using Emotion Flow Encoded Neural Network

Sudipta Kar **Suraj Maharjan** **Thamar Solorio**
Department of Computer Science

Abstract

Folksonomy of movies covers a wide range of heterogeneous information about movies, like the genre, plot structure, visual experiences, soundtracks, metadata, and emotional experiences from watching a movie. Being able to automatically generate or predict tags for movies can help recommendation engines improve retrieval of similar movies, and help viewers know what to expect from a movie in advance. In this work, we explore the problem of creating tags for movies from plot synopses. We propose a novel neural network model that merges information from synopses and emotion flows throughout the plots to predict a set of tags for movies. We compare our system with multiple baselines and found that the addition of emotion flows boosts the performance of the network by learning ≈18% more tags than a traditional machine learning system.

1 Introduction

User generated tags for online items are beneficial for both of the users and content providers in modern web technologies. For instance, the capability of tags in providing a quick glimpse of items can assist users to pick items precisely based on their taste and mood. On the other hand, such strength of tags enables them to act as strong search keywords and efficient features for recommendation engines (Lambiotte and Ausloos, 2006; Szomszor et al., 2007; Li et al., 2008; Borne, 2013). As a result, websites for different medias like photography[1], literature[2], film[3], and music[4] have adopted this system to make information retrieval easier. Such systems are often referred as Folksonomy (Vander Wal, 2005), social tagging, or collaborative tagging.

In movie review websites, it is very common that people assign tags to movies after watching them. Tags for movies often represent summarized characteristics of the movies such as emotional experiences, events, genre, character types, and psychological impacts. As a consequence, tags for movies became remarkably convenient for recommending movies to potential viewers based on their personal preferences and user profiles. However, this situation is not the same for all of the movies. Popular movies usually have a lot of tags as they tend to reach a higher number of users in these sites. On the other hand, low profile movies that fail to reach such an audience have very small or empty tagsets. In an investigation, we found that ≈34% of the movies among the top ≈130K movies of 22 genres[5] in IMDB do not have any tag at all. It is very likely that lack of descriptive tags negatively affects chances of movies being discovered.

An automatic process to create tags for movies by analyzing the written plot synopses or scripts could help solve this problem. Such a process would reduce the dependency on humans to accumulate tags

for movies. Additionally, learning the characteristics of a movie plot and possible emotional experiences from the written synopsis is also an interesting problem by itself from the perspective of computational linguistics. As the attributes of movies are multi-dimensional, a tag prediction system for movies has to generate multiple tags for a movie. The application of predicting multiple tags from textual description is not necessarily limited to the domain of movie recommendation but also appropriate in other domains, such as video games and books, where storytelling is relevant. In this paper, we explore the problem of analyzing plot synopses to generate multiple plot-related tags for movies. Our key contributions in this paper are as follows:

- We create a neural system for predicting tags from narrative texts and provide a robust comparison against traditional machine learning systems. Table 1 shows examples of predicted tags by our system for four movies.
- We propose a neural network model that encodes flow of emotions in movie plot synopses. This emotion flow helps the model to learn more attributes of movie plots.
- We release our source code and a live demo of the tag prediction system at `http://ritual.uh.edu/folksonomication-2018`.

IMDB ID	Movie Title	Predicted Tags
tt0133093	The Matrix	though-provoking, action, sci-fi, suspenseful, mystery
tt0233298	Batman Beyond: Return of the Joker	action, good versus evil, suspenseful, humor, thought-provoking
tt0309820	Luther	murder, melodrama, intrigue, historical fiction, christian film
tt0163651	American Pie	adult comedy, cute, feel-good, prank, entertaining

2 Related Work

Automatic tag generation from content-based analysis has drawn attention in different domains like music and images. For example, creating tags for music has been approached by utilizing lyrics (van Zaanen and Kanters, 2010; Hu et al., 2009), acoustic features from the tracks (Eck et al., 2008; Dieleman and Schrauwen, 2013), categorical emotion models (Kim et al., 2011), and deep neural models (Choi et al., 2017).

AutoTag (Mishne, 2006) and TagAssist (Sood et al., 2007), which utilize the text content to generate tags, aggregate information from similar blog posts to compile a list of ranked tags to present to the authors of new blog posts. Similar works (Katakis et al., 2008; Lipczak, 2008; Tatu et al., 2008) focused on recommending tags to users of BibSonomy[6] upon posting a new web page or publication as proposed systems in the ECML PKDD Discovery Challenge 2008 (Hotho et al., 2008) shared task. These systems made use of some kind of out of content resources like user metadata, and tags assigned to similar resources to generate tags.

Computational narrative studies deal with representing natural language stories by computational models that can be useful to understand, represent, and generate stories computationally. Current works attempt to model narratives using the character's personas and roles (Valls-Vargas et al., 2014; Bamman et al., 2013), interaction information between the characters (Iyyer et al., 2016; Chaturvedi et al., 2016; Chaturvedi et al., 2017) and events taking place throughout the stories (Goyal et al., 2010; Finlayson, 2012; McIntyre and Lapata, 2010). Other works try to build social networks of the characters (Agarwal et al., 2013a; Agarwal et al., 2013b; Agarwal et al., 2014; Krishnan and Eisenstein, 2015). Only a few works explored the possible type of impressions narrative texts can create on their consumers. For instance, different types of linguistic features have been used for success prediction for books (Ganjigunte Ashok et al., 2013; Maharjan et al., 2017) and tag prediction of movies from plot synopses (Kar et al., 2018). The tag prediction system predicts a fixed number of tags for each movie. But the tag space created by the system for the test data covers only 73% tags of the actual tagset as the system could capture a small portion of the multi-dimensional attributes of movie plots.

3 Dataset

We conduct our experiments on the Movie Plot Synopses with Tags (MPST) corpus (Kar et al., 2018), which is a collection of plot synopses for 14,828 movies collected from IMDb and Wikipedia. Most importantly, the corpus provides one or more fine-grained tags for each movie. The reason behind selecting this particular dataset is two-fold. First, the tagset is comprised of manually curated tags. These tags express only plot-related attributes of movies (e.g. suspenseful, violence, and melodrama) and are free of any tags foreign to the plots, such as metadata. Furthermore, grouping semantically similar tags and representing them by generalized tags helped to reduce the noise created by redundancy in tag space. Second, the corpus provides adequate amount of texts in the plot synopses as all the synopses have at least ten sentences. We follow the same split provided with the corpus, using 80% for training and 20% for test set. Table 2 gives statistics of the dataset.

Split	#Plot Synopses	#Tags	#Tags per Movie	#Sentence per Synopsis	#Words per Synopsis
Train	11862	71	2.97	42.36	893.39
Test	2966	71	3.04	42.61	907.96

Table 2: Statistics of the MPST corpus.

4 Encoding Emotion Flow with a Neural Network

Our proposed model simultaneously takes the emotion flow throughout the storyline and the text-based representation of the synopsis to retrieve relevant tags for a movie. Figure 1 shows the proposed architecture. The proposed neural architecture has three modules. The first module uses a convolutional neural network (CNN) to learn plot representations from synopses. The second module models the flow of emotions via a bidirectional long short-term memory (Bi-LSTM) network. And the last module contains hidden dense layers that operate on the combined representations generated by the first and second modules to predict the most likely tags for movies.

(a) Convolutional Neural Network (CNN): Recent successes in different text classification problems motivated us to extract important word level features using convolutional neural networks (CNNs) (dos Santos and Gatti, 2014; Kim, 2014; Zhang et al., 2015; Kar et al., 2017; Shrestha et al., 2017). We design a model that takes word sequences as input, where each word is represented by a 300-dimensional word embedding vector. We use randomly initialized word embeddings but also experiment with the FastText[7] word embeddings trained on Wikipedia using subword information. We stack 4 sets of one-dimensional convolution modules with 1024 filters each for filter sizes 2, 3, 4, and 5 to extract word-level n-gram features (Kim, 2014; Zhang et al., 2015). Each filter of size c is applied from window t to window $t + c - 1$ on a word sequence $x_1, x_2, \ldots, x_n$. Convolution units of filter size c calculate a convolution output using a weight map W_c, bias b_c, and the ReLU activation function (Nair and Hinton, 2010). The output of this operation is defined by:

$$h_{c,t} = ReLU(W_c x_{t:t+c-1} + b_c) \tag{1}$$

The ReLU activation function is defined by:

$$ReLU(x) = max(0, x) \tag{2}$$

Finally, each convolution unit produces a high-level feature map h_c.

$$h_c = [h_{c,1}, h_{c,2}, ..., h_{c,T-c+1},] \tag{3}$$

On those feature maps, we apply max-over-time pooling operation and take the maximum value as the feature produced a particular filter. We concatenate the outputs of the pooling operation for four filter sets that represent the feature representations for each plot synopsis.

(b) CNN with Flow of Emotions (CNN-FE): Stories can be described in terms of emotional shapes (Vonnegut, 1981), and it has been shown that the emotional arcs of stories are dominated by six

[7] https://fasttext.cc/docs/en/english-vectors.html

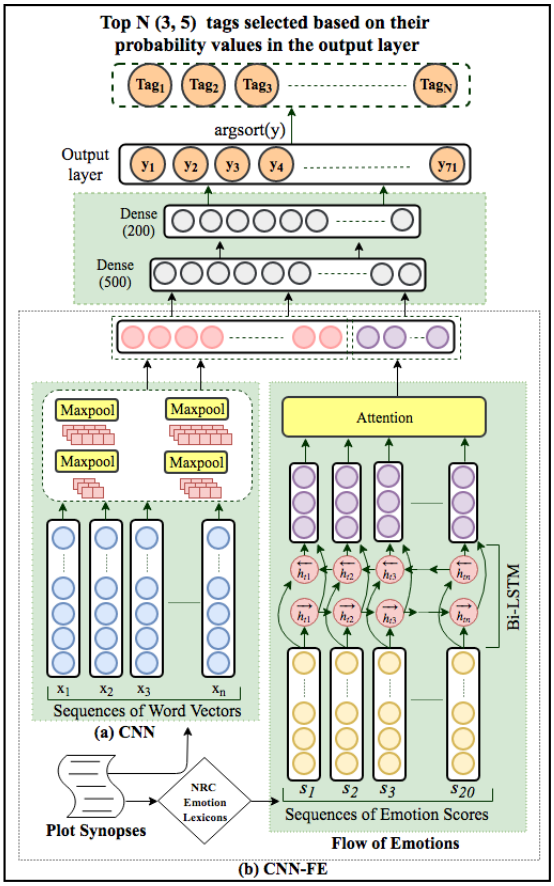

Figure 1: Convolutional Neural Network with Emotion Flow. The entire model is a combination of three modules. Module (a) learns feature representations from synopses using convolutional neural network. Module (b) incorporates emotion flows with module (a) to generate a combined representation of synopses. Module (c) uses these representations to predict the likelihood of each tag.

different shapes (Reagan et al., 2016). We believe that capturing the emotional ups and downs throughout the plots can help better understand how the story unfolds. This will enable us to predict relevant tags more accurately. So we design a neural network architecture that tries to learn representations of plots using the vector space model of words combined with the emotional ups and downs of plots.

Human emotion is a complex phenomenon to define computationally. The Hourglass of Emotions model (Cambria et al., 2012) categorized human emotions into four affective dimensions (*attention, sensitivity, aptitude, and pleasantness*), which started from the study of human emotions by Plutchik (2001). Each of these affective dimensions is represented by six different activation levels that make up to 24 distinct labels called 'elementary emotions' that represent the total emotional state of the human mind. NRC[8] emotion lexicons (Mohammad and Turney, 2013) is a list of 14,182 words[9] and their binary associations with eight types of elementary emotions from the Hourglass of Emotions model (*anger, anticipation, joy, trust, disgust, sadness, surprise,* and *fear*) with polarity. These lexicons have been used effectively in tracking the emotions in literary texts (Mohammad, 2011) and predicting success of books (Maharjan et al., 2018).

To model the flow of emotions throughout the plots, we divide each synopsis into N equally-sized segments based on words. For each segment, we compute the percentage of words corresponding to each emotion and polarity type (positive and negative) using the NRC emotion lexicons. More precisely, for a synopsis $x \epsilon X$, where X denotes the entire collection of plot synopses, we create N sequences of emotion vectors using the NRC emotion lexicons as shown below:

$$x \rightarrow s_{1:N} = [s_1, s_2, ..., s_N] \tag{4}$$

[8]National Research Council Canada

[9]Version 0.92

where s_i is the emotion vector for segment i. We experiment with different values of N, and $N = 20$ works better on the validation data.

As recurrent neural networks are good at encoding sequential data, we feed the sequence of emotion vectors into a bidirectional LSTM (Hochreiter and Schmidhuber, 1997) with 16 units as shown in Figure 1. This bidirectional LSTM layer tries to summarize the contextual flow of emotions from both directions of the plots. The forward LSTMs read the sequence from s_1 to s_N, while the backward LSTMs read the sequence in reverse from s_N to s_1. These operations will compute the forward hidden states $(\overrightarrow{h_1}, \ldots, \overrightarrow{h_N})$ and backward hidden states $(\overleftarrow{h_1}, \ldots, \overleftarrow{h_N})$. For input sequence s, the hidden states h_t are computed using the following intermediate calculations:

$$
\begin{aligned}
i_t &= \sigma(W_{si}s_t + W_{hi}h_{t-1} + W_{ci}c_{t-1} + b_i) \\
f_t &= \sigma(W_{sf}s_t + W_{hf}h_{t-1} + W_{cf}c_{t-1} + b_f) \\
c_t &= f_t c_{t-1} + i_t \tanh(W_{sc}s_t + W_{hc}h_{t-1} + b_c) \\
o_t &= \sigma(W_{sc}s_t + W_{hc}h_{t-1} + b_c) \\
h_t &= o_t \tanh(c_t)
\end{aligned}
$$

where, W and b denote the weight matrices and bias, respectively. σ is the sigmoid activation function, and i, f, o, and c are *input gate, forget gate, output gate*, and *cell* activation vectors, respectively. The annotation for each segment s_i is obtained by concatenating its forward hidden states $\overrightarrow{h_i}$ and backward hidden states $\overleftarrow{h_i}$, i.e. h_i=$[\overrightarrow{h_i}; \overleftarrow{h_i}]$. We then apply attention mechanism on this representation to get a unified representation of the emotion flow.

Attention models have been used effectively in many problems related to computer vision (Mnih et al., 2014; Ba et al., 2014) and have been successfully adopted in problems related to natural language processing (Bahdanau et al., 2014; Seo et al., 2016). An attention layer applied on top of a feature map h_i computes the weighted sum r as follows:

$$r = \sum_i \alpha_i h_i \tag{5}$$

and the weight α_i is defined as

$$\alpha_i = \frac{\exp(score(h_i))}{\sum_{i'} \exp(score(h_{i'}))}, \tag{6}$$

where, $score(.)$ is computed as follows:

$$score(h_i) = v^T tanh(W_a h_i + b_a) \tag{7}$$

where, W, b, v, and u are model parameters. Finally, we concatenate the representation of the emotion flow produced by the attention operation and the output vector with the vector representation generated from the CNN module.

The concatenated vector is then fed into two hidden dense layers with 500 and 200 neurons. To improve generalization of the model, we use dropout with a rate of 0.4 after each hidden layer. Finally, we add the output layer $\hat{y}$ with 71 neurons to compute predictions for 71 tags. To overcome the imbalance of the tags, we weight the posterior probabilities for each tag using different weight values. Weight value CW_t for tag $t \epsilon T$ is defined by,

$$CW_t = \frac{|D|}{|T| \times M_t} \tag{8}$$

where, $|D|$ is the size of the training set, $|T|$ is the number of classes, and M_t is the number of movies having tag t in the training set. We normalize the output layer by applying a softmax function defined by,

$$softmax(\hat{y}) = \frac{exp(\hat{y})}{\sum_{k=0}^{70} exp(\hat{y}_k)} \tag{9}$$

Based on the ranking for each tag, we then select top N (3/5/10) tags for a movie.

5 Experimental Setup

Data Processing and Training: As a preprocessing step, we lowercase the synopses, remove stop-words and also limit the vocabulary to top 5K words to reduce noise and data sparsity. Then we convert each synopsis into a sequence of 1500 integers where each integer represents the index of the corresponding word in the vocabulary. For the sequences longer than 1500 words, we truncate them from the left based on experiments on the development set. Shorter sequences are left padded with zeros.
During training, we use 20% of the training data as validation data. We tune various deep model parameters (dropouts, learning rate, weight initialization schemes, and batch size) using early stopping technique on the validation data. We use the Kullback-Leibler (KL) divergence (Kullback and Leibler, 1951) to compute the loss between the true and predicted tag distributions and train the network using the RMSprop optimization algorithm (Tieleman and Hinton, 2012) with a learning rate of 0.0001. We implemented our neural network using the PyTorch deep learning framework[10].
Baselines: We compare the model performance against three baselines: majority baseline, random baseline, and traditional machine learning system. The majority baseline method assigns the most frequent three or five or ten tags in the training set to all the movies. Similarly, the random baseline assigns randomly selected three or five or ten tags to each movie. Finally, we compare our results with the benchmark system reported in Kar et al. (2018). This benchmark system used different types of hand-crafted lexical, semantic, and sentiment features to train a OneVsRest approach model with logistic regression as the base classifier.
Evaluation Measures: We try to follow the same evaluation methodology as described in Kar et al. (2018). We create two sets of tags for each movie by choosing the most likely three and five tags by the system. Additionally, we report our results on a wider range of tags, where we select top ten predictions. We evaluate the performance using the number of unique tags learned by the system (TL), micro averaged F1, and tag recall (TL). Tags learned (TL) computes how many unique tags are being predicted by the system for the test data (size of the tag space created by the model for test data). Tag recall represents the average recall per tag and it is defined by the following equation:

$$TR = \frac{\sum_{i=1}^{|T|} |R_i|}{|T|} \tag{10}$$

Here, $|T|$ is the total number of tags in the corpus, and R_i is the recall for the i^{th} tag.

6 Results and Discussions

	Top 3			Top 5			Top 10		
Methods	**TL**	**F1**	**TR**	**TL**	**F1**	**TR**	**TL**	**F1**	**TR**
Baseline: Most Frequent	3	29.7	4.23	5	28.4	14.08	10	28.4	13.73
Baseline: Random	71	4.2	4.21	71	6.4	15.04	71	6.6	14.36
Baseline: Kar et al. (2018)	47	**37.3**	**10.52**	52	**37.3**	**16.77**	—	—	—
CNN without class weights	24	36.8	7.99	26	36.7	12.62	27	**31.3**	24.52
CNN with class weights	49	34.9	9.85	55	35.7	14.94	67	30.8	**26.86**

CNN-FE + FastText	53	**37.3**	10.00	59	36.8	15.47	63	30.6	26.45

Table 3: Performance of tag prediction systems on the test data. We report results of two setups using three matrices (TL: Tags learned, F1: Micro f1, TR: Tag recall).

Table 3 shows our results for Top 3, Top 5, and Top 10 settings. We will mainly discuss the results achieved by selecting top five tags as it allows us to compare with all the baseline systems and more tags to discuss about. As the most frequent baseline system assigns a fixed set of tags to all the movies, it fails to exhibit diversity in the created tag space. Still it manages to achieve a micro-F1 score around 28%. On the other hand, the random baseline system creates the most diverse tag space by using all of the possible tags. However its lower micro-F1 score of 6.30% makes it impractical to be used in real world scenario.

[10] https://pytorch.org

At this point, we find an interesting trade-off between accuracy and diversity. It is expected that a good movie tagger will be able to capture the multi-dimensional attributes of the plots that allows to generalize a diverse tag space. Tagging a large collection of movies with a very small and fixed set of tags (e.g. majority baseline system) is not useful for either a recommendation system or users. Equally important is the relevance between the movies and the tags created for those movies. The hand-crafted features based approach (Kar et al., 2018) achieves a micro-F1 around 37%, which outperforms the majority and random baselines. But the system was able to learn only 52 tags, which makes 73% of the total tags.

Our approach achieves a lower micro-F1 score than the traditional machine learning one, but it performs better in terms of learning more tags. We observe that the micro-F1 of the CNN model with only word sequences is very close (36.7%) to the hand-crafted features based system. However, it is able to learn only around 37% of the tags. By utilizing class weights in this model (see Eq. 8), we improve the learning for under-represented tags yielding an increase in *tag recall* (TR) and *tags learned* (TL). But the micro-f1 drops to 35.7%. With the addition of emotion flows to CNN, the CNN-FE model learns significantly more tags while micro-F1 and tag recall do not change much. Initializing the embedding layer with pre-trained embeddings made a small improvement in micro-F1 but the model learns comparatively lesser tags. If we compare the CNN-FE model with the hand-crafted feature based system, micro-F1 using CNN-FE is slightly lower ($\approx 1\%$) than the feature based system. But it provides a strong improvement in terms of the number of tags it learns (TL). CNN-FE learns around 91% tags of the tagset compared to 73% with the feature based system. It is an interesting improvement, because model is learning more tags and it is better at assigning relevant tags to movies. We observe similar pattern for the rest of the two sets of tags where we select top three and ten tags. For all the sets, CNN-FE model learns the highest number of tags compared to the other models. In terms of micro-F1 and tag recall, it does not achieve the highest numbers but performs very closely.

Incompleteness in Tag Spaces: One of the limitations of folksonomies is the incompleteness in tag spaces. The fact that users have not tagged an item with a specific label does not imply that that label does not apply to the item. Incompleteness makes learning challenging for computational models as the training and evaluation process penalizes the model for predicting a tag that is not present in the ground truth tags, even though in some cases it may be a suitable tag. For example, ground truth tags for the movie *Luther (2003)*[11] are *murder, romantic,* and *violence* (Table 1). And the predicted tags from our proposed model are *murder, melodrama, intrigue, historical fiction,* and *christian film*. The film is indeed a Christian film[12] portraying the biography of Martin Luther, who led the Christian reformation during the 16th century. According to the Wikipedia, "*Luther is a 2003 American-German epic historical drama film loosely based on the life of Martin Luther*"[13]. Similarly, Edtv[14] (Table 6) has tags *romantic* and *satire* in the dataset. Our system predicted *adult comedy* and this tag is appropriate for this movie.

In these two cases, the system will get lower micro-F1 since the relevant tags are not part of the ground truth. Perhaps a different evaluation scheme could be better suited for this task. We plan to work on this issue in our future work.

Significance of the Flow of Emotions: The results suggest that incorporating the flow of emotions helps to achieve better results by learning more tags. Figure 2 shows some tags with significant improvements in recall after incorporating the flow of emotions. We notice such improvements for around 30 tags. We argue that for these tags (e.g. *absurd, cruelty, thought-provoking, claustrophobic*) the changes in specific sentiments are adding new information helpful for identifying relevant tags. But we also notice negative changes in recall for around 10 tags, which are mostly related to the theme of the story (e.g. *blaxploitation, alternate history, historical fiction, sci-fi*). It will be an interesting direction of future work to add a mechanism that can also learn to discern when emotion flow should contribute more to the prediction task.

In Figure 3, we inspect how the flow of emotions looks like in different types of plots. Emotions like *joy* and *trust* are continuously dominant over *disgust* and *anger* in the plot of *Arthur (1981)*, which is

[11] http://www.imdb.com/title/tt0309820

[12] https://www.christianfilmdatabase.com/review/luther-2

[14] http://www.imdb.com/title/tt0131369/

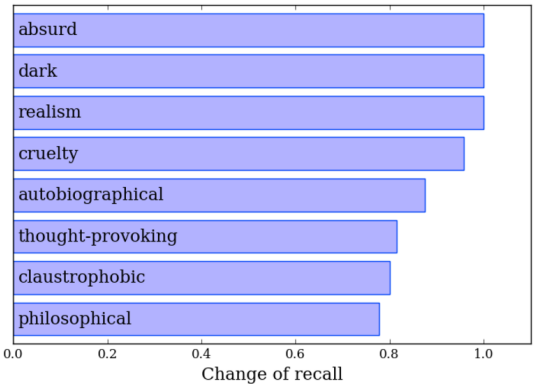

Figure 2: Tags with higher change of recall after adding the flow of emotions in CNN.

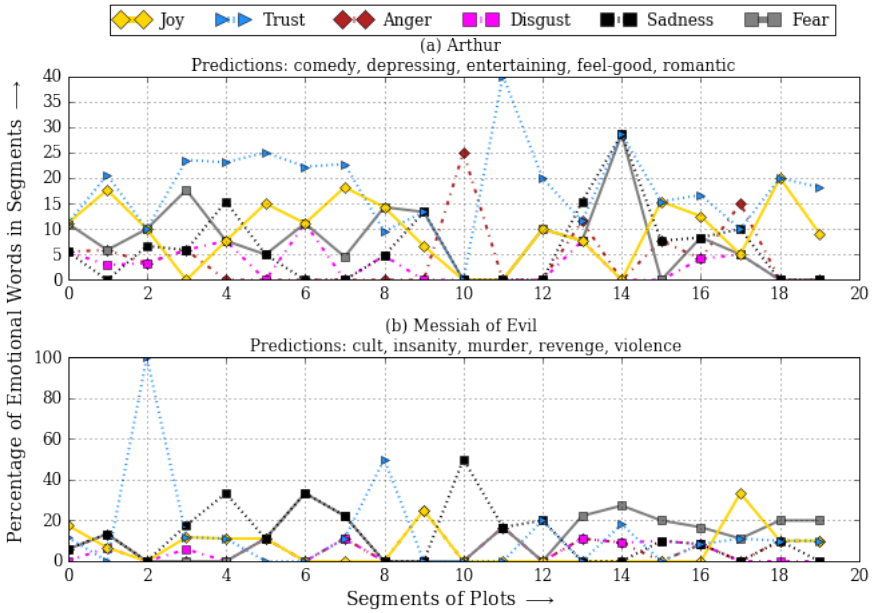

Figure 3: The flow of emotions in the plots of 2 different types of movies. Each synopsis was divided into 20 segments based on the words, and percentage of the emotions for each segment was calculated using the NRC emotion lexicons. The y axis represents the percentage of emotions in each segment; whereas, the x axis represents the segments.

a comedy film. We can observe sudden spikes in *sadness* and *fear* at segment 14, which is the possible reason for triggering the tag *depressing*. We observe a different pattern in the flow of emotions in *Messiah of Evil (1973)*, which is a horror film. Here the dominant emotions are *sadness* and *fear*. Such characteristics of emotions are helpful to determine the type and possible experiences from a movie. Our model seems to be able to leverage this information that is allowing it to learn more tags; specifically tags that are related to feelings.

Learning or Copying? We found that only 11.8% of the 14,830 predicted tags for the ∼3K movies in the test data were found in the synopses themselves. 12.7% of the total 9,022 ground truth tags appear in the plot synopses. These numbers suggest that the model is not dependent on the occurrences of the tags in the synopses to make predictions, rather it seems it is trying to understand the plots and assign tags based on that. We also found that all the tags that were present in the synopses of the test data are also present in the synopses of the training data. Then we investigate what type of tags appear in the synopses and which ones do not. Tags present in the synopses are mostly genre or event related tags like *horror, violence, historical*. On the other hand, most of the tags that do not appear in the synopses are the tags that require a more sophisticated analysis of the plots synopses (e.g. *thought-provoking, feel-good,*

suspenseful). It is not necessarily bad to predict tags that are in the synopses, since they are still useful for recommender systems. However, if this was the only ability of the proposed models, their value would be limited. Luckily this analysis, and the results presented earlier show that the model is able to infer relevant tags, even if they have not been observed in the synopses. This is a much more interesting finding.

Learning Stories from Different Representations: Movie scripts represent the detailed story of a movie, whereas the plot synopses are summaries of the movie. The problem with movie scripts is that they are not as readily available as plot synopses. However, it is still interesting to evaluate our approach to predict tags from movie scripts. For this purpose, we collected movie scripts from our test set. We

	Top 3			Top 5		
	F1	**TR**	**TL**	**F1**	**TR**	**TL**
Plot Synopses	29.3	8.04	28	38.7	15.70	35
Scripts	29.8	5.16	19	37.0	9.27	26

Table 4: Evaluation of predictions using plot synopses and scripts

were able to find 80 movie scripts using the ScriptBase corpus (Gorinski and Lapata, 2015).

In table 4, we show the evaluation of tags generated using plot synopses and scripts. Despite having similar micro-f1 scores, *tag recall* and *tags learned* are lower when we use the scripts. A possible explanation for this is the train/test mismatch since the model was trained using summarized versions of the movie, while the test data contained full movies scripts. Additional sources of error could come from the external info included in scripts (such as descriptions of actions from the characters or settings).

Percentage of Match	**Percentage of Movies**
>=80%	40%
>=40% & <80%	47.5%
>=20% & <40%	11.25%

Table 5: Percentage of the match between the sets of top five tags generated from the scripts and plot synopses.

Table 5 shows that for most of the movies we generate very similar tags using the scripts and plot synopses. For 40% movies, at least 80% tags are the same. While the predictions are not identical, these results show a consistency in the learned tags from our system. An interesting direction for future work would be to study what aspects in a full movie script are relevant to predict tags.

Title: A Nightmare on Elm Street 5: The Dream Child **Ground Truths:** cult, good versus evil, insanity, murder, sadist, violence **Synopsis:** cult, murder, paranormal, revenge, violence **Script:** murder, violence, flashback, cult, suspenseful
Title: EDtv **Ground Truths:** romantic, satire **Synopsis:** adult comedy, comedy, entertaining, prank, satire **Script:** comedy, satire, prank, entertaining, adult comedy
Title: Toy Story **Ground Truths:** clever, comedy, cult, cute, entertaining, fantasy, humor, violence **Synopsis:** comedy, cult, entertaining, humor, psychedelic **Script:** psychedelic, comedy, entertaining, cult, absurd
Title: Margot at the Wedding **Ground Truths:** romantic, storytelling, violence **Synopsis:** depressing, dramatic, melodrama, queer, romantic **Script:** psychological, murder, mystery, flashback, insanity

Table 6: Example of ground truth tags of movies from the test set and the generated tags for them using plot synopses and scripts.

Challenging Tags: We found that these seven tags: *stupid, grindhouse film, blaxploitation, magical realism, brainwashing, plot twist,* and *allegory*, were not assigned to any movies in the test set. One reason might be that these are very infrequent (around 0.06% of movies have them assigned as their tags). This

will obviously make them difficult to learn. Again, these are subjective as well. We believe that tagging a plot as stupid or brainwashing is complicated and depends on perspectives of a tagger. We plan to investigate such type of tags in the future.

7 Conclusions and Future Work

In this paper we explore the problem of automatically creating tags for movies using plot synopses. We propose a model that learns word level feature representations from the synopses using CNNs and models sentiment flow throughout the plots using a bidirectional LSTM. We evaluated our model on a corpus that contains plot synopses and tags of 14K movies. We compared our model against a majority and random baselines, and a system that uses traditional hand-crafted linguistic features. We found that incorporating emotion flows boosts prediction performance by improving the learning of tags related to feelings as well as increasing the overall number of tags learned.
Predicting tags for movies is an interesting and complicated problem at the same time. To further improve our results, we plan to investigate more sophisticated architectures and explore ways to tackle the problem of incompleteness in the tag space. We also plan to evaluate the quality of predicted tags using a human study evaluation and experiment on predicting tags in other storytelling related domains.

Emotion Representation Mapping for Automatic Lexicon Construction (Mostly) Performs on Human Level

Sven Buechel & Udo Hahn

Abstract

Emotion Representation Mapping (ERM) has the goal to convert existing emotion ratings from one representation format into another one, e.g., mapping Valence-Arousal-Dominance annotations for words or sentences into Ekman's Basic Emotions and vice versa. ERM can thus not only be considered as an alternative to Word Emotion Induction (WEI) techniques for automatic emotion lexicon construction but may also help mitigate problems that come from the proliferation of emotion representation formats in recent years. We propose a new neural network approach to ERM that not only outperforms the previous state-of-the-art. Equally important, we present a refined evaluation methodology and gather strong evidence that our model yields results which are (almost) as reliable as human annotations, even in cross-lingual settings. Based on these results we generate new emotion ratings for 13 typologically diverse languages and claim that they have near-gold quality, at least.

1 Introduction

From its inception, researchers in the field of sentiment analysis aimed at predicting the affective state that is typically associated with a given word based on a list of linguistic features, a problem referred to as *word emotion induction* (WEI) (Hatzivassiloglou and McKeown, 1997; Turney and Littman, 2003). Early research activities have focused on *semantic polarity* (the positiveness or negativeness of a feeling) for quite a long time. But more recently this focus on binary representations has been replaced by more expressive *emotion representation formats* such as Basic Emotions or Valence-Arousal-Dominance. In the meantime, WEI has become an active area of research, regularly featured in shared tasks (Rosenthal et al., 2015; Yu et al., 2016b). Based on these achievements, WEI techniques have become a natural methodological choice for the automatic construction of emotion lexicons (Köper and Schulte im Walde, 2016; Shaikh et al., 2016).

Yet, only very recently, a radically different approach to automatic emotion lexicon construction has been proposed. Instead of relying on linguistic features (such as similarity with seed words or word embeddings), the goal of *emotion representation mapping* (ERM) is to derive new emotional word ratings *in one format* based on known ratings of the same words *in another format* (Buechel and Hahn, 2017a). For example, ERM could use empirically gathered ratings for Basic Emotions and convert them into a Valence-Arousal-Dominance representation scheme, with greater precision than currently achievable by WEI algorithms. As a much appreciated side effect, one of the promises of ERM is to make otherwise incompatible resources (lexicons or annotated corpora, as well as tools) compatible, and incomparable systems comparable. Thus, this approach has the potential to mitigate some of the negative effects that arise from not having a community-wide standard for emotion annotation and representation (Calvo and Mac Kim, 2013; Buechel and Hahn, 2018a).

We here want to contribute to this endeavor by providing a large-scale evaluation of previously proposed ERM approaches for four typologically diverse languages and report evidence that ERM clearly

Proceedings of the 27th International Conference on Computational Linguistics, pages 2892–2904
Santa Fe, New Mexico, USA, August 20-26, 2018.

outperforms current state-of-the-art WEI algorithms. Furthermore, we present our own deep learning model which performs even better against all competitors. Most importantly, however, we propose a new methodology for comparing the reliability of ERM against human annotation reliability, a major shortcoming of previous work. As a result, we find that our proposed model performs competitive to a reasonably large group of human raters, *even in cross-lingual settings*. Based on this evidence, we automatically construct emotion lexicons for 13 languages and claim that they have (near) gold quality. These lexicons as well as our experimental code base and results are publically available.[1]

2 Related Work

Psychological Models of Emotion. Models of emotion typically fall into two main groups, namely *discrete* (or *categorical*) and *dimensional* ones (Stevenson et al., 2007; Calvo and Mac Kim, 2013). Discrete models are built around particular sets of emotional categories deemed fundamental and universal. Ekman (1992), for instance, identifies six *Basic Emotions* (Joy, Anger, Sadness, Fear, Disgust and Surprise). In contrast, dimensional models consider emotions to be composed out of several influencing factors (mainly two or three). These are often referred to as *Valence* (corresponding to the concept of polarity), *Arousal* (a calm–excited scale), and *Dominance* (perceived degree of control over a (social) situation)—the VAD model. The last dimension, Dominance, is quite often omitted, thus constituting the VA model. For convenience, both will be jointly referred to as VA(D). An illustration of VAD and its relationship to Basic Emotions is given in Figure 1.

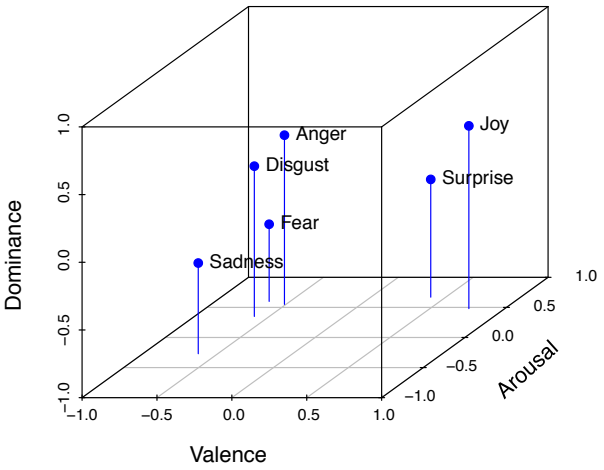

Figure 1: Affective space spanned by the Valence-Arousal-Dominance (VAD) model, together with the position of six Basic Emotions. Adapted from Buechel and Hahn (2016).

Lexical Data Sets. In contradistinction to NLP where many different representation formats for emotions are being used, lexical resources originating from psychology labs almost exclusively subscribe either to VA(D) or Basic Emotions models (typically omitting Surprise; the BE5 format). Over the years, a considerable number of resources built on these premises have emerged from psychological research for various languages.[2] In more detail, these lexical ratings have been gathered via questionnaire studies by collecting individual ratings from a large number of subjects for each lexical item under consideration (typically between 20 to 30 individual ratings per item). These individual assessments are then averaged to yield aggregated scores on which we base our experiments. The emotion values we deal with must thus be understood as an average emotional reaction when presenting a lexical stimulus to a group of human judges.

In this paper, we restrict ourselves to the VA(D) and BE5 format. Following the conventions of the emotion lexicons used in our experiments (Table 1), each VA(D) dimension receives a value from the interval $[1, 9]$ where '1' means "most negative/calm/submissive", '9' means "most positive/excited/dominant" and '5' means "neutral". Conversely, values for BE5 categories range in the interval $[1, 5]$ where '1' means "absence" and '5' means "most extreme" expression of the respective emotion.[3] Consequently, the VA(D) and BE5 formats are conceptually different from one another insofar as VA(D) dimensions are bi-polar, whereas BE5 categories are uni-polar.

[1] `https://github.com/JULIELab/EmoMap`

[2] See, e.g., Tables 1 and 6. An enhanced list of these and similar data sets is provided in Buechel and Hahn (2018a).

[3] Although these intervals are fairly well established conventions, in some data sets different rating scales were used, nevertheless. In these cases, we linearly transformed the ratings so that they match the defined intervals.

Word Emotion Induction. Automatically constructing such word-level emotion data sets has been a focus of NLP-based sentiment analysis studies from the beginning. In fact, the problem to automatically predict polarity or emotion scores for a given word based on some linguistic features—often referred to as Word Emotion Induction (WEI)—is already dealt with in the seminal work of Hatzivassiloglou and McKeown (1997). At first, the features taken into account were typically derived from co-occurrence or terminology-based similarity with a small set of *seed word* with known emotional scores (Turney and Littman, 2003; Esuli and Sebastiani, 2005). Nowadays, these features are almost completely replaced by *word embeddings*, i.e., dense, low-dimensional vector representations of words that are trained on large volumes of raw text in an unsupervised manner. WORD2VEC (Mikolov et al., 2013), GLOVE (Pennington et al., 2014) and FASTTEXT (Bojanowski et al., 2017) are among today's most popular algorithms for generating embeddings.

WEI algorithms constitute a natural baseline for ERM because, first, they produce the same output (emotion ratings for words according to some emotion representation format), yet their predictions are based on expressively weaker features (word embeddings instead of emotion ratings for the same word but in another format), thus constituting a harder task. Second, they form the currently prevailing paradigm for the automatic construction of emotion lexicons (Köper and Schulte im Walde, 2016; Shaikh et al., 2016), a problem for which ERM offers a promising alternative.

Emotion Representation Mapping. In contrast to WEI, ERM is based on the condition that the pairs of data sets in Table 1 are complementary in the sense that, when combining these lexicons, a subset of their entries are then encoded in *both* emotion formats, i.e., VA(D) *and* BE5. This condition is illustrated for three lexical items in Table 2.

Word	V	A	D	J	A	S	F	D
sunshine	8.1	5.3	5.4	4.3	1.2	1.3	1.3	1.2
terrorism	1.6	7.4	2.7	1.1	3.0	3.4	4.1	2.5
orgasm	8.0	7.2	5.8	4.3	1.3	1.3	1.4	1.2

Table 2: Three lexical items and their emotion values in VAD (second column group) and BE5 (third column group) format. VAD scores are taken from Warriner et al. (2013), BE5 scores were automatically derived (see Section 4.4).

Although such complementary data sets have been available for quite some time, ERM has only recently been introduced to NLP by Buechel and Hahn (2016) in order to compare a newly proposed VAD-based prediction system against previously established results on Basic Emotion gold standards. In a follow-up study, Buechel and Hahn (2017b) devised EMOBANK, a VAD-annotated corpus which, in part, also bears BE5 ratings on the *sentence* level. They found that both kinds of annotation were highly predictive for each other using a k-Nearest-Neighbor approach. In later studies, they examined the potential of ERM as a substitute for manual annotation of *lexical* items, also in cross-lingual settings (Buechel and Hahn, 2017a; Buechel and Hahn, 2018a). Although their evaluation was limited in expressiveness, they already found evidence that ERM may be comparable to human performance in terms of the quality of the resulting ratings.

Similar work has, to the best of our knowledge, only been done in the psychology domain. However, related work from this area does not target the goal of predictive modeling (Stevenson et al., 2007; Pinheiro et al., 2017). In both contributions, linear regression models were fitted to predict VAD di-

mensions given BE5 categories and vice versa. Yet, this was mainly done to inspect the respective slope-coefficients as an indicator of the relationship of dimensions and categories. Thus, the overall goodness of the fit was *not* in the center of interest and was not even reported by Stevenson et al. (2007).

3 Methods

Let $L := \{w_1, w_2, ..., w_n\}$ be a set of words. Let s,t denote two distinct *emotion representation formats* such that *both* $emo^s(w_i) \in \mathbb{R}^{|s|}$ and $emo^t(w_i) \in \mathbb{R}^{|t|}$ describe the emotion vector associated with w_i relative to s and t, respectively, where $|s|$, $|t|$ denote the number of variables which each format employs (e.g., 3 for VAD and 5 for BE5). The task we address in this paper is to predict the *target emotion ratings* $T := \{emo^t(w_i)|\ w_i \in L\}$ given the set L and the corresponding *source emotion ratings* $S := \{emo^s(w_i)|\ w_i \in L\}$. Performance will be measured as Pearson correlation r between the predicted values and human gold ratings (one r-value per element of the target representation). In general, the Pearson correlation between two data series $X := x_1, x_2, ..., x_n$ and $Y := y_1, y_2, ..., y_n$ takes values between $+1$ (perfect positive correlation) and -1 (perfect negative correlation) and is computed as

$$r_{xy} := \frac{\sum_{i=1}^{n}(x_i - \bar{x})(y_i - \bar{y})}{\sqrt{\sum_{i=1}^{n}(x_i - \bar{x})^2}\ \sqrt{\sum_{i=1}^{n}(y_i - \bar{y})^2}} \tag{1}$$

where $\bar{x}$ and $\bar{y}$ denote the mean values for X and Y, respectively.

3.1 Reference Methods

The first method against which we will compare our proposed model is linear regression (LR) as used by Stevenson et al. (2007) in their early study. LR predicts an emotion value in the target representation t as the affine transformation

$$emo^t_{\text{LR}}(w_i) := W\ emo^s(w_i) + b \tag{2}$$

where W is a $|t| \times |s|$ matrix and b is a $|t| \times 1$ vector. The model parameters are fitted using ordinary least squares. In contrast, Buechel and Hahn (2017b) proposed the use of *k*-Nearest-Neighbor Regression (KNN) for ERM. This simple supervised approach predicts the target value as

$$emo^t_{\text{KNN}}(w_i) := \frac{1}{k} \sum_{w_i' \in \text{NEAREST}(w_i,k,S)} emo^t(w_i') \tag{3}$$

where NEAREST yields the k nearest neighbors of w_i in the training set (determined by the Euclidean distance between the source representations of two words). The k parameter was fixed to 20 based on a pilot study.[4] We used the `scikit-learn.org` implementation for both LR and KNN.

3.2 Proposed Model: A Multi-Task Feed-Forward Neural Network for ERM

Despite the fact that the above set-ups already perform quite well for ERM (see Section 4), both LR and KNN are rather basic types of models lacking deeper sophistication. As a consequence, we here propose the use of Feed-Forward Neural Networks[5] (FFNNs) for ERM which have been shown to be capable of approximating arbitrary functions, in theory at least (Hornik, 1991). In general, an FFNN consists of an *input layer* with activation $a^{(0)} := emo^s(w_i) \in \mathbb{R}^{|s|}$ followed by multiple hidden layers with activation $a^{(l+1)} := \sigma(W^{(l+1)}a^{(l)} + b^{(l+1)})$ where $W^{(l+1)}$ and $b^{(l+1)}$ are the weights and biases for layer $l+1$ and σ is a nonlinear activation function. Since the emotion formats under scrutiny capture affective states as real-valued vectors, the activation on the output layer a^{out} (where out is the number of non-input layers in the network) is computed as the affine transformation

$$emo^t_{\text{FFNN}}(w_i) := a^{(out)} := W^{(out)}a^{(out-1)} + b^{(out)} \tag{4}$$

[4] In contrast, Buechel and Hahn (2017a) determined k for each lexicon *individually* based on a dev set. Now, we deviate from this approach since it is inapplicable for the cross-lingual lexicon construction presented in Section 4.4.

[5] Note that applying neural architectures currently popular for other NLP tasks is not advisable because of the simplicity of our input data (feature vectors of length 2 to 5). These more complex architectures are instead designed for, e.g., *sequential* data (such as the RNN family) or *spatially arranged* data (such as CNNs).

Consequently, our model differs from the other approaches presented in this section by *sharing* model parameters (weights and biases of the hidden layers) across the different dimensions/categories of the target format with only the last layer having parameters which are uniquely associated to one of the outputs (see Equation 4). This can be considered as a mild form of multi-task learning (Caruana, 1997), a machine learning technique which has been shown to strongly decrease the risk of overfitting (Baxter, 1997) and also speeds up computation by greatly decreasing the number of tunable parameters compared to training individual layers for each affective dimension/category.

The remaining specifications of our model are as follows. We train two-hidden layer FFNNs (both with 128 units), ReLU activation, .2 dropout on the hidden layers (none on the input layer)[6] and Mean-Squared-Error loss. Each model was trained for $10,000$ iterations (well beyond convergence, independently of the size of the training set) using the ADAM optimizer (Kingma and Ba, 2015). `Keras.io` was used for implementation.

3.3 Baseline: Word Emotion Induction

As a natural baseline for ERM, we will use a recent state-of-the-art method for word emotion induction (WEI) by Du and Zhang (2016).[7] They propose Feed-Forward Neural Networks (similar to our proposed model for ERM) in combination with a boosting algorithm. The authors used FFNNs with a single hidden layer of 100 units and ReLU activation. The boosting algorithm ADABOOST.R2 (Drucker, 1997) was used to train the ensemble (one per target variable). We implemented this approach with `scikit-learn` using exactly the same settings as in the original publication.[8] As for the word embeddings this method needs as input, we used the pre-trained FASTTEXT embeddings that Facebook Research makes available for a wide range of languages trained on the respective Wikipedias.[9] This way, we hope to achieve a particularly high level of comparability across languages because, for each of them, embeddings are trained on data from the same domain and of a similar order of magnitude.[10]

3.4 Comparison to Human Reliability

Since common metrics for Inter-Annotator Agreement (IAA), such as Cohen's Kappa, are not applicable for real-valued emotion scores (Carletta, 1996), we will now discuss how to compare our own results against human assessments in order to put their reliability on a safe ground.

One possible point of comparison that has been used in previous work (Buechel and Hahn, 2017a; Buechel and Hahn, 2018a) is *inter-study reliability* (ISR), i.e., the correlation between the ratings of common words in different data sets. However, this procedure comes with a number of downsides. First, the number of pairs of data sets with substantially overlapping entries is rather small since researchers focus mainly on acquiring ratings for *novel* words instead of gathering annotations anew for ones already covered. Thus, employing ISR comparison with human performance is only possible on few data sets. In particular, we are not aware of any pair of data sets with significantly overlapping BE5 ratings. Second, ISR is sensitive to differences in acquisition methodologies (e.g., alternative sets of instructions or rating scales) and may thus vary substantially between different pairs of data sets.

As an alternative, these shortcomings lead us to propose *split-half reliability* (SHR) as a new basis for our comparison. SHR is computed by splitting all individual ratings for each of the items into two groups. These individual ratings are then averaged for both groups and the Pearson correlation between the group averages is computed. The whole processes is repeated (typically 100 times) with random splits before averaging the results from each iteration (Mohammad and Bravo-Marquez, 2017). Thus, an

[6] We found the usual recommendation of .2 on input and .5 on hidden layers (Srivastava et al., 2014) too high given the small number of features in our task (2 to 5).

[7] In our most recent contribution featuring a large-scale evaluation of many current WEI approaches on numerous data sets, we found that among the existing ones the model proposed by Du and Zhang (2016) performs best, only beaten by our own, newly proposed model (Buechel and Hahn, 2018b). Note that even compared to this more advanced approach to WEI, the performance figures we report here for ERM still remain much higher (see Section 4). Hence, the claim of this paper that ERM is superior to WEI, remains valid even despite most recent achievements for the latter task.

[8] Publicly available at: `https://github.com/StevenLOL/ialp2016_Shared_Task`

[9] `https://github.com/facebookresearch/fastText/blob/master/pretrained-vectors.md`

[10] For English, much larger embedding models are publicly available, yet not for the other languages under consideration; cf. Buechel and Hahn (2018b).

important difference between SHR and ISR is that the former is computed on a *single* data set whereas the latter requires two *different* data sets with overlapping items. On the other hand, ISR can be computed on the final ratings alone, whereas SHR requires knowledge of the judgments of the individual raters. Most often, these individual ratings are not distributed. Yet, luckily, SHR values are commonly reported when publishing emotion lexicons (see below).

Still, both SHR and ISR—as well as other popular approaches to reliability estimation for numerical emotion scores, e.g., the leave-one-out approach presented by Strapparava and Mihalcea (2007)—are heavily influenced by the number of participants of a study. For SHR, this is intuitively clear because with enough subjects, both groups should yield reliable estimates of the true population mean ratings, leading to very high correlation values between the groups. As a result, by splitting the number of raters into two groups for the SHR estimate, this technique will on average produce lower correlation values than if the study was repeated with the full number of participants and correlation between the first and second study had been computed (test-retest reliability). To counterbalance this effect, when reporting SHR values, authors often turn to *Spearman-Brown adjustment* (SBA; Vet et al. (2017)), a technique which estimates the reliability r^* of a study if the number of subjects was increased by the factor k:

$$r^* := \frac{k\, r}{1 + (k-1)\, r} \tag{5}$$

were r is the *empirically measured* SHR and k is set to 2 for the use case discussed above (virtually doubling the number participants).

Since some authors of the data sets in Table 1 apply SBA while others do not, the reported SHR values must be normalized to guarantee a consistent evaluation. Going one step further, we can even apply SBA to normalize the reported values with respect to the number of participants in a given study, thus establishing an even more consistent ground for evaluation.

We chose the *normalized number of participants* to be 20, i.e., the adjusted scores (reported in Table 3) estimate the *empirical* SHR values, if the given study was conducted with 20 participants (the average correlation between two randomly assigned groups of 10 raters). Normalization was conducted by applying Equation (5) to the reported values with $k := N^*/N$, if SBA was not already applied, or $k := N^*/(2 \times N)$, if SBA was already applied to the reported values; N being the actual number of participants and $N^* := 20$ being the normalized number of participants.

Table 3: Normalized split-half reliabilities for VAD and BE5 for the data sets used in our experiments. "—" indicates that reliability has not been reported.

It is important to note that the decision for $N^* = 20$ is necessarily arbitrary, to some degree, with higher SHR estimates arising from higher values of N^*. However, 20 raters are often used in psychological studies (Warriner et al., 2013; Stadthagen-Gonzalez et al., 2017b), while being way higher than the number of raters typically used in NLP for emotion annotation, both for the word and sentence level (Yu et al., 2016a; Strapparava and Mihalcea, 2007). Thus, we argue that this choice constitutes a rather challenging line of comparison for our system.

Since model performance will be measured in terms of Pearson correlation (see above), the performance figures achieved on the gold data can be compared with the adjusted SHR (also based on correlation). We can interpret cases where the former outperforms the latter as *the model agreeing more with the gold data than two random groups of ten annotators would agree with each other*. Thus, for these cases we say our model achieves *super-human* performance, as it cannot be expected that a well-conducted annotation study leads to more reliable results.

4 Results

4.1 Ablation Experiments on Affective Dimensions and Categories

Previous work has limited itself to data sets comprising all three VAD dimensions with the implicit belief that Dominance provides valuable affective information which is important for ERM. However, since only about half of the data sets developed in psychology labs (and even less provided by NLP groups) actually *do* comprise Dominance, this decision massively decreases the amount of data sets at hand. To resolve this dilemma, the following experiment aims at quantifying the relative importance of the different affective variables of the VAD and the BE5 format.

Our set-up works as follows: For each data set from Table 1 that includes the Dominance dimension, we trained one LR model[11] (Section 3.1) to map VAD to BE5 and another one to map BE5 to VAD ('dim2cat' and 'cat2dim' for short) applying 10-fold cross-validation. The resulting performance measurements were averaged over all data sets.

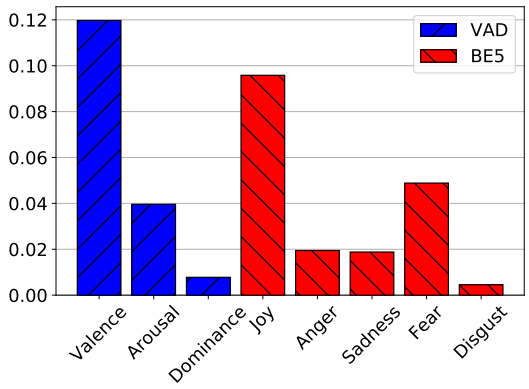

Figure 2: Relative importance of the affective variables of VAD and BE5 for predicting the alternative format, respectively; measured in drop of Pearson r when using all variables vs. omitting the one under scrutiny.

We then repeated this procedure once for each VAD dimension (when mapping dim2cat) and each BE5 category (when mapping cat2dim), omitting one of the dimensions/categories from the source representation in every iteration, thus constituting a kind of ablation experiment. Next, for each of the "incomplete" models, we computed the difference between its performance and the performance of the "complete" model (not lacking any of the variables). Now, we can use this loss of performance as an estimate of the *relative importance* of the respective left-out dimension or category. The results of this experiment are depicted in Figure 2.

As can be seen, regarding VAD, Valence is by far the most important dimension with a performance drop of .12 when ablating it. In turn, Arousal, the second-best dimension only increases performance by .04, whereas Dominance contributes to less than .01 of the performance. Similarly, for Basic Emotions, Joy is the most important category, although BE5 seems to distribute the affective information more equally across its variables (with the exception of Disgust which contributes far less than .01 to the performance).

Since our data suggest that Dominance plays only a minor role within the VAD framework, we will *not* limit our further experiments to data sets including this dimension—as it was done in previous work (Section 2)—but rather include the large variety of bi-representational data sets which leave it out (see Table 1).

4.2 Monolingual Representation Mapping

In this experiment, we compared the performance of the WEI baseline, the LR- and KNN-based reference methods for ERM and our newly proposed FFNN model. For each of these methods and data sets in Table 1, we trained one model to map cat2dim and another one to map dim2cat (for the ERM methods) or to predict VA(D) ratings and BE5 ratings based on word embeddings for the WEI baseline. The whole process was conducted using 10-fold cross-validation where we used identical train/test splits for all methods.[12] The results of this experiment are displayed in Table 4a, only showing the average values over VA(D) and BE5, respectively, but allowing for an easy comparison between the different approaches.

[11] Linear regression was used because it does not comprise any hyperparameters that might heavily influence the outcome of this experiment (thus leading to greater generality of the results).

[12] This procedure constitutes a more direct comparison than using different splits for each method and allows *paired* t-tests.

As can be seen, all of the ERM approaches (LR, KNN, FFNN) perform more than 10%-points better than the state of the art in word emotion induction (WEI) for VAD prediction and at least about 5%-points better for BE5 predictions (on average over all data sets and affective variables). This finding already strongly suggests that ERM is the superior approach for automatic lexicon creation, given that the required data are available. This might be especially useful in situations where, say, large VAD but only small BE5 lexicons are available for a given language (see Section 4.4). Regarding the ordering of the ERM approaches, KNN outperforms LR in almost all cases. The advantage is more pronounced for mapping dim2cat (2.5%-points difference on average) than cat2dim (.4%-points difference). On top of that, our proposed FFNN model outperforms KNN by a 1.2%-point margin for cat2dim and a .8%-point margin for dim2cat (again as average over all data sets) performing best on each single data set. Regarding the 16 cases of Table 4a (8 data sets times two mapping directions), the performance gain of FFNN compared to the respective second best system is statistically significant[13] in all but 2 cases. The differences between the individual ERM approaches might appear quite small, yet become a lot more meaningful considering the proximity to human annotation capabilities as discussed in the following paragraphs.

(b) Results of the monolingual experiment per affective dimension in Pearson r. Color indicates outperforming human SHR (blue), being outperformed (red) or SHR not being reported (white; "—" meaning that the respective variable is not included).

Table 4: Results of the monolingual experiment.

Table 4b displays the performance figures of the FFNN model relative to each affective variable. As can be seen, among VAD, Valence is the easiest dimension to predict ($r = .956$ on average over all data sets) whereas for Arousal the performance is worst . Similarly, for BE5, Joy obtains the best values ($r = .932$) and Disgust is the hardest to predict. Interestingly, the overall ordering of performance within the two formats is consistent with the ordering of human reliability (see Table 3).

Comparing our system performance against human SHR (based on 20 participants per study; see Section 3.4), again our approach seems to be highly reliable (color coding of Table 4b). In particular, ERM using the FFNN model outperforms SHR in over half of the applicable cases (25 of 38). For mapping cat2dim it surpasses human reliability in all but 2 cases whereas when mapping dim2cat the reported SHR is surpassed in over half of the cases (14 out of 25).

This result, astonishing as it might appear, is yet consistent with findings from previous work which, in turn, were based on ISR (not on SHR) data (Buechel and Hahn, 2017a; Buechel and Hahn, 2018a). We conclude that in the monolingual set-up, ERM using the FFNN model substantially outperforms current capacities in word emotion induction and is even more reliable than a medium sized human rating study. Thus these automatically produced ratings should be cautiously attributed gold standard quality.

[13] Paired two-tailed t-tests based on the 10 train/test splits during cross-validation; $p < .05$.

4.3 Crosslingual Representation Mapping

In the crosslingual set-up, we make use of the fact that our model does not rely on any language-specific information, since the categories/dimensions describe supposedly universal affective states rather than linguistic entities. Thus, models trained on one language could, in theory, be applied to another one without any need for adaptation. This capability comes in handy when only data sets according to *one* emotion format exist for a given language. In such cases we could still train our model on data available for other languages and use it to produce new ratings for the language in focus. This section aims at estimating the performance of lexicons derived in this manner.

Table 5: Results of crosslingual experiment in Pearson r. Color indicates outperforming human SHR (blue), being outperformed (red) or SHR not being reported (white).

For each of the data sets in Table 1, we trained FFNN models to map cat2dim and dim2cat, respectively. We trained on each gold lexicon that did not cover the language of the data set under scrutiny (e.g., for testing on en_1, the models were trained on all Spanish, Polish and German data sets, but not on en_2). Since this set-up leads to fixed train and test sets, we did not perform cross-validation. For comparability between data sets, the Dominance dimension was excluded for this experiment.

Overall, the results remained astonishingly stable compared to the monolingual set-up, with performance figures for Valence and Joy dropping by less than 1%-point on average over all data sets (see Table 5). Also, Anger, Sadness, Fear and Disgust only suffer a moderate decrease of about 5%-points at most—only the performance of Arousal decreased more than that.

A possible explanation for these strong results is the marked increase in the amount of training data that comes along with training on the majority of the available data (independent of language). This circumstance seems to counterbalance much of the negative effects that may arise in this crosslingual applications.

In comparison to SHR, the ERM approach still turns out to work quite well. Regarding VA, we outperform human reliability in 8 of 10 cases. Concerning BE5, SHR was beaten in about half of the cases (11 of 25). We conclude that, although the capability of our mapping approach suffers a bit in the crosslingual set-up, it still produces very accurate predictions and can thus be attested *near* gold quality, at least.

4.4 Automatic Lexicon Construction for Diverse Languages

After the positive evaluation of the FFNN model for ERM, the last bit of our contributions is to apply the created models to a wide variety of data sets which so far bear emotion ratings for *one* format only (either VA(D) or BE5). Based on the experiments reported so far, we claim that these have gold quality (for the monolingual approach, Section 4.2) or near-gold quality (for the crosslingual approach, Section 4.3).

For the monolingual approach, we train our model on the data set on which we achieved the highest performance in Section 4.2 for the respective language (assuming this hints at particularly "clean" data). In contrast, in the crosslingual set-up, training data are acquired by concatenating *all* the available data sets from Table 1 (consequently ignoring Dominance for compatibility).

Table 6 lists the emotion lexicons constructed in this manner together with their most important characteristics. The number of new ratings ranges from almost 13,000 (for English) and 10,500 (for Spanish), over several thousands (for Dutch, Chinese and Polish,) and around 1,500–1,000 (for Indonesian, Italian, Portuguese, Greek, French and German) to 200–100 (for Finnish and Swedish). For illustration, Table 2 displays three entries of the English BE5 lexicon, the largest one we constructed.

5 Conclusion

In this paper, we addressed the relatively new task of *emotion representation mapping*. It aims at transforming emotion ratings for lexical units from one emotion representation format into another one, e.g., mapping from Valence-Arousal-Dominance representations to Basic Emotion ones. Based on a large-scale evaluation we gathered solid empirical evidence that the proposed neural network model consistently outperforms the previous state-of-the-art performance figures in both word emotion induction and emotion representation mapping. Hence, the approach we propose currently constitutes the best-performing method for automatic emotion lexicon creation.

Table 6: Overview of automatically constructed emotion lexicons; mapping methodology (monolingual or crosslingual), language (codes according to ISO 639-1), target emotion format, source lexicon of the mapping process and number of previously unknown ratings (excluding those present in other lexicons).

We also proposed a novel methodology for comparison against human rating capabilities based on normalized split-half reliability scores. For the first time, this allows for a large-scale evaluation against human performance. Our experimental data suggest that our models perform competitive relative to human assessments, even in cross-lingual applications, thus producing (near) gold quality data. We take this as a strong hint towards the reliability of the methods we propose.

Finally, we used these models to produce new emotion lexicons for 13 typologically diverse languages which are publicly available along with our code and experimental data (see Footnote 1).

Abstract

Detection and classification of emotion categories expressed by a sentence is a challenging task, due to subjectivity of emotion. To date, most of the models are trained and evaluated on single genre and when used to predict emotion in different genre, their performance drops by a large margin. To address the issue of robustness, we model the problem within a joint multi-task learning framework. We train this model with a multigenre emotion corpus to predict emotions across various genres. Each genre is represented as a separate task, we use soft parameter shared layers across the various tasks. our experimental results show that this model improves the results across the various genres, compared to a single genre training in the same neural net architecture.

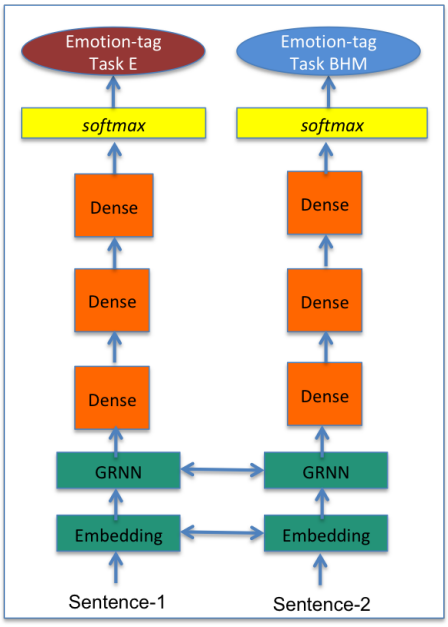

Figure 1: Joint Multi-Task Emotion neural net architecture. In this multi-task framework, Task-E and Task-BHM (explained in section 3) demonstrate different genres.

1 Introduction

Sentence-level emotion detection is garnering a lot of attention recently. To date, most systems are trained and evaluated on a single genre resource. However, the problem is robustness, when such models are applied to new genres, the performance expectedly drops significantly. In this paper, we propose a model to address the genre robustness issue.

Proceedings of the 27th International Conference on Computational Linguistics, pages 2905–2913

Table 1: Data statistics illustrating the distributions of the various emotion tags from PL8 across the different genres.

We frame the problem as a joint multi task learning problem, where each of the genres is represented as a separate task that shares information with other tasks (genres). Our model, the Joint Multi-Task Emotion (JMTE), illustrated in figure 1, trains on emotions in four genres of data: Blog Posts, News Headlines, Movie Reviews, and Tweets. Experimental results show that using JMTE achieves better results, over a single model trained on a single of these different genres. We also study the impact of specifically adding Twitter data that is distantly supervised to the training models.
The rest of this paper is organized as follows: We describe our multigenre corpus in section 2; We present our devised JMTE model in section 3; Experimental conditions and results are presented in section 4; Discussion is presented in section 5; We review related studies in section 6; Conclusions are described in section 7.

2 Data

We create a unified multigenre data set annotated on the sentence and clause level using the 8 emotions from Plutchik (Plutchik, 1962), which includes the following 8 emotions: *joy, trust, anticipation, surprise, anger, fear, sadness, disgust* (PL8) and a *no-emotion* category (Tafreshi and Diab, 2018). [1]
Our combined multigenre corpus includes the following data sets: The emotional blog post (BLG) (Saima and Stan, 2007) comprising 4,115 sentences; The headlines dataset (HLN) (Carlo and Rada, 2007) comprising 1,250 sentences; a movie review dataset (MOV) (Bo and Lillian, 2005) where people express their opinions about movies, sound tracks, and casts. The MOV dataset contains 11,855 sentences. Both BLG and HLN were originally annotated using the 6 basic emotion categories from (Paul, 1992), *happiness, sadness, fear, anger, surprise and disgust* (EK6), while the MOV data set was annotated for sentiment and sentiment intensity. The three corpora resulted in 17,220 sentences annotated with the PL8 emotion tag set, from which 3993 sentences are annotated with *no-emotion*. That corpora annotated using the crowd sourcing platform CrowdFlower[2]. The inter-annotator agreement (IAA) achieved was 79.95%. We refer to this data set as BHM corresponding to BLG, HLN, and MOV, respectively.
We further experiment with a fourth dataset from Twitter. We added 13,227 randomly selected tweets (to match the BHM collection size) from the EmoNet (Muhammad and Ungar, 2017) tweet collection, which has a total of 547,555 tweets tagged with PL8 and its extension into 16 fine grained emotion tags. EmoNet is labeled using distant supervision, namely relying on hashtag information to render the emotion tag. We only selected for our corpus tweets that had emotion tags corresponding to the PL8 emotions. This collection has no *no-emotion* tag. We refer to this data set as TweetEN. Accordingly, our annotated multigenre corpus includes: BLG, HLN, MOV, and TweetEN, comprising a total of 26,454 annotated sentences with PL8 labels. We refer to this combined corpus as BHMT. Table-1 shows data statistics.

3 Proposed Approach

We model the problem as a joint multitask learning architecture. We use a Gated Recurrent Neural Network architecture (GRU), inspired by (Muhammad and Ungar, 2017). We create two tasks in JMTE,

[1] You can download BHM dataset and JMTE python code from `https://github.com/shabnamt/jointMultitaskEmo`

[2] `https://www.crowdflower.com`

one trained on the TweetEN data set (Task-E) and the other trained on the BHM data (Task-BHM). The reason to model them separately is that they are annotated in very different ways: TweetEN is annotated using distant supervision relying on hashtags, vs. BHM which is annotated completely manually. We balance the distribution of labeled data per emotion across the two tasks.

Recurrent Neural Network (RNN)- has been widely used in the literature to model sequential problems. RNN applies the same set of weights recursively as follow:

$$h_t = f(W_{x_t} + Uh_{t-1} + b) \tag{1}$$

RNN input vector $x_t \in R^n$ at time step t is calculated based on a hidden state and an input from the current state based on Eq. 1. The function f is a nonlinearity such as tanh or ReLU. Long Short Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) and Gated Recurrent Neural Nets- (Cho, 2014; Chung, 2015) are implementations of RNNs that circumvent some of the major issues with RNNs as they are much better at capturing long-term dependencies, and dealing with the vanishing gradient problem (Bengio et al., 1994; Pascanu et al., 2013).

Gated Recurrent Neural Nets- (Cho, 2014; Chung, 2015) is very similar to LSTM with the following equations:

$$r_t = \sigma(W^r_{x_t} + U^r h_{t-1} + b^r) \tag{2}$$

$$z_t = \sigma(W^z_{x_t} + U^z h_{t-1} + b^z) \tag{3}$$

$$\hat{h_t} = \tanh(W_{x_t} + r_t \times U^{\hat{h}} h_{t-1} + b^{\hat{h}}) \tag{4}$$

$$h_t = z_t \times h_{t-1} + (1 - z_t) \times \hat{h_t} \tag{5}$$

GRU has two gates, a reset gate r_t, and an update gate z_t. Intuitively, the reset gate determines how to combine the new input with the previous memory, and the update gate defines how much of the previous memory to keep around. We use Keras[3] GRNN implementation to setup our experiments. We note that GRU units are a concatenation of GRU layers in each task.

Shared layers - these two tasks, Task-E and Task-BHM share the word embedding (*i.e.* Keras embedding) layer. We setup this layer in two different ways: a) initiating random weights for each word vector and tune these weights using the training set, b) initiating the weights from pre-trained word embedding model and let the embedding layer to tune the weights using the training set. The task specific GRU layers share soft parameters between each of the two layers, we observed that soft parameter sharing creates better weights for this layer. Shared GRU takes advantage of the underlying emotion cues structure shared among the genres (*e.g.* presence of adjective and adverbs) as well as semantic and syntactic emotion features that improve emotion detection and classification in different genres.

Task Specific Layers - each task has 3 hidden dense layers and a *softmax* layer for prediction, this setup allows freedom for each task to have auxiliary input layers and be optimized per task. We optimize these layers per task.

3.1 Training JMTE Model

We set the dimensionality of the input embedding layer to 300 and the hidden GRU to 70. We concatenate clause feature, explained at 4.2 to Task-BHM embedding layer. At each training epoch, we train the model in the following order: shared embedding, shared soft parameters of the hidden GRU, 3 specified hidden dense layers for each task. We experimented with different number of units in dense layers and our results on dev set suggest the following setup for dense layers: 300 units for Task-E and 200 units for Task-BHM. We use a *softmax* layer for predicting emotion tags. Further, we use an input maximum length of 70, 10 epochs, and Adam (Kingma and Ba, 2014) optimizer with a learning rate 0.001. We use

LL2	BLG+HLN	37.0%	***38.3%***	62.4%
LL3	MOV	25.2%	17.0%	*32.1%*
LL4	BHMT	**43.9%**	21.7%	**79.0%**

Table 2: LIBLINEAR weighted F1 scores for different experimental conditions where we train on various training data set combinations and test within and across genres. Within genre is marked in italics. It should be noted that we did not balance the size of the training data across the different experimental conditions.

dropout (Graves et al., 2013) for regularization, with a dropout rate: 0.3 for both tasks. The loss function is a categorical-cross-entropy function. We use a mini batch (Cotter, 2011) of size 65.

4 Experiments and Results

4.1 Data

We split the data representing each emotion category per genre into 70%,10%,20% for train, dev, and test, respectively. We added dev set to training set after tuning our model parameters on dev set.

4.2 Baseline Models

We compare our proposed models to two baselines: a feature engineering architecture LIBLINEAR from the SVM family. We leverage LIBLINEAR architecture implementation in Weka.[4]; and a single GRU model architecture where we use all the data from both TweetEN and BHM in a single model.

Feature Engineering Baseline: For the LIBLINEAR setting, we build our model combining a number of features: character and word n-grams (uni-gram and bi-gram); POS: presence of POS tags taken from PennTreebank; syntactic features like presence of adjective, adverbs, or negation; and semantic features like presence of emotion words based on EmoNet lexicon (Mohammad, 2012), and clause feature, which we explain below. We report weighted F1 scores across the 8 PL8 emotion tags.
Clause feature - for this feature, we study the distribution of clauses emotion tags in multi-clausal sentences. We note that the majority of those sentences with multiple clauses tend to have clauses with specific emotion labels (e.g. sentence emotion tag *joy*, have clauses with tags *trust, anticipation, no-emotion, and surprise*). We model this feature as an 8-dimension vector, where each dimension represent one emotion tag with a binary value: 1 indicates the presence of sub-sentential emotion clause tag and 0 otherwise.

Table 2 illustrates the results of the LIBLINEAR models. We combine the test sets for BLG and HLN as they are relatively small. In LL1, training with TweetEN yields the worst results on all 3 data sets even on the TweetEN test set (within genre setting). In LL3, training with MOV yields the lowest within genre results compared to the other sets. In LL4, training with a combination of BLG+HLN+MOV and TweetEN yields the best results on TweetEN and MOV data sets. In addition, in this condition we combine gold annotated set, BHM, with distant supervision set TweetEN. In LL2, training with BLG+HLN, which is the smallest training set yields the best results on BLG+HLN, and compare to LL1, yields better results on TweetEN and MOV. Hence, size is not a factor in the performance and the feature engineering approach is not robust towards genre variation.
Single Task NN Learning Baseline: We experiment with a GRU architecture as a single task. The architecture is similar to the JMTE framework with an embedding layer, followed by a GRU, then 3 dense layers followed by a softmax classification layer. Both the GRNN and JMTE are implemented using Keras and Tensorflow[5] in the backend. Table 3 present the results for single task GRU baseline. We mentioned earlier about embedding layer setup in our model, we experimented with two different

Condition	training set	TweetEN	BLG+HLN	MOV
GRNN1	TweetEN	61.9%	27.2%	36.5%
GRNN1-pt		65.5%	29.9%	45.7%
GRNN2	BLG+HLN	33.7%	31.2%	27.4%
GRNN2-pt		40.2%	37.2%	38.2%
GRNN3	MOV	45.3%	26.4%	66.2%
GRNN3-pt		46.6%	28.02%	69.6%
GRNN5	BHMT	76.2%	81.2%	89.8%
GRNN5-pt		**78.1%**	**83.6%**	**91.0%**

Table 3: Single task GRNN F-score results on all the test data sets. Using pre-train (GRNN-pt) word embedding to initiate the weights for embedding layers, creates better results across all conditions. Colored results are out-of-genre evaluations.

Model	TweetEN	BLG+HLN	MOV
LL5	43.9%	21.7%	79.0%
GRNN5-pt	78.1%	83.6%	91.0%
JMTE	78.5%	82.3%	92.2%
JMTE-pt	**80.0%**	**84.0%**	**92.6%**

Table 4: Weighted macro F1-scores yielded by baseline models using all the training data BHMT compared against the JMTE model.

setup, a) we initiate random weights for word vectors b) we initiate the weights using pre-trained word embedding; in both of these settings we tuned the word vectors using the training set. We experimented with different word embedding models, mainly to have a better coverage for all these 4 genres in our corpus. Common training set for word embedding models are wiki+news, news, tweets, and common crawl, and the methods are Word2Vec (Mikolov et al., 2013), GloVe (Pennington et al., 2014), and fasText (Bojanowski et al., 2016). Our results indicate that common crawl corpus with 2 million words, trained using fastText model has the most word coverage among these genres. [6] We experimented with google news (trained using word2vec), wikipedia+Gigaword (trained using GloVe), Twitter (trained using GloVe).[7]

The best results are obtained using all the data in condition GRNN5-pt which trains on all the labeled data, and we used pre-trained word embedding to initialize the wights for embedding layer. The results yielded by the Deep learning model surpass those of the LIBLINEAR baseline by a significant margin comparing GRNN5-pt (F1 scores of: 78.1%, 83.6%, 91.0%, for TweetEN, BLG+HLN, MOV, respectively) compared with LL5 (F1 scores of: 43.9%, 21.7%, 79%, for TweetEN, BLG+HLN, MOV, respectively). GRNN1-pt and GRNN3-pt indicate that within genre training and testing yields the best results. Even when there is more data available for training, comparing GRNN1-pt (more training data) compared to GRNN3-pt condition, GRNN3-pt yields higher results on the MOV (within genre) test data at 69.9% vs. 45.7% F1 score as yielded from GRNN1-pt condition. GRNN1-pt consistently beats LL1 across all test sets, likewise for GRNN3-pt and LL3. The pattern is consistent.

Joint MultiTask Learning of Emotion Model: Table 4 shows the performance of the JMTE model proposed in this paper against the two baselines GRNN (GRNN5-pt) and LIBLINEAR (LL5) when using all the data for training. Overall, the JMTE-pt yields the best results across all test data sets, significantly outperforming the LIBLINEAR baseline as well as beating the single task GRNN architecture.

5 Discussion

It is worth noting that we could not compare our results against other systems in the literature since available systems are typically trained on the EK6 tag set. The only system we know that is trained and tested on the PL8 tag set is that of Muhammad and Ungar (2017) but the test set is twitter data which is

Table 5: F-score results with LIBLINEAR and JMTE across different emotion tags, per genre. Emotion tags *anger* and *trust* are minority in MOV, hence, the model could not predict correct instances in these two emotion categories.

not a stable data set.[8] Furthermore, in an attempt to understand the performance of the various models per emotion tag. Table 5 compares F-score per emotion tag between LIBLINEAR and JMTE, which indicates JMTE is able to learn each emotion tag better than LIBLINEAR and GRNN models. We built JMTE to generalize emotion detection and classification across different genres.
Certainly, adding more data would create better results, but this is not the aim of our study. We observe that LIBLINEAR has shortcoming when we add TweetEN to the training set, and when we train LIBLINEAR with different genre than TweetEN. JMTE and GRNN overcome this shortcoming across all genres, and for some genres the improvement is significant (*i.e.* BLG+HLN and TweetEN).
GRNN produces close results to JMTE, however JMTE has the advantage to be specialized per genre by adding auxiliary layers and genre specific layers.

LIBLINEAR trained on BLG+HLN+MOV performed poorly on tweetsEN, this model can only classify *joy* and *disgust*, with f-score 42.0% and 63.0% respectively and these two emotion tags are the most populated tags in this set.
Although JMTE is able to generalize emotion classification across genres and create the best results, however, GRNN trained on BLG+HLN+MOV created better results for HLN, which indicates JMTE needs auxiliary (*i.e.* specific) layer for different genres, particularly if the genre has lower amount of test and train data (HLN) or genre is very different compare to other genres (MOV). In our setup HLN has the minimum number of instances in multigenre corpus (training: 825 and test: 425) and MOV is very different compare to tweets, BLG, and HLN, hence, adding specific layers for these genres can improve the results.
Other challenge here is pre-trained word embedding model. We observed that pre-trained word embedding creates better results, however, none to the best of our knowledge are trained using different genres to correspond to our need. We observe the results in Table 3 using pre-trained word embedding, and the significance of better coverage for all the genres. Comparing GRNN4 vs GRNN4-pt on TweetEN 31.7% vs. 32.9%, which has only 1% improvement, vs., GRNN2 vs. GRNN2-pt on TweetEN 33.7% vs. 40.2% which has 7% improvement, which, is an indication that an effective word embedding can improve the results by a large margin, as GRNN2-pt has less training data compare to GRNN-4.
Further, we observed that most of the instances that are misclassified in BLG, HLN, and MOV, are the ones with lower confidence score annotation, as these sets are manually annotated. In addition, observing the confusion matrix in JMTE suggests that in both tasks data points are separable, since misclassified data points are not skewed towards particular or the most popular classes. However, emotion tag *surprise* is mainly misclassified with *joy* and *discussed*, we further observed the data points to address this issue and noticed most of these data points imply surprise and even as human it was difficult for us to categorize them as surprise.

[8]Unfortunately due to licensing issues, exact tweets can't be shared, only IDs, hence when retrieving the actual tweets, we noted that we can only retrieve 75% of the exact tweets.

6 Related Work

6.1 Emotion Detection and Classification

Emotion detection has attracted several NLP applications like chatbots, stock market, and human personality analysis. Several studies investigated the problem in various genres. We present some of the studies most relevant to this paper. In the literature, emotion detection is cast as a classification problem, hence, the objective is to effectively learn emotion cues. Among the feature engineering approaches, we review the following works:Gilad (2005) collected a set of blog posts - online diary entries - which include an indication of the writers' mood. Carlo and Rada (2007) collected and manually labeled 1,250 headlines (HLN) for emotion classification and valence (*i.e.* positive, negative) using the 6 basic emotions identified by Ekman (Paul, 1992) (EK6) tags. Saima and Stan (2007) collected and labeled a blog posts corpus (BLG) using EK6 tags on both the sentence and the phrase levels, they annotated emotion categories, emotion intensity, and identifying emotion phrases in blog posts. Diman et al. (2010) experimented with hierarchical classification for emotion analysis which considers the relation between neutrality, polarity and emotion of a text. Diana and Carlo (2010) presented a categorical model and dimensional model for recognition of affective states (emotion cues). Mohammad (2012) investigated word-level affect lexicons features on sentence-level emotion detection. Özbal and Daniele (2013) showed the effect of incorporating different levels of syntactic and semantic information on sentence level emotion detection.
In recent years, unlimited access to social media data such as *Twitter and Facebook*, enabled the community to have access to large amount of data. In these works researchers have used supervised learning model trained on lexical, semantic, and stylistic features to classify emotion in Twitter (Wenbo et al., 2012; Roberts et al., 2012; Ashequl and Ellen, 2013; Yan, 2014; Saif and Svetlana, 2015; Yan and Howard, 2016; Svitlana and Yoram, 2016). Muhammad and Ungar (2017) proposed a gated recurrent neural network architecture to classify emotion in tweets.

6.2 Multi-Task Learning in Deep Neural Net

Multi-Task learning is inspired by human learning. As human, when we learn new tasks, often we apply the knowledge we have gathered from related tasks. In the literature, multi-task learning comes in different forms: joint learning, learning to learn, and learning with auxiliary tasks. The following studies show the benefit of multi-task learning in closely-related or different type of tasks (R, 1993; Ronan and Jason, 2008; Collobert et al., 2011; Xiao et al., 2011; Seltzer and Droppo, 2013; Devries et al., 2014; Xia and Liu, 2015; Luong et al., 2015; Anders and Goldberg, 2016; Kazuma et al., 2016; Andor et al., 2016; Jonathan et al., 2016; Makoto and Bansal, 2016).
To the best of our knowledge multi-task learning has not been studied to detect emotion in multigenre text input. The closest work to ours is the work of (Xia and Liu, 2015). In the latter study of (Xia and Liu, 2015), they proposed a multi-task learning framework that leverages activation and valence information for acoustic emotion recognition.
Our work contributes the following: a) we empirically illustrate that emotion cues can be learned robustly across genres by framing the problem as a Joint Multi-Task learning problem.

7 Conclusion

Combination of different genre datasets can improve and generalize emotion detection in sentences. We showed multi-task deep neural net models are able to successfully classify emotion in multigenre and across genres. We showed that unified annotation is beneficial for emotion detection through combining different genres to augment and create larger training sets. We discuss the impact of pre-trained word embedding in emotion classification and the challenges involve finding a proper word embedding that has the most coverage among different genres in our corpus.
Our future direction is to increase number of instances for minority genres and experiment with formal and informal text to represent different tasks. We aim to experiment with more robust tuning method to create better pre-trained word embedding. Further, we aim to add genre specific layer to improve results across different genres.

Abstract

Social media based micro-blogging sites like Twitter have become a common source of real-time information (impacting organizations and their strategies), and are used for expressing emotions and opinions. Automated analysis of such content therefore rises in importance. To this end, we explore the viability of using deep neural networks on the specific task of emotion intensity prediction in tweets. We propose a neural architecture combining convolutional and fully connected layers in a non-sequential manner - done for the first time in context of natural language based tasks. Combined with lexicon-based features and transfer learning, our model achieves state-of-the-art performance, outperforming the previous best system by 4.4% Pearson correlation on the WASSA'17 EmoInt shared task dataset. We investigate the performance of deep multi-task learning models trained for all emotions at once in a unified architecture and get encouraging results. Experiments performed on evaluating correlation between emotion pairs offer interesting insights into the relationship between them. The code for our experiments is publicly available.

1 Introduction & Related Work

One can use text in any language not only to express a variety of emotions but also to convey the associated 'intensity' of the emotion. *Emotion intensity* is the degree of an emotion (like anger or fear) expressed by the speaker or author. For example, *'When you lose somebody close to your heart you lose yourself as well. Crying my heart out!!!'* expresses *more* sadness than, say, *'All friends are out of town. Feeling a bit lonely...'*. Automatic detection of emotion intensity can be useful for natural language based systems. An e-commerce firm seeking to publicize positive reviews of its products would want to use the statements expressing high amount of joy or happiness. The intensity of anger expressed in a grievance can be used to automatically decide the priority of addressing complaints. A possible example scenario: based on the tweet *'X box one controller jockey update is the fucking worst! #fuming'* expressing a higher intensity of anger than the tweet *'New madden bundle code for x box one is stupid, takes forever to download lol'*, may point to the need of prioritizing addressing issues with the new jockey stick before looking into the madden bundle of the same product (an Xbox One).

The WASSA'17 workshop conducted the EmoInt shared task (Mohammad and Bravo-Marquez, 2017b) where given a tweet and the emotion it exhibits, systems had to predict the intensity of this given emotion as a real valued score between 0 and 1. We use the shared task setting and the dataset they provide to develop and evaluate all our approaches. The main contributions of our work are:

a) A neural architecture for emotion intensity detection which combines convolutional layers with fully connected layers in a non-sequential or 'parallel' fashion. Such a combination of these neural models or layers has been explored in computer vision (Antol et al., 2015; Vijayanarasimhan et al., 2017) but, to the best of our knowledge, our work is the first to utilize this in Natural Language Processing based tasks. Our results will motivate the NLP community to take an increased interest in such architectures. We also rely on lexicon-based linguistic information in our network, and use transfer learning by incorporating

* The two first authors have equal contributions to the paper

Proceedings of the 27th International Conference on Computational Linguistics, pages 2914–2926
Santa Fe, New Mexico, USA, August 20-26, 2018.

activations of a pre-trained convolutional neural network which uses emojis to learn representations for related tasks of sentiment and emotion detection in tweets (Felbo et al., 2017). Our model achieves *state of the art performance* on the EmoInt dataset.

b) Two multi-task neural network based models which successfully handle all emotions jointly, as opposed to having a separate network for each individual emotion. Our best multi-task learning based approach performs relatively well when compared to other approaches and previous systems while benefiting from better generalization, speed and lesser trainable network parameters.

c) A comprehensive set of ablation tests to show how the various components within our models contribute, to help guide the design of future systems for our task as well as other, related tasks.

d) Experiments to gauge the correlation between different pairs of emotion and an effort to link our observations with past findings in linguistic and psychological experiments.

e) Error analysis to assess reasons for erroneous intensity prediction in tweets.

The code for all our approaches is publicly available [1].

Most datasets and systems focus on emotion classification or detecting the presence or absence of an emotion (Brooks et al., 2013; Alm et al., 2005; Aman and Szpakowicz, 2007; Bollen et al., 2011; Wang et al., 2016). To the best of our knowledge, apart from the dataset used for conducting the EmoInt shared task, there is only one resource annotated for the intensity of emotion in text, which was released by Strapparava and Mihalcea (2007) as part of SemEval 2007. Annotators gave a score between 0 and 100 for the degree of emotion in newspaper headlines using a slide bar in a web interface.

We perform our experiments on a Twitter dataset (Mohammad and Bravo-Marquez, 2017a) (Table 4). Users from many backgrounds express emotions via tweets. Increasing activity of bots on Twitter (Gilani et al., 2017) and companies aiming to accurately respond to tweets about their products or services makes Twitter an attractive domain for sentiment analysis (Fan and Gordon, 2014; Nakov et al., 2016).

Twenty two systems participated in the EmoInt shared task. Approaches included random forest regressors, neural approaches and lexicon-based methods (Mohammad and Bravo-Marquez, 2017b).

2 Proposed Neural Framework: LE-PC-DNN

We propose a novel neural network based architecture that combines - (i) Convolutional layers, (ii) Fully-connected layers, (iii) Linguistic features, and (iv) Pretrained CNN activations in a non-sequential fashion (detailed below). The architecture and the hyperparameter setting is consistent across all emotions.

2.1 Embedding Layer ($l^{(1)}$)

The input to our network's first layer is a sequence of tokens $\{w_1, w_2, ...w_n\}$ (padded when necessary). $l^{(1)}$ begins by associating each word w with a feature vector $\mathbf{e}_w$, also called *word embeddings* (Bengio et al., 2003). The obtained embedding matrix $\mathbf{E} \in R^{n*d}$ serves as the input to next layer.

The model consists of two different types of layers - *Parallelly-connected layers* and *Sequential fully-connected layers* (Figure 1).

2.2 Parallelly-connected layers

The output E of the embedding layer ($l^{(1)}$) above is fed to two parallel layers - the **CNN layer** ($l_a^{(2)}$), which applies convolutional operation on the embedding matrix $\boldsymbol{E}$ followed by a max-pooling-over-time operation to get the $l_a^{(2)}$ layer representation (Figure 1) and the **Average Embedding Layer** ($l_b^{(2)}$), which is calculated by taking the mean of word embeddings $\boldsymbol{E}$ across the length of the tweet, giving us a d-dimensional feature vector. $l_b^{(2)}$ is supposed to capture the global context of the tweet. The CNN layer and the average embedding layer are both fully connected to layers $l_a^{(3)}$ and $l_b^{(3)}$ respectively after applying Dropout (Srivastava et al., 2014) in each case to control over-fitting of parameters.

The network consists of two more parallel layers ($l_c^{(2)}$, $l_d^{(2)}$), which process the input tweet $\boldsymbol{T}$ directly. For emotion intensity prediction task, the **Linguistically Informed Layer** ($l_c^{(2)}$) uses the *TweetToLexiconFeatureVector* filter developed in the Affective Tweets[2] package to get 43 tweet-level features, cal-

[1] https://github.com/Pranav-Goel/Neural_Emotion_Intensity_Prediction

[2] https://github.com/felipebravom/AffectiveTweets

culated using several lexicons (details in Mohammad and Bravo-Marquez (2017b)). Sentiment-based lexicons and other resources of linguistic knowledge can capture some aspects of data that are different than those learned by CNN/LSTM relying on word embeddings (Chen et al., 2017) and boost performance (Ebert et al., 2015). There are different ways to use linguistic features with neural architectures (Ebert et al., 2015; Park et al., 2016). We incorporate these external features in a simple manner (Figure 1). The input to the layer $l_c^{(2)}$ is a tweet T. Applying TweetToLexiconFeatureVector filter gives a 43-dimensional feature vector.

We also use **Pretrained CNN features** ($l_d^{(2)}$) by leveraging the activations of a Convolutional Neural Network (CNN) pre-trained on emoji prediction task called DeepMoji (Felbo et al., 2017) [3]. This CNN was trained on 1.3 billion emoji-containing tweets and tested on eight benchmark datasets within emotion, sarcasm and sentiment detection. Since emoji prediction is closely related to emotion intensity prediction, we hypothesize that transferring knowledge via pre-trained CNN activations could help improve performance for our task. Each tweet is converted into a 2304-dimensional feature vector $l_d^{(2)}$ by feeding the tweet into the DeepMoji-CNN and extracting activations of the last hidden layer.

2.3 Sequential Fully-Connected Layers ($l^{(4)}, l^{(5)}, l^{(6)}$)

The layer ($l^{(4)}$) is obtained by concatenating the feature activations of layers $l_a^{(3)}, l_b^{(3)}, l_c^{(2)}, \& l_d^{(d)}$. $l^{(4)}$ is connected to $l^{(5)}$, which is a fully-connected layer. Additionally, a linear hidden layer ($l^{(6)}$) with lesser number of neurons is introduced on top of $l^{(5)}$.

2.4 Output Layer ($\hat{y}$)

Finally, we use a sigmoid neuron after $l^{(6)}$ to compute the intensity score $\hat{y}$ of between 0 and 1.

It is quite common to have fully connected layers or small feedforward neural networks connected in a sequential or hierarchical manner to sequence-to-sequence models like CNNs/LSTMs (Lee and Dernoncourt, 2016; Plahl et al., 2013). The feedforward networks in this case take in the pooled output of CNNs/LSTMs as input. Our architecture (Figure 1), however, combines feedforward, convolutional layers and manually extracted features in a non-hierarchical manner (layer $l_a^{(3)}$) as well as in hierarchical fashion (layer $l_b^{(3)}$). Such a non-sequential combination of fully-connected and convolutional networks is *novel* for NLP tasks, to the best of our knowledge (though this has been used by the vision community (Antol et al., 2015; He et al., 2017; Vijayanarasimhan et al., 2017)). We call this neural framework with a non-hierarchical or *parallel* combination of CNNs/LSTMs, fully-connected layers, lexical features and pretrained CN activations as **PC-DNN** (Parallel Combination of Deep Neural Networks). As it incorporates **L**inguistic features (layer $l_c^{(2)}$) and **E**moji-based pretrained CNN activations (layer $l_d^{(2)}$) as well, we will refer to the network discussed in this section as **LE-PC-DNN** (Figure 1).

3 Deep Multi-Task Learning (DMTL): Handling all Emotions in a Unified Architecture

Multi-task Learning (Caruna, 1993; Caruana, 1998) has resulted in successful systems for various NLP tasks (Collobert and Weston, 2008), especially in cross-lingual settings (Huang et al., 2013). MTL was first applied to Emotion Intensity prediction in (Goel et al., 2017). In their neural architecture, the initial network layers are shared across multiple emotions upto a certain point, after which the architecture gets diverged for each emotion. The objective is to jointly train on different emotion datasets such that initial layers increase generalization and the individual final layers can learn task specific features. The network input features are the concatenation of average word embeddings across the length of the tweet and linguistic features (using *Tweet2LexiconFeatureExtractor*), and the neural layers were fully-connected.

3.1 LE-PC-DMTL for Emotion Intensity Prediction

The above DMTL model only uses feed-forward layers as the input is a 1-dimensional representation of the tweet. Our proposed LE-PC-DNN network, on another note includes convolutional layers and pre-trained CNN activations in the architecture. The model however is separate for each emotion. We

[3] https://github.com/bfelbo/DeepMoji

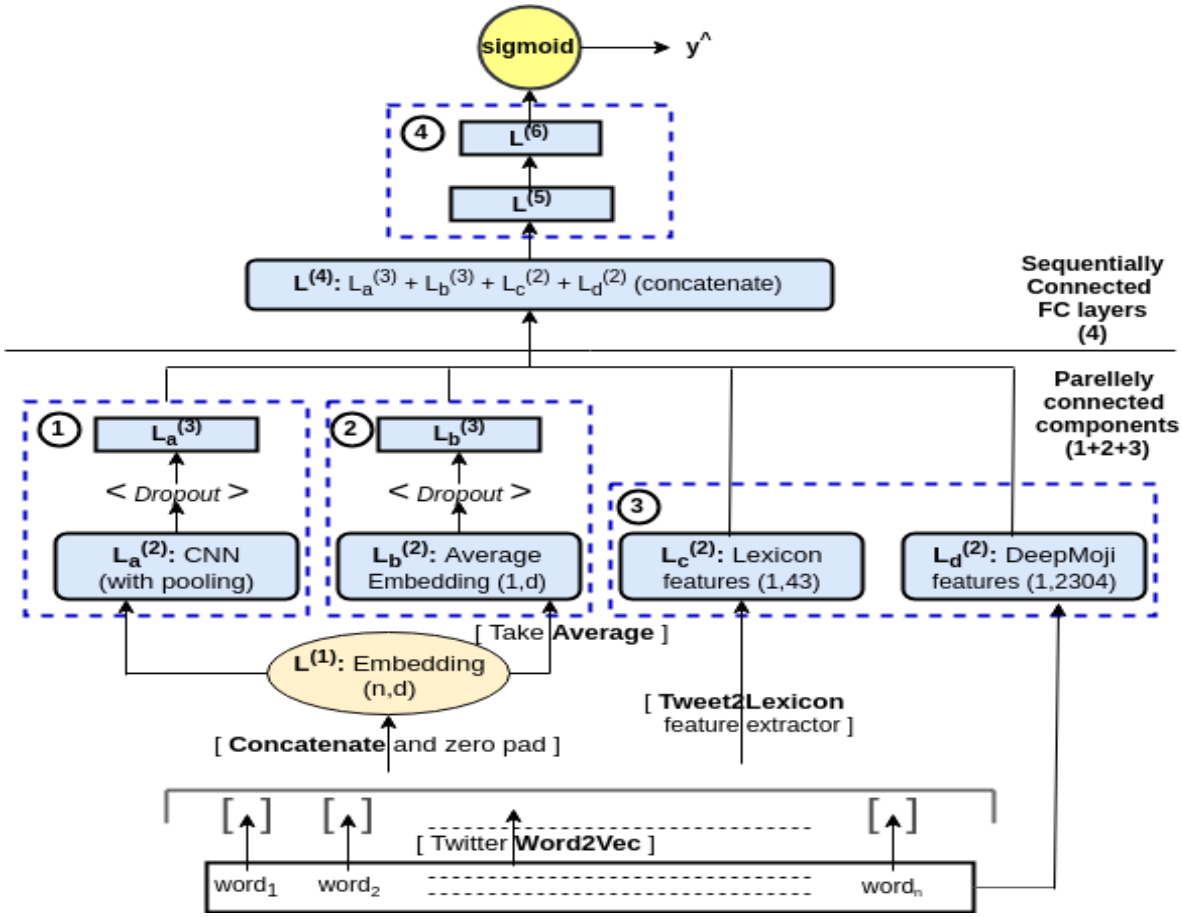

Figure 1: Network architecture for the **LE-PC-DNN** model: Various components - ***L***exicon-based features, an ***E***moji detecting CNN's pre-trained activations, fully connected layers, and a CNN/LSTM undergo a ***P***arallel ***C***ombination (parallelly-connected) to form a ***D***eep ***N***eural ***N***etwork (Section 2).

can combine the different emotion models of LE-PC-DNN architecture into a unified network by using the idea of Multi-Task learning proposed in (Goel et al., 2017). In order to that, we adopt the initial architecture of LE-PC-DNN and then the final fully-connected layers are different for each emotion.

Our basic model (Figure 2a) consists of two different types of layers: *shared representation layers* and *task-specific representation layers*. The network receives a tweet-emotion pair (T, e) and produces an intensity score between 0 and 1.

3.1.1 Shared Representation Layers

These layers receive tweets from all emotions which helps in achieving better generalization as the layers are forced to learn features which work for multiple subtasks. Similar to LE-PC-DNN (Figure 2a), there are four such levels of layers - $l^{(1)}$ (Embedding layer), $l^{(2)}$ (CNN layer, Avg. Embedding layer, Linguistic layer, Pretrained CNN features), $l^{(3)}$ (Fully-connected layers), and $l^{(4)}$ (concatenation layer).

3.1.2 Task-specific Representation Layers

The last two layers are allowed to be different across the different sub-tasks to learn task-specific features.

1. **Fully Connected Layers ($l^{(5)}, l^{(6)}$):** For every emotion, a ReLu transformation will map shared layer $l^{(4)}$ to task-specific layers $l^{(5)}$ ($l_a^{(5)}, l_f^{(5)}, l_j^{(5)}, l_s^{(5)}$ - separate for each emotion), with the separate outputs going to another hidden layers - $l_a^{(6)}, l_f^{(6)}, l_j^{(6)}, l_s^{(6)}$.

2. **Output Layer ($\hat{y}$) :** $l^{(6)}$ is connected to a single sigmoid output neuron – $\hat{y}$, which gives the predicted intensity score between 0 and 1.

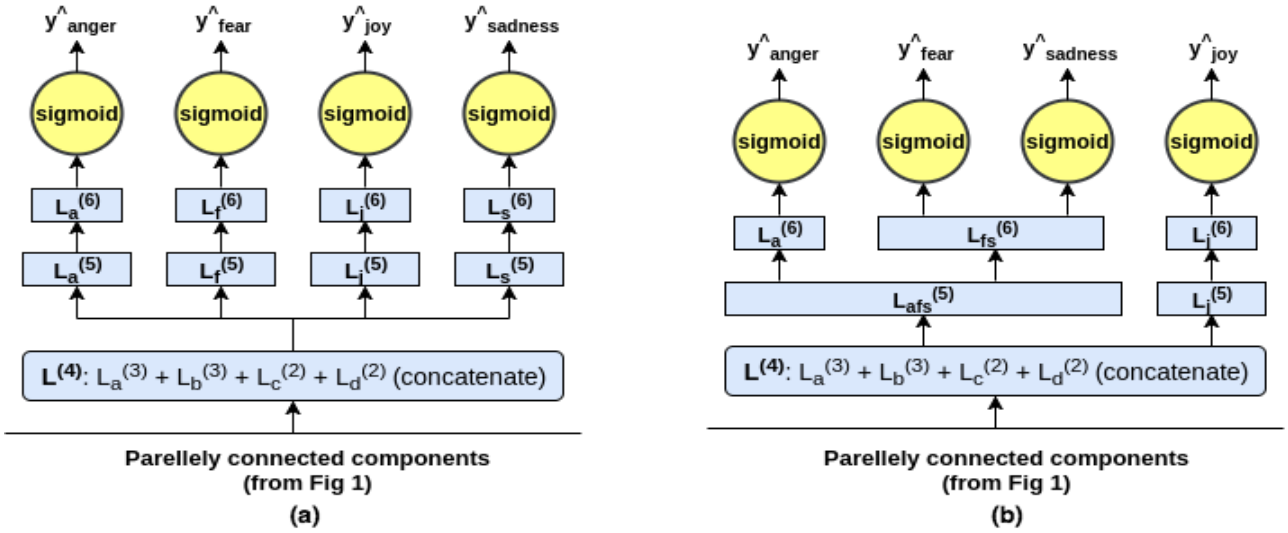

Figure 2: **(a) LE-PC-DMTL**: A deep multi-task learning neural network that uses parallelly connected components - a CNN/LSTM, fully connected layers, a feature vector derived from linguistic lexicons and pre-trained activations of a network trained for Emoji detection (DeepMoji). So, a ***L***exicon and ***E***moji detection based, ***P***arallelly ***C***onnected ***D***eep ***M***ulti-***T***ask ***L***earning neural network and **(b) LE-PC-DMTL-EI**: This network branches differently to exploit the different pairwise correlations between the different emotions (some emotion pairs sharing more layers than others), to optimize performance. So, a ***L***exicon and ***E***moji detection based, ***P***arallelly ***C***onnected ***D***eep ***M***ulti-***T***ask ***L***earning neural network, optimized specifically for the task of ***E***motion ***I***ntensity detection. Both these models handle all the four emotions together in a single architecture (Section 3).

Figure 2a clearly demonstrates that replacement of individual bottom layers with shared layers reduces the network's parameters significantly, less hyper-parameters required to be fine-tuned and speedup during training the network compared to the scenario of having separate networks for each emotion.

3.2 LE-PC-DMTL-EI: A Task-Optimized DMTL Model

The architecture of our proposed LE-PC-DMTL model is that the shared layers will be common across all emotions, *irrespective* of the degree of correlation between any particular pair. The correlations between emotions are investigated via experiments described in section 6. We would like the model to incorporate or *learn* relationships between different emotions and not treat all emotions or subtask in a similar manner since we cannot expect all emotions to be related to each other in the same way.

Inspired by Lu et al. (2016) and some results discussed in section 6, we propose to learn a network architecture which *allows grouping of similar emotions and separate branching of unrelated tasks*. Here we remove the constraint of feature sharing up to a certain level and allow sharing of more parameters between correlated emotions.

Learning the Network Architecture: We initialize the network with our basic LE-PC-DMTL model (Figure 2a). Our objective is to learn an architecture where similar emotions are grouped together and uncorrelated emotions are branched out. After initialization, we refine the architecture step-by-step by experimenting with various combinations. Since manual exploration of such a combinatorially large space is not possible, we follow two heuristics:

1. A model is favored over other if it gives a higher Pearson correlation on the cross-validation set.

2. Models where emotion pairs having high positive correlation (Section 6) share more parameters.

The refinement process is repeated manually for fixed iterations or until no further gain in Pearson correlation is observed (on development set). Since we start from our basic multi-task model, the final model would definitely be an improved version. We apply this heuristic-based algorithm to the EmoInt shared

Emotion	Train	Dev	Test	Total
Anger	857	84	760	1701
Fear	1147	110	995	2252
Joy	823	74	714	1611
Sadness	786	74	673	1533
Total	3613	342	3142	7097

Table 1: The number of instances (tweets) in the EmoInt shared task dataset

Model /	**LE-PC-DNN**					**LE-PC-DMTL**		**LE-PC-DMTL-EI**	
Emotion	$L_a^{(2)}$	$L_a^{(3)}$	$L_b^{(3)}$	$L^{(5)}$	$L^{(6)}$	$L_x^{(5)}$	$L_x^{(6)}$	$L_x^{(5)}$	$L_x^{(6)}$
Anger	CNN (250,Max)	128	256	128	32	64	32	256	64
Fear						75	40		75
Sadness						64	32		
Joy						40	20	125	50

Table 2: Summary of network hyperparameters for our proposed models (Figures 1 and 2).

task dataset (Mohammad and Bravo-Marquez, 2017b). The resulting architecture is shown in Figure 2b. Though the algorithm is general, the resulting architecture is meant to be optimal for the task to which it is applied. We refer to this resulting architecture as **LE-PC-DMTL-EI** (**LE-PC-DMTL** for **E**motion **I**ntensity prediction). Note that the pairwise correlations (heuristic 2) is only a guiding principle - the multi-task model discovers the optimal branching or sharing of layers based on the performance across a lot of variations. The captions of Figures 1 and 2 also serve to summarize the three models we propose.

4 Experimental Setting

4.1 Data

We use the *training*, *development*, and *testing* datasets provided within the WASSA EmoInt shared task (Mohammad and Bravo-Marquez, 2017b) to train and evaluate the various approaches (Table 4). The data files include the tweet ID, the tweet, the emotion of the tweet and the emotion intensity. Details regarding creation and annotation can be found in Mohammad and Bravo-Marquez (2017a).

4.2 Implementation Details

Word Embeddings: We use publicly available pre-trained word embeddings called the Twitter word2vec model (Godin et al., 2015). These were trained on 400 million tweets for the ACL-WNUT 2015 shared task (Baldwin et al., 2015) using the word2vec approach (Mikolov et al., 2013). The large number of tweets in training data makes it a better choice than others available. We choose it over other pre-trained models like Google word2vec (Mikolov et al., 2013) and the GloVe (Pennington et al., 2014) Twitter model. This was backed by cross validation results (not shown for brevity).

Preprocessing: Before forming word vector based embeddings of the Twitter tweets, we employed some preprocessing steps including removal of URLs and user mentions, stripping punctuations from word boundaries, hashtag segmentation ('#wearethebest' to 'we are the best' using the Word Segment [4] module in Python) and elongation removal ('goooooood' to 'good') (inspired by the work in Akhtar et al. (2017)). Such preprocessing helped in improving cross-validation performance.

Network Hyper-Parameters and Architecture Settings: We show the final hyper-parameter values for the LE-PC-DNN (section 2), and the multi-task models LE-PC-DMTL and LE-PC-DMTL-EI (section 3) in Table 2. These values were chosen on the basis of 7-fold cross validation results on the combined training and validation sets. We changed various network hyper-parameters like number of layers, output dimensionality, the type of pooling for CNNs (max versus average) and dropout value.

[4] https://github.com/grantjenks/wordsegment

Training: The network parameters are learned by directly minimizing the Mean Absolute Error between the actual and predicted intensity values. We optimize the above function by back-propagating through layers via Mini-batch Gradient Descent. We use a batch size of 8, 25-30 training epochs and Adam optimization algorithm (Kingma and Ba, 2014) with the parameters set as $\alpha = 0.001, \beta_1 = 0.9, \beta_2 = 0.999\ and\ \epsilon = 10^{-9}$. These settings are common across all our models.

4.3 Evaluation

We evaluate the performance of all systems using the Pearson correlation coefficient (r) between gold ratings and predicted output intensities. This was the metric used in the EmoInt shared task. The Pearson coefficient measures linear correlation between two variables and is always between -1 and 1. A high (positive) value indicates strong (positive) correlation and a value of 0 indicates no correlation. We use following baselines to benchmark our results:

1. *Weka*: The Weka system (Mohammad and Bravo-Marquez, 2017a) served as the baseline for EmoInt shared task (Mohammad and Bravo-Marquez, 2017b) . It uses an SVM regressor on pre-trained word embeddings and lexicon based features.

   The other two baselines are the two top performing systems in the shared task:

2. *Prayas*: (Goel et al., 2017) used weighted ensembling technique to combine 3 different models - feedforward neural network on average word embeddings and sentiment features, CNN/LSTM+max-pooling on concatenated word embeddings, and deep multi-task learning model (described in Section 3). Note that they combine only the outputs (predicted intensities) of their different models, but the fact that combining outputs of different models helped with performance indicates that the architectures are able to complement each other. Our model (Figure 1) exploits this observation by letting the network learn how to best combine different neural models.

3. *IMS*: (Köper et al., 2017) use a random forest regressor on features based on manually created resources, automatically extended lexicons and the output of CNNs/LSTMs.

5 Results and Discussion

We show the Pearson correlation scores for all our proposed neural models and baselines (section 4.3) on the test set in Table 3. The major takeaways from these results and the ablation tests (Figure 3) are:

- **State-of-the-Art Performance** The proposed LE-PC-DNN model (section 2) outperforms all the baselines for all emotions (except for sadness in which our proposed multi-task architecture LE-PC-DMTL-EI fares better), setting a new state of the art score of **0.791** on average. It significantly outperforms the previous best model (Prayas) by 4.4% Pearson score on average.

- **A Solid Case for Multi-Task Learning for Emotion Intensity Prediction**: While the multi-task architecture used in the system Prayas (Goel et al., 2017) used just fully-connected layers, our proposed multi-task models uses CNNs, lexicon-based features and activations of a pre-trained CNN (section 3, Figure 1) to improve performance by a comprehensive 9.6-11.0% Pearson score (the last 3 columns of Table 3) and also gives competitive scores when compared to our state-of-the-art

Emotion	LE-PC-DNN	Prayas	IMS	Weka	LE-PC-DMTL-EI	LE-PC-DMTL	MTL (Prayas)
Anger	**0.767**	0.765	0.767	0.639	0.735	0.731	0.645
Fear	**0.791**	0.732	0.705	0.652	0.760	0.755	0.677
Joy	**0.803**	0.762	0.726	0.654	0.785	0.758	0.654
Sadness	0.803	0.732	0.690	0.648	**0.808**	0.786	0.672
Average	**0.791**	0.747	0.722	0.648	0.772	0.758	0.662

Table 3: Pearson correlations (r) obtained by the systems on the full test sets.

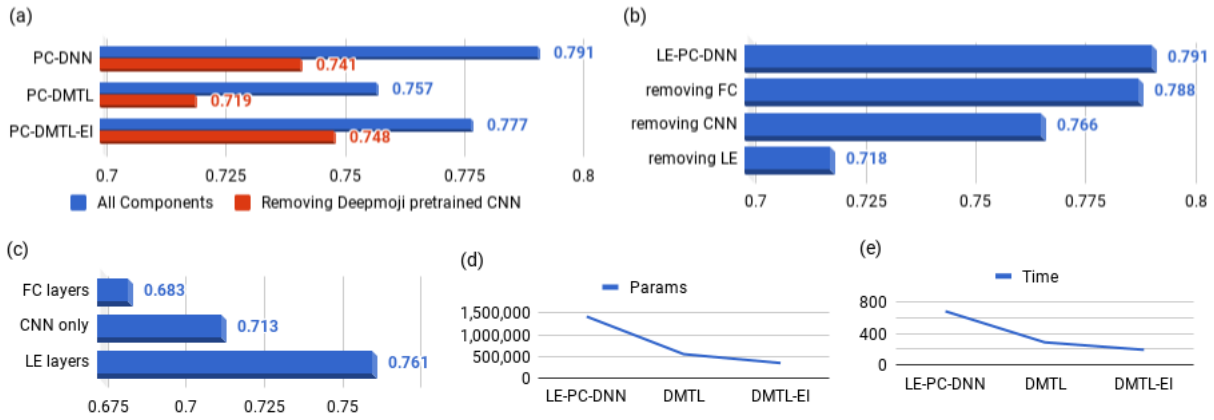

Figure 3: **Ablation test visualizations (scores are average Pearson correlation**: a) Effect of Transfer Learning, b) Effect of removing one of the parallel connected components from LE-PC-DNN architecture (Figure 1), c) Comparing individual parallel components of LE-PC-DNN (section 2.2), d) Comparing number of trainable parameters and e) training time with proposed multi-task learning models.

LE-PC-DNN model trained on and used for each emotion individually. Out of our two multi-task models, LE-PC-DMTL-EI (section 3.2) gives better performance by 1.4% Pearson score. It benefits from being optimized for our task by exploiting the correlation among certain pairs of emotions. The major advantage of using the multi-task models offer is the use of a unified architecture instead of separate models for each emotion, which means *less computational complexity*. This is established in Figures 3d and 3e, which show that our LE-PC-DMTL and LE-PC-DMTL-EI architectures (section 3) have less than one-third number of trainable parameters and take less than one-third the training time compared to our LE-PC-DNN model (section 2). This established the viability of our multi-task approach, which will only increase with the number of different emotions!

- **Effect of Transfer Learning**: Removing the deepmoji *pre-trained CNN activations* (section 2.2) has a significant effect of performance of all our proposed models including the multi-task ones (Figure 3a), with the drop of 5% Pearson score in case of the PC-DNN model (section 2) being the most notable. Transferring features from a related task (like emoji detection) trained on a much larger dataset (1.3 billion tweets compared to about just 1,000 in our case) proves to be very useful in terms of prediction performance. This also means that the representations learned by the Deepmoji model (Felbo et al., 2017) work well for the emotion intensity detection task.

- **Impact of the Different Non-Sequential Components in our Neural Architecture**: From Figures 3b and 3c, it is clear that all of our parallelly connected components (components 1, 2 and 3 in Figure 1) have a positive role in the overall performance. Lexicon-based features and pre-trained activations of a CNN trained for Emoji detection task (section 2; component 3 in Figure 1) contribute the most followed by CNN and then the fully-connected layers.

Note: For the training time results shown in Figure 3e, the experiments were run on a CPU with 4 GB RAM and 1.7 GHz Intel core i5 processor. Also, the time for LE-PC-DNN is the sum of the times taken for training of the individual models (since the architecture is run separately for each emotion unlike multi-task models which handle all emotions in one architecture).

6 Cognitive Implications of Emotions' Pairwise Similarity

To quantify various correlations that different pairs of emotions exhibit in social media microblogs, we perform two experiments. First, we train the best-performing LE-PC-DNN model on one emotion and test on another emotion (Table 4) (also explored in Mohammad and Bravo-Marquez (2017a)). Then, we train the model on the combined datasets of two emotions and see the performance on the test sets of individual emotions (Table 5) to further test how well different pairs of emotions complement each other.

Emotion i/j	anger	fear	joy	sadness
anger	0.766	0.447	-0.526	0.443
fear	0.533	0.791	-0.57	0.712
joy	-0.592	-0.387	0.803	-0.537
sadness	0.586	0.628	-0.567	0.803

Table 4: Pearson correlation scores (trained on emotion *j* (row); tested on emotion *i* (column)).

Emotion i/j	anger	fear	joy	sadness
anger	-	0.779	0.66	0.79
fear	0.73	-	0.687	0.802
joy	0.637	0.675	-	0.728
sadness	0.745	0.787	0.677	-

Table 5: Pearson correlation scores (trained on combined data of emotion *i*, *j*; tested on *i*).

6.1 Training on One Emotion and Testing on Another

Table 4 shows that there exists significant correlations between all the emotions, ranging from absolute Pearson scores of 0.387 (between fear and joy) to 0.803. This indicates that *all emotions are at least somewhat correlated*. This is backed in part by observations made in Wilson-Mendenhall et al. (2013), where the authors claim that 'all human emotions share core affective properties' (note that they relied on arousal and valence of emotions).

The negative emotions ('anger', 'fear' and 'sadness') are *positively correlated with each other* and *negatively correlated with 'joy'*. The *correlations are asymmetric*, *i.e.*, a pair of emotions does not show similar predictive power in either direction. For example, training on anger predicts intensity of sadness with 0.443 correlation with actual sadness intensities (a drop of about 0.36 Pearson score from when training happens on the sadness training set), whereas training on sadness predicts intensity of anger with 0.586 correlation (a drop of about 0.22 Pearson score). These last two observations match well with the results of the experiments carried out in Rutherford et al. (2008). In that work, visual aftereffects of certain emotional scenarios on the participants' faces were observed in various settings. They found that the results of their functional approach suggests (in their own language): "Negative emotions are many and specific. In contrast, positive emotions are few and less specific." The results further backed their hypothesis that "emotions share an asymmetric relationship as a group, in which numerous negative emotions together oppose the relatively small set of positive emotions". Schwartz and Weinberger (1980) also hint at the asymmetric nature of emotions (for fear and anger in particular).

6.2 Training on a Combined Dataset of Two Emotions and Testing on Both of them

Table 5 investigates the impact of combining the datasets of two emotions for training. All negative emotions (anger, fear and sadness) exhibit good performance in this scenario. The Pearson correlation suffers a drop of 0.02-0.03 in case of anger, and training on combined datasets of fear and sadness results in very similar performance for the individual emotions as compared to using just the individual emotion's dataset for training (the results in the diagonal of Table 4). The idea for using combined emotion datasets was motivated in Mohammad and Bravo-Marquez (2017a), who hinted at an increase in performance when combining fear and sadness training sets (but we do not see an increase, although the performance remains basically unaffected). High correlation among the negative emotions was also established in Barrett (2006) and Feldman (1993). However, the specific relationship between fear and sadness seems to be unexplored. It is possible that this relationship is a characteristic of the domain of Twitter tweets or our dataset. These observations comply with our LE-PC-DMTL-EI architecture (Figure 2b), where the emotion 'joy' is the first to get separated while the emotions 'fear' and 'sadness' are learned jointly for many layers in the architecture which gave optimal performance.

7 Error Analysis

We present some examples from the test dataset (Table 6) where the predictions were off by about 0.3 in intensity in either direction. Note that intensities are real-values scores between 0 and 1. To help future systems better predict emotion intensity in tweets, we present plausible explanations for the errors:

- **Incorrect Modeling of the Full Tweet Context**: It can become necessary to correctly model the overall context of the tweet. In Tweet #2, words like 'angry','anger' and 'hurt' indicate high intensity of anger. But the tweet is more of a moral preaching than an angry outburst, which explains an

#	Tweet	Emotion	Actual Intensity	Predicted Intensity
1	Oi @THEWIGGYMESS you've absolutely fucking killed me.. 30 mins later im still crying with laughter.. Grindah.. Grindah...hahahahahahaha	Joy	0.846	0.417
2	People are #hurt and #angry and it's hard to know what to do with that #anger Remember, at the end of the day, we're all #humans #bekind	Anger	0.25	0.580
3	T minus 10 hours till I meet with a designer who wants me to model his new fashion line !!!	Fear	0.667	0.286
4	Ibiza blues hitting me hard already wow	Sadness	0.833	0.533

Table 6: Examples of tweets with absolute difference in predicted and actual intensity greater than 0.3

actual anger intensity of 0.25. In Tweet #1, the latter half of the tweet makes it clear that 'absolutely fucking killed me' is a strong expression of joy and not some negative emotion.

- **Context Outside the tweet**: Tweet #3 requires common sense or world knowledge to know that an important meeting drawing near is generating anxiety with high intensity. This fear or anxiety is not obvious from the text itself which might explain the predicted intensity of 0.291 when the actual intensity is 0.667. Tweet #4 suffers from a similar problem. World knowledge is required to know the relationship between 'Ibiza blues' and sadness.

- **Metaphors**: Metaphorical expressions, like 'crying with laughter' in Tweet #1 or 'Ibiza blues' in Tweet #4, pose a significant challenge to computational models (Ghosh et al., 2015).

We carried out the above analysis after concluding all the experiments. The number of tweets where the predicted intensity was higher than actual and vice-versa were almost equal for any emotion. Hence, our system is not biased towards predicting higher or lower intensities than the annotated ones.

8 Conclusion & Future Work

We proposed various deep neural architectures for the task of emotion intensity prediction on micro-blogging data, specifically, Twitter data. This problem was recently brought to light by the EmoInt shared task (Mohammad and Bravo-Marquez, 2017b). Combining fully-connected layers with CNN in a parallel or non-sequential manner helped performance, and while we see such combinations in works tackling Vision tasks, the NLP community should also try this in their experiments. Transfer learning proved very effective in terms of performance since it helped us utilize the pre-trained activations of a CNN trained on more than a billion tweets for the related task of emoji detection in the same domain of Twitter tweets. These techniques when combined allow us to set the new state-of-the-art performance in emotion intensity detection, considerably outperforming all previous systems. We also proposed two deep neural network based multi-task learning methods with one of them learning to group similar emotions together using a heuristic based algorithm. The models compare well with the best performing system, and give significant gains in terms of computational complexity when compared to having a separate architecture for each emotion. Our multi-task model will be even more useful when the number of emotions are large. The optimized multi-task model and focused correlation tests brought out an especially strong correlation between 'fear' and 'sadness' for our dataset. Our error analysis on the test set using predictions from the best performing system will help future systems aiming to predict emotion intensity in tweets.

For future work, we would like to exploit topic modeling to find out correlations between certain topics and high intensity emotional outbursts, and to see if knowing the topic of a tweet can help with intensity prediction. We also plan to exhibit our models' effectiveness in real-world applications by using them, for example, to rank product reviews in terms of priority on basis of the emotion intensity. Another planned direction is to extend the four emotions used in this task to Ekman's six basic emotions (anger, happiness, surprise, disgust, sadness, and fear) (Ekman and Friesen, 1971).

Abstract

Vulgarity is a common linguistic expression and is used to perform several linguistic functions. Understanding their usage can aid both linguistic and psychological phenomena as well as benefit downstream natural language processing applications such as sentiment analysis. This study performs a large-scale, data-driven empirical analysis of vulgar words using social media data. We analyze the socio-cultural and pragmatic aspects of vulgarity using tweets from users with known demographics. Further, we collect sentiment ratings for vulgar tweets to study the relationship between the use of vulgar words and perceived sentiment and show that explicitly modeling vulgar words can boost sentiment analysis performance.

1 Introduction

Vulgarity is common in language use, with vulgar words appearing with a frequency estimated between 0.5% and 0.7% in day-to-day conversational speech (Jay, 2009; Mehl et al., 2007) and 1.15% in Twitter (Wang et al., 2014). Vulgarity can employed for multiple goals: as an intensifier for subjective opinions, as a way to offend or express hate speech towards others, to describe vulgar activities or as a way to signal an informal conversation. Understanding the expression of vulgarity in naturally occurring text is thus important for several disciplines such as linguistics, which aims to better understand the pragmatics of vulgarity, for computer scientists which can explicitly model vulgarity in downstream NLP applications and for psychologists who study the socio-cultural factors of profanity.

Social media offers researchers access to vast volumes of naturally occurring user-generated content, with language use on social media containing a high level of expression of thoughts, opinions and emotions (Java et al., 2007; Kouloumpis et al., 2011). Furthermore, it is a platform for observing written interactions and conversations between users (Ritter et al., 2010). Thus, social media is a ideal medium to observe and study the expression of vulgar words and, in addition, allows us to study the socio-cultural context of this phenomenon.

Given the fact that most thoughts can be rephrased to not include vulgarity, the use of vulgar words indicates a purposeful attempt of performing a specific function. Table 1 includes examples of tweets containing vulgar words that perform different functions.

Vulgarity is often employed used to express emotion in language and can be used either to express negative sentiment or emotions or to intensify the sentiment present in the tweet (Wang, 2013). In one of the examples, 'I am stupid as f*ck' conveys more intense anger, while 'I am stupid' conveys a less emotional expression of irritation. Hence, understanding vulgar words is expected to have practical implications in sentiment analysis on social media. Furthermore, vulgar word usage is dependent on the user socio-cultural context with demographic and social information shown to improve sentiment analysis performance (Volkova et al., 2013; Yang and Eisenstein, 2017).

Hence, this study aims to address the following research questions:

- Is the expression of vulgarity and its function different across author demographic traits?

[*] Equal contribution.

Proceedings of the 27th International Conference on Computational Linguistics, pages 2927–2938
Santa Fe, New Mexico, USA, August 20-26, 2018.

Tweet	Function
I have made the awful decision to stay up all night. Why? Because I'm stupid as fuck.	emphasize
It's annoying when a program does the "you sure you want to quit?" thing but I'd be lying if I said it hasn't saved my ass a number of times	neutral/idiomatic
U got some shitty weather Illinois.... I miss texas heat	express negative sentiment
<USER> I had that game it was the shit I believe it was something like baseball 2121	express positive sentiment

Table 1: Examples of tweets with vulgar words and their function.

- Does vulgarity impact perception of sentiment?
- Does modeling vulgarity explicitly help sentiment prediction?

To this end, we collect a new data set of 6.8K tweets labeled for sentiment on a five-point scale by nine annotators. We found that the expression of vulgarity interacts with many key demographic variables, including gender, age, education, income, religiosity and political ideology. Vulgarity is also used to convey different sentiment polarities by users that differ in age and religiosity. When studying the impact of vulgarity on sentiment perception, we show that vulgarity is most often used as an intensifier for the original sentiment. Finally, we show that explicitly informing sentiment analysis systems about vulgarity usage helps boost predictive performance.

This study aims to develop a quantitative understanding of the way in which social demographics interact with how vulgarity is actively and intentionally employed and show that this can be used to improve end-user applications such as sentiment analysis. We release our novel annotated corpus as well as the accompanying code to the community at `https://github.com/ericholgate/vulgartwitter`.

2 Related Work

Vulgarity The study of vulgar language – also referred to as profanity or use of swear/curse words despite the fact that they can be used for different goals – is of interest to linguists, psychologists and computer scientists. Vulgar words are very versatile, with a vulgar word being able to perform different interpersonal functions according to different contexts (Andersson and Trudgill, 1990). Several studies have examined these different uses and pragmatic functions. Pinker (2007) groups use of swear words into five roles: abusive (intention to offend or cause psychological harm), cathartic (used in response to pain), dysphemistic (intention to convey negative sentiment), emphatic (intention to draw attention) and idiomatic (used for no purpose or to signal informality). Wang (2013) identifies four pragmatic roles of swear words: express emotion, express emphasis (either in presence of additional sentiment or not), to signal group identity and for aggression – in this latter case, swearing is a face-threatening act (Brown and Levinson, 1987). Overall, the function and effects of vulgar word usage are highly dependent on the context and the social factors (e.g., inter-personal relationships, setting), which we aim to further study and capitalize on in this study.

Recently, there has been a surge in interest in studying hate speech online (Warner and Hirschberg, 2012). A better understanding of vulgar words and the context they are used in can aid models that aim to automatically detect and categorize hate speech, which is harder to distinguish when profanity is employed (Malmasi and Zampieri, 2018).

Vulgar words have been quantitatively studied in social media and online communities. Liu et al. (2010) identified and filtered vulgar content distributed via peer-to-peer applications. Wang et al. (2014) presents a quantitative analysis of the frequency of curse word usage on Twitter, their variation with time and location, their gender usage and use in conversations across genders. An analysis of swear word usage across gender and age on Twitter was performed in Gauthier et al. (2015). Vulgar words are obfuscated in mediums where messages are censored or for other goals, and an analysis of these techniques is presented in Laboreiro and Oliveira (2014). Our paper expands the scope of this research by studying several other demographic traits beyond gender, aiming to identify different uses of swear

words through eliciting sentiment annotations and uses these to improve sentiment prediction methods.

Sentiment analysis Sentiment analysis on Twitter is a very popular research topic, anchored in a wide range of industry applications and with several shared tasks over the past years (Rosenthal et al., 2017). Several studies have looked at the effects of intensifiers and words that switch their polarity in sentiment dictionaries (Flekova et al., 2015). Vulgar words are commonly part of popular sentiment and emotion analysis lexicons (Mohammad and Turney, 2013).

Demographics & Vulgarity Use of vulgar or swear words is influenced by pragmatic or contextual factors such as the inter-personal relationship between the speakers or their social factors such as gender, occupation or social status (Jay and Janschewitz, 2008). The most studied social factor was gender, with several studies finding that males employ profanity much more often than females (Selnow, 1985; Wang et al., 2014). Other social factors such as age, religiosity or social status were found to be related with the rate of using vulgar words (McEnery, 2004). In studying the task of user trait prediction from social media texts, several vulgar words were shown to be characteristic of demographic traits such as political ideology (Preoţiuc-Pietro et al., 2017).

Explicitly modeling demographic (Lynn et al., 2017) and other social factors such as community membership (Yang and Eisenstein, 2017) have to date been successfully used for improving accuracy of several tasks including sentiment analysis (Volkova et al., 2013) or document classification (Hovy, 2015).

3 Data

In exploring the role of vulgarity in written interactions, social media and Twitter in particular stands out as an ideal medium for collecting data. Twitter provides vast volumes of naturally occurring text, which are less affected by formal and curated text such as newswire, and can be studied together with socio-demographic attributes of their authors.

Data Collection We collect a novel corpus of tweets, all of which contain vulgar words, and annotate this for sentiment, as to the best of our knowledge, no such corpus focusing on vulgar expressions exists in past research. This data is used in the sentiment analysis section of this study.

In order to enable the analysis of demographics and vulgarity in the analysis section of this study, the above tweets were deliberately sampled from those posted by a set of 4,132 users with known socio-demographic traits obtained through asking the users to self-report them in an online survey. For the demographic analysis, we have downloaded and used all most recent 3,200 tweets (per Twitter API limitations) from these users. This data set was used in prior research and for a full description of the data collection process and quality control processes, we refer the interested reader to Preoţiuc-Pietro et al. (2017).

Demographic Variables and Coding The Twitter users self-reported through a survey the following demographic variables: gender, age, education level, annual income level, faith and political ideology. All users solicited for data collection were from the United States in order to limit cultural variation.

- Gender was considered as binary[2] and coded with Female – 1 and Male – 0. All other variables are treated as ordinal variables.
- Age is represented as a integer value in the 13–90 year old interval.
- Education level is coded as an ordinal variable with 6 values representing the highest degree obtained, with the lowest being 'No high school degree' (coded as 1) and the highest being 'Advanced Degree (e.g. PhD)' (coded as 6).
- Income level is coded as on ordinal variable with 8 values representing the annual income of the person, randing from '<20,000$' to '>200,000$').
- Faith is coded as a ordinal variable with 6 levels, representing the average number a time a user attends religious service. The answers range from 'Never' (coded as 1) through to 'Multiple times a week' (coded as 6).

[2]We asked users to report gender as either 'Female', 'Male' or an open-ended field, and removed the few users which did not select 'Male' or 'Female'

- Political ideology is measured on the conservative–liberal spectrum, the common way of representing ideology in the US (Ellis and Stimson, 2012). Ideology option are: Very conservative (1), Conservative (2), Moderately conservative (3), Moderate (4), Moderately liberal (5), Liberal (6), Very liberal (7); Other (8) and Apathetic (9). In order to convert this to a ordinal scale, we only perform political ideology analysis with users with a ideology in the set 1, 2, 3, 5, 6, 7 (1290 users removed in total, similar to (Preoţiuc-Pietro et al., 2017)).

Identifying vulgar tweets In order to identify tweets containing vulgarity, we start with the vulgarity lexicon available at `www.noswearing.com`. This lexicon comprises 349 items including general vulgarities, slurs, and sex-related terms.[3] We manually removed a total of 82 items from this list that were deemed not to be unambiguously vulgar.[4] Additionally, we employed a manually crafted list of regular expressions to identify common intentional spelling variations in vulgar terms (e.g., vowel reduplication such as *fuuuuu*k* or sibilant reduplication such as *asssss*).

We identified 261,592 tweets containing at least one vulgar word, from 3,626 users featuring 222 unique vulgar tokens, many of which are either compounds of vulgar tokens with non-vulgar words or are morphological derivations (e.g., *assbag* or *f*ck* vs. *f*cking*). Of these, 149 words occur in the data less than 100 times, while the top 20 most frequent words account for 90% of total vulgar word occurrences. The median frequency of the vulgarity lexicon is 27 in our larger data set. These results are in line with previous analyses of vulgar word frequencies and their distribution (Wang et al., 2014).

Data Processing To preserve anonymity, we replace URL's by a <URL> token and usernames are masked by a <USER> token. Further, punctuation is removed and all words are lowercased.

Sentiment Annotation Human annotations of sentiment were solicited for 7,800 vulgar tweets (excluding retweets) via Amazon Mechanical Turk (MTurk) platform. These tweets were sampled uniformly from a randomly sampled set of 2,000 users in our corpus that posted at least one vulgar tweet. We perform this sampling of users in order to have a broad range of users, but have more than one sample tweet for each user.

The task setup and guidelines follow the settings of SemEval 2016 Task 4 subtask C (Nakov et al., 2016). Annotators evaluated tweet sentiment on a five-point scale: (1) *very negative*, (2) *somewhat negative*, (3) *neutral*, (4) *somewhat positive*, and (5) *very positive*. The numeric coding for this scale follows a gradual movement from more negative to more positive, allowing sentiment to be treated as a continuous variable. A sixth option, *not applicable*, was available to workers to cover instances in which there was missing contextual information or a tweet was illegible. Each tweet was annotated by nine different and independent annotators to allow for sufficient data to generalize across individual sentiment perception boundaries.[5]

Annotation results were checked for inter-annotator agreement by comparing individual user responses to the average annotation of their peers across all tweets that they annotated (Li et al., 2016). Annotations from users with a Spearman correlation coefficient less than 0.3 were removed from computing consensus labels. Tweets with less than five remaining annotations were excluded. We also excluded tweets whose majority ratings are *not applicable*. This resulted in a final data set consisting of 6,791 annotated vulgar tweets. Following the procedure for SemEval, Sentiment annotations for these tweets were consolidated by majority vote. If a majority rating was not present, the consolidated score was set to the mean of all ratings (ratings of *not applicable* were excluded).

The consolidated sentiment ratings were distributed as follows: 1.94% *very positive*, 14.57% *somewhat positive*, 26.51% *neutral*, 46.62% *somewhat negative*, 10.14% *very negative*.

[3]While this initial method we use is not fully accurate (Sood et al., 2012a), it reaches high accuracy levels of more than 90% (Sood et al., 2012b)

[4]These terms were largely anatomical words or general verbs like *penis*, *vagina*, and *blow*, but some identity descriptors like *gay*, *queer*, and *lesbian* were also excluded after manual review of a large sampling of uses revealed they were not overwhelmingly employed as slurs.

[5]We asserted the following qualifications on MTurk: locale=US, approval rate >90%, number of HITs approved >100.

Demographic Trait	Pearson r	p-value
Gender	-0.077	1.61^{-4}
Age	-0.233	6.64^{-31}
Education	-0.100	7.62^{-07}
Income	-0.087	1.73^{-05}
Faith	-0.187	2.74^{-20}
Political Ideology	0.124	8.69^{-10}

Table 2: Relationship between user demographic traits and percentage of vulgar tweets of total tweets sent by the user. Results are computed using Pearson correlation (point-biserial correlation for gender), with gender and age as controls in partial correlation.

4 Analysis

4.1 Demographics & Frequency of Vulgarity

We first analyze the differences in frequency of employing vulgarity and how this relates to demographic traits. We use partial Pearson correlation where the dependent variable is the fraction of vulgar tweets from the total number of tweets sent by a user. For all analyses, we consider gender and age basic traits and control for data skew by introducing both variables as controls in partial correlation, as done in prior work (Schwartz et al., 2013; Preoţiuc-Pietro et al., 2016). When studying age and gender, we use only the other trait as the control. We have experimented with percentage of vulgar words as an alternative outcome, but the results were very similar, hence we exclude them for brevity. We also experimented with log-scaling the age variable, but found no major differences.

Gender results show that females are less likely to post vulgar tweets than males. Several previous studies have reported a similar effect, in written text in the BNC (McEnery, 2004), on social networks (Wang et al., 2014), speech (Jay, 1980; Jay, 1992) or as self-reported using questionnaires (Selnow, 1985; Pilotti et al., 2012). In our data, the average vulgar tweet percentages per user are 3.332% for males and 3.060% for females.

Age exhibits the largest effect on posting vulgar tweets, with younger users much more likely than older to post, which aligns to analysis of speech (Jay, 1992) and tweets as previously performed in Gauthier et al. (2015).

Both higher education and income are anti-correlated with usage of vulgarity on social media even when controlling for gender, with education being slightly more strongly associated with lack of vulgarity than income. Previously, McEnery (2004) suggested that social rank, which is related to both education and income, is anti-correlated to use of swear words. In a study on perceptions of user traits from tweets, raters that were exposed to vulgar words were more likely to consider the user as being less educated than in reality (Carpenter et al., 2016).

Faith is anti-correlated with use of vulgar words with the second strongest effect, a correlation also previously identified by Jay (1992).

Finally, liberal users are more likely to use vulgarity on social media, an association on Twitter also uncovered by Sylwester and Purver (2015) and Preoţiuc-Pietro et al. (2017).

4.2 Demographics & Sentiment Perception

Next, we analyze the relation between the demographic traits of the tweet authors to the perceived (annotated) sentiment of the tweet. We perform this analysis in order to uncover potentially different types of uses of vulgar words. If vulgar words are used as an intensifier, they are used with both positive and negative sentiment, while if expressing emotion they are expressed mainly with negative sentiment. If vulgar words are used in neutral tweets, then their role is more likely to be idiomatic.

We test this using partial Pearson correlation with user demographics as the independent variable and with the polarity of the rating (positive, negative or neutral) as a dependent indicator variable. Again, we consider gender and age as basic demographic traits and introduce these variables as controls. Similarly, for age and gender analysis, we the other basic trait as the only control. The results of these analyses are

	Positive vs. All		Negative vs. All		Neutral vs. All	
Demographic Trait	r	p	r	p	r	p
Gender	0.024	0.334	-0.006	0.797	-0.030	0.222
Age	-0.107	$\mathbf{2.11}^{-5}$	0.061	**0.015**	0.093	$\mathbf{2.305}^{-4}$
Education	-0.049	0.052	-0.018	0.470	0.076	**0.002**
Income	-0.024	0.324	0.016	0.524	0.001	0.966
Faith	-0.108	$\mathbf{1.640}^{-5}$	0.008	0.741	0.128	$\mathbf{3.539}^{-7}$
Political Ideology	-0.032	0.276	0.057	0.051	0.008	0.765

Table 3: Relationship between user demographic traits and perceived sentiment rating by MTurk workers. Results are computed once more using Pearson correlation (point-biserial correlation for gender), with gender and age as controls in partial correlation.

presented in Table 3.

Positive Sentiment With positive sentiment as an indicator variable, we see that both age and faith have significant correlations. This indicates that younger and less religious users are more likely to express vulgar words in presence of positive sentiment, which represents use of vulgarity as an intensifier for sentiment.

Negative Sentiment With negative sentiment as an indicator variable, we again see a weaker (yet still significant) correlation with age. This shows that older users are prefer to use vulgar words to deliberately express negative emotions and sentiment, with other functions being less frequent.

Neutral Sentiment Finally, vulgar words are present with neutral sentiment when this is used idiomatically for signaling informality or other functions. Neutral sentiment is most often employed by religious, older and more educated users. The latter correlation is especially relevant, as higher education leads to better social adaptation.

Overall, gender, income and political ideology exhibit no significant correlations with sentiment ratings of vulgar tweets.

4.3 Vulgar vs. Censored Tweet Sentiment Perception

To test whether vulgarity impacts the *perceived* sentiment of tweets, we removed the vulgar terms in the tweets from the vulgar corpus, arriving at an *original-censored* parallel dataset. We then crowdsourced the sentiment judgments of the censored tweets using the same method as before.

Among the censored tweets, annotators indicated that 355 —around 5%—of the tweets were rated by more than 5 (out of 9) workers to be unintelligible after censorship. The distribution of sentiment in this subset was originally 21.40% positive, 21.97% neutral, 56.62% negative. This loss of intelligibility is expected and an additional indication that vulgarity bears semantic content and by censoring these words, the resulting tweet looses coherence.

To determine the extent to which the use of vulgar terms impacts the perception of tweet sentiment, we calculated the direction and magnitude of the change in sentiment between the vulgar and censored pairs. For original tweets that are not neutral, we consider three situations: (a) **intensify**, where the magnitude of the sentiment towards a tweet intensifies after censorship, e.g. with score changes from 2 to 1 (for negative tweets) or from 4 to 5 (for positive tweets); (b) **weaken**, where the magnitude changes in the other direction, e.g., with score changes from 1 to 2 (for negative tweets) and from 5 to 4 (for positive tweets); (c) **flip**, where the censored sentiment is opposite from the original sentiment, i.e., negative becomes positive or positive becomes negative. For neutral tweets, we consider situations where the censored sentiment becomes positive (**to-pos**), or negative (**to-neg**), or stays neutral (**same**).

In Table 4, we present the numbers and magnitudes of changes observed in these 6,436 tweets (this number reflects the size of the censored corpus after excluding the 593 which were rated unintelligible and those which did not have at least five ratings after removing annotators with low inter-annotator agreement scores). Clearly, for original positive or negative tweets, censoring has a significant weakening

	Positive			Negative			Neutral		
	intensify	weaken	flip	intensify	weaken	flip	to-pos	to-neg	same
% changed	15.17	34.09	3.69	5.53	40.34	7.44	24.07	19.34	56.59
mean $\|\Delta\|$	0.591	0.785	1.597	0.521	0.936	1.569	0.817	0.825	—

Table 4: Change in perceived sentiment score with censored vulgarity. Results are grouped by initial perceived sentiment polarity, scored from 1 (*very negative*) to 5 (*very positive*). The *intensify* subcondition indicates that the censored tweet had the same polarity, but with greater magnitude (i.e., original 2, censored 1; or original 4, censored 5). The *weaken* subcondition describes the opposite effect. The *flip* subcondition indicates that the polarity of the perceived sentiment inverted. All of the changes are statistically significant ($p < 0.01$)

effect for sentiment. Censored tweets that are originally negative also have a stronger tendency than originally positive ones to flip sentiment. For neutral tweets, most of the time the sentiment does not change.

Kruskal-Wallis H-tests were conducted to determine if changes in sentiment rating were significant, and all results were shown to be statistically significant ($p < 0.01$). The strongest effect was seen in the *to-pos* and *negative-flip* conditions, indicating that vulgarity is frequently employed by users to emphasize or introduce a negative sentiment.

About half of the tweets in the corpus did not exhibit a change in sentiment. Of those that didn't change, 21.31% were positive, 21.11% were neutral, and 56.14% were negative. Vulgar tweets which were initially positive or negative were slightly more likely to exhibit some change in perceived sentiment rating than not, while vulgar tweets that were initially neutral were 8% more likel y to exhibit no change at all than they are to exhibit change.

5 Modeling Vulgarity

We now consider whether explicitly inserting knowledge about vulgarity into sentiment models will help sentiment prediction. To do this, we build on top of a base model that has been shown to be effective in Twitter sentiment prediction (Rosenthal et al., 2017; Cliche, 2017), and propose three ways of inserting vulgar features into the system.

Base architecture The basis of our system is a bidirectional Long-Short Term Memory Network (LSTM) (Hochreiter and Schmidhuber, 1997), which utilizes memory cells to capture long-term dependencies. This architecture is similar to the LSTM models in BB_twtr (Cliche, 2017), the best system participated in SemEval 2017 task 4 subtask C (Rosenthal et al., 2017).

For a given tweet of n words, we encode each word w_t into an embedding vector x_t; we then pass the embedding matrix to a bidirectional LSTM, arriving at a sentence representation where each hidden state h_t for word w_t encodes the context from both words before w_t (i.e., w_1 to w_t) and after w_t (i.e., w_t to w_n). The hidden state is the concatenation of two directions: $h_t = [\overrightarrow{h_t}, \overleftarrow{h_t}]$.

The bidirectional LSTM sentence representation is then passed into a dense layer with a RELU activation function $RELU(x) = max(0, x)$. The dense layer is then followed by a dropout layer, and a softmax classification layer.

Vulgarity features We propose and compare three different ways to account for vulgarity:

- **Masking**: Mask all vulgar words with a vulgar token, e.g., *This is the <VG>*. This method essentially considers all vulgar words to be the same token and informs the model of such, but removes lexical variances and different expressions of vulgarity.
- **Token insertion**: Insert a vulgar token after each vulgar word, e.g, *This is the shit <VG>*. This method allows the curse word to retain its original meaning, while giving it the same representation as other curse words.

System	Overall	Very positive	Positive	Neutral	Negative	Very negative
Bi-LSTM	0.791	3.000	1.978	1.008	0.049	1.084
+ Masking	0.898	**2.000**	**1.030**	**0.028**	1.000	1.979
+ Token Insertion	0.761	3.000	2.000	0.996	**0.002**	**1.000**
+ Concatenation	**0.759**	3.000	1.993	0.992	**0.002**	**1.000**

Table 5: MAE for each system on Vulgar-Tweet dataset. The best per-class results are significantly better than the baseline Bi-LSTM with the Wilcoxon signed-rank test.

- **Concatenation**: Count the number of vulgar words n_v in a tweet, and use it as a feature in concatenation with the tweet representation from Bi-LSTM h_t, before feeding it to the next layer, whose new input would be $[h_t, n_v]$. Effectively, this informs the classifier of the number of vulgar words, but removes contextual information of where a curse word appears.

6 Experiments

The goal of our evaluation is to assess how explicit knowledge of vulgarity can help in sentiment prediction. Hence we focus on tweets with vulgarity present, and we train and evaluate on our Vulgar-Tweet dataset. We further compare the aforementioned three ways to encode vulgarity features.

6.1 Systems and training

Systems We train and compare the following systems: *Bi-LSTM*, i.e., the base architecture without explicit knowledge about vulgarity; and the base architecture with each of the vulgarity features stated: *Bi-LSTM + Masking*, *Bi-LSTM + Token insertion*, and *Bi-LSTM + Concatenation*.

Data We develop, train and evaluate our system on our Vulgar-Tweet dataset, from which we carved out a development set of 500 tweets, a test set of 1,000 tweets. The remaining 5,291 tweets were used for training.

It is worth noting that the SemEval data is not viable for evaluating the effects of modeling vulgarity. There are only 1,235 (4%) of vulgar tweets in the 2016 data, and 339 (2.75%) in the 2017 testing data. For the sake of comparison, we also train a system with SemEval 2016 training data, and report on the 2017 test set where there is at least one vulgar word in each tweet.

Settings We used 200 dimensional embeddings trained on a corpus of 50 million tweets (Astudillo et al., 2015). We do not tune the embeddings. Embeddings for unknown words are randomly initialized. The LSTM dimension is 128 and we use a batch size of 256. We use accuracy as our metric and optimize using the Adam optimizer (Kingma and Ba, 2014). The dropout layer uses a dropout rate of 0.4. We train until the validation accuracy stops improving with a learning rate of 0.001. All hyperparameters are tuned on the SemEval development set. The model is implemented in Keras (Chollet and others, 2015).

6.2 Evaluation

Metrics Since our data is annotated on a 5-point ordinal scale, we used mean absolute error (MAE), which asserts more penalty when the predicted label is further away from the true label, i.e., if the system predicts 1, and the true label is -2, the error will be 3 (instead of just "incorrect"). On a test set Te where the true class of tweet i is c_i, the mean absolute error (MAE) is:

$$MAE = \frac{1}{|Te|} \sum_{x_i \in Te} |y_{pred} - y_{true}| \quad (1)$$

We report the overall MAE as well as the MAE values for each sentiment class.

Results Table 5 tabulates the MAE values for each system. Due to the fact that our data set is largely negative, our systems in general are better at predicting negative and very negative tweets. Except masking, vulgarity features improves the overall performance of the system. Concatenating a vulgar token

Bi-LSTM	+ Masking	+ Token Insertion	+ Concatenation
1.320	1.666	**1.068**	1.148

Table 6: MAE on SemEval 2017 task 4 subtask C test set, vulgar tweets only.

Text	**True Label**	**Baseline Prediction**	**Insertion Prediction**	**Concatenation Prediction**
the bitch is back jamies new tumblr page	Negative	Neutral	Negative	Negative
welcome to my personal hell	Negative	Neutral	Negative	Negative
the simpsons donut hell apptrailers 0 likes	Neutral	Neutral	Negative	Negative
so fucking excited	Very Positive	Neutral	Negative	Negative

Table 7: Example Tweets and their predictions.

produced the lowest MAE overall, followed by insertion. The best per-class results are significantly better than the baseline Bi-LSTM with the Wilcoxon signed-rank test.

Across sentiment labels, masking improves the prediction of positive tweets; however, the prediction of negative tweets suffer. With masking, the actual vulgar word is replaced by a special token, stripping its meaning. One reason for this behavior could be that for positive tweets, vulgarity is more often used as an intensifier than other sentiment classes (Table 4, positive-weaken), so there is less of an impact on the loss of meaning, vs. the benefit of explicit vulgarity information. Token insertion and concatenation improves the prediction of negative tweets, and the prediction of non-negative tweets remain stable. This shows that retaining the meaning of vulgar expressions is in general more helpful and especially for negative sentiment.

Finally, we report on systems trained on SemEval and tested on the 339 vulgar-only tweets in the SemEval test set, shown in Table 6. Again, we see that inserting and concatenating vulgar word count both improves performance.[6]

Qualitative Analysis In Table 7, we show example tweets along with their labels and predictions. The first two are correct predictions, and the two others are incorrect predictions.

In the first tweet, "is back" is often used in positive sentences. For example, the tweet "pretty little liars is back in action hell yes" is rated very positive. However, "bitch" is often used as a negative word, making the baseline predict the sentence is neutral. The addition of vulgar features gave greater significance to the word "bitch," pulling the sentiment in the negative direction. The baseline may have rated the second tweet as neutral because the combination of the positive word "welcome" and the negative word "hell" gives the tweet a neutral prediction. Again, the vulgarity features give "hell" more significance, allowing the system to pick up on the negativity of the tweet.

In the third sentence, the presence of the word "hell" pushed the prediction to be negative, although in this case it made the prediction incorrect. In the last sentence, the systems with vulgar features predicted negative although the sentence is very positive. The baseline predicted negative, indicating that it did not have enough power to counterbalance "fucking" and "excited". However, our systems pulled the sentiment in the wrong direction. This may also be because vulgarity is often used in a negative form in this context (e.g. "so fucking angry").

7 Conclusions

We have introduced a new data set of 6.8K vulgar tweets labeled for sentiment on a five-point scale by nine annotators. Analysis of the ratings revealed that the expressiveness of vulgarity interacts with a number of demographic features, including age, gender, education, income, religiosity, and political ideology. Vulgarity is used to different ends by users who differ in age and faith. An examination of the impact of vulgarity on tweet sentiment perception showed that, in cases where the presence of vulgarity

[6]The MAE of Bi-LSTM on all the SemEval 2017 test set is 0.52, comparable with submitted systems (Rosenthal et al., 2017).

influences sentiment perception, it is most often used to intensify existing sentiment. Finally, we have shown that utilizing vulgarity-centric features yields increased sentiment analysis system performance. Future work will look directly at modeling the functions of vulgar words.

Abstract

We extend the coverage of an existing grammar customization system to clausal modifiers, also referred to as adverbial clauses. We present an analysis, taking a typologically-driven approach to account for this phenomenon across the world's languages, which we implement in the Grammar Matrix customization system (Bender et al., 2002, 2010). Testing our analysis on testsuites from five genetically and geographically diverse languages that were not considered in development, we achieve 88.4% coverage and 1.5% overgeneration.

Title and Abstract in Russian

Обстоятельственные придаточные в системе LinGO Grammar Matrix

В данной работе мы представляем новую библиотеку для системы LinGO Grammar Matrix. LinGO Grammar Matrix—это платформа для автоматического построения грамматик, где под грамматикой подразумевается программа, которая принимает на вход строку и возвращает соответствующие синтаксическую и семантическую структуру, построенные на основе синтаксической теории HPSG и семантического формализма MRS. Пользователь системы заполняет типологический опросник (отвечает на вопросы о конкретном языке, для которого требуется построить грамматику) и автоматически получает спецификацию, которую затем можно загрузить в различные приложения и получить собственно программу (грамматику). Ранее LinGO Grammar Matrix не поддерживала никаких придаточных предложений; в данной работе мы описываем новую библиотеку для обстоятельственных придаточных. Библиотека включает в себя новую страницу типологического опросника, набор признаковых структур HPSG, которые, с учетом уже имеющихся, позволяют составить корректные грамматики с обстоятельственными придаточными, и, наконец, собственно логику программы, которая и составляет эти грамматики в ответ на конкретный запрос пользователя. В процессе разработки мы проверяем, что система работает корректно в отношении списка возможных (coverage; охват грамматики) и невозможных (overgeneration; избыточные порождения грамматики) предложений из некоторого набора релевантных искусственных псевдоязыков (которые мы определяем как комбинации возможных выборов пользователя), а также из четырех естественных языков, отобранных из типологической литературы, посвященной обстоятельственным придаточным. Для оценки качества нашей библиотеки мы смотрим на охват и избыточные порождения грамматик, полученных нами для пяти естественных языков из разных языковых семей, отобранных уже после окончания разработки.

Proceedings of the 27th International Conference on Computational Linguistics, pages 2939–2952
Santa Fe, New Mexico, USA, August 20-26, 2018.

1 Introduction

The value of large-scale implemented precision grammars to linguists is twofold. First, by including analyses for linguistic phenomena that interact with each other, they are useful for verifying the consistency of linguistic theories (Bender, 2008; Müller, 2015); and second, they facilitate linguistic hypothesis testing by allowing the comparison of multiple analyses for a single phenomenon (Bender, 2010; Fokkens, 2014). Precision grammars parse and generate grammatical strings, emphasizing the linguistic correctness of an analysis by prioritizing *precision* (the number of inputs correctly parsed) over *recall* (the total number of inputs parsed), and in doing so allow linguists to test hypotheses over corpora. While the development of such grammars is time consuming, precision grammar starter kits can speed up the process by using stored analyses to create customized grammars (Bender et al., 2002).

Our present work is situated within the LinGO Grammar Matrix, a precision grammar customization system in which users answer typological questions about their language and a precision grammar fragment in the Head-driven Phrase Structure Grammar formalism (HPSG; Pollard and Sag, 1994) is produced. These starter grammars have given rise to such broad coverage grammars as the Spanish Resource Grammar (Marimon, 2010). We build on previous work in the Grammar Matrix by Trimble (2014), Poulson (2011) and others, following the methodology set forth by Drellishak (2009).

While language-specific analyses for clausal modifiers exist in the English Resource Grammar (ERG; Flickinger, 2000, 2011), the Jacy Grammar of Japanese (Siegel et al., 2016) and the Spanish Resource Grammar (Marimon, 2010), we are not aware of an implemented cross-linguistic analysis that has been applied to a broad range of typologically diverse languages. As subordinate clauses of any kind were not previously supported by the Grammar Matrix customization system and they are common in natural speech, their addition will extend the coverage of grammar fragments produced by this system. Restricting our focus to subordinate clauses that modify verbal projections, we present a library for clausal modifiers (or adverbial clauses) that supports numerous subordination strategies.

Languages typically employ multiple clausal modifier strategies which are marked by a wide range of characteristics. Supporting this variety poses a challenge for customization due to the range of complexity within each clausal modifier strategy, the multiplicity of syntactic phenomena that these strategies interact with and the possibility of multiple strategies within each language. We accomplish this with minimal additions to the Grammar Matrix, adding only two new lexical types and two phrase structure rules and defining strategy-specific subtypes to capture fine-grained complexity.

We begin with a description of related grammar engineering frameworks and annotation schemes (§2) followed by an overview of clausal modifiers, as seen in the typological literature (§3). Next we present an HPSG analysis of the phenomena (§4) and our contribution to the grammar customization system (§5). We describe our development data and evaluation on languages not considered during development, providing error analysis (§6) and conclude with a discussion of the uses for this library (§7).

2 Background

A variety of frameworks have been developed to support grammar engineering. While the Grammar Matrix uses the DELPH-IN Joint Reference Formalism (Copestake, 2002), a Head-driven Phrase Structure Grammar (HPSG; Pollard and Sag, 1994) based formalism that balances expressive power with computational efficiency, CoreGram (Müller, 2015) uses another HPSG-based formalism – TRALE (Meurers et al., 2002; Penn, 2004). Other frameworks include ParGram (Butt et al., 2002), the MetaGrammar project (de La Clergerie, 2005) and Grammatical Framework (Ranta, 2004). However, the Grammar Matrix provides a particularly suitable framework for our analyses because it requires its libraries to be typologically robust. As a result, multiple analyses must be developed for a particular phenomenon to account for its cross-linguistic distribution, and these analyses must interact with other phenomena in the customization system in order to produce customized grammars for any given language.

The grammars created by the Grammar Matrix produce syntactic annotations in the HPSG formalism and semantic annotations using Minimal Recursion Semantics (MRS; Copestake et al., 2005) for the strings they parse. These representations can capture information akin that captured by the Universal Dependencies annotation scheme and annotations in PropBank. On the syntactic side, the Universal

Dependencies annotation scheme (McDonald et al., 2013) uses the SCONJ and ADV part of speech tags for subordinators, corresponding to our adposition lexical type in §4.1 and adverb lexical type in §4.2, respectively. These are dependents of the subordinate verb, via a MARK dependency relation, which corresponds to our *basic-head-comp-phrase* in §4.1 and *isect-mod-phrase* in §4.2. In UD, the subordinate verb is a dependent of the matrix verb, via the ADVCL relation, which corresponds to our *scopal-mod-phrase*, described in §4.1. On the semantic side, PropBank (Kingsbury and Palmer, 2002; Palmer et al., 2005) marks different semantic classes of clausal modifiers, such as temporal (ARGM-TMP) and purposive (ARGM-PURP). One key difference is that in PropBank the subordinate clause is a dependent of the matrix verb, whereas in our MRS representations the matrix verb is an argument of the subordinator.

3 Typological Patterns

The typological literature describes a number of strategies for clausal modifiers and, in any given language, multiple strategies may be employed. Drawing on the review in Thompson et al. (2007), we can describe the range of clausal modification strategies in terms of the subordinator on the one hand, and additional characteristics of the subordinate clause on the other. A clausal modifier may be marked by a subordinator,[1] as in (1) from Japanese [jpn]; a subordinator pair comprising a subordinator in the embedded clause and an adverb in the matrix clause, as in (2) from Mandarin [cmn]; or special verbal morphology, as in (3) from Luiseño [lui].

(1) Ame ga agaru **to**, Gon wa hotto shite ana kara haidemashita
rain NOM stop when Gon TOP relief perform.INF hole from sneak.out.PST
'When the rain stopped, Gon got relieved and came out of the hole' [jpn]
(adapted from Thompson et al. 2007)

(2) **Yīnwèi** tiān hēi le, **suǒyǐ** wǒ méi chū - qu
because sky black CRS so 1SG NEG exit - go
'Because it had gotten dark, I didn't go out.' [cmn] (adapted from Li and Thompson 1989)

(3) Yaʔáʃ ŋéŋi ʂuŋá·l kí·ʃ pu-wá·qi-**pi**
man leave.remote woman house.ACC her-sweep-PURP
'The man left in order for the woman to sweep the house' [lui]
(Davis 1973 in Thompson et al. 2007)

Subordinators can occur either before or after the verb phrase or sentence in the subordinate clause. While in some languages their position is restricted to only before or only after the clause, in others the subordinator may attach freely before or after the clause, attaching at either the verb phrase (VP) or sentence (S) level. Clausal modifier strategies with subordinator pairs have an adverb in the matrix clause, which must co-occur with a particular subordinator, as in (2), and the position of that adverb may also be strict or free, attaching before or after the VP or S (Li and Thompson, 1989). Cross-linguistically, the subordinator pair strategy is particularly common for *if ... then* constructions.

The clausal modifier itself shows variation in both its external distribution and internal characteristics. The clausal modifier may attach before or after the matrix clause at the either the VP or S level. This distribution might also be strict or free.

Internal characteristics of the subordinate clause include constraints on the subject, word order and verbal morphology. In some strategies the subject of the modifying clause is shared with the matrix clause. In this case the subject of the subordinate verb and the matrix verb are co-referential and it is unexpressed in the subordinate clause. Additionally, some languages have a distinct word order in the subordinate clause. For example, German is a verb second language with verb final word order in embedded clauses (Thompson et al., 2007).

Finally, the clausal modifier may also be marked by special verbal morphology. Certain subordinators often occur with a particular morphological form or, if the clausal modifier strategy does not involve a subordinator, the morphological form itself may be associated with a particular semantic predication, as in (3). Many Turkic and Austronesian languages, require subordinate clauses to be nominalized.

[1] These are sometimes called subordinating conjunctions or clause linkers.

As described in Noonan (2007), this generally involves a nominalization morpheme on the verb and a change in the clause's internal distribution from that typical of verbal projections to that typical of nominal projections. Furthermore, this often includes an alternate case frame for nominalized verbs.

Our review of the typological literature reveals that clausal modifiers can be marked with a subordinator, a subordinator paired with a matrix adverb or no suborinator at all, illustrated in (1)–(3), and that the clause may bear a number of additional characteristics. We also find that it is common for languages to employ different strategies for different classes of clausal modifiers. In the next section we will develop an analysis to account for these typological patterns.

4 Analysis

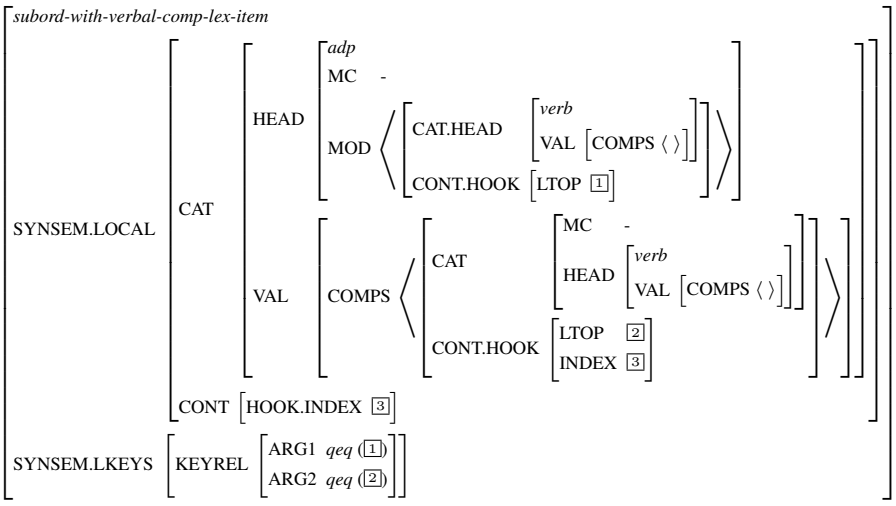
We present an analysis for clausal modifiers using the HPSG formalism (Pollard and Sag, 1994) for syntactic structure and Minimal Recursion Semantics (MRS; Copestake et al., 2005) for semantic representation. HPSG uses lexical entries, lexical rules and phrase structure rules, encoded as feature structures, to model language. Central to HPSG is a notion of headedness, such that most phrases have a distinguished head daughter and syntactic features are passed up from the head daughter to the mother. Additionally, HPSG describes its features using a multiple inheritance hierarchy, allowing supertypes to capture broad generalizations and subtypes to add fine-grained detail. While there is little theoretical HPSG literature on a cross-linguistic analysis of clausal modifiers, we do find target semantic representations in the ERG (Flickinger, 2000, 2011), and take advantage of existing type definitions in the Grammar Matrix (Bender et al., 2002) on which to build our analysis.

Whereas we described the typology of clausal modifiers in terms the surface forms possible in each strategy, we develop our analysis with respect to underlying lexical type of the subordinator. We posit two types of subordinators: an adposition (§4.1), which is the head of its clause, and therefore must attach to to the subordinate clause at the sentence (S) level, and whose position (before or after the sentence) is strict; and an adverb (§4.2), whose distribution is more free—it may attach to the subordinate clause at either the S or verb phrase (VP) level and may attach either before or after the S or VP constituent.[2] If there is no subordinator, we analyze subordination as morphological (§4.3). For each of these three analyses, we define a new lexical type and/or unary rule for subordination. Finally, we add additional constraints, or feature specifications, to subtypes of the lexical types and unary rules to capture the variation described in §3.

4.1 The Adposition Subordinator

The adposition subordinator is the head of the subordinate clause, defined in (4) as a scopal modifier that takes a clause as its complement.[3] The subordinator is a type of adposition ([HEAD *adp*]) whose comp-

(4)



[2]While we suggest the adposition analysis unless there is evidence that the subordinator is an adverb, the strict S-attachment associated with adpositions is also possible under our adverb analysis.

[3]Due to limited space, we use the notation *qeq*() as a stand-in for the way we build the handle constraint. For a more detailed account of the handle constraint, see Copestake et al. 2005.

lement is [HEAD *verb*].[4] The complement clause is constrained with a boolean feature MC, indicating that it is not compatible with the characteristics of matrix clauses in the language, and has an empty complement list ([COMPS ⟨ ⟩]), requiring that the verb's complement requirements have been satisfied. Similarly, the subordinator modifies a clause (specified on the MOD list), which is [HEAD *verb*] and [COMPS ⟨ ⟩].[5]

Abstracting away from some of the details of semantic composition, the main semantic contribution of this type is a predication (the value of KEYREL), whose first semantic argument (ARG1) is the matrix clause and whose second argument (ARG2) is the subordinate clause. The result of these constraints is an MRS representation, like that in (5) for the sentence *Kim left when Pat arrived*, such that the predication _when_subord_rel[6] has two arguments which point (via *qeq*) to the matrix and subordinate verbs.

(5)
$$\left\langle h_1, e_3, \left| \begin{array}{l} h_4{:}\text{proper\_q}\langle 0:3\rangle(\text{ARG0 } x_6\{\text{PERS 3, NUM sg, IND +}\}, \text{ RSTR } h_5, \text{ BODY } h_7), \\ h_8{:}\text{named}\langle 0:3\rangle(\text{ARG0 } x_6, \text{ CARG } \textit{Kim}), \\ h_9{:}\text{\_leave\_v\_1}\langle 4:8\rangle(\text{ARG0 } e_3\{\text{SF prop, TENSE past}\}, \text{ ARG1 } x_6, \text{ ARG2 } p_{10}), \\ h_2{:}\text{\_when\_x\_subord}\langle 9:13\rangle(\text{ARG0 } e_{11}\{\text{SF prop}\}, \text{ ARG1 } h_{12}, \text{ ARG2 } h_{13}), \\ h_{14}{:}\text{proper\_q}\langle 14:17\rangle(\text{ARG0 } x_{16}\{\text{PERS 3, NUM sg, IND +}\}, \text{ RSTR } h_{15}, \text{ BODY } h_{17}), \\ h_{18}{:}\text{named}\langle 14:17\rangle(\text{ARG0 } x_{16}, \text{ CARG } \textit{Pat}), \\ h_{19}{:}\text{\_arrive\_v\_1}\langle 18:25\rangle(\text{ARG0 } e_{20}\{\text{SF prop, TENSE past}\}, \text{ ARG1 } x_{16}) \end{array} \right| \\ \{\, h_{15}\ qeq\ h_{18}, h_{13}\ qeq\ h_{19}, h_{12}\ qeq\ h_9, h_5\ qeq\ h_8, h_1\ qeq\ h_2 \,\} \right\rangle$$

We take advantage of existing phrase structure rules in the Grammar Matrix for complement and modifier attachment. The *basic-head-comp-phrase* phrase structure rule attaches the adposition to its complement (the subordinate clause) and the *scopal-mod-phrase* attaches the subordinate clause to the constituent it modifies (the matrix clause).

4.2 The Adverb Subordinator

In contrast with the adposition subordinator, the adverb subordinator is not a syntactic head, and therefore has more flexibility with respect to its position in the subordinate clause. As described in this section, because adverbs are not syntactic heads, many features will not be passed up the tree. Thus, rather than adding constraints on the matrix clause to the adverb's lexical type, we add them to the clausal modifier via a non-branching rule and use a new feature, SUBORDINATED to constrain the non-branching rule's daughter to contain the appropriate adverb.

The Lexical Type We define the adverb subordinator type as a non-scopal adverb. It has one element on its MOD list, the subordinate clause, which it can attach to at the VP or S level via the *isect-mod-phrase* rule, already in the Grammar Matrix. The element on the adverb's MOD list, like the complement of the adposition subordinator, is [HEAD *verb*] and [MC −] to prevent the adverb subordinator from occurring in matrix clauses.

The SUBORDINATED Feature Due to the constraints on composition in MRS (as codified, for example, in Copestake et al. 2001), we cannot introduce the subordinate predication on the adverb. MRS composition is done locally at each level in the tree, and though the adverb has access to the semantic head of the subordinate clause (the verb), it doesn't have access to any information about the matrix clause. Therefore, we add the predication and related semantic constraints with a unary rule, after the clause is fully formed. To link each adverb subordinator to a unary rule that contributes the corresponding predication, we introduce the SUBORDINATED feature, which is passed up by the various phrase structure rules. For each adverb, a feature value is created under SUBORDINATED and the unary rule that adds the predication will select for a daughter with the right SUBORDINATED value. To prevent multiple subordinators in the same sentence, all lexical entries for verbs are [SUBORDINATED none] as is the element on the adverb subordinator's MOD list. Once an adverb subordinator attaches, changing the clause's SUBORDINATED value, it will not be compatible with any other adverb subordinator.

[4]Note that this type will not extend to nominalized clauses. A type with a nominalized complement is described in §4.4.

[5]Additional constraints regarding the subjects of these clauses, which will determine whether or not the subject is expressed in the subordinate clause and if the subordinate clause modifies a VP or S, are added to subtypes, as described in §4.4.

[6]The specific predication symbol is specified on the lexical entry for each subordinator.

The Unary Rule We define the *adv-marked-subord-clause-phrase* such that it constrains its daughter to be [HEAD *verb*], [MC −] and, to prevent the rule from applying more than once, [MOD ⟨ ⟩]. The valence features must be fully satisfied on the mother and daughter, with the exception of the SUBJ list, which is identified between daughter and mother in order to accommodate subject sharing.

The main contribution of this rule is the addition of the matrix clause to the subordinate clause's MOD list as well as the subordinating predication and corresponding constraints. The element added to the MOD list is the same as that on the adposition subordinator's MOD list. The unary rule adds an *arg-12-ev-relation*, which has two arguments that are identified with the semantic content of the matrix and subordinate clauses respectively. The unary rule's daughter is identified with ARG2 and the matrix clause is identified with ARG1. Subtypes of this rule include a specific predication value, and we use the SUBORDINATED feature to identify the daughter of the unary rule with a clause marked by the appropriate subordinator for that predication. The resulting MRS is the same as that produced by the adposition subordinator in (5).

4.3 Morphological Subordination

Finally, morphological subordination involves a unary rule that selects a clause with particular morphological features and adds an element to the modifier list and a predication with the appropriate semantic identities. The *morphological-subord-clause-phrase* is identical to the *adv-marked-subord-clause-phrase* with one key difference: It selects a daughter with one or more syntactic or semantic features that are specific to the strategy, as described in §4.4, rather than using the SUBORDINATE feature.

4.4 Additional Constraints

For each clausal modifier strategy, we create a subtype of the appropriate lexical type and/or unary rule described in §4.1–4.3, adding additional constraints that capture the variation described in §3. Table 1 presents the additional features that constrain each phenomenon and indicates whether those features are expressed on the lexical type or unary rule.

Table 1: Features for Clausal Modifier Strategies

Constraints	Adposition Subordinator	Adverb Subordinator	No Subordinator
Clause Position	{POSTHEAD $+, -, bool$} (lexical type)	{POSTHEAD $+, -, bool$} (unary rule)	{POSTHEAD $+, -, bool$} (unary rule)
Clause Attachment	{MOD.SUBJ $\langle\,\rangle, \langle[\,]\rangle, none$} (lexical type)	{MOD.SUBJ $\langle\,\rangle, \langle[\,]\rangle, none$} (unary rule)	{MOD.SUBJ $\langle\,\rangle, \langle[\,]\rangle, none$} (unary rule)
Subordinator Position	{INIT $+, -$} (lexical type)	{POSTHEAD $+, -, bool$} (lexical type)	
Subordinator Attachment	{COMPS.SUBJ $\langle\,\rangle$} (lexical type)	{MOD.SUBJ $\langle\,\rangle, \langle[\,]\rangle, none$} (lexical type)	
Matrix Pair	{SUBPAIR} (lexical type)	{SUBPAIR} (lexical type)	
Special Morphology	{COMPS.FEATURE} (lexical type)	{MOD.FEATURE} (lexical type)	{DTR.FEATURE} (unary rule)
Nominalization	{COMPS.NMZ +} (lexical type)		{DTR.NMZ +} (unary rule)
Shared Subject	{COMPS.SUBJ $\boxed{0}\langle unexpressed\rangle$} {MOD.SUBJ $\boxed{0}$} (lexical type)	{DTR.SUBJ $\boxed{0}\langle unexpressed\rangle$} {MOD.SUBJ $\boxed{0}$} (unary rule)	{DTR.SUBJ $\boxed{0}\langle unexpressed\rangle$} {MOD.SUBJ $\boxed{0}$} (unary rule)

Clause Position and Attachment The first constraints we add govern the external distribution of the clausal modifier. Head-modifier rules are sensitive to the feature POSTHEAD, so if a clausal modifier strategy occurs strictly before the matrix clause, we add the constraint [POSTHEAD −]; if it occurs strictly after, [POSTHEAD +]; and if it can occur in either position, we leave this feature underspecified. We constrain clause attachment with the subject list of the matrix clause. If the modifier attaches to a sentence, the matrix clause must already have a subject, signified by an empty subject list ([SUBJ ⟨ ⟩]). On the other hand, if it attaches to a verb phrase, we constrain this list to be non-empty ([SUBJ ⟨ [ ] ⟩]) and if it can attach to either the VP or S, we leave this constraint underspecified. These constraints go directly on the lexical type of the adposition subordinator and on the unary rule for the adverb subordiantor.

Subordinator Position and Attachment If the subordinator is an adverb, the subordinator position and attachment are constrained the same way as the clausal modifier's, except that these constraints are

specified on the lexical type, so that they will govern the adverb's distribution in the subordinate clause. If the subordinator is an adposition, it is the head of its clause and attaches strictly to a sentence, so the element on its COMPS list is necessarily [SUBJ $\langle\ \rangle$]. It can attach at the beginning or end of the clause (but only one or the other), which is constrained with the INIT feature. We add INIT to the head-complement rules to constrain the order of the head and complement. If an adposition attaches at the beginning of the clause, it is [INIT +] and if it attaches at the end it is [INIT −].[7]

Subordinator Pairs Both adverbial and adpositional subordinators can require a adverb in the matrix clause (as illustrated in (2)), which we treat as a scopal modifier, constraining its position and attachment the same way as the adverb subordinator. We introduce the SUBPAIR feature, and for each pair of subordinators in the language, we create a unique value, which is added to the matrix adverb's lexical type. The head-modifier rule passes the SUBPAIR value up from the non-head daughter and this feature is propagated up through the head daughter by the other phrase structure rules. In the subordinate clause, this feature is specified on the MOD list of the adposition subordinator, or the lexical type of the adverb subordinator.[8] Finally the *scopal-head-mod-phrase* identifies the SUBPAIR value of the non-head-daughter's MOD list with that of the head-daughter.

Special Morphology and Nominalization Many subordination strategies, whether they include a subordinator or not, require special morphology on the embedded verb. Certain morphological forms can be associated with with features in the morphology library (O'Hara, 2008; Goodman, 2013). For adverb and adposition subordinators, morphological constraints are specified on the lexical type, and if there is no subordinator, these constraints are specified on the unary rule. Supported morhpological features include FORM, ASPECT, MOOD, NOMINALIZATION and user-defined syntactic features.

If NOMINALIZATION is among the specified features, we use a different set of lexical types and unary rules. The nominalized clauses library (Howell et al., to appear) allows users to define nominalization strategies in which nominalization occurs at the verb, verb phrase or sentence level and either adds a nominalized predication or not. This library changes clauses to [HEAD *noun*], adds the feature [NMZ +] and may add a nominalization predication that scopes over the event. Therefore, we define new lexical types and unary rules that select a clause that is [HEAD *noun*] [NMZ +].[9] Lexical nouns are constrained to [NMZ –], preventing the subordinator from selecting a lexical noun rather than a nominalized clause.

Shared Subjects If the subject is shared between the matrix and subordinate clauses, the embedded clause is constrained with an *unexpressed* element on its SUBJ list. The XARG (external argument; Copestake et al., 2005) of the subordinate clause is identified with the XARG of the subordinator's modifier, creating a semantic identity between the subjects of the subordinate and matrix verbs.

Special Word Order We use the analysis of Fokkens (2014) to accommodate verb second word order in the matrix clause and verb final in the subordinate clause. Under this analysis, a clause with subordinate word order is [MC −], which is compatible with our adposition lexical entry and unary rules.

Summary The analyses presented in this section build on the existing customization system, interaction with many different libraries, including word order, nominalization, aspect and mood, among others. We have accounted for the distribution of clausal modifiers, as described in §3, with the addition of two new lexical types and two unary rules to the Grammar Matrix. We create subtypes of those lexical types and unary rules that are further constrained according to Table 1 to account for the diversity of clausal modifier strategies in the typological literature.

[7] These rules are added by the word order library (Bender and Flickinger, 2005). In the rare case that the word order library does not add the necessary rule (for example, an otherwise head-final language has a head-initial subordinator), we add a special head-complement rule that selects for an adposition head daughter. Further detail is provided by Zamaraeva et al. (2018).

[8] This feature is then copied to the modifier list of the clausal modifier by the unary rule.

[9] If the nominalization strategy adds a nominalized_rel predication, the lexical type for adposition subordinators and unary rule for adverb or morphological subordination identify the subordinator's ARG2 with the local top of the _nominalized_rel, rather than the INDEX of the verb.

5 Customized Grammar Development

The Grammar Matrix customization system (Bender and Flickinger, 2005; Bender et al., 2010; Drellishak, 2009) uses a web-based questionnaire to elicit user input regarding the typological characteristics of their language on the front end and a customization script that produces a grammar that handles these phenomena on the back end. The two are linked via a 'choices' file, containing values that correspond to the user's input and can be read by the customization script. Thus to integrate the analysis described in §4, we first developed a clausal modifiers page in the questionnaire[10] to elicit the user's choices and then modified the customization script to add the appropriate analyses to the output grammar.

The clausal modifiers questionnaire uses an iterator so that users can define any number of clausal modifier strategies found in their language. For each strategy the user is asked about the clausal modifier's position and attachment and if the subordinating predication is contributed by a subordinator, a subordinator pair or if it does not involve a subordinator, as illustrated in (1), (2) and (3), respectively. Subsequent questions are based on this first choice.

If the user selects subordinator or subordinator pair, they are asked if the subordinator is an adverb or adposition. If they choose adposition, they are asked if it occurs at the beginning or end of the clause. If it's an adverb, they are asked whether it attaches strictly before, strictly after or freely before or after a VP, S or either a VP or S. If they select subordinator pair, they are also asked about the position of the matrix adverb. The user may enter any number of subordinators or subordinator-matrix adverb pairs, including an orthographic representation and a predicate symbol for each. If there is no subordinator, the user may enter only one predication per strategy. The user may add any number of verbal features associated with the clausal modifier strategy and can check a box to indicate subject sharing.

The choices file generated by the questionnaire goes through a script which validates if the choices are 'legal' and will result in a working grammar. If validation fails, the user is prompted to make changes; otherwise, the customization script adds a basic lexical type and/or unary rule to the grammar, based on the subordinator type, and creates a subtype of that lexical type and/or unary rule that is specific to the strategy. Constraints corresponding to the other choices are added to the subtypes, according to §4.4.

6 Testing, Evaluation and Error Analysis

We use two types of testing during development, which we follow with held out evaluation. Each test involves a testsuite, a choices file and a grammar produced by the customization system. The testsuites are small and designed to be representative of the relevant contrasts in the language, including the full range of possible grammatical sentences for each clausal modifier strategy as well as ungrammatical sentences that are each ungrammatical in one specific way. While our testsuites are small, they are robust in that they contain an example that targets each feature in Table 1 as well as any relevant interacting phenomena individually. We create choices files that define each clausal modifier strategy and account for interacting phenomena and load the resulting grammars into the LKB (Copestake, 2002) to parse each sentence. We inspect the parse trees and semantic representations to verify their correctness. [11]

6.1 Pseudo Languages

During development we tested our analyses on pseudo languages—artificial languages with a minimal lexicon which exhibit each of the phenomena outlined in Table 1 as well as known interacting phenomena. The typological space is large, including 1008 possible combinations for the features in Table 1.[12] Rather than test all combinations exhaustively, we created tests by sampling each constraint from the first column with each subordinator type, rather than each value, and added additional tests for interacting phenomena, including word order, verbal features and nominalization. To test the interaction between different strategies (which may result in overgeneration if under-constrained), we included multiple strategies in some tests. This resulted in 16 pseudo languages, containing a total of 33 distinct

[10] http://matrix.ling.washington.edu/customize/matrix.cgi?subpage=clausalmods

[11] Our code and testsuites can be checked out from svn://lemur.ling.washington.edu/shared/matrix/trunk at revision 41464.

[12] This is a conservative estimate, bundling many features and suppressing interacting phenomena, such as special word order, matrix adverb position, nominalization strategy and different types of verbal features. In reality, the space is much larger.

strategies. We refined our analysis during testing to achieve full coverage over these languages.

6.2 Development Languages

Next we tested our system on natural languages that illustrate particular phenomena in our library. We selected four languages, based on the characteristics their clausal modifiers exhibit and developed a testsuites of ten sentences for each, illustrating which characteristics of clausal modifiers are exhibited in the language and which would result in ungrammatical sentences, according to descriptive grammars.

Mandarin Mandarin [cmn] has a number of subordinator pairs, of which some subordinators can occur without their matrix adverb and some matrix adverbs are homophonous with conjunctions (Li and Thompson, 1989). We illustrated this range with one such pair *yīnwèi...suǒyǐ*, defining two clausal modifier strategies, one with the pair and one with just *yīnwèi* as a subordinator, and one coordination strategy,[13] with *suǒyǐ* as a conjunction.

Wambaya Wambaya [wmb] expresses purposive and prior clauses with a special purposive or prior morpheme on the verb (Nordlinger, 1998). Purposive can also be expressed with the infinitive suffix. These morphological strategies exhibit subject sharing and require dative instead of absolutive case on the object. 'When or because' and 'right after' clauses are finite clauses with no subordinator.[14] 'When or because' clauses attach strictly after the matrix clause, whereas 'right after' clauses attach strictly before. The inherent ambiguity from having both of these strategies in the same language is captured by our grammar. Our typological survey did not reveal case change outside of nominalized clauses, so it was not accounted for in our analysis. For this reason, our Wambaya testsuite has one grammatical sentence that does not parse, a purposive clause with dative case on the object, and one ungrammatical sentence that does parse, a purposive clause with absolutive case on the object.

Rukai We used Rukai [dru], as described by Zeitoun (2007), to test nominalization as a primary strategy for clausal modifiers. We tested two strategies, one in which the nominalization morpheme is also associated with 'reason' and another in which a generic nominalization morpheme is paired with a subordinator, meaning 'reason'. To capture the distinction between these morphemes, we defined a feature in customization that is suitable for both verbs and nouns (so that it will mark the clause both before and after nominalization), and associated it with each morpheme and each clausal modifier strategy.

German Finally German [deu] has verb final word order in the subordinate clause, while matrix clauses are verb second. We used a strategy with a clause initial subordinator from Thompson et al. (2007) to test this word order variation.

Table 2: Development Languages

Language	Family	Test Items	Coverage	Overgeneration
Wambaya [wmb]	Mirndi	10	5/6	1/4
German [deu]	Indo-European	10	2/2	0/8
Rukai [dru]	Austronesian	10	2/2	0/8
Mandarin [cmn]	Sino-Tibetan	10	6/6	0/4

We summarize our results on development languages in Table 2. The two errors are the result of case-frame changes, which are more closely related to verbal morphology than subordination. As a this is an interacting phenomenon and not specific to clausal modifiers we leave this out of scope for our library.

6.3 Evaluation with Held-out Languages

We evaluate on languages that are genetically and geographically diverse from the languages considered in development. These languages are chosen at random from the set of descriptive grammars available at the University of Washington library, and discarded if (a) they come from the same language family as an illustrative language or previous held-out language, (b) they do not contain (or the grammar does

[13] Using the coordination library contributed by (Drellishak and Bender, 2005)

[14] While this could be analyzed as juxtaposition, we illustrate the user's analytic freedom to treat these as subordinate clauses.

not describe) clausal modifiers or (c) the data does not contain a sufficient level of annotation to reliably construct additional examples. From the descriptive grammars, we develop testsuites that capture the range of clausal modifiers according to the linguist's description, constructing grammatical and ungrammatical sentences from examples in the descriptive grammar to contrast each characteristic of the clausal modifier strategy.[15] For each language we include up to four clausal modifier strategies, as described by the author, which may translate to between three and ten strategies in the choices file, depending on the type of variation therein.[16]

Ma'di Ma'di [mhi] has a wide range of clausal modifier strategies, including postposition subordinators, adverb subordinators (some requiring the subordinate clause to occur first, and others allowing it in either position) and subordinate clauses marked by the directive mood (Blackings and Fabb, 2003). Our analysis of adverb subordinators, based on the typological literature and a generalization that adverbials related to time and modality tend to attach higher in the tree (Cinque, 1999), only allows VP and S attachment. In Ma'di, however, adverb subordinators may intervene between the verb and object, suggesting V attachment as well. Since we do not support this, one sentence in our testsuite is not parsed.

Mosetén Strategies in Mosetén [cas], include subordinators in finite clauses, subordinators that require special morphology and strictly morphological subordination. Sakel (2004) states that the clausal modifier can occur in any position that an adverb can, but only shows S attachment in examples. The adverb chapter does not discuss the distribution of adverbs, but shows examples of S and VP attachment, so we infer that clausal modifiers may attach at the S and VP level. This testsuite revealed a bug in the customization code, that was not sampled in pseudo language evaluation. The unary rule supertype for morphological subordination is constrained to be [SUBJ $\langle\ \rangle$], barring VP attachment for morphologically subordinated clauses, and resulting the failure of two strings to parse.

Lavukaleve Subordination in Lavukaleve [lvk] is primarily morphological and various clausal modifier strategies position the subordinate clause differently (Terrill, 2003). Although Lavukaleve is a nominative-accusative language in general, it has a split ergative system in subordinate clauses, such that third person subjects take canonical object marking, but first and second person subjects take the usual subject marking. Alternate case frames in subordinate clauses are not modeled in the Grammar Matrix or by our library, so this results in one ungrammatical string parsing and one grammatical string failing to parse. Another interesting phenomenon in Lavukaleve, as described by Terrill (2003), is an adverb that occurs in the matrix clause when the subordinate clause is marked by special morphology, but no subordinator. This is not captured in our analysis of subordinator pairs, which require a subordinator, so another sentence in our testsuite fails to parse.

Basque Hualde and de Urbina (2003) provide an extremely thorough description of clausal modifiers in Basque [eus], including numerous clausal modifier strategies with different morphological forms that combine with various adpositions and adverbs. We do our best to select a representative set of combinations, including two sets of adpositions that co-occur with different morphemes, one adverb that co-occurs with another morpheme and a nominalization strategy whose meaning differs based on the case of the nominalized clause. This results in 10 clausal modifier strategies in the choices file and a special feature with 7 values (such as purposive, conditional, etc.) that is suitable for both verbal and nominal projections. Our test sentences contained dropped subjects which revealed that the nominalized clauses library does not provide a phrase structure rule for subject dropping in nominalized clauses. This results in three sentences failing to parse. However, upon constructing such a rule, we confirmed that if this rule were in the grammar, those sentences would parse correctly.

Uranina Finally, Uranina [ura] primarily uses subordinators (a clause final clitic and a number of postpositions) for clausal modifiers (Olawsky, 2006). The majority require a finite verb, but in the

[15] This is necessary for robust testing, as the descriptive grammar will often include only grammatical examples, but explain the full paradigm in prose.

[16] For example the choices file requires separate strategies for each morphologically contributed predication, even if they might be grouped under one strategy in the descriptive grammar.

innovative dialect (spoken by younger members of the community), some of these postpositions co-occur with non-finite verbs. There is also a subordinator pair for conditional clauses. We created three clausal modifier strategies, with multiple subordinators to successfully capture this variation.

Table 3: Held-out Language Evaluation

Language	Family	Test Items	Coverage	Overgeneration
Ma'di [mhi]	Central Sudanic	23	16/17	0/6
Mosetén [cas]	Mosetenan	26	13/15	0/11
Lavukaleve [lvk]	Solomons East Papuan	23	8/10	1/13
Basque [eus]	Basque	26	13/16	0/10
Uranina [ura]	Uranina	21	12/12	0/9

The average coverage over 5 test suites was 88.4% and overgeneration was 1.5%, as detailed in Table 3. With the exception of case frame change on embedded verbs in Wambaya and Lavukaleve, our library does a good job of preventing the parsing of ungrammatical strings, upholding our emphasis on precision. Our recall is lower, as we are not able to parse 8 strings, due to 5 errors, which we can classify in 3 groups. The first group includes bugs: the inability to parse VP attachment of clausal modifiers in Mosetén is due to a mistake in the supertype of the non-branching rule, and the lack of a subject dropping rule for nominalized verbs for Basque is due to an oversight in the nominalized clauses library. These bugs are easily fixed, now that they have been identified. The next group is out-of-scope phenomena: valence change (Wambaya and Lavukaleve) is more closely associated with verb form than clausal modifier strategy and should be handled in a library for valence change. The third type of error comes from phenomena that were not brought to light in the typological survey, but were found during held-out evaluation. First, we expected that adverb subordinators would be high-attaching, based on a cross linguistic generalization about adverb classes and the absence of any attested low-attaching adverbs in our literature review. Ma'di brings to light an interesting contradiction to this assumption and we will add the option of V attachment in the matrix clause now that it has been attested. Second, the typological literature did not suggest that matrix "pair" adverbs could occur without a subordinator in the embedded clause. If this is in fact the case in Lavukaleve, this poses a interesting direction for future work.

7 Conclusion

We presented a cross-linguistic HPSG analysis of clausal modifiers, which we implemented in the LinGO Grammar Matrix. We demonstrated the effectiveness of this library over the known typological space in §6.1, tested the application of specific clausal modifier strategies on real languages in §6.2, and evaluated its generalizability on 5 held-out languages in §6.3. Because our analysis is implemented within a larger grammar engineering environment, we were able to test its interaction with relevant phenomena. We contributed all testsuites and choices files back to the project so that they can be added to regression testing to ensure that downstream changes will not impact the coverage of this library and future developers can test their phenomena with clausal modifiers. The grammars produced by the Grammar Matrix with the addition of the clausal modifiers library are useful starting points to linguists who wish to develop broad coverage grammars, as the starter grammar can now include not only matrix clause phenomena, but analyses for subordinate clausal modifiers. In addition to developing broad coverage grammars, the grammars produced by the Grammar Matrix can be used to teach grammar engineering and for linguistic hypothesis testing, as our approach allows user-linguists analytic freedom in their implementation, so that multiple analyses can be explored.

Abstract

Recurrent neural networks have achieved great success in many NLP tasks. However, they have difficulty in parallelization because of the recurrent structure, so it takes much time to train RNNs. In this paper, we introduce sliced recurrent neural networks (SRNNs), which could be parallelized by slicing the sequences into many subsequences. SRNNs have the ability to obtain high-level information through multiple layers with few extra parameters. We prove that the standard RNN is a special case of the SRNN when we use linear activation functions. Without changing the recurrent units, SRNNs are 136 times as fast as standard RNNs and could be even faster when we train longer sequences. Experiments on six large-scale sentiment analysis datasets show that SRNNs achieve better performance than standard RNNs.

1 Introduction

Recurrent neural networks (RNNs) have been widely used in many NLP tasks, including machine translation (Cho et al., 2014; Bahdanau et al., 2015; Luong et al., 2015; Bradbury and Socher, 2016), question answering (Xiong et al., 2016; Chen et al., 2017), image caption (Xu et al., 2015; Karpathy and Li, 2015), and document classification (Tang et al., 2015; Yang et al., 2016; Zhou et al., 2016). RNNs have the ability to obtain the order information of the input sequences. The two most popular recurrent units are long short-term memory (LSTM) (Hochreiter and Schmidhuber, 1997) and gated recurrent unit (GRU) (Cho et al., 2014), both of which could store previous memory in hidden states and use a gating mechanism to determine how much previous memory should be combined with the current input. Unfortunately, because of the recurrent structure, RNNs cannot be computed in parallel. Therefore, training RNNs takes much time, which limits academic research and industrial applications.

To solve this problem, several scholars try to use convolutional neural networks (CNNs) (Lecun et al., 1998) instead of RNNs in the field of NLP (Kim, 2014; Kalchbrenner et al., 2014; Gehring et al., 2017). However, CNNs may not obtain the order information of the sequences, which is very important in NLP tasks.

Some scholars tried to increase the speed of RNNs by improving the recurrent units and they have achieved good results. Quasi-recurrent neural networks (QRNNs) (Bradbury et al., 2017) got up to 16 times faster speeds by combining CNNs with RNNs. Lei et al. (2017) proposed the simple recurrent unit (SRU), which is 5-10 times faster than LSTM. Similarly, strongly-typed recurrent neural networks (T-RNN) (Balduzzi and Ghifary, 2016) and minimal gated unit (MGU) (Zhou et al., 2016) are also methods that could change the recurrent units.

Although RNNs have achieved faster speeds in these researches with the recurrent units improved, the recurrent structure among the entire sequence remains unchanged. As we still have to wait for the output of previous step, the bottleneck of RNNs still exists. In this paper, we introduce sliced recurrent neural networks (SRNNs), which are substantially faster than standard RNNs without changing the recurrent units. We prove that when we use linear activation functions, the standard RNN is a special case of the SRNN, and the SRNN has the ability to obtain high-level information of the sequences.

In order to compare our model with the standard RNN, we choose GRU as the recurrent unit. Other recurrent units could also be used in our structure, because we improve the overall RNN structure among the whole sequence rather than just changing the recurrent units. We complete experiments on six large-scale datasets and SRNNs perform better than standard RNNs on all the datasets. We open source our implementation in Keras (François et al, 2015).[1]

2 Model Structure

2.1 Gated Recurrent Unit

The GRU (Bahdanau et al., 2014) has the reset gate *r* and the update gate *z*. The reset gate decides how much of the previous memory is combined with the new input, and the update gate determines how much of the previous memory is retained.

$$r_t = \sigma(W_r x_t + U_r h_{t-1} + b_r) \tag{1}$$

$$z_t = \sigma(W_z x_t + U_z h_{t-1} + b_z) \tag{2}$$

where x is the input and h is the hidden state.

$$\tilde{h}_t = \tanh(W_h x_t + U_h(r_t \circ h_{t-1}) + b_h) \tag{3}$$

The candidate hidden state $\tilde{h}_t$ is controlled by the reset gate. When the reset gate is 0, the previous memory is ignored.

$$h_t = z_t \circ h_{t-1} + (1 - z_t) \circ \tilde{h}_t \tag{4}$$

When the update gate is 1, the hidden state could copy the previous memory to the current moment and ignore the current input.

2.2 The Standard RNN Structure

The standard RNN structure is shown in Figure 1, where A denotes the recurrent units.

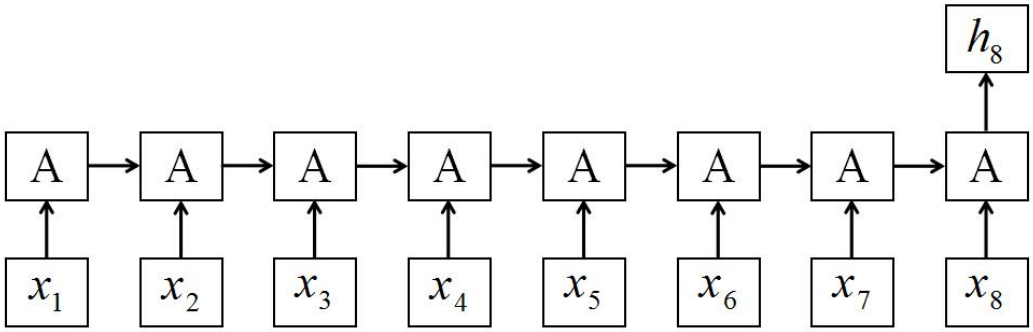

Figure 1: The standard RNN structure. Each step waits for the output of its previous step, which is computed by the recurrent unit A.

The length of the input sequence *X* is *T*, and here we assume $T = 8$ as Figure 1 shown. The standard RNN uses the last hidden state as the representation of the whole sequence, and then add a softmax classifier to predict the labels. In addition to GRU and LSTM, QRNN and SRU could be seen as one form of recurrent unit A as well. However, the overall RNN structure has not been improved, at each step we need to wait for the output of the previous step:

$$h_t = f(h_{t-1}, x_t) \tag{5}$$

where *h* is the previous hidden state. This standard RNN structure in which every two adjacent cells are connected causes the bottleneck: the longer the input sequence is, the longer it takes.

[1] https://github.com/zepingyu0512/srnn

2.3 Sliced Recurrent Neural Networks

We construct a new RNN structure called sliced recurrent neural networks (SRNNs), which is shown in Figure 2. In Figure 2 the recurrent unit is also referred to as A.

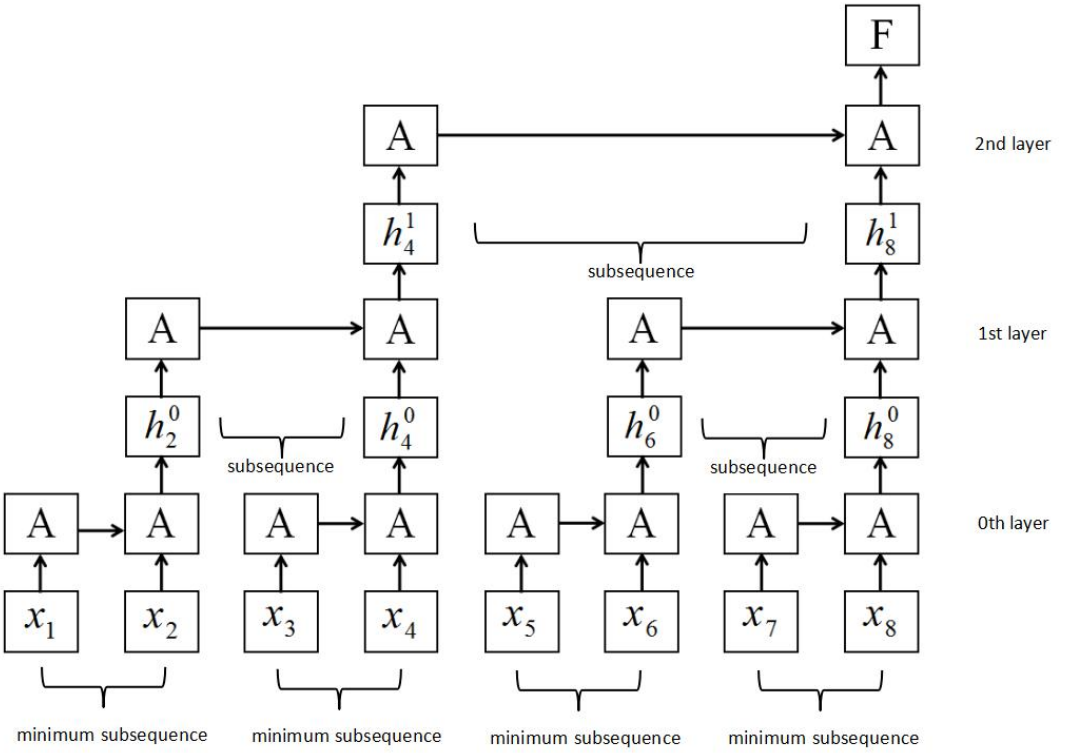

Figure 2: The SRNN structure. It is constructed by slicing the input sequence into several minimum subsequences with equal length. The recurrent units could work on each subsequence simultaneously on each layer, and the information could be transmitted through multiple layers.

The length of input sequence X is T, and the input sequence is:

$$X = [x_1, x_2, ..., x_T] \tag{6}$$

where x is the input at each step and it may have multiple dimensions such as word embeddings. Then we slice X into n subsequences of equal length, and the length of each subsequence N is:

$$t = \frac{T}{n} \tag{7}$$

where n is the slice number, and the sequence X could be represented as:

$$X = [N_1, N_2, ..., N_n] \tag{8}$$

where each subsequence is:

$$N_p = [x_{(p-1)\times t+1}, x_{(p-1)\times t+2}, ..., x_{p\times t}] \tag{9}$$

Similarly, we slice each subsequence N into n subsequences of equal length again, and then repeat this slice operation k times until we have an appropriate minimum subsequence length on the bottom layer (we call it 0th layer, which is shown in Figure 2), and k+1 layers are obtained by slicing k times. The minimum subsequence length of 0th layer is:

$$l_0 = \frac{T}{n^k} \tag{10}$$

and the number of the minimum subsequences on 0th layer is:

$$s_0 = n^k \tag{11}$$

Because every parent sequence on pth layer (p>0) is sliced into n parts, the number of the subsequences on pth layer is:

$$s_p = n^{k-p} \tag{12}$$

and the subsequence length of pth layer is:

$$l_p = n \tag{13}$$

Take Figure 2 as an example. The sequence length T is 8, the slice operation times k is 2, and the slice number n of each pth layer is 2. After slicing the sequence twice, we get four minimum subsequences on 0th layer, and the length of each minimum subsequence is 2. If the length of the sequence or the length of its subsequences cannot be divided by n, we may exploit padding method or choose different slice number on each layer. Different k and n may be used on different tasks and datasets.

The difference between the SRNN and the standard RNN is that the SRNN slices the input sequence into many minimum subsequences and utilizes the recurrent units on each subsequence. In this way, the subsequences could be easily parallelized. On 0th layer, the recurrent units are acted on each minimum subsequence through the connection structure. Next, we obtain the last hidden states of each minimum subsequence on 0th layer, which are used as the input of their parent sequences on 1st layer. And then we use the last hidden state of each subsequence on (p-1)th layer as the input of their parent sequence on pth layer and compute the last hidden states of the subsequences on pth layer.

$$h_t^1 = \overrightarrow{GRU}^0(mss^0_{(t-l_0+1)\sim t}) \tag{14}$$

$$h_t^{p+1} = \overrightarrow{GRU}^p(h^p_{t-l_p} \sim h_t^p) \tag{15}$$

where h_l^p is the number l hidden state on pth layer, mss denotes minimum subsequences on 0th layer, and different GRUs could be used on different layers. This operation is repeated between each sub-parent sequence on each layer until we get the final hidden state F of the top layer (kth layer).

$$F = \overrightarrow{GRU}^k(h^k_{t-l_k} \sim h_t^k) \tag{16}$$

2.4 Classification

Similar to the standard RNN, the softmax layer is added after the final hidden state F to classify the labels:

$$p = \text{softmax}(W_{\text{F}}F + b_F) \tag{17}$$

and the loss function is negative log-likelihood:

$$loss = -\sum \log p_{dj} \tag{18}$$

where d is each document of the dataset with label j.

2.5 Speed Advantage

The reason why SRNNs could be parallelized is that SRNNs improve the traditional connection structure. In SRNNs, not every current input is connected with its previous moment, but the entire sequence is connected together by a sliced method. SRNNs could also obtain the sequence order by the recurrent units in each subsequence, and transmit the information through multiple layers. We assume that the time spent in each recurrent unit is r, then the time spent in the standard RNN is:

$$t_{RNN} = T \times r \tag{19}$$

where T is the input sequence length. In the SRNN, each minimum subsequence could be parallelized, so the time spent on 0th layer is:

$$t_0 = (\frac{T}{n^k}) \times r \tag{20}$$

and similarly, the time spent on pth layer (not including 0th layer) is:

$$t_p = n \times r \tag{21}$$

so the total time in the SRNN is:

$$t_{SRNN} = (n \times k + \frac{T}{n^k}) \times r \tag{22}$$

At last we could compute the speed advantage of the SRNN:

$$R = \frac{t_{SRNN}}{t_{RNN}} = \frac{1}{n^k} + \frac{n \times k}{T} \tag{23}$$

where R is how much faster the SRNN gets. We could choose different n and k to get different speed advantage.

2.6 Relations between the SRNN and the Standard RNN

In this part we describe the relations between the SRNN and the standard RNN. In the standard RNN structure, each step is related to the input and the previous step, which could be computed by:

$$h_t = f(Ux_t + Wh_{t-1} + b) \tag{24}$$

where x is the input and h is the hidden state. The function f could be a nonlinear activation function such as sigmoid, or a linear activation function such as rectified linear units (Le et al., 2015). To simplify the question, here we discuss the case when we use a linear function:

$$f(x) = x \tag{25}$$

and we set the bias b and h_0 to be zero. When we use the standard RNN, we could get the last hidden state:

$$h_T = Ux_T + Wh_{T-1} = Ux_T + W(Ux_{T-1} + Wh_{T-2}) = ... = Ux_T + WUx_{T-1} + W^2Ux_{T-2} + ... + W^{T-1}Ux_1 \tag{26}$$

where T is the sequence length. And then we construct the SRNN structure. When $T = n^{k+1}$, we choose SRNN (n,k), which means slicing k times with the slice number n. The SRNN has k+1 layers, on each layer the length of each subsequence is n. We could compute the last hidden state of each minimum subsequence on 0th layer:

$$h_n^0 = U_0x_n + W_0U_0x_{n-1} + W_0^2U_0x_{n-2} + ... + W_0^{n-1}U_0x_1$$

$$h_{2n}^0 = U_0x_{2n} + W_0U_0x_{2n-1} + W_0^2U_0x_{2n-2} + ... + W_0^{n-1}U_0x_{n+1}$$

...

$$h_T^0 = U_0x_T + W_0U_0x_{T-1} + W_0^2U_0x_{T-2} + ... + W_0^{n-1}U_0x_{T-n+1} \tag{27}$$

where h_l^p is the number l hidden state on pth layer. There are n^k last hidden states on 0th layer. Similarly, we could take the hidden states on (p-1)th layer as the input, and compute the last hidden states of the subsequences on pth layer (p>0).

$$h_{n^{p+1}}^p = U_ph_{n^{p+1}}^{p-1} + W_pU_ph_{n^{p+1}-n^p}^{p-1} + W_p^2U_ph_{n^{p+1}-2n^p}^{p-1} + ... + W_p^{n-1}U_ph_{n^p}^{p-1}$$

$$h_{2n^{p+1}}^p = U_ph_{2n^{p+1}}^{p-1} + W_pU_ph_{2n^{p+1}-n^p}^{p-1} + W_p^2U_ph_{2n^{p+1}-2n^p}^{p-1} + ... + W_p^{n-1}U_ph_{n^{p+1}+n^p}^{p-1}$$

...

$$h_T^p = U_ph_T^{p-1} + W_pU_ph_{T-n^p}^{p-1} + W_p^2U_ph_{T-2n^p}^{p-1} + ... + W_p^{n-1}U_ph_{T-(n-1)n^p}^{p-1} \tag{28}$$

There are n^{k-p} last hidden states on pth layer. And this operation is repeated from 0th layer to kth layer. At last we get the final hidden state F of kth layer.

$$F = U_kh_T^{k-1} + W_kU_kh_{T-n^k}^{k-1} + W_k^2U_kh_{T-2n^k}^{k-1} + ... + W_k^{n-1}U_kh_{n^k}^{k-1} \tag{29}$$

When we compute equation (29) using each hidden state calculated by equation (27) and (28), we could get:

$$F = U_kU_{k-1}...U_0x_T + U_kU_{k-1}...W_0U_0x_{T-1} + U_kU_{k-1}...W_0^2U_0x_{T-2} + ... + W_k^{n-1}U_kW_{k-1}^{n-1}U_{k-1}...W_0^{n-1}U_0x_1 \tag{30}$$

When we compare equation (30) with equation (26), we could find that the two equations compute the same results when:

$$U_0 = U$$

$$U_k = U_{k-1} = \ldots = U_1 = I$$

$$W_k = W^{n^k} \tag{31}$$

where I is the identity matrix, U and W are the parameters in equation (26). This means that SRNNs could have the same output as standard RNNs when equation (31) is satisfied. For example, when $T = 4$, $k = 1$ and $n = 2$, we get a SRNN (2,1) with two layers and compare it with the standard RNN. The last hidden state of the standard RNN is:

$$h_4 = Ux_4 + WUx_3 + W^2Ux_2 + W^3Ux_1$$

In SRNN (2,1), the hidden states on 0th layer are:

$$h_2^0 = U_0x_2 + W_0U_0x_1$$

$$h_4^0 = U_0x_4 + W_0U_0x_3$$

and the final hidden state of 1st layer is:

$$F = U_1h_4^0 + W_1U_1h_2^0 = U_1U_0x_4 + U_1W_0U_0x_3 + W_1U_1U_0x_2 + W_1U_1W_0U_0x_1$$

When we use equation (31) to set $W_0 = W$, $W_1 = W^2$, $U_0 = U$ and $U_1 = I$, we could get:

$$F = Ux_4 + WUx_3 + W^2Ux_2 + W^3Ux_1$$

which is equal to h_4 above.

We have proved that when the function f is linear, the output of the SRNN is equal to the output of the standard RNN when the parameters satisfy equation (31), so the standard RNN is a special case of the SRNN. Furthermore, the SRNN may get high-level information when they have different parameters on different layers, so the SRNN is able to obtain more information from the input sequences than the standard RNN.

3 Experiments

3.1 Datasets

We evaluate SRNNs on six large-scale sentiment analysis datasets. Table 1 shows the information of the datasets. We choose 80% data for training, 10% for validation and 10% for testing.

Dataset	Classes	Documents	Max words	Average words	Vocabulary
Yelp 2013	5	468,608	1060	129.2	202,058
Yelp 2014	5	670,440	1053	116.1	210,353
Yelp 2015	5	897,835	1092	108.3	228,715
Yelp_P	2	598,000	1073	139.7	308,028
Amazon_F	5	3,650,000	441	82.7	1,274,916
Amazon_P	2	4,000,000	257	80.9	1,348,126

Table 1: Dataset information. Max words denotes the max sequence length, and Average words denotes the average length of the sentences in each dataset.

Yelp reviews: The Yelp reviews datasets are obtained from the Yelp Dataset Challenge, which has 5 sentiment labels (the higher, the better). This dataset consists of 4,736,892 documents, and we extract three subsets Yelp 2013, 2014, 2015 containing 468,608, 670,440 and 897,835 documents separately. Zhang et al. (2015) created the polarity dataset including 598,000 documents with two sentiment labels, and we obtain the polarity dataset from them.

Amazon reviews: The Amazon reviews dataset is a commentary dataset containing 34,686,770 reviews on 2,441,053 products from 6,643,669 users (He and McAuley, 2016). One review has a review title, a review content and a sentiment label, and we combine the title and content into one

document. The dataset is also constructed into a full dataset with 3,650,000 documents and a polarity dataset with 4,000,000 documents, which is also obtained from Zhang et al. (2015).

3.2 Baseline

We compare SRNNs with standard RNNs and take GRU as the recurrent unit. The output of the last hidden state is the representation of each document, and then we add a softmax layer on it to predict the sentiment labels. In order to compare SRNNs with convolutional structures, we also build a stack of dilated casual convolutional layers as a baseline, which is proposed in wavenet (Oord et al., 2016). The dilated casual convolutional structure could maintain the order information of the sequences. The dilation is 1, 2, 4, ... , 256 for Yelp datasets, and 1, 2, 4, ... , 128 for Amazon datasets. The number of filters is 50, and the activation function after each layer is rectified linear units.

3.3 Training

We use the sequence preprocessing tool of Keras (François et al, 2015) to pad sequences into the same length *T*. Sequences shorter than *T* are padded with zero at the end, and sequences longer than *T* are truncated. In this work, *T* is set to be 512 on Yelp datasets, and 256 on Amazon datasets. Different *n* and *k* values, which separately denotes the slice number and the slice times, are used on the experiments. For each dataset, we retain the top 30,000 words of the vocabulary. The pre-trained GloVe embeddings (Pennington et al., 2014) are utilized to initialize the word embeddings.

We set GRU as the recurrent unit of the SRNN. We have discussed the relations between the SRNN and the standard RNN in section 2.6 and have proved that the standard RNN is a special case of the SRNN when we use linear activation function between the recurrent units. However, it does not mean only linear activation function could be used in the SRNN. Both linear activation function such as hard sigmoid, and nonlinear activation function such as hyperbolic tangent could be used in or after each layer in the SRNN. In this paper, the recurrent activation function in GRU is sigmoid, and the activation function after each layer is linear function $f(x) = x$.

The dimension of GRU on each layer is set to be 50 and the word embedding dimension is 200. In SRNNs, the final state *F* also has 50 dimensions. We set the mini-batch size to be 100 for training and use Adam (Kingma and Ba, 2014) with $\alpha = 0.001$, $\beta_1 = 0.9$, $\beta_2 = 0.999$ and $\varepsilon = 10^{-8}$. We tune the hyper parameters on the validation set and select the best model to predict the sentiment labels on the test set. We train the models with an NVIDIA GTX 1080 GPU, and record the training time per epoch on each dataset.

3.4 Results and Analysis

The results on each dataset are shown on Table 2. We choose different *n* and *k* values and get different SRNNs. For example, SRNN (16,1) means *n*=16 and *k*=1, which could get a 32-length minimum subsequence when *T* is 512 or a 16-length minimum subsequence when *T* is 256. We compare four SRNNs with the standard RNN. For each dataset, we use bold words to label the highest-performing model and the fastest model.

Dataset	Model	Parameters	Validation	Test	Time/Epoch
Yelp 2013	GRU	5.76M	66.56	66.12	3172s
	SRNN (16,1)	5.77M	67.18	**67.03**	270s
	SRNN (8,2)	5.79M	67.11	66.80	**145s**
	SRNN (4,3)	5.80M	67.26	66.72	164s

	SRNN (8,2)	5.79M	95.21	95.18	**1309s**
	SRNN (4,3)	5.80M	95.12	95.12	1567s
	SRNN (2,7)	5.85M	94.98	95.02	1886s
	DCCNN	5.78M	94.72	94.69	448s

Table 2: The accuracy and training time on validation and test sets of the models on each dataset. Four different structures of SRNNs are constructed. DCCNN is dilated casual convolutional neural network, which is described in section 3.2.

The results show that SRNNs achieve better performance and attain much faster speeds than standard RNNs on all the datasets with few extra parameters. Different SRNNs have achieved the best performance on different datasets. SRNN (16,1) gets the highest accuracy on Yelp 2013, Yelp 2015, Amazon_F and Amazon_P; SRNN (8,2) performs best on Yelp 2014; SRNN (4,3) is the best on Yelp_P. SRNNs with k more than 1 could get nearly 15 times faster than standard RNNs on the Yelp datasets, and the speed advantage depends on k, n and T. In this work, SRNN (4,3) has the fastest speed on Yelp 2015, while SRNN (8,2) is the fastest on the rest (except DCCNN).

When we focus on the results of SRNN (2,8) on Yelp datasets and SRNN (2,7) on Amazon datasets, we could find that even if they did not achieve the best performance, they did not lose much accuracy. This means that SRNNs are able to transmit information through multiple layers, and because of this, SRNNs may achieve remarkable results when we train very long sequences. When n is 2, SRNN has the same number of layers as DCCNN, and it has much higher accuracy than DCCNN. So it means that the recurrent structure in SRNN is better than the dilated casual convolutional structure.

When we go back to equation (23), we may find that when n and k are not set to be too small, we could get much faster. In this work, we set $n = 8$, $k = q - 1$ when $T = 8^q$. We use an NVIDIA GTX 1080 GPU to train the models on 5120 documents, since the standard RNN would take too much time if we use more data. The training time is shown on Table 3.

We could get the amazing results from Table 3: the longer the sequence length is, the bigger speed advantage the SRNN achieves. When the sequence length is 32768, SRNN would take only 52s while the standard RNN would take nearly 2 hours. The SRNN is 136 times as fast as the standard RNN, and the speed advantage may be even bigger when longer sequences are used. Therefore, SRNNs may achieve much faster speeds on long-sequence tasks such as speech recognition, character-level text classification and language modeling.

Model	Sequence length		
	$8^3 = 512$	$8^4 = 4096$	$8^5 = 32768$
SRNN (8,2)	4s	-	-
SRNN (8,3)	-	9s	-
SRNN (8,4)	-	-	52s
GRU	54s	476s	7074s
Speed advantage	13.5x	52.9x	136.0x

Table 3: The training time and speed advantage on different sequence length. For each sequence length we choose a different SRNN structure.

3.5 Why SRNN

In this part we will discuss the advantages and importance of the SRNN. With the success of RNNs in many NLP tasks, many scholars have proposed different structures to increase the speed of RNNs. Most of the researches get faster by improving the recurrent units. However, the traditional connection structure has scarcely been questioned, in which each step is connected to its previous step. It is this connection structure that limits the speed of RNNs. The SRNN has improved the traditional connection method. Instead, a sliced structure is constructed to implement the parallelization of RNNs. The experimental results on six large-scale sentiment analysis datasets show that SRNNs achieve better performance than the standard RNN. The reasons are as follows:

(1) When we use the standard RNN connection structure, recurrent units with gated structures such as GRU and LSTM are useful, but they are not able to store all the important information when the sequences are very long. The SRNN, however, could divide the long sequence into many short subsequences and obtain the important information in short sequences. SRNNs are able to transmit the important information through the multiple-layers structure from 0th layer to the top layer.

(2) SRNNs have the ability to obtain high-level information from the sequences, instead of just the word-level information. When we use SRNN (8,2) in a document with 512 words, 0th layer may get the sentence-level information from the word embeddings, 1st layer may gain the paragraph-level information from the sentence-level information and 2nd layer could generate the final document-level representation from the paragraph-level information. The standard RNN, however, could only get the word-level information. Although it is impossible to have 8 paragraphs in each document, 8 sentences in each paragraph and 8 words in each sentence, the overall order information and structure information is uniform. Take the paragraph information as an example. People always express their opinions at the beginning or end of an article, and show examples in the middle of the article to explain their views. Compared to standard RNN, it is much easier for SRNNs to gain this information on the top layer.

(3) In terms of handling sequences, the SRNN is akin to the human brain mechanism. For example, if we, as humans, are given an article and asked to answer some questions about it, we usually do not need to read the whole article intensively. To answer the questions correctly, we try to locate the paragraph which mentions the specific information, and then find sentences and words in this paragraph that can answer the question. The SRNN could easily do this through multiple layers.

In addition to the improvement of accuracy, the most significant advantage of SRNNs is that SRNNs can be computed in parallel and achieve much faster speeds. Equation (23) computes the speed advantage of SRNN, and experiments of different sequence length also show that SRNNs could run much faster than standard RNNs. SRNNs could be even faster on longer sequences. As the Internet develops, hundreds of millions of data are generated every day, and SRNNs have devised new ways for us to handle these data.

4 Related Work

In order to increase the speed of RNNs, many scholars tried to improve the traditional RNN and achieved great results. Kim (2014), Kalchbrenner et al. (2014), and Gehring et al. (2017) tried to use CNNs in NLP tasks, which are usually used in computer vision (Lecun et al., 1998). Several structures get faster with the recurrent units changed (Greff et al., 2015; Balduzzi and Ghifary, 2016; Bradbury et al., 2017; Lei et al., 2017). As an overall structure improvement, the SRNN are related to these models,

because different types of recurrent units could be used in SRNNs. In this work we choose GRU (Cho et al., 2014), but other recurrent units are able to work in SRNNs as well.

The SRNN is related to the hierarchical structure proposed by Tang et al. (2015) and Yang et al. (2016). Tang et al. (2015) use CNN or LSTM to obtain the sentence representations, and then exploit gated RNN to generate the document representations. Yang et al. (2016) build a hierarchical network on both word-level and sentence-level, then use attention mechanism on both level. The difference between the SRNN and the hierarchical structure is that the documents do not need to be split into sentences when we use the SRNN, and the SRNN could have multiple layers. The hierarchical structure could be viewed as a special case of the SRNN, where k is 1 and all the sentences have equal length.

Several other architectures have been proposed to improve the connection structure of RNNs (Sutskever and Hinton, 2010; Koutnik et al., 2014; Chang et al., 2017). The SRNN is different from those architectures in the connection structure. The SRNN could be computed in parallel by slicing the sequences into many subsequences, but these models may still limit parallelization.

Also, the SRNN structure is similar to the overall structure of wavenet (Oord et al., 2016), which is used for audio generation. The difference between the SRNN and wavenet, which is also the most important innovation of the SRNN, is that we use recurrent units on each layer. For sequences, recurrent structure has its inherent advantages than convolutional structure.

5 Conclusion

In this paper we present the sliced recurrent neural network (SRNN), which is an overall structure improvement of RNN. The SRNN could reach a remarkably faster speed than the standard RNN and achieve better performance on six large-scale sentiment datasets.

6 Future Work

The SRNN has been successful in text classification. In future work, we hope to promote it to other NLP applications, such as question answering, text summarization, and machine translation. In sequence to sequence model, the SRNN can be used as the encoder, and the decoder may be improved by using an inverse SRNN structure. Also, we hope to use the SRNN in several long sequence tasks, such as language model, music generation and audio generation. And we want to explore more about variants of the SRNN. For example, bidirectional structure and attention mechanism could be added.

In section 2.6, we have discussed the relations between the SRNN and the standard RNN when choosing the linear activation function. In future work, we will try to research the situation of using nonlinear recurrent activation functions by mathematics, though it may be harder.

Abstract

We study three general multi-task learning (MTL) approaches on 11 sequence tagging tasks. Our extensive empirical results show that in about 50% of the cases, jointly learning all 11 tasks improves upon either independent or pairwise learning of the tasks. We also show that pairwise MTL can inform us what tasks can benefit others or what tasks can be benefited if they are learned jointly. In particular, we identify tasks that can always benefit others as well as tasks that can always be harmed by others. Interestingly, one of our MTL approaches yields embeddings of the tasks that reveal the natural clustering of semantic and syntactic tasks. Our inquiries have opened the doors to further utilization of MTL in NLP.

1 Introduction

Multi-task learning (MTL) has long been studied in the machine learning literature, cf. (Caruana, 1997). The technique has also been popular in NLP, for example, in (Collobert and Weston, 2008; Collobert et al., 2011; Luong et al., 2016). The main thesis underpinning MTL is that solving many tasks together provides a shared inductive bias that leads to more robust and generalizable systems. This is especially appealing for NLP as data for many tasks are scarce — shared learning thus reduces the amount of training data needed. MTL has been validated in recent work, mostly where auxiliary tasks are used to improve the performance on a target task, for example, in sequence tagging (Søgaard and Goldberg, 2016; Bjerva et al., 2016; Plank et al., 2016; Alonso and Plank, 2017; Bingel and Søgaard, 2017).

Despite those successful applications, several key issues about the effectiveness of MTL remain open. Firstly, with only a few exceptions, much existing work focuses on "pairwise" MTL where there is a target task and one or several (carefully) selected auxiliary tasks. However, *can jointly learning many tasks benefit all of them together*? A positive answer will significantly raise the utility of MTL. Secondly, *how are tasks related such that one could benefit another?* For instance, one plausible intuition is that syntactic and semantic tasks might benefit among their two separate groups though cross-group assistance is weak or unlikely. However, such notions have not been put to test thoroughly on a significant number of tasks.

In this paper, we address such questions. We investigate learning jointly multiple sequence tagging tasks. Besides using independent single-task learning as a baseline and a popular shared-encoder MTL framework for sequence tagging (Collobert et al., 2011), we propose two variants of MTL, where both the encoder and the decoder could be shared by all tasks.

We conduct extensive empirical studies on 11 sequence tagging tasks — we defer the discussion on why we select such tasks to a later section. We demonstrate that there is a benefit to moving beyond "pairwise" MTL. We also obtain interesting pairwise relationships that reveal which tasks are beneficial or harmful to others, and which tasks are likely to be benefited or harmed. We find such information correlated with the results of MTL using more than two tasks. We also study selecting only benefiting tasks for joint training, showing that such a "greedy" approach in general improves the MTL performance, highlighting the need of identifying with whom to jointly learn.

Proceedings of the 27th International Conference on Computational Linguistics, pages 2965–2977
Santa Fe, New Mexico, USA, August 20-26, 2018.

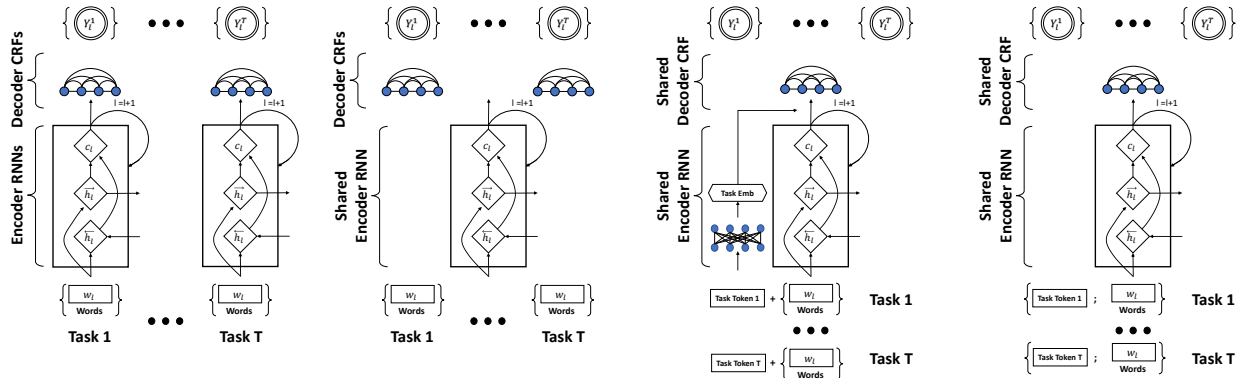
The rest of the paper is organized as follows. We describe different approaches for learning from multiple tasks in Sect. 2. We describe our experimental setup and results in Sect. 3 and Sect. 4, respectively. We discuss related work in Sect. 5. Finally, we conclude with discussion and future work in Sect. 6.

2 Multi-Task Learning for Sequence Tagging

In this section, we describe general approaches to multi-task learning (MTL) for sequence tagging. We select sequence tagging tasks for several reasons. Firstly, we want to concentrate on comparing the tasks themselves without being confounded by designing specialized MTL methods for solving complicated tasks. Sequence tagging tasks are done at the word level, allowing us to focus on simpler models while still enabling varying degrees of sharing among tasks. Secondly, those tasks are often the first steps in NLP pipelines that come with extremely diverse resources. Understanding the nature of the relationships between them is likely to have a broad impact on many downstream applications.

Let T be the number of tasks and $\boldsymbol{D}^t$ be training data of task $t \in \{1, \ldots, \mathsf{T}\}$. A dataset for each task consists of input-output pairs. In sequence tagging, each pair corresponds to a sequence of words $w_{1:\mathsf{L}}$ and their corresponding ground-truth tags $y_{1:\mathsf{L}}$, where L is the sequence length. We note that our definition of "task" is not the same as "domain" or "dataset." In particular, we differentiate between tasks based on whether or not they share the label space of tags. For instance, part-of-speech tagging on weblog and that on email domains are considered the same task in this paper.

Given the training data $\{\boldsymbol{D}^1, \ldots, \boldsymbol{D}^{\mathsf{T}}\}$, we describe how to learn one or more models to perform all the T tasks. In general, our models follow the design of state-of-the-art sequence taggers (Reimers and Gurevych, 2017). They have an encoder e with parameters θ that encodes a sequence of word tokens into a sequence of vectors and a decoder d with parameters ϕ that decodes the sequence of vectors into a sequence of predicted tags $\hat{y}_{1:\mathsf{L}}$. That is, $c_{1:\mathsf{L}} = e(w_{1:\mathsf{L}}; \theta)$ and $\hat{y}_{1:\mathsf{L}} = d(c_{1:\mathsf{L}}; \phi)$. The model parameters are learned by minimizing some loss function $\mathcal{L}(\hat{y}_{1:\mathsf{L}}, y_{1:\mathsf{L}})$ over θ and ϕ. In what follows, we will use superscripts to differentiate instances from different tasks.



Single-task learning | MTL (**MULTI-DEC**) | MTL (**TE⊕DEC**) | MTL (**TE⊕ENC**)

Figure 1: Different settings for learning from multiple tasks considered in our experiments

In **single-task learning (STL)**, we learn T models independently. For each task t, we have an encoder $e^t(\cdot; \theta^t)$ and a decoder $d^t(\cdot; \phi^t)$. Clearly, information is not shared between tasks in this case.

In **multi-task learning (MTL)**, we consider two or more tasks and train an MTL model *jointly* over a combined loss $\sum_t \mathcal{L}(\hat{y}^t_{1:\mathsf{L}}, y^t_{1:\mathsf{L}})$. In this paper, we consider the following general frameworks that are different in the nature of how the parameters of those tasks are shared.

Multi-task learning with multiple decoders (Multi-Dec) We learn a shared encoder $e(\cdot; \theta)$ and T decoders $\{d^t(\cdot; \theta^t)\}_{t=1}^{\mathsf{T}}$. This setting has been explored for sequence tagging in (Collobert and Weston, 2008; Collobert et al., 2011). In the context of sequence-to-sequence learning (Sutskever et al., 2014), this is similar to the "one-to-many" MTL setting in (Luong et al., 2016).

Multi-task learning with task embeddings (TE) We learn a shared encoder $e(\cdot; \theta)$ for the input sentence as well as a shared decoder $d(\cdot; \phi)$. To equip our model with the ability to perform one-to-many mapping (i.e., multiple tasks), we augment the model with "task embeddings." Specifically, we additionally learn

Dataset	# sentences	Token/type	Task	# labels	Label entropy

Table 1: Datasets used in our experiments, as well as their key characteristics and their corresponding tasks. / is used to separate statistics for training data only and those for all subsets of data.

a function $f(t)$ that maps a task ID t to a vector. We explore two ways of injecting task embeddings into models. In both cases, our f is simply an embedding layer that maps the task ID to a dense vector.

One approach, denoted by **TE⊕DEC**, is to incorporate task embeddings into the decoder. We concatenate the task embeddings with the encoder's outputs $c^t_{1:\mathsf{L}}$ and then feed the result to the decoder.

The other approach, denoted by **TE⊕ENC**, is to combine the task embeddings with the input sequence of words at the encoder. We implement this by prepending the task token (`<<upos>>`, `<<chunk>>`, `<<mwe>>`, etc.) to the input sequence and treat the task token as a word token (Johnson et al., 2017).

While the encoder in **TE⊕DEC** must learn to encode a general-purpose representation of the input sentence, the encoder in **TE⊕ENC** knows from the start which task it is going to perform.

Fig. 1 illustrates different settings described above. Clearly, the number of model parameters is reduced significantly when we move from STL to MTL. Which MTL model is more economical depends on several factors, including the number of tasks, the dimension of the encoder output, the general architecture of the decoder, the dimension of task embeddings, how to augment the system with task embeddings, and the degree of tagset overlap.

3 Experimental Setup

3.1 Datasets and Tasks

Table 1 summarizes the datasets used in our experiments, along with their corresponding tasks and important statistics. Table 2 shows an example of each task's input-output pairs. We describe details below. For all tasks, we use the standard splits unless specified otherwise.

We perform universal and English-specific POS tagging (UPOS and XPOS) on sentences from the English Web Treebank (Bies et al., 2012), annotated by the Universal Dependencies project (Nivre et al., 2016). We perform syntactic chunking (CHUNK) on sentences from the WSJ portion of the Penn Treebank (Marcus et al., 1993), annotated by the CoNLL-2000 shared task (Tjong Kim Sang and Buchholz, 2000). We use sections 15-18 for training. The shared task uses section 20 for testing and does not designate the development set, so we use the first 1001 sentences for development and the rest 1011 for testing. We perform named entity recognition (NER) on sentences from the Reuters Corpus (Lewis et al., 2004), consisting of news stories between August 1996-97, annotated by the CoNLL-2003 shared task (Tjong Kim Sang and De Meulder, 2003). For both CHUNK and NER, we use the IOBES tagging scheme.

We perform multi-word expression identification (MWE) and supersense tagging (SUPSENSE) on sentences from the reviews section of the English Web Treebank, annotated under the Streusle project (Schneider and Smith, 2015)[1]. We perform supersense (SEM) and semantic trait (SEMTR) tagging on SemCor's sentences (Landes et al., 1998), taken from a subset of the Brown Corpus (Francis and Kučera, 1982), using the splits provided by (Alonso and Plank, 2017) for both tasks[2]. For SEM, they are annotated with supersense tags (Miller et al., 1993) by (Ciaramita and Altun, 2006)[3]. For SEMTR, (Alonso and Plank, 2017) uses the EuroWordNet list of ontological types for senses (Vossen et al., 1998) to convert supersenses into coarser semantic traits.

[1] https://github.com/nert-gu/streusle

[2] https://github.com/bplank/multitasksemantics

[3] We consider SUPSENSE and SEM as different tasks as they use different sets of supersense tags.

Table 2: Examples of input-output pairs of the tasks in consideration

For sentence compression (COM), we identify which words to keep in a compressed version of sentences from the 1996 English Broadcast News Speech (HUB4) (Graff, 1997), created by (Clarke and Lapata, 2006)[4]. We use the labels from the first annotator. For frame target identification (FRAME), we detect words that evoke frames (Das et al., 2014) on sentences from the British National Corpus, annotated under the FrameNet project (Baker et al., 1998). For both COM and FRAME, we use the splits provided by (Bingel and Søgaard, 2017). For hyper-link detection (HYP), we identify which words in the sequence are marked with hyperlinks on text from Daniel Pipes' news-style blog collected by (Spitkovsky et al., 2010)[5]. We use the "select" subset that correspond to marked, complete sentences.

3.2 Metrics and Score Comparison

We use the span-based micro-averaged F1 score (without the O tag) for all tasks. We run each configuration three times with different initializations and compute mean and standard deviation of the scores. To compare two scores, we use the following strategy. Let μ_1, σ_1 and μ_2, σ_2 be two sets of scores (mean and std, respectively). We say that μ_1 is "higher" than μ_2 if $\mu_1 - k \times \sigma_1 > \mu_2 + k \times \sigma_2$, where k is a parameter that controls how strict we want the definition to be. "lower" is defined in the same manner with $>$ changed to $<$ and $-$ switched with $+$. k is set to 1.5 in all of our experiments.

3.3 Models

General architectures We use bidirectional recurrent neural networks (biRNNs) as our encoders for both words and characters (Irsoy and Cardie, 2014; Huang et al., 2015; Lample et al., 2016; Ma and Hovy, 2016). Our word/character sequence encoders and decoder classifiers are common in literature and most similar to (Lample et al., 2016), but we use two-layer biRNNs (instead of one) with Gated Recurrent Unit (GRU) (Cho et al., 2014) (instead of with LSTM (Hochreiter and Schmidhuber, 1997)).

Each word is represented by a 100-dimensional vector that is the concatenation of a 50-dimensional *embedding* vector and the 50-dimensional output of a *character* biRNN (whose hidden representation dimension is 25 in each direction). We feed a sequence of those 100-dimensional representations to a *word* biRNN, whose hidden representation dimension is 300 in each direction, resulting in a sequence of 600-dimensional vectors. In **TE⊕DEC**, the token encoder is also used to encode a task token (which is then concatenated to the encoder's output), where each task is represented as a 25-dimensional vector. For decoder/classifiers, we predict a sequence of tags using a linear projection layer (to the tagset size) followed by a conditional random field (CRF) (Lafferty et al., 2001).

Implementation and training details We implement our models in PyTorch (Paszke et al., 2017) on top of the AllenNLP library (Gardner et al., 2018). Code is to be available at https://github.

[4] http://jamesclarke.net/research/resources/

[5] https://nlp.stanford.edu/valentin/pubs/markup-data.tar.bz2

com/schangpi/.

Words are lower-cased, but characters are not. Word embeddings are initialized with GloVe (Pennington et al., 2014) trained on Wikipedia 2014 and Gigaword 5. We use strategies suggested by (Ma and Hovy, 2016) for initializing other parameters in our networks. Character embeddings are initialized uniformly in $[-\sqrt{3/d}, \sqrt{3/d}]$, where d is the dimension of the embeddings. Weight matrices are initialized with Xavier Uniform (Glorot and Bengio, 2010), i.e., uniformly in $[-\sqrt{6/(r+c)}, \sqrt{6/(r+c)}]$, where r and c are the number of of rows and columns in the structure. Bias vectors are initialized with zeros.

We use Adam (Kingma and Ba, 2015) with default hyperparameters and a mini-batch size of 32. The dropout rate is 0.25 for the character encoder and 0.5 for the word encoder. We use gradient normalization (Pascanu et al., 2013) with a threshold of 5. We halve the learning rate if the validation performance does not improve for two epochs, and stop training if the validation performance does not improve for 10 epochs. We use L2 regularization with parameter 0.01 for the transition matrix of the CRF.

For the training of MTL models, we make sure that each mini-batch is balanced; the difference in numbers of examples from any pair of tasks is no more than 1. As a result, each epoch may not go through all examples of some tasks whose training set sizes are large. In a similar manner, during validation, the average F1 score is over all tasks rather than over all validation examples.

3.4 Various Settings for Learning from Multiple Tasks

We consider the following settings: (i) "STL" where we train each model on one task alone; (ii) "Pairwise MTL" where we train on two tasks jointly; (iii) "All MTL" where we train on all tasks jointly; (iv) "Oracle MTL" where we train on the Oracle set of the testing task jointly with the testing task; (v) "All-but-one MTL" setting where we train on all tasks jointly except for one (as part of Sect. 4.4.)

Constructing the Oracle Set of a Testing Task The Oracle set of a task t is constructed from the pairwise performances: let $\mu(A,t), \sigma(A,t)$ be the F1 score and the standard deviation of a model that is jointly trained on a set of tasks in the set A and that is tested on task t. Task s is considered "beneficial" to another (testing) task t if $\mu(\{s,t\},t)$ is "higher" than $\mu(\{t\},t)$ (cf. Sect. 3.2). Then, the "Oracle" set for a task t is the set of its all beneficial (single) tasks. Throughout our experiments, we compute μ and σ by averaging over three rounds (cf. Sect. 3.2, standard deviations can be found on the arXiv version.)

4 Results and Analysis

4.1 Main Results

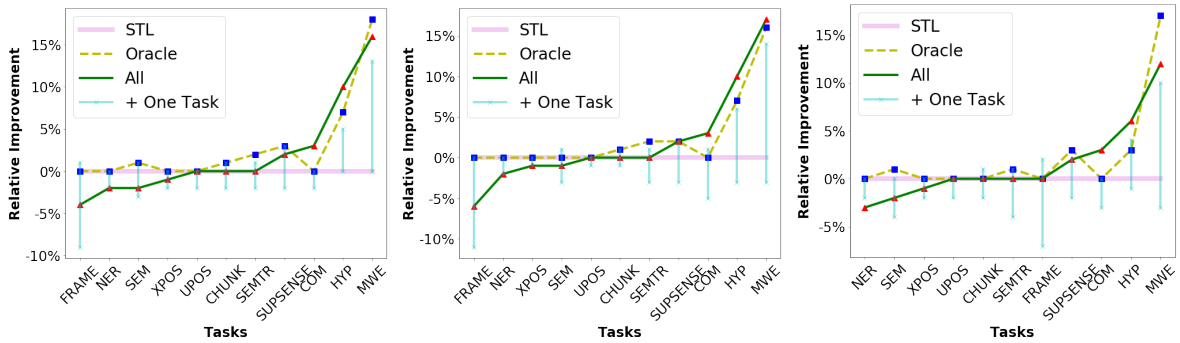

Figure 2: Summary of our results for MTL methods **MULTI-DEC** (left), **TE⊕DEC** (middle), and **TE⊕ENC** (right) on various settings with different types of sharing. The vertical axis is the relative improvement over STL. See texts for details. Best viewed in color.

Fig. 2 summarizes our main findings. We compare relative improvement over single-task learning (STL) between various settings with different types of sharing in Sect. 3.4. Scores from the pairwise setting ("+One Task") are represented as a vertical bar, delineating the maximum and minimum improvement over STL by jointly learning a task with one of the remaining 10 tasks. The "All" setting (red triangles) indicates the joint learning all 11 tasks. The "Oracle" setting (blue rectangles) indicates the joint learning using a subset of 11 tasks which are deemed beneficial, based on corresponding performances in pairwise MTL, as defined in Sect. 3.4.

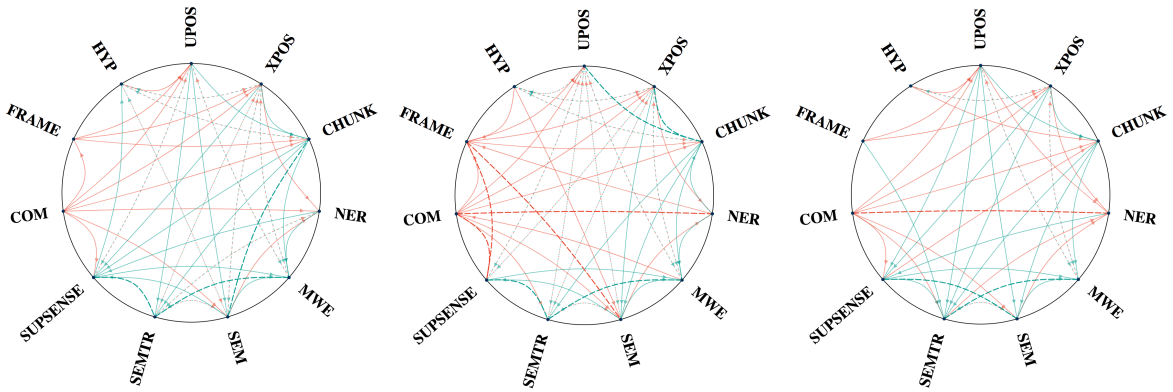

Figure 3: Pairwise MTL relationships (benefit vs. harm) using **MULTI-DEC** (left), **TE⊕DEC** (middle), and **TE⊕ENC** (right). **Solid** green (red) directed edge from s to t denotes s benefiting (harming) t. **Dashed** Green (Red) edges between s and t denote they benefiting (harming) *each other*. **Dotted** edges denote asymmetric relationship: benefit in one direction but harm in the reverse direction. Absence of edges denotes neutral relationships. *Best viewed in color and with a zoom-in.*

We observe that (1) [STL vs. Pairwise/All] Neither pairwise MTL nor All always improves upon STL; (2) [STL vs. Oracle] Oracle in general outperforms or at least does not worsen STL; (3) [All/Oracle vs. Pairwise] All does better than Pairwise on about half of the cases, while Oracle almost always does better than Pairwise; (4) [All vs. Oracle] Consider when both All and Oracle improve upon STL. For **MULTI-DEC** and **TE⊕ENC**, Oracle generally dominates All, except on the task HYP. For **TE⊕DEC**, their magnitudes of improvement are mostly comparable, except on SEMTR (Oracle is better) and on HYP (All is better). In addition, All is better than Oracle on the task COM, in which case Oracle is STL.

In the arXiv version, we compare different MTL approaches: **MULTI-DEC**, **TE⊕DEC**, and **TE⊕ENC**. There is no significant difference among them.

4.2 Pairwise MTL results

Summary The summary plot in Fig. 3 gives a bird's-eye view of patterns in which a task might benefit or harm another one. For example, MWE is always benefited from jointly learning any of the 10 tasks as the *incoming edges* are green, so is SEMTR in most cases. On the other end, COM seems to be harming any of the 10 as the *outgoing edges* are almost always red. For CHUNK and U/XPOS, it generally benefits others (or at least does not do harm) as most of their *outgoing* edges are green.

In Table 3-5, we report F1 scores for **MULTI-DEC**, **TE⊕DEC**, and **TE⊕ENC**, respectively. In each table, rows denote settings in which we train our models, and columns correspond to tasks we test them on. We also include "Average" of all pairwise scores, as well as the number of positive (↑) and negative (↓) relationships in each row or each column.

Which tasks are benefited or harmed by others in pairwise MTL? MWE, SUPSENSE, SEMTR, and HYP are generally benefited by other tasks. The improvement is more significant in MWE and HYP. UPOS, XPOS, NER, COM, and FRAME (**MULTI-DEC** and **TE⊕DEC**) are often hurt by other tasks. Finally, the results are mixed for CHUNK and SEM.

Which tasks are beneficial or harmful? UPOS, XPOS, and CHUNK are universal helpers, beneficial in 16, 17, and 14 cases, while harmful only in 1, 3, and 0 cases, respectively. Interestingly, CHUNK never hurts any task, while both UPOS and XPOS can be harmful to NER. While CHUNK is considered more of a syntactic task, the fact that it informs other tasks about the boundaries of phrases may aid the learning of other semantic tasks (task embeddings in Sect. 4.4 seem to support this hypothesis).

On the other hand, COM, FRAME, and HYP are generally harmful, all useful in 0 cases and causing the performance drop in 22, 10, 12 cases, respectively. One factor that may play a role is the training set sizes of these tasks. However, we note that both MWE and SUPSENSE (Streusle dataset) has smaller training set sizes than FRAME does, but those tasks can still benefit some tasks. (On the other hand, NER has the largest training set, but infrequently benefits other tasks, less frequently than SUPSENSE does.) Another potential cause is the fact that all those harmful tasks have the smallest label size of 2. This combined with small dataset sizes leads to a higher chance of overfitting. Finally, it may be possible that harmful

tasks are simply unrelated; for example, the nature of COM, FRAME, or HYP may be very different from other tasks — an entirely different kind of reasoning is required.

Finally, NER, MWE, SEM, SEMTR, and SUPSENSE can be beneficial or harmful, depending on which other tasks they are trained with.

4.3 All MTL Results

In addition to pairwise MTL results, we report the performances in the All and Oracle MTL settings in the last two rows of Table 3-5. We find that their performances depend largely on the trend in their corresponding pairwise MTL. We provide examples and discussion of such observations below.

How much is STL vs. Pairwise MTL predictive of STL vs. All MTL? We find that the performance of pairwise MTL is predictive of the performance of All MTL to some degree. Below we discuss the results in more detail. Note that we would like to be predictive in both the performance direction and magnitude (whether and how much the scores will improve or degrade over the baseline).

When pairwise MTL improves upon STL even slightly, All improves upon STL in all cases (MWE, SEMTR, SUPSENSE, and HYP). This is despite the fact that jointly learning some pairs of tasks lead to performance degradation (COM and FRAME in the case of SUPSENSE and COM in the case of SEMTR). Furthermore, when pairwise MTL leads to improvement in all cases (all pairwise rows in MWE and HYP), All MTL will achieve even better performance, suggesting that tasks are beneficial in a complementary manner and there is an advantage of MTL beyond two tasks.

The opposite is almost true. When pairwise MTL does not improve upon STL, most of the time All MTL will not improve upon STL, either — with one exception: COM. Specifically, the pairwise MTL performances of UPOS, XPOS, NER and FRAME (**TE⊕DEC**) are mostly negative and so are their All

Table 6: F1 scores for **MULTI-DEC**. We compare All with All-but-one settings (All - ⟨TASK⟩). We test on each task in the columns. Beneficial settings are in green. Harmful setting are in red.

MTL performances. Furthermore, tasks can also be harmful in a complementary manner. For instance, in the case of NER, All MTL achieves the lowest or the second lowest score when compared to any row of the pairwise MTL settings. In addition, SEM's pairwise MTL performances are mixed, making the average score about the same or slightly worse than STL. However, the performance of All MTL when tested on SEM almost achieves the lowest. In other words, SEM is harmed more than it is benefited but pairwise MTL performances cannot tell. This suggests that harmful tasks are complementary while beneficial tasks are not.

Our results when *tested on* COM *are the most surprising*. While none of pairwise MTL settings help (with some hurting), the performance of All MTL goes in the opposite direction, outperforming that of STL. Further characterization of task interaction is needed to reveal why this happens. One hypothesis is that instances in COM that are benefited by one task may be harmed by another. The joint training of all tasks thus works because tasks *regularize* each other.

We believe that our results open the doors to other interesting research questions. While the pairwise MTL performance is somewhat predictive of the performance direction of All MTL (except COM), the magnitude of that direction is difficult to predict. It is clear that additional factors beyond pairwise performance contribute to the success or failure of the All MTL setting. It would be useful to automatically identify these factors or design a metric to capture that. There have been initial attempts along this research direction in (Alonso and Plank, 2017; Bingel and Søgaard, 2017; Bjerva, 2017), in which manually-defined task characteristics are found to be predictive of *pairwise* MTL's failure or success.

Oracle MTL Recall that a task has an "Oracle" set when the task is benefited from some other tasks according to its pairwise results (cf. Sect. 3.4). In general, our simple heuristic works well. Out of 20 cases where Oracle MTL performances exist, 16 are better than the performance of All MTL. In SEM, UPOS and XPOS (**TE⊕DEC**, Oracle MTL is able to reverse the negative results obtained by All MTL to the positive ones, leading to improved scores over STL in all cases. This suggests that pairwise MTL performances are valuable knowledge if we want to go beyond two tasks. But, as mentioned previously,

pairwise performance information fails in the case of COM; All MTL leads to improvement but we do not have an Oracle set in this case.

Out of 4 cases where Oracle MTL does not improve upon All MTL, 3 is when we test on HYP and one is when we test on MWE. These two tasks are not harmed by any tasks. This result seems to suggest that sometimes "neutral" tasks can help in MTL (but not always, for example, in **MULTI-DEC** and **TE⊕ENC** of MWE). This also raises the question of whether there is a more effective way to construct an oracle set.

4.4 Analysis

Task Contribution in All MTL How much does one particular task contribute to the performance of All MTL? To investigate this, we remove one task at a time and train the rest jointly. Results are shown in Table 6 for the method **MULTI-DEC**– results for other two methods are in the arXiv version as they are similar to **MULTI-DEC** qualitatively. We find that UPOS, SEM and SEMTR are in general sensitive to a task being removed from All MTL. Moreover, at least one task significantly contributes to the success of All MTL at some point; if we remove it, the performance will drop. On the other hand, COM generally negatively affects the performance of All MTL as removing it often leads to performance improvement.

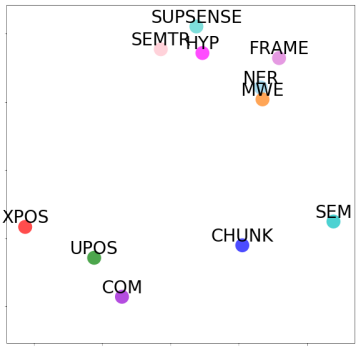

Figure 4: t-SNE visualization of the embeddings of the 11 tasks that are learned from **TE⊕DEC**

Task Embeddings Fig. 4 shows t-SNE visualization (Van der Maaten and Hinton, 2008) of task embeddings learned from **TE⊕DEC**[6] in the All MTL setting. The learned task embeddings reflect our knowledge about similarities between tasks, where there are clusters of syntactic and semantic tasks. We also learn that sentence compression (COM) is more syntactic, whereas multi-word expression identification (MWE) and hyper-text detection (HYP) are more semantic. Interestingly, CHUNK seems to be in between, which may explain why it never harms any tasks in any settings (cf. Sect. 4.2).

In general, it is not obvious how to translate task similarities derived from task embeddings into something indicative of MTL performance. While our task embeddings could be considered as "task characteristics" vectors, they are not guaranteed to be interpretable. We thus leave a thorough investigation of information captured by task embeddings to future work.

Nevertheless, we observe that task embeddings disentangle "sentences/tags" and "actual task" to some degree. For instance, if we consider the locations of each pair of tasks that use the same set of sentences for training in Fig. 4, we see that SEM and SEMTR (or MWE and SUPSENSE) are not neighbors, while XPOS and UPOS are. On the other hand, MWE and NER are neighbors, even though their label set size and entropy are not the closest. These observations suggest that hand-designed task features used in (Bingel and Søgaard, 2017) may not be the most informative characterization for predicting MTL performance.

5 Related Work

For a comprehensive overview of MTL in NLP, see Chapter 20 of (Goldberg, 2017) and (Ruder, 2017). Here we highlight those which are mostly relevant.

[6]We observed that task embeddings learned from **TE⊕ENC** are not consistent across multiple runs.

MTL for NLP has been popular since a unified architecture was proposed by (Collobert and Weston, 2008; Collobert et al., 2011). As for sequence to sequence learning (Sutskever et al., 2014), general multi-task learning frameworks are explored by (Luong et al., 2016).

Our work is different from existing work in several aspects. First, the majority of the work focuses on two tasks, often with one being the main task and the other being the auxiliary one (Søgaard and Goldberg, 2016; Bjerva et al., 2016; Plank et al., 2016; Alonso and Plank, 2017; Bingel and Søgaard, 2017). For example, POS is the auxiliary task in (Søgaard and Goldberg, 2016) while CHUNK, CCG supertagging (CCG) (Clark, 2002), NER, SEM, or MWE+SUPSENSE is the main one. They find that POS benefits CHUNK and CCG. Another line of work considers language modeling as the auxiliary objective (Godwin et al., 2016; Rei, 2017; Liu et al., 2018). Besides sequence tagging, some work considers two high-level tasks or one high-level task with another lower-level one. Examples are dependency parsing (DEP) with POS (Zhang and Weiss, 2016), with MWE (Constant and Nivre, 2016), or with semantic role labeling (SRL) (Shi et al., 2016); machine translation (TRANSLATE) with POS or DEP (Niehues and Cho, 2017; Eriguchi et al., 2017); sentence extraction and COM (Martins and Smith, 2009; Berg-Kirkpatrick et al., 2011; Almeida and Martins, 2013).

Exceptions to this include the work of (Collobert et al., 2011), which considers four tasks: POS, CHUNK, NER, and SRL; (Raganato et al., 2017), which considers three: word sense disambiguation with POS and coarse-grained semantic tagging based on WordNet lexicographer files; (Hashimoto et al., 2017), which considers five: POS, CHUNK, DEP, semantic relatedness, and textual entailment; (Niehues and Cho, 2017; Kiperwasser and Ballesteros, 2018), which both consider three: TRANSLATE with POS and NER, and TRANSLATE with POS and DEP, respectively. We consider as many as 11 tasks jointly.

Second, we choose to focus on model architectures that are generic enough to be shared by many tasks. Our structure is similar to (Collobert et al., 2011), but we also explore frameworks related to task embeddings and propose two variants. In contrast, recent work considers stacked architectures (mostly for sequence tagging) in which tasks can supervise at different layers of a network (Søgaard and Goldberg, 2016; Klerke et al., 2016; Plank et al., 2016; Alonso and Plank, 2017; Bingel and Søgaard, 2017; Hashimoto et al., 2017). More complicated structures require more sophisticated MTL methods when the number of tasks grows and thus prevent us from concentrating on analyzing relationships among tasks. For this reason, we leave MTL for complicated models for future work.

The purpose of our study is relevant to but different from transfer learning, where the setting designates one or more target tasks and focuses on whether the target tasks can be learned more effectively from the source tasks; see e.g., (Mou et al., 2016; Yang et al., 2017).

6 Discussion and Future Work

We conduct an empirical study on MTL for sequence tagging, which so far has been mostly studied with two or a few tasks. We also propose two alternative frameworks that augment taggers with task embeddings. Our results provide insights regarding task relatedness and show benefits of the MTL approaches. Nevertheless, we believe that our work simply scratches the surface of MTL. The characterization of task relationships seems to go beyond the performances of pairwise MTL training or similarities of their task embeddings. We are also interested in exploring further other techniques to MTL, especially when tasks become more complicated. For example, it is not clear how to best represent task specification as well as how to incorporate them into NLP systems. Finally, the definition of tasks can be relaxed to include domains or languages. Combining all these will move us toward the goal of having a *single* robust, generalizable NLP agent that is equipped with a diverse set of skills.

Abstract

K-fold cross validation (CV) is a popular method for estimating the true performance of machine learning models, allowing model selection and parameter tuning. However, the very process of CV requires random partitioning of the data and so our performance estimates are in fact stochastic, with variability that can be substantial for natural language processing tasks. We demonstrate that these unstable estimates cannot be relied upon for effective parameter tuning. The resulting tuned parameters are highly sensitive to how our data is partitioned, meaning that we often select sub-optimal parameter choices and have serious reproducibility issues.

Instead, we propose to use the less variable J-K-fold CV, in which J independent K-fold cross validations are used to assess performance. Our main contributions are extending J-K-fold CV from performance estimation to parameter tuning and investigating how to choose J and K. We argue that variability is more important than bias for effective tuning and so advocate lower choices of K than are typically seen in the NLP literature, instead use the saved computation to increase J. To demonstrate the generality of our recommendations we investigate a wide range of case-studies: sentiment classification (both general and target-specific), part-of-speech tagging and document classification.

1 Motivation

In recent years, the main focus of the machine learning community has been on model performance. We cannot, however, hope to improve our model's predictive strength without being able to confidently identify small (but genuine) improvements in performance. We require an accurate measurement of how well our model will perform once in practical use, known as prediction or generalisation error; the model's ability to generalise from its training set (see Friedman et al (2001) for an in depth discussion). The accurate estimation of model performance is crucial for selecting between models and choosing optimal model parameters (tuning).

Estimating prediction error on the same data used to train a model can lead to severe under-estimation of the prediction error and is unwise. Simple alternatives use a random splitting of data into training and testing sets, or training, validation and testing sets, with the model trained using the training set, tuned on the validation set and performance on the testing set used to report the quality of the fitted model. More sophisticated approaches are based on re-sampling and make more efficient use of the data; including bootstrapping (Efron and Tibshirani, 1994) and K-fold cross validation (CV) (Kohavi, 1995). Since bootstrapping has prohibitive computational cost and is prone to underestimating prediction error, the machine learning community have coalesced around CV as the default method of estimating prediction error. For a snapshot into prediction error techniques currently used in NLP, we look at the proceedings from COLING 2016, focusing on papers that include estimation of model performance. While some submissions use the more sophisticated K-fold CV, the majority use a single data split. Between those that use K-fold CV, 19 use 10-fold, 14 use 5-fold and a further 2 use 3-fold.

(a) Prediction error estimates based on leaving $\frac{1}{K}$ of the data for testing

(b) Prediction error estimates based on K-fold CV for different choices of K

Figure 1: The substantial variability in performance estimates for IMDB sentiment classification. The horizontal line represents the true performance of the model. Each box-plot summarises 1,000 estimations of prediction error based on a different random shuffle of our $1,000$ reviews.

Each of these estimation methods involves making one or more random partitions of the data. This partitioning means the estimated prediction error is a random quantity, even when conditioned on the data available to the algorithm. This random splitting of the data leads to variation in our prediction estimates, which we define as internal variability. Although this internal variability has been discussed before (Jiang and Wang, 2017; Rodriguez et al., 2010; Bengio and Grandvalet, 2004), it is poorly understood for which datasets and models this is a problem. Note that we are referring to variation between separate estimations by K-fold CV and not variability between the K prediction error estimates that make up a single round of K-fold CV. The estimates are also biased (with their expected value not equal to the truth). Since the model is only trained on a subset it cannot achieve as high performance as if it had access to all the data. Zhang and Yang (2015) argue that evaluating performance, model selection and parameter tuning have distinct requirements in terms of the bias and variance of our estimators. In particular, as long as bias is approximately constant across different models/parameters, it will have little effect on the selected model. However, variability is critical. If our estimates have variance that swamps the real differences in model performance, we cannot tell the difference between genuinely superior parameters and noise. Reducing the internal variance of cross-validation is the main focus of this paper.

To motivate the need for the paper and demonstrate the typical size of this variability, we now introduce a simple NLP task; classifying the sentiment of IMDB movie reviews using a random forest (described in detail in Section 2). Figure 1 shows that for K-fold CV and, to an even greater extent single train-test splits, the prediction error estimates have variability substantially larger than performance differences (less than 1% accuracy improvements between models) identified using the same prediction error estimation methods at COLING 2016. Without analysing the variability of each prediction error estimate it is impossible to say whether we have a genuinely improved model or are just looking at noise. Just because one model outperforms another by a small amount on a particular data-split there is no guarantee that it is genuinely superior and, by changing the partitioning, we may in fact see the opposite. Despite the potentially large variability of the performance estimate, it is common to ignore the stochasticity and just use the results from a single partitioning. The following arguments and experiments are all with respect to the internal variability of K-fold CV. However, as single train-test splits produce less stable prediction error estimates, our arguments are still valid for single data-splits but to an even greater degree.

In the machine learning literature the usual method for reducing the internal variability of prediction error estimates is stratification (Kohavi, 1995), used five times at COLING 2016. This keeps the proportions of classes constant across partitioning and so forces each partition to be more representative of the whole data. Stratification reduces variability due to unbalanced classes. However, as demonstrated in

Figure 1, NLP tasks still suffer from large variability even when the classification classes are perfectly balanced. For natural language, representativity is a much more complicated concept than just matching class proportions. Although having been discussed in the corpus linguistics literature (Biber, 1993), representativity remains a sufficiently abstract task to not have a clear definition that can be used in NLP. We wish to split our data in a way that avoids under-representing the diversity and variability seen in the whole data, however, complicated structural properties like discourse and syntactic rules make it very difficult to measure this variability.

We present, to the best of the authors' knowledge, the first investigation into prediction error variability specifically for NLP and the first in the machine learning literature to investigate the effect of this variability on parameter tuning, questioning both reproducibility and the ability to reliably select the best parameter value. We argue that variability in our prediction error estimates is often significantly larger than the small performance gains searched for by the NLP community, so these estimates are unsuitable for model selection and parameter tuning (Section 2). We instead propose using repeated K-fold CV (Kohavi, 1995) to reduce this variability (Section 3). This is not a new idea, yet has failed to be taken up by the NLP community. Repeated CV was used only twice at COLING 2016 and both times only used for improving the stability of prediction error estimates for a chosen model: 10 repetitions of 10-fold CV by Bhatia (2016) and 2 repetitions of 5-fold CV by Collel (2016). Our main contribution is to extend this method to parameter tuning, alongside investigating guidelines for choosing the number of repetitions and K. Finally, we demonstrate that stable prediction error estimates lead to more effective parameter tuning across a wide range of typical NLP tasks (Section 4).

2 Current Practice: Tuning by K-fold CV

K-fold CV consists of averaging the prediction estimates of K train-test splits, specifically chosen such that each data point is only used in a single test set (for more information see Kohavi (1995)). The data is randomly split into K folds of roughly equal size (known as partitioning the data) before each fold is held out to evaluate a model trained on the remaining $K-1$ folds. Increasing K improves stability by averaging over more models. However, each evaluation is performed on a smaller subset of the available data and so the evaluations themselves become less stable. The combination of these competing variabilities makes up the total internal variance which, as confirmed by Figure 1, is nevertheless smaller than with single train-test splits. If we have enough data that using $1/K^{th}$ of the data still provides stable evaluations then we can see a reduction in internal variability as we increase K. However, this is not a general statement (Bengio and Grandvalet, 2004), as we will demonstrate in Section 4. It is common to choose $K = 5$ or $K = 10$, based on a study by Kohavi (1995) where empirical evidence is presented for these choices producing a reasonable trade-off between bias and variance for some specific statistical examples. We will see that the optimal choice of K is problem-specific so there is no guarantee that Kohavi's studies are comparable to modern NLP tasks. As K-fold CV requires the training of K models, there is a clear incentive to choose the smallest suitable value of K. This idea is developed in Section 3.

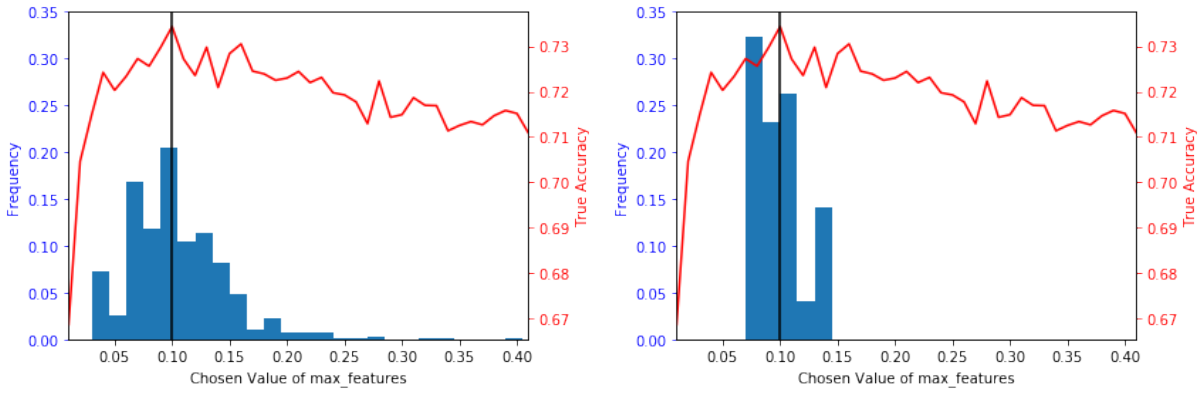
In this paper, we consider an exhaustive method used to tune parameters; grid search. Here we calculate K-fold CV performance estimation across a set of possible parameter values (our grid) and select the value that gives us the best estimated performance. Other popular tuning procedures from the machine learning literature include random search (Bergstra and Bengio, 2012) and Bayesian optimisation (Snoek et al., 2012). Grid search is often not the most efficient approach as it scales poorly with dimensionality. However, its simplicity and interpretability means that it is the standard tuner in NLP and a simple scenario for clearly demonstrating the impact of internal variability on the effectiveness of parameter tuning. Note that all tuning procedures rely on individual prediction error estimates, so our analysis of the problems of grid search is indicative of similar problems with more sophisticated tuning procedures.

To demonstrate the unsuitability of K-fold CV for tuning a typical NLP task, we train a sentiment classifier on a bag-of-word features model using a random forest (Breiman, 2001), a common set-up in the NLP literature (Gokulakrishnan et al., 2012; Da Silva et al., 2014; Fang and Zhan, 2015). We use a large corpus of $25,000$ positive and $25,000$ negative IMDB movie reviews (originally used to train word

embeddings (Maas et al., 2011)) and randomly choose a fixed $1,000$ to act as our training set (on which we need to train and tune our model). The purpose of this contrived task is simply to demonstrate the variability that can result from the random partitioning in K-fold CV. Thus "true performance", consists of the global score on the held-out reviews. We acknowledge that the exact scores depend on which $1,000$ reviews are used for training, so should not be taken as the ground truth. They do, however, allow us to roughly quantify the sub-optimality of our tuned parameters and so measure the effectiveness of different tuning procedures. Even without these scores, the variability of the tuned parameter values raises concerns regarding reproducibility (as decisions cannot be reproduced without exact knowledge of the partitioning).

Using Python's [1] random forest implementation, we consider tuning the maximum proportion of features ($max\_features$) considered at a single time by our model; a parameter whose accurate tuning is crucial to prevent over-fitting. We initially focus on $K = 5$, as Figure 1 shows a lack of significantly improved bias or variance for the increased computational cost of higher K. For each of 1,000 random 5-fold partitions of our training set, we estimate the performance for each parameter value in the set $\{0.01, 0.02, ..., 0.5\}$ and choose the value that gives us the best performance estimate. Aside from maximum depth and number of trees, which we set to 4 and 100 respectively, we keep all other parameters as their SKLEARN defaults. We limit ourselves to the 300 features with the highest tf-idf score (Salton and Buckley, 1988). Note that random forests are stochastic, with a sub-sampling step used to fit the individual tree classifiers. However, as this additional variation cannot be fixed between successive performance estimates (with the sampling being dependent on how our data is partitioned) this should be considered as part of the internal variability.

Figure 2(a) shows that partitioning can have a large effect on the chosen parameter, leading to choices of $max\_features$ across the wide range of 0.03 to 0.4 (almost covering the whole search space). This variability means that our tuning procedure is often failing to choose the parameter that gives the best global performance and so produces sub-optimal models. Depending on the initial partitioning, our tuning procedure can lead to tuned models with global performance varying from 71% to 73.5% accuracy. In Section 4, we will see that the variability is even larger when tuning multiple parameters at once.



(a) Tuning of $max\_features$ by 5-fold CV.

(b) Tuning of $max\_features$ by 10-5-fold CV.

Figure 2: Distribution of our chosen $max\_features$ across $1,000$ random data partitions. We compare the industry standard (a) with our proposed solution (b). The global performance of a model for a given value of $max\_features$ is superimposed in red, with the global optimal choice represented by the vertical line.

3 Proposed Approach: Tuning By Repeated J-K-fold Cross Validation

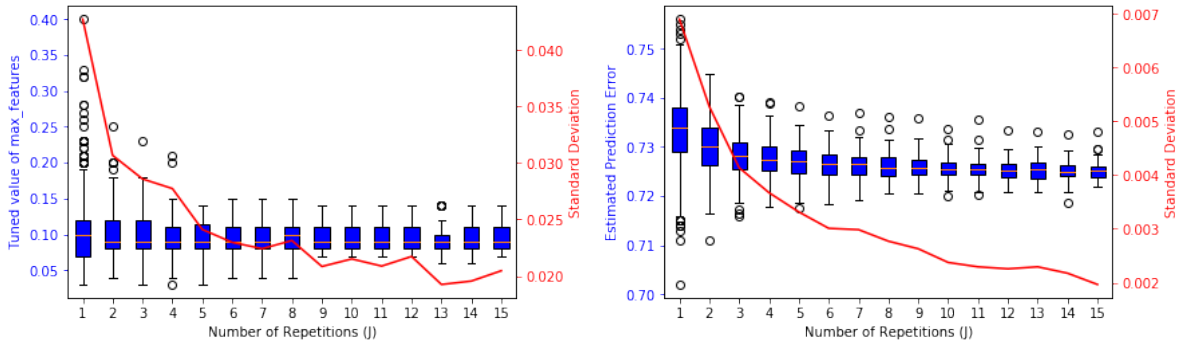
Unfortunately, only considering a single partitioning cannot give us information about the amount of variability present in our performance estimates. To produce Figure 2, we had to look at the tuned model resulting from $1,000$ different partition choices. This observation motivates the use of repeated K-fold

[1] http://scikit-learn.org/stable/index.html

CV, also known as J-K-fold CV; averaging the K-fold CV estimate from J different partition choices. It has been shown empirically that repeated CV reduces internal variability and so stabilises prediction error (Chen et al., 2012; Vanwinckelen and Blockeel, 2015; Jiang and Wang, 2017), especially for smaller datasets (Rodriguez et al., 2010). These authors, however, only investigate the use of J-K-fold CV to reduce the variability of individual performance estimates and do not consider its use for tuning.

We propose the following novel extension to grid search, which extends the improved stability of J-K-fold CV to parameter tuning. For each of J random partitionings, we calculate a K-fold CV estimate for every parameter choice on our grid. The average over these partitions produces performance estimates for each parameter choice and we choose the parameter value that maximises these stable estimates of prediction error. For the rest of the paper we will refer to this procedure as tuning by J-K-fold CV. We believe that using J-K-fold CV will also improve the effectiveness of the more sophisticated parameter tuning procedures, however, this requires further investigation.

Returning to our IMDB example, Figure 2(b) shows that using information from multiple partitioning choices greatly reduces variability in the chosen parameter value, with standard deviation dropping from 0.0427 to 0.0221 when tuning by 10-5-fold CV (Figure 2(b)) instead of vanilla 5-fold CV (Figure 2(a)). This corresponds to the worse performing tuned model over 1,000 random partition choices improving from 71.3% to 72.1% accuracy. We also see a significant reduction in the standard deviation of our performance estimate of the tuned model from 0.700% to 0.233%, greatly improving our ability to discern between closely performing models.



(a) Variability of the tuned $max\_features$ value.

(b) Variability of the performance estimate for the tuned model.

Figure 3: Diminishing reductions in variance as we increase the number of repetitions J for tuning by J-5-fold CV. As before, for each value of J we retune our model over $1,000$ different random partitioning.

	SD of chosen $max\_features$ value	Range of chosen $max\_features$ value	SD of the accuracy estimate of tuned model
1-10-fold CV	0.0396	0.03-0.38	0.550 %
2-5-fold CV	0.0307	0.04-0.25	0.528 %
1-20-fold CV	0.0337	0.03-0.24	0.483 %
2-10-fold CV	0.0301	0.03-0.23	0.400 %
4-5-fold CV	0.0278	0.03-0.21	0.367 %

Table 1: Standard deviation (SD) performance of J-K-fold tuning on the IMDB dataset over $1,000$ different partitions (3 s.f).

We now discuss how to choose the values of J and K in terms of computational cost and effective tuning, a concept we define as selecting near-optimal parameter values irrespective of how the data is partitioned. At a first approximation the cost of J-K-fold CV is proportional to $J * K$ (the number of models trained and evaluated). If, as is the case for sophisticated models, training and evaluation costs are more than linear in the amount of data, then the computational cost grows faster in K, but are still linear in J. So for fixed computational resources we have a trade-off between increasing either J or K.

First, consider increasing K. As previously mentioned there is no clear general relationship between K and the internal variability of K-fold CV. As long as $K \geq 3$ (to guarantee overlapping training sets), we can have comparable variance across K (see Section 4). This means that the only reliable reason to increase K is to reduce bias, however, there is no clear argument for how the bias of each individual performance estimate relates directly to bias in our tuning procedure (the difference between the expected value of our tuned parameter and the true optimal parameter choice). As long as the bias of the estimate for each parameter choice is roughly constant across the parameter grid, then we would expect this bias to have a limited effect on our tuned parameter value (as is assumed for tuning by vanilla K-fold CV). A further research interest is to investigate exactly when this assumption is violated and the effect that this can have on the effectiveness of parameter tuning.

In contrast, increasing J has no effect on bias but does significantly reduce the internal variability. For fixed data, the estimations from each repetition are independent and identically distributed, so prediction error estimates from vanilla K-fold CV have J times as much variability as J-K-fold CV but the same bias. Figure 3 demonstrates that we see similar variance reduction returns in the choice from tuning and also the performance estimate of the tuned model as we increase J. This means we can access the largest drops in variability within the first few repetitions (Kim, 2009).

We can therefore consider our choices of K and J in isolation. K is increased to reduce bias whereas J reduces the internal variability. We commented earlier that effective parameter tuning is more sensitive to variance than bias. This is confirmed by our IMDB task, where we see that although the tuned value from 5-fold CV has a mean close to the best performing parameter choice (calculated for our held-out $49,000$ reviews), the tuned value has significant variability. Sub-optimal tuning is a consequence of this large variance, which overshadows any potential problems from the bias. Therefore we first need to reduce internal variability before our tuning can benefit from reduced bias.

Table 1 summarises the tuning performance of five different J and K choices. We see that between 1-10-fold CV and 2-5-fold CV, and between 2-10-fold, 4-5-fold and 1-20-fold (choices of equivalent computational cost), we have the least variability when reducing K and using the saved computation for increasing J. Note that the naive approach of using all available computation to increase K (1-20-fold CV) produces a wider range of parameter choices than 2-10-fold and 4-5-fold CV. This is despite any bias reductions from choosing a higher K and so we do not recommend 1-$J * K$-fold CV. This analysis questions the rule of thumb selection of $K = 10$ common in NLP, as 2-5 CV seems to produce superior tuning at the same cost, a hypothesis we now test across a range of NLP tasks.

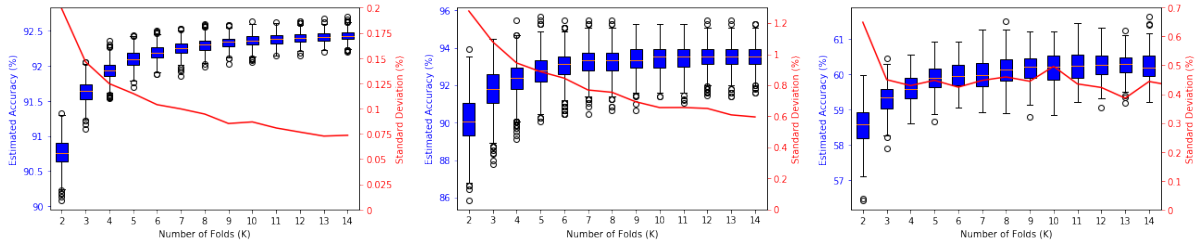
4 Case Studies

We now widen our investigation into the suitability of K-fold CV by analysing three further NLP tasks, chosen to cover a wide range of typical models and datasets. Note that we are not trying to improve the modelling of these standard models, just showing that ineffective tuning due internal variability is a general issue across NLP. We look at a simple part-of-speech tagger using logistic regression, document classification with support vector machines, and target-dependent sentiment classification with an LSTM. Each task is treated the same as our IMDB example; comparing the performances of tuning by 1-10-fold CV (the industry standard) against the computationally equivalent 2-5-fold CV. We also investigate the situation where we have two and four times the computational budget by comparing 2-10-fold with 4-5-fold and 4-10-fold with 8-5-fold. Our first task shows a case where tuning by vanilla K-fold is still reasonably effective. For task two we tune multiple parameters at once, seeing substantial variation in our tuning and so a real need for J-K-fold CV. Our final example shows that our criticisms still hold for more sophisticated models, where it can be necessary to have even more than 8 repetitions for reliable tuning. All code is available [2].

Before investigating tuning the different models, we use these examples to provide empirical evidence for our recommendation of using lower K than the common choice of ten. We argued that increasing K has no clear effect on the internal variance of individual performance estimates from K-fold CV and diminishing bias reduction returns. These are presented in Figure 4. Note that although our POS

[2] https://github.com/henrymoss/COLING2018

tagger and topic classifier do in fact become less variable for larger K, this is not a general rule, with our LSTM providing a counter-example (with comparable variance for choices of K above three). Even when we do see reductions in variability when increasing K beyond five, the following experiments show that reductions in internal variability from increasing J dominate those gained from higher K, failing to provide justification for choosing K as large as ten. Note also that the accuracy estimates for all three tasks show significant variation and so predictions by vanilla K-fold CV are unsuitable for the comparison of even relatively closely performing models.



(a) K-fold CV for logistic regression part-of-speech tagger.

(b) K-fold CV for support vector machine topic classifier

(c) K-fold CV for LSTM target-dependent sentiment classification.

Figure 4: Prediction error estimates based on K-fold CV. The variation is calculated across 1000 random partitionings for (a) and (b)) and 100 for (c).

4.1 Part-of-speech tagger

For our first task we are not directly recreating a method from a particular paper, just demonstrating that J-K-fold CV can improve the tuning of even the most common NLP models. To find such a task we consulted Jurafsky and Martin (2000), choosing logistic regression and part-of-speech tagging. We train and evaluate our model on a fixed $10,000$ word subset of the Brown Corpus (as available in Python's NLTK package (Bird, 2006)). As with our IMDB example, we use the remaining $90,000$ words as an independent global test set to check the validity of our parameter tuning. We classify with respect to the Penn Treebank tagging guidelines (Santorini, 1990) based on simple intuitive features including information about prefixes, suffixes, capital letters, position in sentence and adjacent words. We tune the amount of l2 regularisation (described by C in SKLEARN) on the grid $\{0.001, 0.005, 0.01, 0.05, 0.1, 0.5, 1, 5, 10, 50, 100\}$.

Table 2 shows that larger choices of J with smaller K provide the most effective tuning at each computational budget. Our most unstable tuning is by 1-10-fold CV. However when checked on the held-out population, the tuned model with the worst true performance only loses 0.05% accuracy from the parameter choice with best global performance. So although increasing J does reduce variability, it is not always necessary for effective tuning, as vanilla 10-fold CV produced consistently near-optimal models. The size of variability, however, is still a concern for reproducibility, as different random partitions can lead to choosing C as 10, 50 or 100.

4.2 Document Classification

We now consider a task where tuning by vanilla K-fold CV is inadvisable; topic classification on the Reuters-21578 dataset (Lewis, 2006) via support vector machines (SVM) (Cortes and Vapnik, 1995). This exact task is well-studied in the NLP literature (Joachims, 1998; Tong and Koller, 2001; Leopold and Kindermann, 2002) however no details are provided regarding the tuning of model parameters. Note that SVM are still commonly used for document classification. This dataset and a specific train-test split (known as the ApteMod version) are available in NLTK. For ease of explanation, we focus on just the corn and wheat categories, producing a binary classification task with 334 instances. We tune two parameters; the flexibility of the decision boundary and the RBF kernel coefficient (denoted in SKLEARN as C and $gamma$ respectively). We search for C in $\{1, 5, 10, 50, 100, 500, 1000, 5000, 10000\}$ and $gamma$ in $\{0.05, 0.1, 0.15, 0.2, 0.25, 0.3, 0.35, 0.4, 0.45\}$.

	SD of chosen C value	SD of the accuracy estimate of the tuned model
1-10-fold CV	34.6	0.0915 %
2-5-fold CV	31.0	0.0874 %
2-10-fold CV	29.0	0.0653 %
4-5-fold CV	27.3	0.0653 %
4-10-fold CV	23.2	0.0472 %
8-5-fold CV	24.4	0.0439 %

Table 2: Performance of different J-K-fold tuning procedures for a logistic regression part-of-speech tagger over $1,000$ different partitions (3 s.f).

SD of chosen C value	SD of chosen $gamma$ value	SD of the accuracy estimate of the tuned model
28.7	0.121	0.807 %
30.7	0.0987	0.615 %
21.3	0.105	0.580 %
20.4	0.0766	0.445 %
20.0	0.0708	0.407 %
17.5	0.0563	0.330 %

Table 3: Performance of different J-K-fold tuning procedures for a support vector machine topic-classifier (3 s.f).

As summarised in Table 3, this task suffers from much larger variability than the part-of-speech tagger. Once again, at each computational cost, the most effective tuning (in terms of $gamma$ and variability of the performance estimate of the tuned model) is from the lower choice of K and higher J. Note that for C variability, there is an slight increase when moving from 1-10-fold to 2-5-fold CV, however, this corresponds to a large drop in the other variabilities and so 2-5-fold CV still provides more effective tuning overall. Also note that we see a larger reduction in $gamma$ variability than C variability for larger J choices. This is explained in Figure 5, where we see substantially more variation in the tuned value of $gamma$ than in C when tuning with no repetitions (Figure 5(a)). Note that effective parameter tuning corresponds to a single predominately large bin, i.e. selecting a single parameter choice irrespective of the partitioning. This is achieved by increasing J (Figures 5(b) and 5(c)). Also note that the accuracy estimate for the model tuned by 1-10-fold CV is not stable enough to allow comparison with other models of close performance. To be able to reliably distinguish between our tuned model and alternatives with performance differing by only a couple of percentage points, we require higher choices of J.

4.3 Target-Dependent Sentiment Classification

For our final task we consider a much more sophisticated model using LSTMs (with Python's KERAS [3]) to perform target-dependent sentiment classification (Tang et al., 2016) using twitter-specific sentiment word vectors (Tang et al., 2014) on the benchmark twitter dataset collected by Dong et al (2014). Our implementation relies heavily upon the reproduction study of Moore et al (2018). Each of $6,248$ sentences are annotated with a target element and the task is to predict the sentiment regarding that element (positive, negative or neutral). Unfortunately little information is provided about model architecture or parameter tuning. However, we can still investigate the effectiveness of tuning by J-K-fold CV. Throughout these experiments we fix the maximum number of epochs as 100 and stop training when we see no improvements in validation set performance for five successive epochs. For each of our $J * K$ models, the validation set is a random 20% of that model's training data, and so can be thought of just another part of the random partitioning. We use an ADAM optimiser with the default learning parameters and a batch size of 32.

We perform two experiments: tuning the number of nodes in the LSTM layer (known as width) across the grid $\{10, 20, 30, .., 90\}$, and separately tuning the amount of l2 regularisation on the inputs and biases (for a fixed width of 50) each across $\{0.00001, 0.001, 0.1\}]$. Tables 4 and 5 provide further support for our claim that the most effective tuning for a specified computational budget comes from lower K and higher J. Note that, as shown in Figure 6(a), vanilla 1-10-fold CV is not at all suitable for tuning the width of our LSTM, as it produces almost uniform values between 30 and 90. It also fails to consistently select a single choice for the regularisation scheme (Figure 6(b)). In contrast, tuning with 8-5-fold produces much more consistent choices, the majority of the time choosing 70 for the optimal width (Figure 6(a)) and 0.001 for both the input and bias regularisation (Figure 6(c)). Although variability in our chosen LSTM parameters does reduce as we increase J, it remains significantly higher than the gaps in our parameter grid. When coupled with the relative stability of the accuracy estimates of this tuned model, this suggests that the performance differences between the most frequent choices by 8-5-fold CV are small. However, to consistently tune the model to this specificity we require larger choices of J than 8.

5 Discussion and Conclusions

The aim of this paper has been to demonstrate the significant variability of current performance estimation techniques when applied to NLP tasks. We argue that the size of this variability is poorly understood by practitioners, which has serious implications for both model selection and parameter tuning. We show that the variability in estimates can often be larger than the performance improvements sought by the NLP community; questioning conclusions regarding the comparison of techniques. For parameter tuning, the variability can lead to unstable, irreproducible and significantly sub-optimal parameter choices.

We advocate the use of J-K-fold CV, which we extend to parameter tuning. By using information from multiple estimations we stabilise our tuning procedure. To counteract the computational cost of increasing J, we suggest lower choices of K, as effective tuning is more reliant on variability than bias.

Although we have shown the effectiveness of some specific choices of J and K on our NLP examples, there is still work to be done regarding choosing their optimal configuration, which is problem dependent. Unlike K, J can be chosen adaptively, allowing practitioners to respond to the amount of observed variability and efficiently manage computational resources. We would also like to analyse the current common practice of early stopping (as in our LSTM example), which requires evaluations on another held-out set to prevent over-fitting. This is likely to suffer from the concerns outlined in this report and it is poorly understood how best to incorporate early stopping into a wider parameter tuning framework.

Incremental Natural Language Processing: Challenges, Strategies, and Evaluation

Arne Köhn
Natural Lanuguage Systems Group
Department of Informatics
Universität Hamburg
koehn@informatik.uni-hamburg.de

Abstract

Incrementality is ubiquitous in human-human interaction and beneficial for human-computer interaction. It has been a topic of research in different parts of the NLP community, mostly with focus on the specific topic at hand even though incremental systems have to deal with similar challenges regardless of domain. In this survey, I consolidate and categorize the approaches, identifying similarities and differences in the computation and data, and show trade-offs that have to be considered. A focus lies on evaluating incremental systems because the standard metrics often fail to capture the incremental properties of a system and coming up with a suitable evaluation scheme is non-trivial.

Title and Abstract in German

Inkrementelle Sprachverarbeitung:
Herausforderungen, Strategien und Evaluation

Inkrementalität ist allgegenwärtig in Mensch-Mensch-Interaktiton und hilfreich für Mensch-Computer-Interaktion. In verschiedenen Teilen der NLP-Community wird an Inkrementalität geforscht, zumeist fokussiert auf eine konkrete Aufgabe, obwohl sich inkrementellen Systemen domänenübergreifend ähnliche Herausforderungen stellen. In diesem Überblick trage ich Ansätze zusammen, kategorisiere sie und stelle Ähnlichkeiten und Unterschiede in Berechnung und Daten sowie nötige Abwägungen vor. Ein Fokus liegt auf der Evaluierung inkrementeller Systeme, da Standardmetriken of nicht in der Lage sind, die inkrementellen Eigenschaften eines Systems einzufangen und passende Evaluationsschemata zu entwickeln nicht einfach ist.

1 Introduction

Interaction using language is incremental in many forms: In a dialogue, understanding takes place continuously and participants are able to interrupt each other or signal whether they understand the currently ongoing utterance. Simultaneous interpreters translate speeches as they are spoken. Texts are (partially) understood before they are fully read. Incremental processing exploits this property by starting to compute before all input is available, allowing a system to already act on partial input. Without incremental processing, an NLP system is unable to perform any of these tasks as it is bound to wait for complete utterances or a finished text and only afterwards it can compute how to (re-)act, leading to deficiencies in human-computer interaction.

First, I want to delimit this notion of incrementality from other notions: Systems that work on a complete input but generate output layer by layer, e.g. shallow to deep syntax, are sometimes called incremental, e.g. by Aït-Mokhtar et al. (2002). These systems are not discussed in this survey. Anytime algorithms are incremental in the sense that they iteratively improve their output for a fixed input, given more and more processing time. They can play an important role in incremental systems as they allow to

Proceedings of the 27th International Conference on Computational Linguistics, pages 2990–3003
Santa Fe, New Mexico, USA, August 20-26, 2018.

perform a trade-off between processing time – i.e. system responsiveness – and quality. The question of whether to employ anytime algorithms is however orthogonal to the approaches discussed in this survey[1].

In an incremental system, all processors need to work incrementally. A prime example is the Verbmobil project, which set out to develop a portable simultaneous interpreter (Kay et al., 1994). The project developed speech recognition and synthesis components, syntactic and semantic parsers, self-correction detection, dialogue modeling and of course machine translation, showing that incrementality is an aspect that touches nearly all topics of NLP. This project also exemplifies that building incremental systems is not easy, even with massive funding[2]: Only one of the many components ended up being incremental and the final report makes no mention of *simultaneous* interpretation (Wahlster, 2000).

The incremental nature is more obvious in speech than in written language because language processing often processes already-written text in bulk whereas interactive systems are a major research focus for speech-based applications. As the benefits of incrementality are more prominent in processing dialogues compared to text, research on incrementality in NLP has been primarily driven by speech-based research questions, such as understanding based on partial speech recognition (Sagae et al., 2009), determining when to respond during ongoing utterances (DeVault et al., 2009), training actor policies for rapid task-based dialogue (Paetzel et al., 2015), continuous understanding and acting (Stoness et al., 2005), incremental repair detection (Hough and Purver, 2014), or incremental reference resolution (Schlangen et al., 2009).

2 Psycholinguistic evidence

Humans still pose the gold standard for language processing, especially if the processing does not happen on large scale but in an interactive setting. When speaking, they perform several tasks incrementally and in parallel, from conceptualization to articulation (Levelt, 1989). Machines mimicking human behavior need to be able to perform similar computations as humans in such settings to be seen as a competent partner, and psycholinguistic research gives insight into the processes that humans perform. Psycholinguistic research is often carried out by timing experiments, i.e. they make use of the incremental processing by humans to gain insights into linguistic processes, mostly by eye-tracking (Tanenhaus et al., 1995; Sturt and Lombardo, 2005; von der Malsburg and Vasishth, 2011), but also by timing word-by-word reading of sentences (Gibson and Warren, 2004).

Language is perceived incrementally and this incremental processing is influenced by other modalities even while speech is perceived (Tanenhaus et al., 1995). Humans seem to create fully connected structures for sentence prefixes, even for coordinate structures, and a continuation of a sentence that does not match the predicted structure can be measured by increased reading times (Sturt and Lombardo, 2005). They perform syntactic re-analysis and use various strategies to rescan sentences (von der Malsburg and Vasishth, 2011).

3 A typology for incremental problems

When working on an incremental processor, it is helpful to know which other already existing processors had to deal with similar challenges despite being designed for completely different NLP tasks. In this section, I will examine properties relevant for classifying processors. These properties describe the input and output data as well as the relation between input and output and help classifying concrete tasks in Section 4. For an in-depth discussion of properties relevant to incremental processing, see Chapter 5 of Guhe (2007)[3].

3.1 Data types

Data can be *structured* (e.g. syntactic or semantic structures) or *sequential*. Sequential data can be *discrete* (e.g. words) or *continuous* (e.g. speech signals) along the time axis[4]. Structured data is always discrete on

[1] An anytime algorithm could be seen as a simply another non-monotonic processor, as described in Section 3.4.

[2] Verbmobil had a funding of 116 million DM, (~60 million €, or 78 million € when adjusted for inflation).

[3] The properties discussed by Guhe (2007) are mostly complementary to the ones discussed here.

[4] Data that is discrete along the time axis can of course include continuous data such as word embeddings.

Process	Data	**Data** / *alignment* properties
		**structured, including prediction**
Parsing		*vertices partially grounded, edges not grounded*
		discrete, sequential
Machine translation		*reordering, fuzzy mapping*
		discrete, sequential
Speech recognition		*order-preserving, clear mapping*
		continuous

Figure 1: Different types of data, groundings, and processors. Note that for parsing only the prefix "Peter bought" is processed to exemplify intermediate structure generated for incomplete input. Incremental systems can take many forms, and this example is not meant to perform a specific task.

the time axis. A processor can take one type of data as an input and create another one as output; some examples are depicted in Figure 1.

Sequential data can usually be subdivided along a time axis, i.e. there exists a total ordering between the elements of the input (or output respectively). Structured data does not exhibit this property: Given, for example, the dependency tree produced by parsing in Figure 1, the words are ordered, but the dependencies between the words can't be clearly attributed to a word: They could be attributed to the head or the dependent; this poses an additional challenge for evaluation.

3.2 Granularity

The *granularity* determines the size into which the input and output is subdivided. Assuming coarse enough granularity, every system can be seen as incremental: A normal syntax parser works non-incremental inside a sentence, but incrementally if processing a paragraph with the basic units being sentences. Grapheme to phoneme conversion is incremental when processing text with the basic unit of words. When considering a larger incremental system, a processor usually seen as non-incremental might be incremental enough: If a language generation system works on the level of words, the grapheme to phoneme conversion does not need to be able to process sub-word input. On the other hand, if input typed by a user should be vocalized, sub-word granularity might be needed. The granularity of a pipeline is determined by its most coarse-grained component. In general, fine-grained processing is harder than coarse-grained processing; a system can always process data fine-grained internally while having coarse-grained interfaces, whereas the opposite is not possible.

3.3 Grounding

Grounding describes the alignment from the generated output to the elements of the input that yielded evidence for this output (Schlangen and Skantze, 2009). Grounding allows to reason about which part of the output can be reasonably generated given only partial input. In some cases, this alignment is explicit in both test and training data, e.g. in sequence labeling tasks where each element of the input is assigned a label. In other cases such as machine translation, there is no gold standard word alignment[5] and even a human-generated alignment would not create a one-to-one mapping between input and output. In addition, the alignments may or may not be *order-preserving*: A tagging task preserves the ordering, whereas in translation reordering takes place (cmp. "hat Mehl gekauft" → "bought flour" in Figure 1).

[5] At least not on the word level, but alignments can be generated automatically, see e.g. Och and Ney (2003)

3.4 Monotonicity

A system is *non-monotonic* if it is allowed to retract output it has previously produced. For example, an incremental sequence labeler that is free to re-assign labels can change its mind about every element for a sentence once the sentence is complete. A *monotonic system* on the other hand is required to only extend previously generated output without retracting information. Some components are inherently monotonic because their output is not fed to another processor of the system but to the outside world; e.g. a speech synthesizer is inherently monotonic as it cannot retract sound waves realized through a loudspeaker.

Monotonicity limits the quality a component can produce as it can not revert a decision that turns out to be wrong later on in light of additional available input. In contrast, a non-monotonic component can always achieve the same non-incremental output as a non-incremental component by simply replacing all intermediate output with the one of the non-incremental component once all input is available.

The precise meaning of monotonicity needs to be defined for each component. For sequential output, the most common definition is to only allow appending to the output. For structured output, the structure of an increment could be required to be a super-set of its predecessor.

Non-monotonic output can only be generated sensibly if the consumers of the output can deal with non-monotonic input. Otherwise these consumers might ignore the revisions made to previous output and end up with an inconsistent input or have to restart their computation in light of new input.

3.5 Timeliness

Each NLP processor has to optimize *what* to output given an input. An incremental system also needs to decide *when* to provide output. Discrete input provides specific anchors for this decision, continuous input does not and new output can be generated continuously[6]. Such decisions also need to be made by human interpreters while performing simultaneous translation; they need to buffer input until they are able to produce additional output. The characteristics of this (human) process varies by language, e.g. the delay is relatively long when translating from German to English because the verb in the input tends to be delayed (Goldman-Eisler, 1972).

3.6 Trade-Off between properties

Incremental components have to make a trade-off between timeliness (i.e. the amount of delay introduced between input and output), output quality, and the amount of non-monotonicity (Beuck et al., 2011a; Baumann et al., 2009). High-quality, monotonic output can be obtained by delaying all output. This strategy taken to the extreme results in a non-incremental system that only produces one complete output once all input is available. To reduce the delay, non-monotonicity via output revisions can be allowed, or compromises with respect to the quality of the output can be made. Gradual trade-offs can also be performed: allowing infrequent revisions and/or mild delays can lessen the negative impact on accuracy. These trade-offs are universal to all incremental processors.

4 Incremental processors

This section discusses three tasks that can be performed incrementally to exemplify strategies to "incrementalize" a processor: first, incremental speech recognition, a continuous sequence labeling problem that is usually implemented as a non-monotonic processor, then incremental machine translation, which is a sequence to sequence task with reordering implemented monotonically, and third parsing, a sequence to structure task, which is implemented both monotonic an non-monotonic.

4.1 Speech recognition

Speech recognition lends itself to incremental processing because it is used in all interactive spoken dialogue systems and the decoding happens incrementally even for non-incremental use-cases. It is therefore possible to look into a speech recognizer (SR) to obtain the most probable hypothesis at each point in time without modifying the recognizer (Baumann et al., 2009). Because the SR is not changed

[6]While continuous input is made discrete before reaching a processor, the discretization is usually in the order of milliseconds and can be seen as continuous for all practical purposes.

from the non-incremental one, the only optimization point is when to let new output through, i.e. to implement a *gatekeeper*. Its policy can be guided by observing the time that a hypothesis survived without being discarded (Baumann et al., 2009) or based on the internal state of the recognizer (Selfridge et al., 2011). McGraw and Gruenstein (2012) show that even sophisticated stability estimation only slightly improves upon the simple age-based estimation by Baumann et al. (2009). Given that the SR is the same for the incremental case as for the non-incremental one, no trade-off is performed against the accuracy. In addition, Selfridge et al. (2011) noted that if during decoding all beams in the beam search pass through the same state, the prefix up to that state can be declared stable because future decoding will not change the most probable path up to that state; this observation essentially makes use of the Markov property and is primarily useful if grammar-based recognition is performed.

4.2 Machine translation

Translation can be performed as batch processing (e.g. for websites) or incrementally, to facilitate human-human interaction. Modern approaches to machine translation, i.e. neural machine translation, employ a sequence to sequence model where the input sequence is encoded into a representation and then decoded again. This can be performed using recurrent networks which represent the input as a single fixed-length vector and possibly modeling attention to the input when generating the output sequence (Bahdanau et al., 2014) or even without a recurrent network, using only attention to model the influences from the input sequence to the output sequence to generate (Vaswani et al., 2017). In all these cases, all input is consumed before translation happens.

4.2.1 Incremental Neural Machine Translation (NMT) by using a gatekeeper

As already discussed, machine translation is a sequence to sequence problem where the output ordering does not conform to the input ordering and the ground truth for the grounding often is missing. As the incremental machine translation systems found in the literature are monotonic, the systems need to decide at which point they have enough information from the input to generate the next output token with high confidence. Gu et al. (2017) propose a system where an NMT processor repeatedly proposes an output token based on the currently available input and the generated output to a gatekeeper. The gatekeeper either accepts this output, resulting in a write operation to the output, or rejects it, resulting in a read operation on the input. The gatekeeper can work based on different policies, yielding different trade-offs between timeliness and accuracy: rejecting all output until the input is complete means falling back to a non-incremental behavior; performing alternating read and write actions eliminates delay but results in bad translations. Gu et al. (2017) train the policy using reinforcement learning with the reward based on the resulting BLEU score and the delay incurred; weighting them differently results in different trade-offs. Humans have different preferences regarding this trade-off, depending on whether the output is speech or subtitles (Mieno et al., 2015). The underlying NMT model is trained on complete sentences and therefore not adapted to incremental processing. An example of an incremental translation can be seen in Figure 2.

4.2.2 Reordering output

Reordering phenomena are a major hindrance to timely translation, as exemplified in Figure 2. Grissom II et al. (2014) deal with this by training a classifier to predict verbs needed for the output but not yet seen in the input, allowing the MT system to produce a verb without having seen its counterpart on the input. He et al. (2015) instead propose to edit the gold standard translations to better fit the source ordering for training the MT system by trying to imitate the transformations a human translator would perform. This approach tackles the problem that the training data is only available for the non-incremental case, which is not optimal for simultaneous translations. Human simultaneous translators produce sentences that systematically deviate from the "normal" target language but such data is not readily available for training (He et al., 2016). The training data is adapted by generating phrase-structure trees for the target sentences and applying (manually written) syntax-based reordering rules. The system then checks whether the reordering has reduced the delay based on an automatically computed alignment and if so uses the reordered version instead of the original one. As in the approach by Gu et al. (2017), the average delay induced by the system can be tuned, see Figure 2. Because the processor was not trained on gold-standard

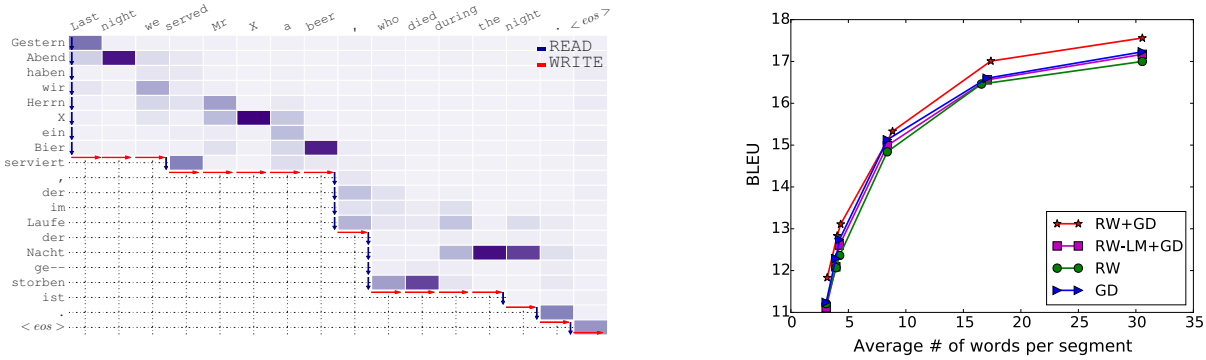

Figure 2: Left: Incremental NMT with attention, from Gu et al. (2017). Colors denote the attention given to each input token when generating an output token. Note the delay induced by the reordering for "serviert" (*served*) and "gestorben" (*died*). Right: trade-off decisions between delay (x-axis, measured in words translated at once) and accuracy (y-axis, measured in BLEU) from He et al. (2015).

data, it might yield sub-optimal results on gold-standard test data. He et al. (2015) evaluate on both gold-standard and transformed data and show that the system in fact performs better on both targets.

4.3 Parsing

Many state-of-the-art parsers work incrementally internally, both for semantic and for syntactic parsing: they use a transition system with a scorer and optionally combine that with beam search to find the best parse (Nivre, 2008; Huang and Sagae, 2010; Dyer et al., 2015; Swayamdipta et al., 2016; Kiperwasser and Goldberg, 2016; Zhou et al., 2016; Damonte et al., 2017, *inter alia*). While they build a structure incrementally going from left to right, they don't produce intermediate structures meant for incremental consumption; the intermediate states consist of several unconnected sub-structures. In addition, they usually employ look-ahead which delays the processing; approaches using Bi-LSTMs (such as Kiperwasser and Goldberg (2016)) effectively make use of the whole sentence during each step, making the computation non-incremental as it depends on the complete input being available. Noji and Miyao (2014) propose a transition system based on the ones discussed by Nivre (2008) that introduces dummy nodes which denote an expectation of upcoming words. This transition system still produces disconnected trees for sentence prefixes but is able to predict processing difficulties humans have when reading sentences with center embeddings. The other approaches described in this section all produce connected structures for sentence prefixes.

4.3.1 Incremental parsing with monotonic expansions

One approach to incremental parsing that produces connected structures at each step is to monotonically extend a connected structure and to employ a beam of possible structures to prevent being stuck with a structure that does not fit the continuation of the sentence. Using beam search, a parser does not provide monotonic output but still guarantees that one of the beam entries will be selected for a continuation.

Hassan et al. (2009) show why either a beam or delay is necessary if performing incremental parsing with monotonic extensions: They experiment with a parser based on Combinatory Categorial Grammar (Steedman, 2000). Their parser achieves an accuracy of 86% when using lookahead and performing greedy parsing (i.e. it does not use a beam). This accuracy drops significantly to 56% without lookahead because the parser often commits to a structure incompatible with the continuation of a sentence.

Roark (2001) presents a top-down phrase structure parser that performs beam-search to generate connected intermediate structures for every sentence prefix. As the parser is based on a probabilistic generative model, it can be used for language modeling and beats trigram models on the Penn Treebank (Marcus et al., 1994) (but not other sequence models, see e.g. Merity et al. (2017)). Demberg and Keller (2008) describe the PLTAG formalism, which is based on Tree Adjoining Grammar (Joshi and Schabes, 1997) and strives for psycholinguistic plausibility. It not only predicts upcoming structure needed for connectedness, but also structure required by e.g. valencies not yet filled in the prefix. The

predictions of the second type are automatically extracted from the treebank during lexical induction by learning the distinction between modifiers and arguments. The PLTAG formalism provides better predictions for reading-time experiments than predictions based on Roark's parser (Demberg et al., 2013). The combination of only extending entries in the beam and prediction leads to some sentences being unparseable for both parsers because the structures stored in the beam can all become incompatible with the input to be consumed. A larger beam reduces the number of unparseable sentences at the cost of additional memory and processing cost, but can not eliminate the problem.

4.3.2 Incremental gold standards for parsing

Köhn and Menzel (2014) go in the opposite direction and perform incremental parsing using restart-incrementality, i.e. performing a complete new parse for each sentence prefix without reusing previously generated output. This approach gives no guarantees that a certain structures will still be present in subsequent outputs but on the other hand is able to react on any upcoming input without constraints, yielding – in contrast to the approaches described in § 4.3.1 – the same accuracy for complete sentences as its non-incremental counterpart. The underlying parser performs a graph-based optimization (Martins et al., 2013) and has no notion of incrementality; instead, the gold standard the parser is trained on is adapted to consist of syntactic structures for sentence prefixes which contain prediction nodes as stand-ins for upcoming words. The partial dependency structure for a prefix is created by a rule based system that works on the complete dependency structure for the sentence. It keeps all dependencies between words in the prefix and delexicalizes words that are needed to connect the words in the prefix to the sentence root as well as arguments that are deemed to be predictable. Words outside the prefix that are neither needed for connection nor deemed to be predictable are deleted. The downside of this approach (in contrast to Demberg and Keller (2008), but similar to the reordering of output discussed in § 4.2.2) is that a rule set needs to be manually created for each language and that the linguistic intuition encoded into this rule set might be a bottleneck for the parser as structures not envisioned by the rule writer might be a better fit than the one created by the rules. Köhn and Baumann (2016) show that using the delexicalized predictions to augment 5-gram language models improves perplexity on the Billion Word Corpus (Chelba et al., 2013).

4.4 Natural language generation

Skantze and Hjalmarsson (2013) compare a non-incremental dialogue system and an incremental one, with which language learners interact to buy items at a flea market. The speech recognition component was performed manually, i.e. a human manually transcribed the speech. As the manual transcription takes time, the system response is noticeably delayed in a non-incremental system where the dialogue system only starts to plan its response once transcription is complete. In contrast, the incremental system constructs a response as soon as possible, based on partial input. The response is recomputed on changed input, which can have three effects: If the update is consistent with what has been said already, the continuation of what to say is simply changed (a *covert change*). If the system has to retract information already uttered, an explicit repair has to be produced (an *overt change*). If not all information to produce a complete utterance is available, fillers are inserted to avoid silence. The system is faster and preferred by users even though it has to explicitly correct itself, resulting in longer responses. Even though its output is monotonic – as it cannot erase information from the hearer's ears – its explicit repairs allow to act with low delay (a similar strategy to the one employed by human speakers (Levelt, 1989, ch. 12)). As the NLG component is rule-based, it is not constrained by the (non-) availability of data suitable for learning incremental language generation.

5 Evaluating incremental systems

An incremental system can be evaluated just as a non-incremental one. Evaluation schemata exist for all established tasks such as speech recognition (quality measured in word error rate), PoS tagging (measured in accuracy), phrase structure parsing (measured in precision/recall), or machine translation (BLEU). Additional evaluation allows to examine the behavior more closely, such as compiling error confusion matrices. These schemata enable a comparison between components in a standardized way.

	non-monotonic (1)	non-monotonic (2)	delayed (3)	erroneous (4)
input: a	a/y	a/y		a/y
b	a/x b/y	a/y b/y	a/x b/y	a/y b/y
c	a/x b/y c/z	a/x b/y c/z	a/x b/y c/z	a/y b/y c/z
inc_acc(i)	2: 1/1; 1: 2/2; 0: 2/3	2: 1/1; 1: 1/2 ; 0: 2/3	2: 1/1; 1: 2/2 ; 0: 2/3	2: 0/1; 1: 1/2 ; 0: 2/3
EO	1/4	1/2	0	0
accuracy	3/3	3/3	3/3	2/3

Table 1: Examples for characteristics of incremental output that need to be captured for evaluation. Correct output: a/x b/y c/z. (1), (2): output for *a* changed; (3): output for *a* held back until input "b" is available; (4): incorrect assignment to "a" stays in output. Dashed: exemplifies output used to compute inc_acc (incremental accuracy). EO: edit overhead. Accuracy: measured on complete output.

The downside of standardized evaluation is the lack of insight for incremental properties. When building incremental systems, not only the final output but also the intermediate behavior is of importance but using evaluations tailored to non-incremental systems fails to give insight into the incremental properties of the system. An incremental system should provide as much correct information as early as possible but using non-incremental evaluation hides all differences in this respect.

Table 1 shows abstract input/output patterns for a sequence labeling task, where the correspondence between input and output is given and no reordering effects take place. A standard accuracy-based evaluation on the complete output would yield a perfect score for the three first systems although their behavior over time is quite different: In addition to the non-incremental evaluation for the complete output, the non-monotonicity in (1) and (2) as well as the delay in (3) need to be covered. It is impossible to boil down all these differences to a single number. We will therefore have a look at distinct metrics for timeliness, monotonicity, and quality.

5.1 Measuring timeliness

Cho and Esipova (2016) propose to measure timeliness by counting for each output element t of an output sequence Y how many input elements from the input sequence X have been consumed before its production ($s(t)$). $\tau(X, Y)$ then computes the translation delay:

$$0 < \tau(X, Y) = \frac{1}{|X||Y|} \sum_{t=1}^{|Y|} s(t) \leq 1$$

This computation is helpful when there is no gold standard alignment between output and input which one could use to obtain the output timing that could be achieved under optimal conditions. $\tau = 0$ means all output was made without consuming input, $\tau = 1$ means all input was read before generating output.

Grissom II et al. (2014) introduce latency-BLEU, a metric that averages the BLEU scores of the outputs corresponding to each input prefix. The complete translation is weighed higher than all other partial translations to penalize incorrect translation. If the resulting translation is the same, a processor with less delay will obtain a higher score. It has to be noted that due to the averaging the sentence-initial output has more influence on the score than output created near the end of a sequence. It is also not possible to completely distinguish between the quality and the timeliness because quality and timeliness are measured in a single metric. In the MT system by He et al. (2015), the timeliness can be (indirectly) tuned by adjusting a threshold at which all yet untranslated words should be translated. Figure 2 (right) shows a plot of the resulting BLEU score against the average number of words translated at once, i.e. the delay. This way, potential users can see the trade-offs that can be made using a system (RW+GD is the proposed architecture, beating the other approaches at each trade-off point).

If an explicit alignment exists between the input and the output – such as in speech recognition – the difference between when an output is made (i.e. which amount of input data has been consumed) and the timing of the corresponding input can be measured to obtain an anchored timeliness measure (Baumann

et al., 2011). Both the relation to the first occurrence of an output (FO) and the relation to the last change of an output (final decision, FD) can be measured. E.g. if a word ends at 2.5 seconds of the input audio, was first recognized after consuming 3 seconds and was part of all outputs produced after consuming 4 seconds, its FO would be 0.5 seconds and its FD would be 1.5 seconds. To separate the timeliness from the quality, these measures can be computed against the final output of the system instead of the gold standard, but then a reliable alignment between the input and the generated output is needed. The advantage to other methods is its interpretability: A FO of 100ms for a speech recognizer means that it produces, on average, an output 100ms after it has consumed input that carries evidence for this output. Obviously, FO and FD only differ for non-monotonic processors; FD measures what delay is necessary on average to rely on an output produced by the processor.

5.2 Measuring incremental quality

When dealing with monotonic output, the incremental quality can be assessed using the non-incremental quality metrics as the processor can't correct previously made output. If a processor can be tuned to provide more or less timely output, the quality can be plotted against delay, as in Figure 2.

If a system is non-monotonic, it makes sense to measure the accuracy not only based on the final output but also on the intermediate output. Averaging the quality for each increment has two downsides: Output for early input is weighed more heavily than for later input, and it is unclear how the non-monotonicity affects the quality. Beuck et al. (2011b) perform an evaluation for incremental dependency parsing by computing the accuracy for the *n*-th word to the right of the frontier in every prefix, with n between zero (measuring the newest words) and five (the accuracy of the sixth-newest word). This way, an accuracy curve relative to the age of the input is generated, Table 1 shows incremental accuracy (*inc_acc*) measures relative to the age of the input; the examples (1) and (2) obtain different incremental accuracy measures even though the non-incremental accuracy is the same.

Incremental structured output might include predictions, which are not accounted for in the metrics discussed up to now. If an incremental gold standard is available (such as the one used for training discussed in § 4.3.2), the precision and recall of those predictions can be computed with respect to the predictions in the gold standard (Beuck et al., 2013).

5.3 Measuring the degree of non-monotonicity

Evaluating non-monotonicity can be viewed from two (similar) standpoints: first, how much intermediate output will be retracted again? And second: how sure can we be that a certain output is reliable, i.e. will also be part of the final output of a processor?

Baumann et al. (2009) and Baumann (2013) tackle the first question by defining the *edit overhead* generated by a non-monotonic processor producing sequential output by defining three edit operations on an output sequence: *add* (append an element to the output), *revoke* (remove the last element from the output), and *substitute* (revoke and then append). The difference $\mathit{diff}(o_i, o_j)$ between two outputs o_i and o_j can then be defined as the minimal number of edits needed to change o_i into o_j. Note that to change the first element of an output of length n, $2(n-1)+1$ operations are needed whereas changing the last element only yields a difference of one. This notation allows to compute the edit overhead: Let $N_{optimal} = |\mathit{diff}(o_0, o_{tmax})|$ be the number of edits necessary to obtain the final output and $N_{actual} = \sum_{t=1}^{tmax} \mathit{diff}(o_{t-1}, o_t)$ be the amount of edit operations actually performed. The edit overhead is then defined as the proportion of unnecessary edits produced by the processor:

$$EO = (N_{actual} - N_{optimal})/N_{actual}$$

Table 1 shows that EO can distinguish between the different levels of non-monotonicity. The edit operations can be adapted to the problem at hand, e.g. if structured output is produced or edits at the start of the sequence should not be penalized heavier than edits at the end.

Regarding the second question, Beuck et al. (2011b) propose to compute the accuracy against the output generated based on the complete input instead of computing against the gold standard to obtain a stability measure. Using the gold standard as reference measures consistency with the ground truth,

i.e. the quality, and using the complete output measures the consistency with that, i.e. the stability. This approach obviously only works if an incremental accuracy is defined for the problem at hand and that accuracy can be measured with respect to a non-incremental gold standard.

6 Combining multiple incremental processors

A NLP system usually consist of several processors. In a non-incremental system, all processors can simply form a pipeline with each processor working on the output of the previous one. This is non-trivial in an incremental system because for a given input, each processor may produce several outputs which may even be contradictory due to non-monotonicity. Therefore, a system either needs to use restart-incrementality throughout the pipeline or track changes to perform partial recomputation. Wirén (1992, ch. 5) introduces the notion of dependencies to track which parts of the input a certain output is based on in a chart parser. This way, only parts of the chart need to be recomputed given a non-monotonic change. Schlangen and Skantze (2009) vastly extend this notion to a general computation model in which multiple processors work on data which is organized in incremental units (IU). An IU stands for a minimal unit of information, such as a recognized word. IUs are grounded in other IUs from a previous level, and linked to other IUs on the same level, e.g. to describe a sequential relationship. Processors create new IUs based on their input and may revoke IUs already generated. A processor can commit to an IU to signify that this IU will not be revoked and other processors may rely on it.

7 Conclusion and outlook

Building incremental processors poses problems that are similar regardless of the domain. Decisions have to be made regarding the amount of delay acceptable, whether non-monotonic output is acceptable for downstream processors, and if so, to what extent. For all these decisions, the relation between input and output is important: Is there a clear mapping between input and output, maybe even a one-to-one mapping, and does reordering happen? Several techniques have been discussed for implementing incremental processors: Training a *gatekeeper* to either perform a trade-off between non-monotonicity and delay (§ 4.1) or – for monotonic processors – between delay and quality (§ 4.2.1), *Beam search* to create non-monotonic output with monotonic extension (§ 4.3.1), and *restart incrementality* for unrestricted non-monotonicity (§ 4.3.2). To evaluate an incremental system, ideally three characteristics should be measured: timeliness (§ 5.1), quality (§ 5.2), and non-monotonicity (§ 5.3). If a system can be tuned in regard to these characteristics, different trade-off points between these properties can be measured (§ 3.6).

There are still open problems for building incremental NLP systems: Processors generating connected structured output need incremental training data to learn intermediate structures not visible in the non-incremental gold standards; as the quality of the training data generation influences the quality of the processor, data-driven approaches producing high-quality incremental training data are needed. Explicit corrections in spoken output are preferred by users to delay (§ 4.4), which could transfer to incremental MT. However, lack of automatic evaluation likely requires an expensive human end-to-end evaluation due to the large deviation from non-incremental gold standard translations. All data-driven processors discussed are able to produce non-monotonic output, but are not able to consume non-monotonic input, a problematic discrepancy for building incremental systems out of multiple processors. To bridge the gap between certainty (monotonic output) and uncertainty (non-monotonic output), the likelihood of an output being stable could be attached to the output (see Selfridge et al. (2011) § 5). Modern NLP processors heavily rely on sub-symbolic representation and use attention mechanisms to obtain the relevant information. With this approach, an explicit grounding for partial recomputation as discussed in Section 6 does not work anymore and would need to be replaced with some notion of soft grounding.

Acknowledgments

I would like to thank Christine Köhn, Sebastian Beschke, and Timo Baumann for valuable feedback, as well as the anonymous reviewers for helpful remarks.

Abstract

This paper describes the augmentation of an existing corpus of child-directed speech. The resulting corpus is a gold-standard labeled corpus for supervised learning of semantic role labels in adult-child dialogues. Semantic role labeling (SRL) models assign semantic roles to sentence constituents, thus indicating who has done what to whom (and in what way). The current corpus is derived from the Adam files in the Brown corpus (Brown, 1973) of the CHILDES corpora, and augments the partial annotation described in Connor et al. (2010). It provides labels for both semantic arguments of verbs and semantic arguments of prepositions. The semantic role labels and senses of verbs follow Propbank guidelines (Kingsbury and Palmer, 2002; Gildea and Palmer, 2002; Palmer et al., 2005) and those for prepositions follow Srikumar and Roth (2011). The corpus was annotated by two annotators. Inter-annotator agreement is given separately for prepositions and verbs, and for adult speech and child speech. Overall, across child and adult samples, including verbs and prepositions, the κ score for sense is 72.6, for the number of semantic-role-bearing arguments, the κ score is 77.4, for identical semantic role labels on a given argument, the κ score is 91.1, for the span of semantic role labels, and the κ for agreement is 93.9. The sense and number of arguments was often open to multiple interpretations in child speech, due to the rapidly changing discourse and omission of constituents in production. Annotators used a discourse context window of ten sentences before and ten sentences after the target utterance to determine the annotation labels. The derived corpus is available for use in CHAT (MacWhinney, 2000) and XML format.

1 Introduction

The study of human language acquisition has greatly benefited from the availability of corpora of language use to, by, and around young children. The CHILDES project (MacWhinney, 2000) makes available transcribed corpora of adult-child dialogue in English and in a growing set of other languages.[1] In recent years, annotations have been added to some CHILDES corpora, including part-of-speech tagging, syntactic parsing, and the identification of grammatical roles (Pearl and Sprouse, 2013; Sagae et al., 2010; Sagae et al., 2007).

In the present paper, we describe an ongoing project that adds a new layer of annotation to selected CHILDES corpora, a hand-checked corpus of semantic role labels that provides a shallow semantic analysis of sentences' predicate-argument structure. Our goal is to support the development of computational models of language acquisition that explore how children come to interpret sentences, assigning semantic roles to sentence constituents to determine who does what to whom in each sentence. An additional goal is to provide new resources for testing the ability of trained NLP systems to generalize to new domains, in this case the challenging linguistic environment of dialogues between toddlers, who are in incomplete stages of language acquisition, and adults.

[1] Corpora and documentation are available at https://childes.talkbank.org.

Proceedings of the 27th International Conference on Computational Linguistics, pages 3004–3014
Santa Fe, New Mexico, USA, August 20-26, 2018.

Semantic role labeling (SRL) is a common task in NLP. For each predicate, an SRL system identifies sentence constituents and assigns to them argument (e.g., agent, patient) or adjunct (e.g., locative, manner) roles. Usually SRL refers to labeling verb semantic roles, but it has been extended to nominal predicates (Meyers et al., 2004), as well as prepositions (Srikumar and Roth, 2011; Srikumar, 2013; Schneider, 2016). SRL has proven useful in areas such as question answering and textual entailment. Annotated data sets for training and evaluating the performance of SRL systems are time-consuming to construct, but new types of annotated data are important for modeling early language acquisition, and for testing the ability of SRL systems to generalize across varieties of language use.

The corpus described in this paper augments portions of an existing partial annotation of child-directed speech corpora, as described in Connor et al. (2010), with additional verb semantic role labeling and preposition semantic role labeling of the adult and child speech. This annotation project involved the Brown corpus (Brown, 1973) from the CHILDES corpora, a classic study of interactions between young children and their caregivers and other adults. The Brown corpus contains data collected in natural conversational contexts at home, and includes multiple sessions with each of three children, called 'Adam', 'Eve', and 'Sarah', learning English as their first language. The transcribed corpora are freely available on the CHILDES site, and have been involved in many analyses of the input for first language acquisition. The Brown corpus was chosen for this project in part because it has been the focus of some of the morphosyntactic annotations mentioned above. The already-released partial annotation of the Brown corpus included verb semantic role labels for some of the parental speech in the Adam, Eve, and Sarah corpora, as described below. In the present extension, we annotate all speech containing a preposition or a verb, spoken by adults or by the child, in Adam files 01-23 for verb or preposition sense and semantic role labels. This project used trained annotators, who followed existing specifications for semantic-role annotation, and where necessary, developed additional specifications for the task.

The previously released partial annotation of child-directed speech was used to train and evaluate a 'BabySRL' model that learned to interpret sentences based on simple representations of syntactic structure, derived from a constrained distributional analysis of child-directed speech, amplified by simple built-in expectations about predicate-argument structure (Connor et al., 2010; Connor, 2011; Connor et al., 2013). This system demonstrated that simple syntactic features based on the set of nouns in a sentence can guide early steps in language learning. The BabySRL learned to label the first of two nouns as an agent in simple sentences with invented verbs (e.g., *'Adam krads Mommy'*), replicating the linguistic behavior of toddlers, as shown in previous experimental work with children (Gertner et al., 2006). The model also made striking errors with two-noun intransitive sentences with invented verbs (e.g., *'Adam and Mommy krad'*), as do toddlers learning English (Gertner and Fisher, 2012). These errors diminished as the model learned to find verbs, gaining data about the importance of verb position in English sentences. These results showed that partial sentence structures grounded in sets of nouns are useful for learning in natural corpora; the model's constrained distributional learning component offers one account of where these partial sentence structures might come from during early acquisition. It also appeals to powerful evidence that infants detect distributional cues that are relevant to discovering grammatical categories (e.g., (Lany and Saffran, 2010; Shi and Melancon, 2010)).

In addition to supporting models of human language development, annotated corpora of adult-child dialogue can provide a useful context in which to evaluate the robustness of NLP learning models. Toddlers producing their early word combinations often omit the function words that support high-accuracy part-of-speech tagging, parsing and semantic-role assignment (e.g., Brown, 1973). Despite these omissions, however, they are often understood by their adult interlocutors. Understanding speech with missing elements requires a flexible knowledge of language.

The partially annotated corpus of child-directed speech that supported the development of the BabySRL model had two main limitations. First, it annotated only verbs' arguments. Second, it annotated only parental speech, leaving out the children's own contributions to the conversation. This work complements the previous corpus, and corpora such as that used in Fernald et al. (2009), which model discourse environments with child-directed speech. Our corpus does not have visual information, but it is compatible with semantic role labeling methods that are standardly used with other corpora.

The corpus labels both adult and child speech in the dialogue, adding to the noisiness of the data and providing a realistic model for the speech of young children. Naturally occurring noise in data is an interesting theoretical problem. Testing existing automatic semantic role labelers on these data provides an engineering challenge for improving tools in a new domain.

The corpus is of dialogue, so semantic arguments of a verb can appear across interlocutors. Though preposition semantic role labels are only given at the sentence level and not at the discourse level (Srikumar 2013:7), they can be used in a way that facilitates identifying semantic arguments across sentences. For example, if one person says, *'Where did the toy fall?'*, and the next line of dialogue is *'on the floor'*, this corpus is annotated in such a way that could support recovery of semantic roles across sentences in a dialogue. That is, the first sentence is annotated with *'fall'* as the main verb. The word *'where'* is the location argument of *'fall'*. The next utterance *'on the floor'* is annotated with semantic role labels for the head preposition *'on'* with the sense of *location*.

These gold labels also provide a new domain for training an automated preposition semantic role labeler. The usefulness of labeling prepositions was demonstrated in the earlier example of finding answers to questions in a dialogue. Preposition roles also add structure to verb semantic role labelers because the prepositions are often contained in an argument of the main predicate. With this corpus, if a verb has a semantic role assigned to a prepositional phrase, it follows that the preposition takes the same verb as a governor. This information can be used to tie prepositions to governing verbs occurring in the discourse.

In section 2, we explain semantic roles in more detail, discussing Propbank and the automatic preposition semantic roles of Srikumar and Roth (2011). Section 3 describes the annotation tool that we used along with modifications added to the tool for our project. In section 4 we discuss special problems presented by the CHILDES data set (Brown, 1973), explaining why it serves to meet an existing need in the community and foster more scientific discovery. Section 5 provides a break-down of our IAA measures and what they mean in terms of accuracy of the labels. Section 5.1 describes the ratings on the held-out data and what users can expect in the final version of the corpus. We note that this data set contains inherent noise and show that annotator scores reflect noise in the areas that have below 90κ scores, and achieve scores above 90κ in other areas. Section 6 discusses the availability and licensing of the corpus, and section 7 concludes the paper.

2 Semantic Role Labels

2.1 Verb Semantic Role Labeling with Propbank

Propbank (Gildea and Palmer, 2002; Kingsbury and Palmer, 2002; Palmer et al., 2005) provides resources for labeling semantic roles for verbs. The original Propbank corpus included a large hand-annotated corpus of semantic verb-argument relations, and extensive guidelines for annotating verb semantic roles in new corpora (Bonial et al., forthcoming). Propbank added semantic role labels to sentences parsed according to Penn Treebank Guidelines (Mitchell et al., 1993). Other corpora have been annotated with Propbank verb senses and semantic roles, including discourses and SMS.[2]

For each verb, Propbank lists a set of senses for the verb and the licit semantic arguments for that sense. The list of semantic arguments includes core arguments like the agent and patient of transitive verbs as well as directional and locational phrases that commonly occur with the verb. Propbank annotations involve annotating the span of each of a verb's arguments. For example, for the verb *'put'*, sense number 01, has the licit semantic roles of *Arg0, Arg1,* and *Arg2*, which are *putter*, *thing put*, and *where put*, respectively. It is not the case that all of these are present in every use of the verb *put* in a corpus.[3]

2.2 Preposition Semantic Role Labeling

Labeling preposition semantic roles helps with NLP tasks by providing additional shallow semantic information about prepositions and their semantic relation to other words in a sentence.

[2]For current information on corpora with Propbank annotations, see `https://propbank.github.io`.

[3]Senses are from the index of Propbank and FrameNet (Baker et al., 1998) for English at `http://verbs.colorado.edu/propbank/framesets-english-aliases/`.

The preposition semantic role labeler is the one described in Srikumar and Roth (2011) and Srikumar (2013). This role labeler was used due to the relatively small number of observed preposition semantic roles, and its integration with the CogComp NLP pipeline used in the current project.[4] Each preposition has the potential semantic roles associated with it of GOVERNOR and GOVERNED. The governed argument in the phrase *'to the store'* is *'the store'*. It is generally a noun phrase that follows the preposition.

The governor of the preposition can be a verb that takes a preposition as an argument. For example, in the sentence *'Take the cart to the store'*, the preposition *'to'* has the verb *'take'* as a governor. The governor can also be a noun phrase. For example, in the sentence *'Give me the horse with the blue mane.'* the governor of *'with'* is *'the horse'*.

3 Jubilee Annotation Tool

The annotation tool was based on the Jubilee tool by (Choi et al., 2010)[5] and the modified version is available at `https://gitlab-beta.engr.illinois.edu/babysrl-group/jubilee`. The original annotation tool used the Penn Treebank annotations (Mitchell et al., 1993) and Propbank's framesets,[6] and after an initial automatic SRL annotation phase, it allowed the annotators to modify the predicate sense and assign the associated semantic roles to constituents of the sentence.

We extended the tool in several ways to accommodate the annotation of children's utterances and prepositional SRL, and provided other improvements for the convenience of the annotators. A summary of the changes is as follows: We used a JSON format for the annotation files and stored the syntactic trees internally, instead of relying on a separate treebank; we added the ability to edit syntax trees with bracket highlighting; we added the ability to delete entire annotations if they had no real predicate, and we allowed the creation of new predicates when an entry was missing; we extended the context window to show more dialogue context; we added an inter-annotator agreement (IAA) calculator; we added the ability to view predicate information via a link to the Propbank website;[7] we added a bookmarking ability to allow annotators to save difficult annotation cases for future discussion.

3.1 Data Sources

The BabySRL Corpus (Connor, 2011; Connor et al., 2013) annotated a portion of the Adam, Eve, and Sarah files from the Brown corpus (Brown, 1973) with verb semantic role labels.[8] The project only annotated adult speech and omitted uses of the copula verb *'to be'*. We imported data from this corpus into the tool. The imported data did not include verb senses, but it had verb semantic role labels.

Utterances that were not part of the previous derived corpus were automatically parsed and labeled for verb and preposition semantic roles and verb and preposition sense using the NLP pipeline tools available through the Cognitive Computation Group.[9] Files were preprocessed from CHAT format to JSON format in order to annotate the data in the Jubilee tool.

After the first five Adam files were annotated, there was additional preprocessing on the xml files. Most of this preprocessing was for the purpose of working with transcriptions. There are several conventions used in the transcription that were changed. Adam's use of interdental fricatives, represented orthographically as *'th'* (phonetically [ð] and [θ] in many adult dialects of North American English), were transcribed orthographically in the CHILDES data with *'d'*, resulting in *'dat'* for *'that'*, for example. Because the entire discourse was not phonetically transcribed, we found the use of orthography

[4] An anonymous reviewer mentioned that we should explain why we did not use the more recent senses of Schneider (2016). Although there is more coverage with the preposition SRL of Schneider (2016), it uses fine-grained relations that are rarely observed. Due to the high ambiguity of preposition use in toddler speech, even the small number of distinctions in Srikumar and Roth (2011) required large amounts of discussion and calibration between annotators.

[5] The Jubilee tool is described at `https://code.google.com/archive/p/propbank/`

[6] Framesets contain a verb's sense, the associated semantic roles, and examples of uses of the intended sense in corpora. For examples, see `https://verbs.colorado.edu/propbank/framesets-english/`

[7] `http://verbs.colorado.edu/propbank/framesets-english-aliases/`

[8] The derived corpus is available through TalkBank derived corpora `https://childes.talkbank.org/derived/`

[9] The relevant tools are available at `https://cogcomp.org/page/software/` under 'NLP Tools'. The specific set of tools and instructions for replicating the results are available at `https://gitlab-beta.engr.illinois.edu/babysrl-group/babysrl-corpus`.

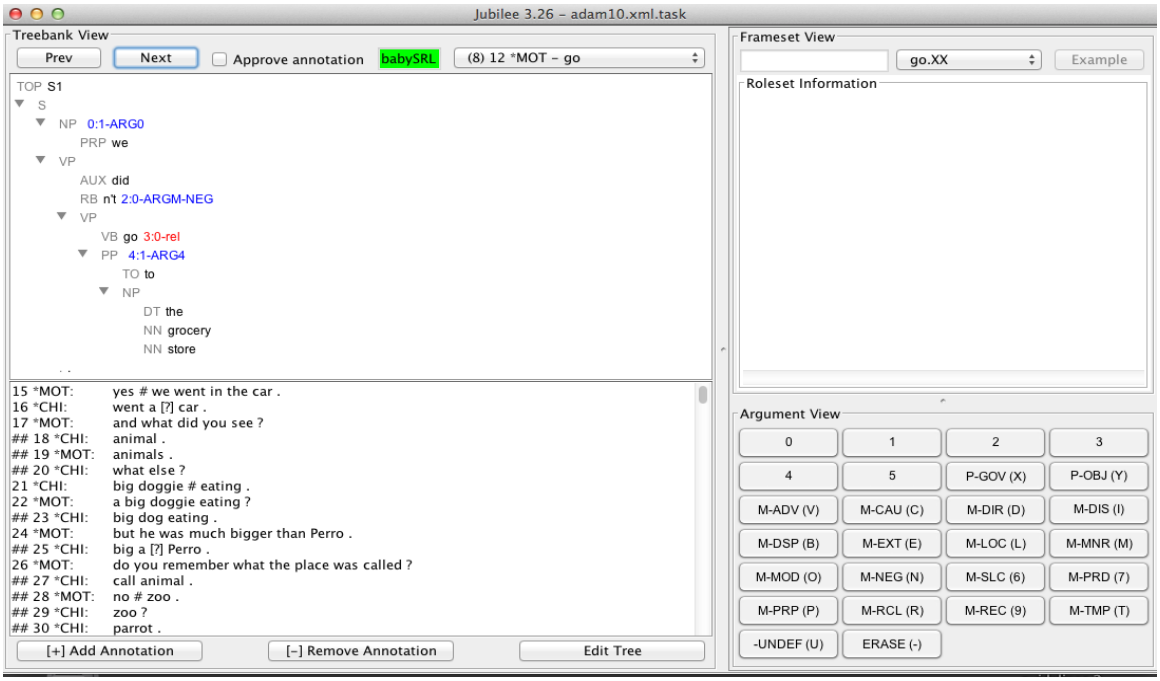

Figure 1: Example from the previous derived BabySRL corpus. 'babySRL' is highlighted in green, indicating that the labels come from the previous corpus. The context window at the bottom shows the surrounding discourse.

to represent the pronunciation inconsistent with the way in which the majority of the corpus was transcribed, so we preprocessed these examples to have standard orthography. Unknown words, transcribed as *'xxx'* were removed, as were symbols for spelling out loud, such as *'@c'*, which indicated someone speaking the name of the letter 'c'. All indicated pauses, which used the symbol *'#'* were changed to commas. Characters following underscores, along with the underscores, were removed.[10]

For utterances that were annotated in the previous round, annotators saw the gold-standard annotation without the verb sense listed. An example is given in Figure 1. Near the center-top of the bar in the Jubilee tool, there is a window that says 'babySRL', highlighted in green. Annotators could see from this window whether they were annotating utterances from the previous corpus, the automatic annotation, or viewing utterances that they had already annotated. Below the window containing the parsed and labeled utterance, there is a context window that shows some of the surrounding discourse.

To the right of the main windows, there is a window in which role set information for a sense appears. In the previous BabySRL example, no sense was imported. Annotators choose the appropriate sense. They could use semantic role labels to help determine the intended sense. The 'View in Browser' button takes the annotator directly to the Propbank online index, where annotators can check senses.

For utterances new to this round of annotation, annotators saw the automated parse and semantic role labeling. Figure 2 shows the output of the NLP pipeline, as the annotator would see the data. Rather than a green window labeled 'babySRL' there is a red window labeled 'auto', indicating that the annotator is viewing an automatic parse and SRL. In this example, the tool assigns the most likely sense, and the roles associated with the sense are shown in the Frameset View window.

4 Annotation Guidelines

The syntactic parses follow the Penn Treebank Guidelines (Santorini, 1990; Mitchell et al., 1993) as outlined in Bies et al. (1995) and the modified guidelines in Warner et al. (2012). Annotators were

[10]These changes are in BrownXMLReader.java at `https://gitlab.engr.illinois.edu/babysrl-group/babysrl-corpus/blob/master/src/main/java/edu/illinois/cs/cogcomp/babySRL/corpus/xml/BrownXMLReader.java`

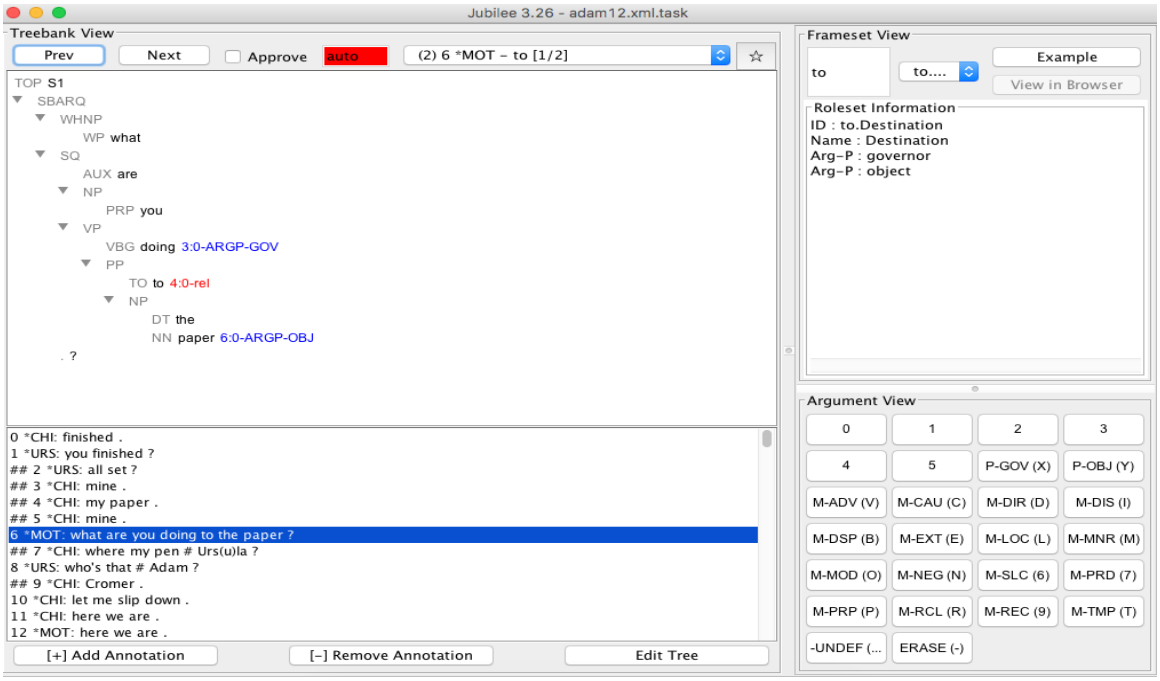

Figure 2: Example from the output of the NLP pipeline parse and semantic role labeler. The label 'auto', is in red, indicating that the labels are the output of the NLP pipeline.

instructed to consult these guidelines for all decisions. Additional decisions that came up are listed in the specifications.[11] Annotators were instructed to make a single-pass of the data. If the output parse interfered with labeling semantic roles, annotators were instructed to change the parse according to the Penn Treebank Guidelines.

In order to check verb senses and semantic role labels, an abbreviated version of Propbank (Kingsbury and Palmer, 2002; Gildea and Palmer, 2002; Palmer et al., 2005) labels appeared in the Jubilee window, and annotators were able to use a link to the Propbank entry in the Unified Verb Index (Bonial et al., 2014; Bonial et al., forthcoming), if additional information was needed.

If a verb sense did not appear to be present in Propbank, annotators consulted a list of previous decisions and, if it was present there, used that decision on semantic role labels. If the verb sense was neither in Propbank nor the list of previous decisions, annotators made note of the sense. However, annotators were instructed to try to use the previous senses as much as possible.[12] The preposition semantic roles, based on those in Srikumar and Roth (2011), had brief example descriptions in the Frameset View window.

4.1 Special Issues in Annotation

The most common issues that came up in annotation involved labeling partial expressions and ambiguous arguments. Because the child speech was labeled, it was often unclear whether expressions were filling semantic roles of a predicate or not and, if they were, it was not clear which role they were filling.

Annotators were instructed to only give a semantic role if it was clear what it was. They were instructed to use only the visible context window at the bottom of the Jubilee tool, which showed about twelve sentences with the target sentence in the middle of the context window, highlighted in blue (see Figure 2) to help determine verb or preposition senses that were uncertain.

[11]The full specifications are available at `https://github.com/CogComp/child-discourse-SRL/tree/master/specs`.

[12]Additional decisions that came up are listed in the specifications available at `https://github.com/CogComp/child-discourse-SRL/tree/master/specs`.

5 Inter-Annotator Agreement

The following four files were held-out data: Adam11, Adam15, Adam17, and Adam19. The data in these files were not discussed. Annotators were instructed to annotate according to the same methods that they used in other non-held-out data. There were 27,380 total sentences for annotation, and the held-out data total 5,804, so nearly one-fifth of the data was held-out for inter-annotator agreement. The files were annotated sequentially according to their numbers. After the IAA scores were measured on Adam 11, the results were discussed and used for calibration on subsequent held-out corpora.[13] The data was annotated by two annotators. Annotator X was an undergraduate student in linguistics and a bi-lingual speaker of English and Spanish. Annotator Y was a graduate student in linguistics and a native speaker of English.

File	total annotator X	total annotator Y	original sentences
Adam 11	1159	1133	1403
Adam 15	909	884	1187
Adam 17	1402	1379	1453
Adam 19	1704	1695	1761

Table 1: Table of total annotations of held-out data for each annotator (annotator *'X'* and annotator *'Y'*). The total annotations for each annotators are the annotations in the final annotated file. The original sentences total is the number of sentences that appeared in the Jubilee window to be annotated. Some were removed due to errors in automatic detection of prepositions and verbs or because they were instances of the child repeating one verb many times.

Table 1 shows the total annotations for each annotator and the starting number of annotations in the task. In the course of annotation, the number of annotations in the automatically annotated corpus and previous BabySRL corpus changes. Annotations are added when there is a preposition or verb in the sentence that the automated annotator missed entirely. Annotations are removed for reasons given in the specifications. For example, if a child utterance repeats the verb *'jump'* seven times, the automatic annotation will give seven entries. We decided to only use one verb in a set of repetitions. Annotations are also removed due to the fact that automatic tagging of modal auxiliaries and auxiliaries *'do'* and *'be'* occurred, but the specifications said not to annotate them.

In the subsequent sub-sections, the IAA is broken down into component parts.

Table 2 provides the inter-annotator agreement measures (raw score and Cohen's *kappa*). Each of the four held-out files are presented, followed by an average of the scores across all of the held-out data. For each file, the data is separated by verb SRL and preposition SRL, followed by the agreement on both, labeled *'predicate'*. For each of the three categories, the scores are further separated into the scores on child utterances and the scores on adult utterances, with the scores on child and adult utterances combined provided as well.

Column labels of Table 2 are the various annotations that were measured. The label *'sense'* refers to the Propbank sense, in the case of verbs, and the Srikumar and Roth (2011) sense in the case of prepositions. The label *'# args'* represents the measure of annotator agreement on how many semantic role arguments were present in the sentence. The *'label id'* measures how often annotators provided the same label name to an argument, and the *'span'* column checks annotator agreement on the span of the expression to which a label was assigned.

The syntactic structures are not explicitly compared, however, if the trees are significantly different between annotators, then it is reflected in the span of the arguments, in some cases.

[13] Non-held-out data was done up to Adam 7 at this point, and annotators were calibrating non-held-out data during the process. Adam 1-5 were later re-annotated due to a post-processing error. The work-flow time-line can be found at `https://docs.google.com/spreadsheets/d/19wJtQjt6D4CtoQH4drrpdsw4jiSkzj24U9L4W7Ob4vc/edit?usp=sharing`

Table 2: For each of the held-out data sets, the IAA is presented for the verb SRL and the preposition SRL separately and for all SRL predicates (verbs and preposition SRL combined). The IAA is presented for adult language data, for child language data, and for both combined. The chart gives the raw IAA score followed by Cohen's κ for each of the following categories: *sense* gives the agreement on the Propbank sense, in the case of verbs, and the Srikumar and Roth (2011) sense, in the case of prepositions. *# arg* gives the IAA on the number of arguments annotators assigned to each predicate. The *label id* measures the agreement on the name of the label given, provided both annotators gave an expression a semantic role label. The *span* gives agreement on the span of a semantic role argument. The asterisks indicate sense data that we did not count due to a misunderstanding in the specifications, which was corrected.

5.1 Analysis

The IAA reports show a high overall agreement on the held-out dataset.[14]

The verb sense agreement κ scores for adults are much higher in the later half of the annotations. The scores for Adam 11 and 15 (not included) were 24.4 and 25.5, going up in Adam 17 and 19 to 71.8 and 77.6. The initial low scores were due to the two annotators following different specifications. The initial specifications said not to add a Propbank sense to expressions imported from the previous corpus. One annotator was adding senses anyway, and this fact was not discovered until the annotators discussed the IAA results of Adam 11. At that time, the annotator who was not adding senses had already completed annotating Adam 15. At meetings, it was decided that the specifications should be changed to say that we would add senses to verbs imported from the previous corpus. We corrected this in annotations that were finished.

The sense agreement scores for child speech and for prepositions are entirely new to this corpus, as are some of the verbs in adult speech, including the copula verb. Overall, the scores reflect high annotator agreement, given the new data. The overall sense agreement κ score is 72.6.

The argument number is simply a calculation of how many arguments the annotators assigned roles to, regardless of whether or not they assigned those arguments the same label or the same span. The effects of the κ score are more drastic on prepositions because the prepositions can only have at most two arguments, whereas verbs, in contrast, can have five. The κ scores for prepositions also tend to be the lowest due to the frequent absence of arguments and ambiguity of expressions. For example, in the child language phrase *'dog on the floor'* the preposition *'on'* governs *'the floor'*, but *'dog'* may or may not be a governor, depending on how the annotator interprets the child's phrase, given the context window. The noun *'dog'* can be considered to be a governor, similar to the sentence *'I meant the dog on the floor'*, or it can be read as being like the sentence *'The dog is on the floor'*, in which case, the governor is *'is'*, and that verb is missing in the child utterance. Because of such problems, a lower agreement occurs on prepositions overall 69.8κ, as opposed to verbs at 85.1κ.

The label identification matching has very high agreement scores, staying over 90κ throughout most of the annotation. The measure checks how often annotators assigned the same label, given that they assigned a label to an argument. Because this project was concerned with child language acquisition and identification of agents and patients in child speech, this was a welcome result. The agent and patient roles, defined in Propbank guidelines, based on a prototype view of semantic roles (Dowty, 1991), are the most common semantic roles associated with verbs in Propbank. Seeing that annotators consistently agreed on how to assign them in a corpus with high ambiguity attests to the specification development in this area and the feasibility of labeling semantic roles in child speech.

The argument span labels also have scores over 90κ in most of the data. Annotators were instructed to alter the parse according to Penn Treebank guidelines only when the parse was incorrect in a way that altered the span of a semantic role argument. Indirectly, the high agreement on argument span indicates a high agreement on decisions regarding changes to the automatic parser output.

Among the areas that had lower agreement, the agreement scores reflect reasonable variation in the interpretation of data that is frequently ambiguous. For example, when the child says *'go mommy'*, it can be read as an imperative telling his mother to leave or as a statement of the child's intention to go to his mother (e.g., 'I am going to mommy.').

In comparison to previous work, according to `http://cogcomp.org/Data/BabySRL.html`, 15 of the 133 files were held-out for measuring IAA. Across all of the files, annotators agreed on an average of 96.57% of the annotated arguments for span and label. Our span and label average is 93.8%. Considering the increased difficulty of SRLs in child speech, the results are comparable.

[14]The code used to calculate IAA is available at `https://gitlab-beta.engr.illinois.edu/babysrl-group/jubilee/blob/master/src/jubilee/agreement/AgreementCalculator.java`.

6 Availability and Licensing of the Corpus

All uses of the CHILDES corpus have general licensing requirements.[15] For this derived corpus, also cite this document.

The xml version is available for download at `http://cogcomp.org/page/resource_view/115`. The CHAT version is available through TalkBank at `https://childes.talkbank.org/derived/`.

7 Conclusion

In this work, we have described a new resource for NLP studies. It applies a commonly used gold standard for shallow semantic labeling, Propbank, as well as a preposition SRL to adult-child interactions. We explained the methods and tools needed for completing the annotation project, and provided support for the quality of the annotation through inter-annotator agreement measures on held-out data.

Abstract

Neural machine translation systems require a number of stacked layers for deep models. But the prediction depends on the sentence representation of the top-most layer with no access to low-level representations. This makes it more difficult to train the model and poses a risk of information loss to prediction. In this paper, we propose a multi-layer representation fusion (MLRF) approach to fusing stacked layers. In particular, we design three fusion functions to learn a better representation from the stack. Experimental results show that our approach yields improvements of 0.92 and 0.56 BLEU points over the strong Transformer baseline on IWSLT German-English and NIST Chinese-English MT tasks respectively. The result is new state-of-the-art in German-English translation.

1 Introduction

Neural models that use the encoder-decoder architecture to capture the translation equivalence relation between languages have been widely adopted over the last few years. The simplest of these relies on one recurrent neural network layer on both the encoder and decoder sides (Bahdanau et al., 2015), whereas others have successfully explored the high-level representation of language via deeper models (Wu et al., 2016; Gehring et al., 2017b; Vaswani et al., 2017). It has been noted that increasing the network depth is one of the factors contributing to the success of neural machine translation (NMT). To this end, one can stack a number of layers for an enriched sentence representation. E.g., popular NMT systems require 4 stacked layers or more for state-of-the-art results on large-scale translation tasks (Wu et al., 2016). Unfortunately, a straightforward implementation of deep neural networks has been found to underperform shallow models due to the poor convergence. One solution to this problem is to add identity mapping (or shortcut connection) between layers. A popular method is the residual network (He et al., 2016a), which has been used in several successful systems, e.g., GNMT and Transformer.

This model offers a good way to ease the information flow in the stack. But they do not make full use of the multi-level representations of the deep networks. E.g., word predictions depend on the sentence representation of the top-most layer with no access to low-level representations. Recent evidence supports that it helps when features from lower-level layers are involved in prediction (Xiong et al., 2017; Gehring et al., 2017b). A good instance is DenseNet that applies a fully-connected convolutional network to computer vision (Huang et al., 2017a). But it is still rare to see studies on this issue in machine translation.

In this paper, we take a further step along the line of this research. Drawing on previous successful attempts to create shortcut connections between adjacent layers, we propose a multi-layer representation fusion (MLRF) approach that connects one layer to all its predecessors. It learns a fused representation by accessing all lower-level representations of sentence, rather than learning from the limited information flow in one residual connection. The contributions of this work are three-fold.

- We propose an approach to learning better sentence representations by accessing lower-level layers. To our knowledge, it is the first time to use densely connected networks in NMT.

- We investigate methods to learn functions that fuse different levels of sentence representations. In particular, we propose to learn a 2D representation by the self-attention mechanism.
- We demonstrate the effectiveness of the approach on top of a strong system (Transformer) which has already used residual networks. It achieves a new state-of-the-art result on the IWSLT German-English MT task.

Our approach is applicable to arbitrary neural architectures and is easy to be implemented. In experiments on IWSLT German-English and NIST Chinese-English translation, it yields improvements of 0.92 and 0.56 BLEU points over the baseline respectively. More interestingly, we find that our approach has a regularizing effect and reduces the risk of over-fitting.

2 The Transformer System

In this work, all discussions and experiments are based on the Transformer system. We choose Transformer because it is one of the most successful NMT systems in recent MT evaluations. Unlike usual NMT models, Transformer does not require any recurrent units for modeling word sequences of arbitrary length. Instead, it resorts to self-attention and standard feed-forward networks for both encoder and decoder.

On the encoder side, there are L identical stacked layers. Each of them is composed of a self-attention sub-layer and a feed-forward sub-layer. The attention model used in Transformer is scaled dot-product attention[1]. Its output is fed into a fully connected feed-forward network. To ease training, the output of each sub-layer is defined as $\text{LayerNorm}(x + \text{sublayer}(x))$, where $\text{LayerNorm}(\cdot)$ is layer normalization (Ba et al., 2016) and $\text{sublayer}(x)$ is the output of the sub-layer. The identical mapping of input x represents the residual connection. To facilitate description, we use $H = \{h^1, \ldots, h^L\}$ to denote the outputs of source-side layers in this paper [2].

Likewise, the decoder has another stack of L identical layers (denoted as the function $\text{Layer}(\cdot)$). It has an encoder-decoder attention sub-layer in addition to the two sub-layers used in each encoder layer. Moreover, because the model is auto-regressive, the decoder attends a target position to all positions up to it. Let z_j^l be the output vector of target position j in the l-th layer, and $z_{\leq j}^{l-1}$ be the vector sequence $\{z_1^{l-1}, \ldots, z_j^{l-1}\}$. The output of the layer can be described as $z_j^l = \text{Layer}(z_{\leq j}^{l-1}, H)$.

The auto-regressive property also persists in the output layer. Given a source sentence $\mathbf{x} = (x_1, \ldots, x_M)$, and a target sentence $\mathbf{y} = (y_1, \ldots, y_N)$, the translation model is defined to be:

$$P(\mathbf{y}|\mathbf{x}) = \prod_{j=1}^{N} \Pr(y_j|y_{<j}, \mathbf{x}) \tag{1}$$

where $\Pr(y_j|y_{<j}, \mathbf{x})$ is the probability of generating a target word y_j given the previously generated words $y_{<j}$ and the source sentence $\mathbf{x}$. To model $\Pr(y_j|y_{<j}, \mathbf{x})$, we have

$$\Pr(y_j|y_{<j}, \mathbf{x}) = \text{Softmax}(W_o \cdot z_j^L + b_o) \tag{2}$$

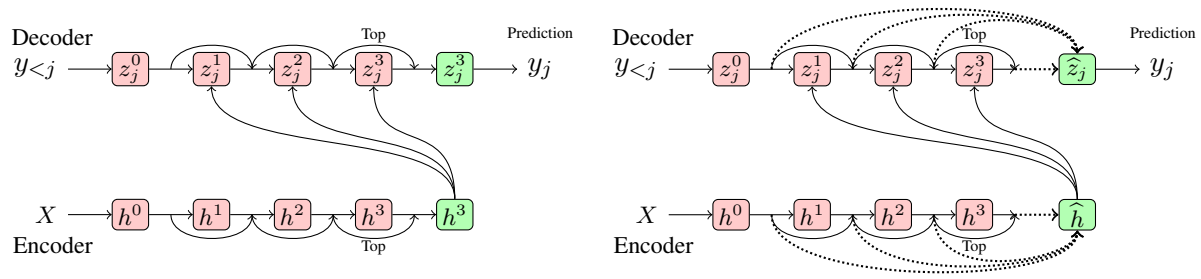
where W_o and b_o are the model parameters of the output layer. Obviously, the word prediction model here depends only on the output of the top-most layer in the stack (i.e., z_j^L).

3 The Approach

The model presented in Section 2 shows a standard way of word prediction where the output layer is connected to the top-most hidden layer only. This is fine if the system is composed of one hidden layer or two. But it may be problematic when the network goes deeper. First, this method has difficulties

[1] Given a sequence of vectors and a position i, the self-attention model computes the dot-product of the input vectors for each pair of positions (i, j), followed by a rescaling operation and Softmax. In this way, we have an attention score (or weight) for each (i, j). It is then used to generate the output by a weighted sum over all input vectors.

[2] We regard the word embedding layer as a special layer at the bottom of the stack, and denote it as h^0.



(a) Standard Architecture (b) The MLRF Architecture

Figure 1: Network Architectures. Dotted lines denote multi-layer fusion connections. Green rectangles denote the representations used in the downstream components.

in training deep models. To learn model parameters, gradients have to be propagated through a single channel of several stacked layers. Previous work has pointed out that it is not easy for lower-level layers to find good parameters due to the vanished or exploded gradients (Srivastava et al., 2015; He et al., 2016a). The situation is even worse when we use many non-linear transformations that are hard to learn. The residual connection between adjacent layers can alleviate the problem, but it is still a long distance for bottom layers to have direct feedbacks from the prediction. Second, there is potential information loss when we feed a single layer to the output layer. Top-level layers may forget previous features, especially when the stacked layers have the same capacity (e.g., the same size of layer output). For a simple solution, one can enlarge the layer size on the top. But it in turn drastically increases the number of parameters and is obviously not efficient for practical systems.

In this work, we propose a multi-layer representation fusion method to address these problems. It learns a fused representation of the sentence by direct access to all the layers in the stack. In this way, the prediction can benefit from the fused representation which has less information loss. As another bonus, this method makes it easier for the deep network to learn parameters because of the efficient information flow in connections from bottom to top.

3.1 Multi-layer Representation Fusion

The idea of representation fusion is pretty simple. We introduce a fusion layer into the network, and connect it to all the stacked layers. This layer can learn a refined representation from different levels of the stack. Let $Z = \{z^1, \ldots, z^L\}$ be the output sequence of the stacked layers on the decoder side. We define $\phi(Z)$ to be the fusion function that fuses $\{z^1, \ldots, z^L\}$ into a single representation. More specifically, given a target word position j, $\widehat{z}_j = \phi(Z_j)$ is defined to be the fused representation of all layer representations $Z_j = \{z_j^1, \ldots, z_j^L\}$ in the stack for position j. Then Eq. (2) can be rewritten as:

$$\Pr(y_j|y_{<j}, \mathbf{x}) = \text{Softmax}(W_o \cdot \phi(Z_j) + b_o) \tag{3}$$

There are many choices to design the fusion function $\phi(Z_j)$. E.g., we can cast the usual method as a special case of our model and do exactly the same thing as in Section 2, i.e., $\phi(Z_j) = z_j^L$. Alternatively, we can fuse more layers with another neural network. Moreover, we can do representation fusion on either the encoder side, the decoder side, or both. See Figure 1 for an illustration of the method.

Another note on representation fusion. The method is applicable to arbitrary neural network architectures with multiple levels of layers. Although we restrict ourselves to Transformer for our experiments, Eq. (3) actually shows a more general case. In a sense, our model is doing something similar to fully connected networks in computer vision (Huang et al., 2017a; Liu et al., 2018). Representation fusion is essentially a process that creates a densely connected network on top of the stack. In this work, we describe the problem in the more general framework, and will show that NMT systems can benefit from better design of fusion functions.

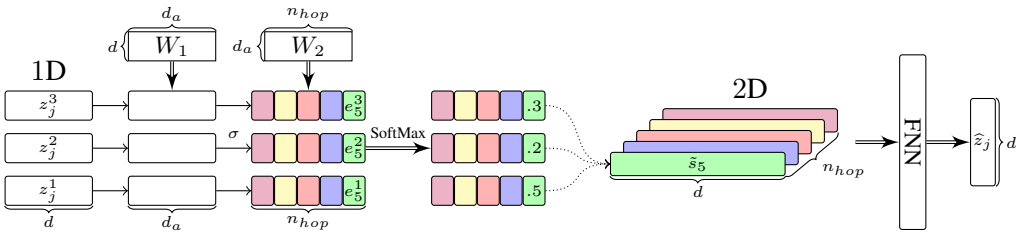


Figure 2: An example of 3-layer representation fusion based on self-attention with 5 hops.

3.2 Fusion Functions

Fusion by Pooling The simplest way of representation fusion is pooling. Here we choose average pooling (avg-pooling) because it shows better results than other pooling methods in our preliminary experiments. Given a sequence of layer outputs at position j, the output of average pooling-based fusion is $\phi(Z_j) = \frac{1}{L}\sum_{l=1}^{L} z_j^l$. In general, this way can be seen as the natural generalization of residual connections (He et al., 2016b; He et al., 2016a). It accumulates all layer features at once when going through the stack, rather than performing identity mapping between adjacent layers at each time. Also, this method is nonparametric and simply assigns an equal weight to each layer in fusion.

Fusion by Feed-forward Neural Network A more sophisticated method is to use feed-forward neural networks (FNNs) for fusion. To this end, we first concatenate all layer outputs to form a big vector. Then, we feed the vector into a single hidden layer FNN with d_f hidden units. Let d be the size of the layer output vector (i.e., $d = |z_j^l| \ \ \forall j, l$). The FNN transforms an $L * d$ dimensional vector to a d dimensional vector. This is good because we do not need to change the size of the downstream components. Moreover, we can learn a better fusion function by the non-linear activation functions used in FNNs. It should be noted that this method can be seen as a special case of dense connection, that is we only concatenate all the features of predecessors in the topmost layer rather than every intermediate layer. As a result, it can reduce the connection complexity from $\mathcal{O}(L^2)$ to $\mathcal{O}(L)$.

Fusion by Multi-hop Self Attention In addition to the pooling and FNN-based methods, we design another fusion function based on the self-attention model with hops [3] (Figure 2). The motivation is straightforward. Different layers reflect different aspects of sentence representation. An ideal way is to take correlations between layers into account, and model the correlation strength (or weight) in generating the fused result. This agrees with the nature of the attention mechanism well (Bahdanau et al., 2015). Beyond this, self-attention with hops can generate a 2D output that explains different meanings of the input vectors. Previous work has reported that 2D matrix-based representations outperform 1D vector-based counterparts in sentence embedding (Lin et al., 2017). So it is worth a study on this issue in NMT.

The idea is that we apply self-attention with multiple hops vertically over the layer sequence (along the axis of depth), and extract a part of layer information by each hop. The new problem that arises here is that we need to perceive the temporal order information in sequence (Shen et al., 2018). Unlike Vaswani et al. (2017)'s work, we do not resort to a fixed positional encoding generated by sine and cosine functions of different frequencies. Instead, we learn an embedding of the layer index, as used in positional embedding (Gehring et al., 2017a). The output of layer embedding is of size d, so it is compatible with the layer representation vector z_j^l. Also, we use a shared layer embedding for the encoder and the decoder for simple implementation.

More formally, let $E^l \in \mathbb{R}^d$ be the embedding of layer l. We inject layer embedding into the original representation of the layer, like this:

$$\tilde{z}^l = z^l + E^l \tag{4}$$

[3] In this work, the term "hop" denotes an independent attention computation, which has the same meaning as Lin et al. (2017). More specifically, one hop can generate a vector as the attention distribution over the layers. And different hops may generate the distinguished distributions.

Entry	Fusion Function	Low-level accessible	Parametric	2D represent.
Baseline	$\phi(Z_j) = z_j^L$	No	No	No
Avg-pooling	$\phi(Z_j) = \frac{1}{L}\sum_{l=1}^{L} z_j^l$	Yes	No	No
FNN-based	$\phi(Z_j) = \text{FNN}([z_j^1, ..., z_j^L])$	Yes	Yes	No
Self-att.-based	$\phi(Z_j) = \text{FNN}(\text{SelfAtt}([z_j^1, ..., z_j^L]))$	Yes	Yes	Yes

Table 1: Comparison of the fusion functions used in this work.

where $\tilde{z}^l \in \mathbb{R}^d$ is the new representation that encodes both the content and index information of layer l. Then the self-attention method is performed over $(\tilde{z}^1, ..., \tilde{z}^L)$. For hop p, the energy of attention weight is computed by an FNN with a single hidden layer,

$$e = W_2(\sigma(W_1 \cdot [\tilde{z}^1, ..., \tilde{z}^L]^T)) \tag{5}$$

where $[\tilde{z}^1, ..., \tilde{z}^L] \in \mathbb{R}^{d \times L}$ is the 2D layout of layer representations, $W_1 \in \mathbb{R}^{d \times d_a}$ and $W_2 \in \mathbb{R}^{d_a \times n_{hop}}$ are model parameters, σ is the activation function, and d_a is the size of inner hidden state. In this model, each hop has an independent parameter vector corresponding to one column of W_2, whereas W_1 is shared across different layers to make efficient use of memory [4]. After that, we obtain the attention weight vector $\mathrm{a}_p = (a_p^1, ..., a_p^L)$ of hop p by Softmax. For each layer index l, we have

$$a_p^l = \frac{\exp(e_p^l)}{\sum_{l'=1}^{L} \exp(e_p^{l'})} \tag{6}$$

The self-attention model generates an intermediate representation by dot-production ($\odot$) of the weights and the layer representations.

$$\tilde{s}_p = a_p \odot [\tilde{z}^1, ..., \tilde{z}^L] \tag{7}$$

In this way, all the hops compose a 2D matrix $\tilde{s} = [\tilde{s}_1, ..., \tilde{s}_{n_{hop}}] \in \mathbb{R}^{d \times n_{hop}}$. This matrix is fed into another single hidden layer FNN with d_f hidden units for the final output. It is worth noting that the model presented here can be enhanced by using an independent weight $a_{p;k}^l$ for each dimension k of $\tilde{z}^l$ (call it feature-wise fusion). But this method is computationally expensive. In our experiments we do not observe improvements by this method. Therefore, we choose the version described in Eqs. (6-7) for the empirical study.

Table 1 shows a comparison of the methods used in this work. For good convergence, we use layer normalization after the fusion layer in this work.

4 Experiments

We evaluate our proposed approach on German-English and Chinese-English translation tasks.

4.1 Setup

For German-English translation, we use the data of the IWSLT 2014 German-English track (Cettolo et al., 2014). We follow Ranzato et al. (2015)'s work for preprocessing. We use a joint source and target byte-pair encoding with 10k merge operations (Sennrich et al., 2016). The source and target vocabulary sizes are 8,389 and 6,428 respectively. We remove the sentences with more than 175 words or 100 sub-word units. This results in 160K sentence pairs for training. We randomly sample 7K sentences from the training data for held-out validation, and concatenate dev2010, dev2012, tst2010, tst2011, and tst2012 for test.

For Chinese-English translation, we use parts of the bitext provided within NIST12 OpenMT[5]. We choose NIST 2006 (MT06) as the validation set, and 2004 (MT04), 2005 (MT05), 2008 (MT08) as the

[4] W_1 can be unique for each layer. We discuss this issue in Section 4.4.

test sets. All Chinese sentences are word segmented using the tool provided within NiuTrans (Xiao et al., 2012). All sentences of more than 50 words are removed. The resulting training corpus consists of 1.85M sentence pairs, with 39.42M Chinese words and 44.92M English words on each language side. We limit the vocabularies to the most frequent 30K words, covering approximately 98.16% and 99.17% of the Chinese and English words respectively. All out-of-vocabulary words are replaced with <UNK>. We report results without any UNK-replacement techniques (Luong et al., 2015).

4.2 Implementation Details

For German-English systems, the model consists of a 3-layer encoder and a 3-layer decoder with $d = 256$ and 1024 hidden units in the FNN sub-layer. For our approach, we set $d_a = 1024$ and $d_f = 512$. Dropout (rate$= 0.1$) is used for regularization. We initialize all word/sub-word embedding matrices using a normal distribution $\mathcal{N}(0, d^{-0.5})$, while initialize the layer embedding matrix using a uniform distribution $\mathcal{U}(-0.1, 0.1)$. The weight and bias in layer-normalization are initialized to constants 1 and 0. All other parameters are initialized from $\mathcal{U}(-\frac{1}{\sqrt{fan_{in}}}, \frac{1}{\sqrt{fan_{in}}})$, where fan_{in} is the input size of the parameter matrix. We use negative Maximum Likelihood Estimation (MLE) as loss function, and train all the models using Adam (Kingma and Ba, 2014) with $\beta_1 = 0.9$, $\beta_2 = 0.98$, and $\epsilon = 10^{-9}$. We run training for 40 epochs with a mini-batch of 80. The learning rate is scheduled as described in (Vaswani et al., 2017): $lr = d^{-0.5} \cdot min(t^{-0.5}, t \cdot 16\text{k}^{-1.5})$, where t is the step number. After that, we restart Adam and continue the training for additional 20 epochs with a fixed learning rate $5e^{-5}$ and a smaller mini-batch of 32 (Denkowski and Neubig, 2017). At test time, translations are generated by beam search with length normalization. By tuning on the validation set, we use a beam of width 8 and a length normalization weight of 1.6.

For Chinese-English systems, we use a 6-layer encoder and a 6-layer decoder, with $d = 512$ and 2048 hidden units in the FNN sub-layer. We restart Adam after 10 epochs and train the model for 5 additional epochs. A beam of width 12 and a length normalization weight of 1.3 are employed.

Note that the network equipped with our fusion layer increases a fraction of the computation cost than original one. E.g., in Chinese-English translation, the training speed reduces from 2.6 batches/second

(baseline) to 2.4 batches/second (Dec-SA, ref. row 11 in Table 3).

4.3 Results on German-English Translation

Table 2 shows the BLEU scores of various NMT systems[6]. For comparison, we list previous results on the same data set. First of all, our baseline is good. The base setting of our baseline system can lead to a similar score to ConvSeq2Seq which is trained for more epochs (Edunov et al., 2017). The baseline is stronger when Adam restart is adopted. It outperforms most of previous systems on this task (only lower than the best reported system by 0.2 BLEU points).

Then, we test different fusion functions (AVG, FNN and SA) on the encoder side (Enc), the decoder side (Dec) and both of them (Both). We see that avg-pooling does not yield promising improvements due to the relatively low expressive power. In addition, the representation fusion on the decoder side is more effective than that on the encoder side. A possible reason is that the prediction can benefit more from the lower-level layers in the decoder due to the "shorter" distance from fusion to prediction. This agrees with the result that representation fusion on both sides (Both-SA) does not improve Enc-SA and Dec-SA significantly. The best result is achieved when we use FNN-based fusion on the encoder side and self-attention-based fusion on the decoder side (Both-FNN-SA). It outperforms the 3-layer baseline by 0.92 BLEU points. Also, we increase the number of layers to 4 and 6 to examine whether the improvement comes from the additional model parameters introduced by the added fusion layer. It results in stronger baselines, but they still underperform the Both-FNN-SA system which has fewer parameters.

4.4 Results on Chinese-English Translation

For Chinese-English translation, we compare our systems with three open source systems: Nematus (Sennrich et al., 2017), NMTTutorial (Luong et al., 2017) and T2T [7]. The first two are based on RNN, while the last one is based on Transformer. Table 3 shows that our baseline with restarting Adam is a bit better than T2T. Like in German-English translation, fusion on the decoder side is superior than that on the encoder side. But both Enc-FNN and Enc-SA are worse than the baseline. We suspect that adding more layers with non-linear transformations makes it more difficult to train the deep network (6 layers in Chinese-English translation) than the shallow counterpart (3 layers in German-English translation). This problem is more evident here because the Chinese-English systems have many more parameters than the German-English systems and are more difficult to optimize. Interestingly, we see that the simple avg-pooling fusion method works well in both encoder and decoder. In addition, using independent W_1 (in

[6] All BLEU results are case-insensitive. For a fair comparison with previous work, we run *multi-bleu.perl* for German-English translation, and run *mteval-v13a.pl* for Chinese-English translation.

self-attention) for each layer is helpful for better fitting. It indicates that the MLRF method can benefit from more sophisticated design of the self-attention model.

4.5 Effect on Attention Hops

Figure 3 shows the BLEU curves by varying n_{hop} on German-English translation with the Dec-SA approach. Clearly, increasing the number of hops improves the system. The improvement is significant when $n_{hop} < 6$ thanks to the 2D representations extracted by multiple hops. Note that when $n_{hop} = 1$, the 2D sentence representation is degraded into the 1D representation. It results in a dramatic decrease in BLEU. However, larger n_{hop} does not make further improvements due to the redundant information in hops and potential overlaps between them.

4.6 Importance of Word Embedding and Layer Embedding

Then, we study the model behavior with/without word embedding or layer embedding on German-English translation. Table 4 shows that removing either word embedding or layer embedding harms the Enc-FNN system. The impact of word embedding is a bit more than that of layer embedding. As a contrast, Dec-SA is more sensitive to the remove of layer embedding. We attribute it to the unawareness of the temporal order information in the self-attention mechanism. More interestingly, when we fuse representations on both sides, almost no BLEU reduction is observed in Both-FNN-SA. It is true even if layer embedding is removed. This result indicates that the layer indexing information can be delivered from the FNN fusion layer in the encoder to the decoder in an implicit way. Also, a significant improvement can be achieved by fusing with the original word embedding features. It agrees with the result reported in (Xiong et al., 2017).

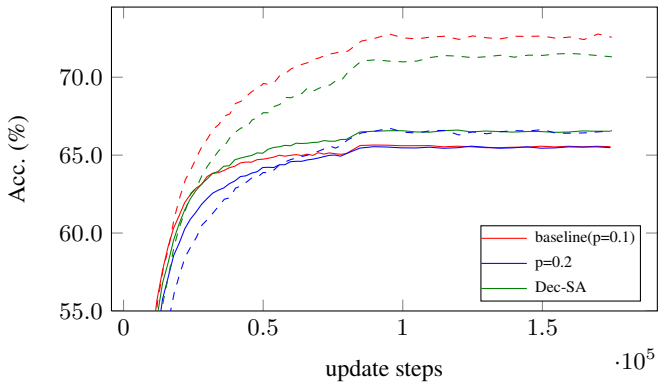

Figure 4: Curve of Accuracy in training-set (dashed lines) and validation-set (solid lines) along with update steps. p is dropout rate.

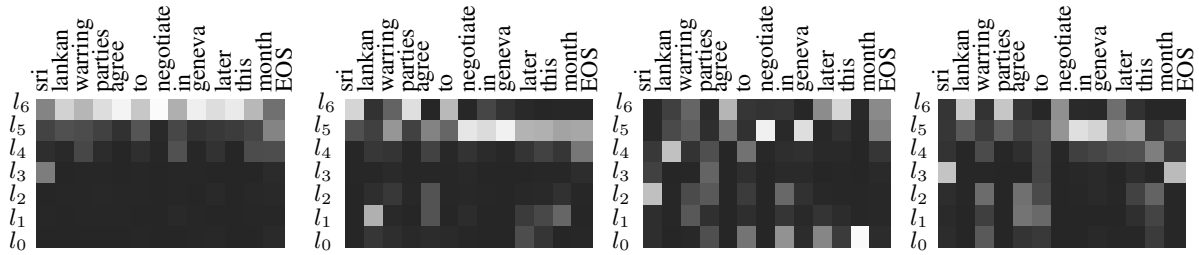

(a) Hop 1 (b) Hop 2 (c) Hop 3 (d) Hop 4

Figure 5: A visualization example of Dec-SA with 4 hops in Chinese-English translation. Colors change between white (probability of 1) to black (probability of 0). The source sentence (pinyin) is *Sīlǐlánkǎ jiāozhàn shuāngfāng tóngyì běnyuè xiàxún zài rìnèiwǎ tánpàn*.

4.7 Regularization

Also, we plot the curves of accuracy on the training and validation sets in Figure 4 (German-English translation). It is obvious that the baseline with dropout rate $p = 0.1$ (red) has a significant lower BLEU score when we switch from training to validation, implying that the model somehow over-fits the data. When we use a larger $p = 0.2$ (blue) for dropout, the accuracy on the training set decreases dramatically, but no promising improvement is observed on the validation set. On the contrary, Dec-SA seems to have a better regularization effect. Although Dec-SA has lower accuracy in training than the baseline, it outperforms the baseline on the validation set. It might be due to the introduced direct connections from lower-level layers to the top of the stack. These connections make the model easier to fit the data because they have no dependence on the non-linear transformations in the stacked layers.

4.8 Layer Attention Visibility

A visualization example of layer attention with multiple hops is presented in Figure 5. The attention result is generated from an example of Chinese-English translation by Dec-SA with 4 hops. The x-axis is the target word sequence, and the y-axis is the indexing of layers (including the word embedding layer denoted by l_0). We can see that most attention weights focus on the high-level layers like hops 1 and 2, while hops 3 and 4 have more dispersive attentions over different layers. It indicates the different aspects of the sentence encoded in different hops. An interesting finding is that those large probability points in the lower-level layers are easier to appear when a noun or pronoun is fed into the decoder. For example, when we feed *sri* into the decoder to generate *lankan*, the first layer is obviously more important in hop 2. Similar cases can be observed for words *geneva* and *this* in hop 3, where the word embedding layer has a larger weight. This is reasonable because most of these words have specific meanings and do not need high-level representations for modeling large context in disambiguation.

5 Related Work

Training neural networks with multiple stacked layers is challenging. It has been observed that introducing direct connections between layers can drastically improve the performance of deep neural models. Methods include highway networks (Srivastava et al., 2015), residual connections (He et al., 2016a), dense connections (Huang et al., 2017a), and fast-forward connections (Zhou et al., 2016). E.g., in machine translation, residual networks have been a popular way to address the issue due to its simplicity (Wu et al., 2016; Gehring et al., 2017a; Gehring et al., 2017b; Vaswani et al., 2017). Another related study is Wang et al. (2017). They introduce linear associative units to reduce the length of gradient propagation in recurrent neural networks (RNNs), and demonstrate promising improvements on their RNN-based NMT systems. But previous studies all focus on using the top-level sentence representation for prediction, and ignore the access to the representations encoded in lower-level layers.

The next obvious step is toward models that make full use of all stacked layers for prediction (call it representation fusion). Some research groups have been aware of this and explored solutions. E.g., Gehring et al. (2017b) find that NMT systems can benefit from shortcut connections from the source word embedding layer to the attention layer. Perhaps the most related work is Xiong et al. (2017). They propose a multi-channel encoder (MCE) which uses an external memory module (Graves et al., 2014) to compose word embeddings and hidden states in their RNN-based encoder. But this model is applied to the shallow network on the encoder side. In this work we instead propose a more general method to do representation fusion in either the encoder, the decoder, or both. In addition, we present a 2D representation of sentence which has not been well studied in machine translation.

6 Conclusion

We have proposed a multi-layer representation fusion approach that densely connects all the stacked layers to a fusion layer for encoder or/and decoder in NMT. Also, we have developed three fusion functions to learn a better representation of sentence. Experimental results on German-English and Chinese-English translation show that our method outperforms the strong Transformer baseline significantly, and achieves new state-of-the-art on the IWSLT German-English MT task. More interestingly, it is observed that our approach has a regularizing effect and reduces the risk of over-fitting.

Abstract

To enrich vocabulary of low resource settings, we proposed a novel method which identify loanwords in monolingual corpora. More specifically, we first use cross-lingual word embeddings as the core feature to generate semantically related candidates based on comparable corpora and a small bilingual lexicon; then, a log-linear model which combines several shallow features such as pronunciation similarity and hybrid language model features to predict the final results. In this paper, we use Uyghur as the receipt language and try to detect loanwords in four donor languages: Arabic, Chinese, Persian and Russian. We conduct two groups of experiments to evaluate the effectiveness of our proposed approach: loanword identification and OOV translation in four language pairs and eight translation directions (Uyghur-Arabic, Arabic-Uyghur, Uyghur-Chinese, Chinese-Uyghur, Uyghur-Persian, Persian-Uyghur, Uyghur-Russian, and Russian-Uyghur). Experimental results on loanword identification show that our method outperforms other baseline models significantly. Neural machine translation models integrating results of loanword identification experiments achieve the best results on OOV translation(with 0.5-0.9 BLEU improvements).

1 Introduction

Almost every natural language processing (NLP) task suffers from data sparseness. This situation is even worse for low resource languages in cross lingual tasks, such as neural machine translation(NMT).Lexical borrowing happens in every language. It is a phenomenon of cross-linguistic influence. A loanword is a word adopted from one language (the donor language) and incorporated into another language (the recipient language) without translation. One reason we choose Uyghur as the example in this study is that Uyghur has been influenced by many languages, both oriental and western languages; another reason is that Uyghur language is low-resource and lack of research in NLP field. If loanwords in a resource poor language can be identified effectively, we can use the loanword and its corresponding donor word to extend the bilingual dictionary (Tsvetkov et al., 2015).

Some researchers take loanword identification as a string similarity problem. They have applied several commonly used methods to detect loanwords (Mi et al., 2014). However, these methods are usually rule-based, so these methods are difficult to deal with ambiguity. Machine learning based models have been proposed to overcome the shortcomings that exist in previous work. Lack of annotated corpora weakens the performance of these methods (Mi et al., 2016). Although some studies combine rule based and machine learning based methods to overcome data sparsity to a certain extent, challenges still exist due to semantic issues.

A loanword usually shares the same/similar semantic space with its corresponding source word in donor language. Word embeddings were first proposed to learn representations where words that have the same meaning have a similar representation (Mikolov et al., 2013). Cross-lingual word embedding is one way to learn word embeddings using information from multiple languages (Klementiev et al., 2012). This inspired us to introduce the cross-lingual embedding into the loanword identification. Additionally,

Proceedings of the 27th International Conference on Computational Linguistics, pages 3027–3037
Santa Fe, New Mexico, USA, August 20-26, 2018.

the loanword often has the similar pronunciation with its source word, the string similarity and character-level language model of receipt and donor languages can reflect this characteristic.

This paper proposes a novel loanword identification model based on both shallow features and semantically-related features. We first use a cross-lingual word embedding based model to generate the loanword candidates; then, an optimized loanword identification model based on shallow features such as pronunciation similarity and hybrid language model is built to output the final results. We conduct experiments on loanword identification in Uyghur and OOV translation in several low-resource language pairs separately.[1] Experimental results show that our proposed approach outperforms other baseline models significantly. The output of our loanword identification model can improve translation results by at least 0.5 BLEU points.

2 Related Work

Our study is mainly inspired by following two fields in NLP: loanword identification in NLP and cross-lingual word embedding.

2.1 Loanword Identification in NLP

Loanwords were mainly studied by linguists (Hoffer et al., 2005; Peperkamp, 2004; Kang et al., 2014; Shinohara, 2015) in the early period; there have been relatively few papers in loanwords research in natural language processing (NLP). (Tsvetkov and Dyer, 2016; Tsvetkov and Dyer, 2016a)proposed a morph-phonological transformation model, where features are based on optimality theory; experiments proved that with a few training examples, this model can obtain good performance at predicting donor forms from borrowed forms. (Tsvetkov et al., 2015a) suggest an approach that uses the lexical borrowing as a model in SMT framework to translate OOV words in a low-resource language. (Mi et al., 2014; Mi et al., 2016) use shallow features such as string similarity to detect loanwords in Uyghur.

2.2 Cross-lingual Word Embedding

Recent advances in cross-lingual word embedding have shown its effectiveness in several cross-lingual NLP tasks (Gouws et al., 2015; Ruder et al., 2017; Duong et al., 2017; Ammar et al., 2016), especially in some under-resourced situations (Adams et al., 2017; Fang and Cohn, 2017; Wei and Deng, 2017). Cross-lingual word embedding has the capacity to learn high quality embeddings even in the absence of bilingual corpora by exploiting bilingual lexicons. This is very useful when creation of high quality lexicons on some low-resource languages.

Previous work mainly focused on one specific language or some context free features. These methods are difficult to adopt in situations such as when the receipt and donor language belong to very different language families or low-resource settings. In this study, we propose a novel loanword identification approach, which is not only based on some shallow features, but also cross-lingual word embeddings.

3 Background

3.1 Loanwords in Uyghur

Uyghur is an official language of the Xinjiang Uyghur Autonomous Region in Western China, and is spoken by 10 to 25 million people. Uyghur is an agglutinative language. Due to the different kinds of language contact through the history of the Xinjiang region, Uyghur has also adopted many loanwords (most of them are nouns) from Persian. Additionally, many words of Arabic origin have also entered the language directly through Islamic literature after the introduction of Islam. Among all languages Uyghur borrowed, Russian and Chinese have the greatest influence in recent years. Due to the globalization, a number of loanwords of European origin have also reached Uyghur through Russia's influence over the region. Loanwords in Uyghur not only include named entities such as person and location names, but also some daily used words (Kontovas, 2008; Sugar, 2017) (Figure 1).

[1] Actually there are two methods to overcome OOV problems in neural machine translation in low-resource settings: 1) use different translation granularities (Nguyen and Chiang, 2017; Sennrich et al., 2016); 2) extend the vocabulary. Our experiments on OOV translation belong to the second.

Donor language	Source word	Uyghur word	English
Persian	افسوس	ئەپسۇس	pity
	گوشت	گۆش	meat
Arabic	ساعة	سائەت	hour
Russian	велосипед	ۋېلىسىپىت	bicycle
	доктор	دوختۇر	doctor
	поезд	پويىز	train
	область	ئوبلاست	oblast
	телевизор	تېلېۋىزور	television
Chinese	凉粉	لەڭپۇڭ	agar-agar jelly
	豆腐	دۇفۇ	tofu

Figure 1: Examples of loanwords in Uyghur.

3.2 Challenges in Loanword Identification

Intuitively, loanwords can be simply detected according to pronunciation similarity. However, the words may have several changes to adopt the recipient language:1) Changes in meaning: words are occasionally changed with a different meaning than that in the donor language; 2) Changes in spelling: although words taken into different recipient languages are sometimes spelled as in the donor language, sometimes borrowed words retain their original (or near-original) pronunciation, but undergo a spelling change to represent the orthography of the recipient language; 3) Changes in pronunciation: in cases where a new loanword has a very unusual sound, the pronunciation of the word can be radically changed.

All above challenges shown that the lexical borrowing is very complicated, so it is difficult to achieve expected results without further semantic information, especially some cross-lingual features.

4 Methodology

In this paper, we propose a novel method to identify loanwords in Uyghur. Inspired by state-of-the-art achievements of word embedding techniques in cross-lingual NLP tasks, we first train a cross-lingual embedding model based on comparable corpora (Uyghur-one donor language) and a small bilingual lexicon; then, given a Uyghur word, we obtain its most sematic related source words (and its semantic distance) in donor language based on cross-lingual embedding model; we set a threshold ρ for each donor language, if a Uyghur word has a semantic distance (the first source word of donor language) lower than this threshold, it will be removed. With the candidate list, we use a log-linear model with pronunciation similarity and hybrid language model features to predict the final results (Figure 2).

4.1 Problem Description

Assume we have a low resource language named $Lang_A$ (receipt language) and a high resource language named $Lang_B$ (donor language). The goal of loanword identification is to find out words w_i in the $Lang_A$ corpus which is originally borrowed from $Lang_B$. In this study, we mainly focus on loanwords that share the same or similar meaning with its corresponding word in the donor language.

4.2 Loanword Candidate List Generation

In this section, we first introduce cross-lingual word embedding model based on comparable data, which is used in our proposed approach as an important feature to represent the semantic relationships between words in donor language and receipt language; then, we present the generation of loanword candidate list.

Cross-lingual Word Embedding Model.

Cross-lingual embedding models learn cross-lingual representations of words in a joint embedding space. They enable knowledge transfer between languages, which is very important between resource-rich language and resource-poor language. Many previous studies on cross-lingual word embedding critically

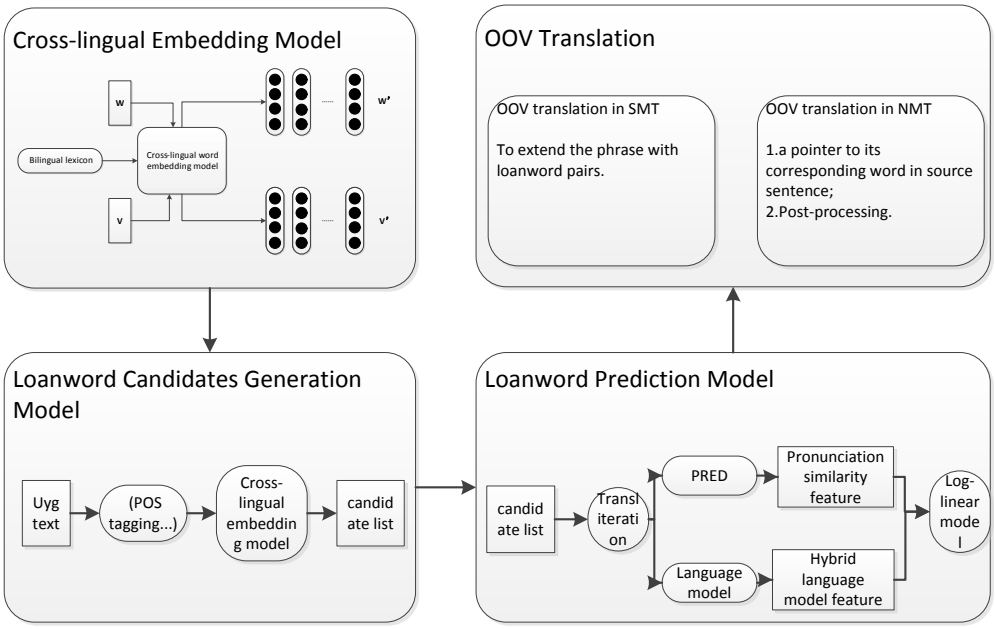

Figure 2: Framework of our proposed model.

require large sentence-aligned parallel data or dictionaries to induce bilingual word emebddings that closely aligned over languages in the same semantic space. However, these bilingual resources are very expensive for low-resource languages like Uyghur. Therefore, in this study we follow the work described by (Vulić and Moens, 2015) to obtain cross-lingual word embeddings with comparable data.

Let $W = \{w_1, w_2, ..., w_{|w|}\}$ be the vocabulary of a language $lang_A$ with $|W|$ words, and $\mathbf{W} \in \mathbb{R}^{|W| \times l}$ be the corresponding word embeddings of length l. Let $V = \{v_1, v_2, ..., v_{|V|}\}$ be the vocabulary of another language $lang_B$ with $|V|$ words, and $\mathbf{V} \in \mathbb{R}^{|V| \times m}$ the corresponding word embeddings of length m. Let d_u(Uyghur) and d_f (donor language) denote a pair of comparable documents with length in words p and q ($p > q$). The comparable data based cross-lingual embeddings (**CdbCLE**) method merges d_u and d_f as one single pseudo-bilingual document exploiting a deterministic strategy based on length ratio of two documents $R = \lfloor \frac{p}{q} \rfloor$ firstly. We sequentially pick word from d_f and put it into the merged document as the Rth word. Then, we train a skip-gram model on merged documents to generate word vectors for all words in $\mathbf{W} \cup \mathbf{V}$. The most important step is to instantiate CdbCLE algorithm. We use the similar objective function with word2vec skip-gram based on pseudo-lingual document described above.

The CdbCLE method can be described as:

$$C(\mathbf{W}, \mathbf{V}) = -\sum_{s \in \mathbf{W} \cup \mathbf{V}} \sum_{t \in NBR(s)} \log P(t|s) \tag{1}$$

where $NBR(s)$ is the context of s in pseudo-lingual document, $P(ts) \propto \exp(t^T s)$. Note that $t, s \in \mathbf{W} \cup \mathbf{V}$.

Candidate List Generation

In this part, we treat the loanword candidate list generation in Uyghur as a procedure to find out the most semantic similar source words in donor language corpora with current Uyghur word.

According to the CdbCLE algorithm described above, to identify loanwords in Uyghur, we must ensure that the current Uyghur word should share the same meaning with the corresponding source word in donor language. This can be indicates that the loanword and its corresponding word in the donor language share the same word embedding space.

To simplify this step and filter some unrelated words in Uyghur, we annotate the Uyghur texts with a part-of-speech tagger firstly. The goal of part-of-speech tagging is to assign to each word in a sentence

its morph-syntactic category. Since loanwords in Uyghur are mainly nouns, we can filter Uyghur word list with POS tags.

We use the CdbCLE algorithm to train a cross-lingual embedding model, the source part is the Uyghur language corpus, and the target parts are the donor language corpora (Chinese, Arabic, Persian and Russian). When testing, the pre-trained model gives more than one sematic similar words in donor languages based on the given Uyghur word.

$$\{u_i, [w_{i1} : v_{i1}, w_{i2} : v_{i2}, ..., w_{ik} : v_{ik}]\} \tag{2}$$

here, k is the length of returned source word list in donor language based on cross-lingual embeddings.

Based on the distance v_i between the embeddings of a Uyghur word u_i and the first source word w_{i1} returned by the CdbCLE, we discard the Uyghur word and source words item when the distance is little than a certain threshold ρ (this value is obtained through experiments)[2]. After that, the loanword candidate list is generated.

4.3 Loanword Prediction Model

Our cross-lingual word embedding based loanword identification approach generates some candidates which are similar semantically. To predict the final outputs, we propose a log-linear model which integrate several features into our approach.

Transliteration

The string similarity feature and hybrid language model features are all rely on writing system heavily. If the receipt and donor languages belong to different writing systems, we can' t compute these two features directly. In this study, we use a transliteration model to generate a character mapping table between Uyghur and donor languages (especially for language has a different writing system with Uyghur) which make sure the receipt and donor language belong to the same writing system.

The transliteration model used in this paper can be define as

$$t_{best} = arg\max_{t} \prod_{i=1}^{I} \phi(s_i|t_i) \prod_{i=1}^{|\mathbf{t}|} p_{LM}(t_i|t_1, t_2, ..., t_{i-1}) \tag{3}$$

this model is actually a phrase-based machine translation model without reordering part. Here, we first segment the training corpus into characters and learn a phrase-based translation system over character pairs (source part:$\{s_0, s_1, s_2, ..., s_{I-1}\}$, target part:$\{t_0, t_1, t_2, ..., t_{I-1}\}$. $\phi(s_i|t_i)$ indicates the phrase translation table, $p_{LM}(t_i|t_1, t_2, ..., t_{i-1})$ means the language model probabilities (built from the target-side if mined transliteration corpus). The transliteration model assumes that source and target characters are generated monotonically. Therefore, we dont use any reordering model.

Pronunciation Similarity Feature

Usually, a loanword has the similar pronunciation to its corresponding word in the donor language. A straightforward way to identify loanword is to compute pronunciation similarity between the current word and its corresponding loanword candidates in the donor language. In this study, we use the edit distance algorithm as a feature in our prediction model.

Edit distance (ED), also known as the Levenshtein distance, is a string metric for measuring the difference between two sequences. Informally, the edit distance between two words is the minimum number of single-character edits (i.e. insertions, deletions or substitutions) required to change one word into the other. However, if two words belong to different word formation systems (Uyghur and Chinese), the original ED algorithm does not perform well. For example, due to the suffixes of a Uyghur word, the number of deletions according to the ED algorithm is equal or even greater than the length of donor word. Intuition might suggest that stemming of a Uyghur word can avoid such problems. However, this approach depends heavily on the performance of stemming algorithm. We propose a position-related edit distance (PRED) method , which ignores deletions at the end of word b. That is,

[2]A word with the semantic similarity lower than a certain threshold is not a loanword or is a loanword changed its meaning; we cant apply this kind of word pairs in low-resource NMT.

$$PRED_{a,b}(i,|b|) = \min\{PRED_{a,b}(i-1,|b|), ED_{a,b}(i,|b|)\} \tag{4}$$

here, a is a Uyghur word and b is a donor word, ED is the traditional edit distance algorithm.

We can define the pronunciation similarity feature function as

$$f(u,t,V) = \begin{cases} \frac{\sum_{i=1}^{k}\psi_i PRED(u,v_i)}{\sum_{i=1}^{k} len(v_i)} & if \frac{\sum_{i=1}^{k}\psi_i PRED(u,v_i)}{\sum_{i=1}^{k} len(v_i)} \leq \frac{1}{2}len(u), \\ 0 & else. \end{cases} \tag{5}$$

here, V is a set of words have similar sematic space in donor language with one candidate loanword in Uyghur u, t is the possible tag of u, $len(v_i)$ indicates the length of word v_i, ψ_i is a parameter.

Hybrid Language Model Feature

When borrowing, a word in the donor language may adopt the receipt languages pronunciation system. Therefore, the pronunciation of a loanword belongs to two different pronunciation systems (receipt and donor). Each pronunciation system can be represented by a character-level language model. This inspired us to combine two language models of pronunciation system to simulate the pronunciation of loanwords.

$$p_{hlm}(c_1,c_2,...,c_l) = (1-\lambda)p_{rec}(c_1,c_2,...,c_l) + \lambda p_{don}(c_1,c_2,...,c_l) \tag{6}$$

where $\{c_1,c_2,...,c_l\}$ is a character sequence of a candidate loanword, p_{rec} is the character level language model probability of a given character sequence in receipt language, p_{don} is the character level language model probability of a given character sequence in the donor language. λ is the prior probability of donor language model.

Accordingly, we can formulize the hybrid language model feature as:

$$f(u,t) = \begin{cases} p_{don}(u), & if p_{don}(u) \geq p_{rec}(u) \\ p_{hlm}(u), & else. \end{cases} \tag{7}$$

Loanword Prediction Model

To integrate above two features together, we use a log-linear model. One important reason is that the log-linear model allows a very rich set of features to be used in a single model, arguably much richer representations than the other machine learning algorithms.

Assume we have a candidate loanword u, and a set of possible tags T (LW/O). LW means loanword and O means not loanword. The goal of our task is to model the conditional probability $p(t|u)$. So we can describe the prediction model as:

$$p(t|u;v) = \frac{exp(v \cdot f(u,t))}{\sum_{t' \in t} exp(v \cdot f(u,t'))} \tag{8}$$

where $f(.)$ indicates a feature function, which maps (u,t) pair to a feature vector $f(u,t)$, and **v** is a parameter vector. Note that the number of features and parameters should be the same.

We use the maximum-likelihood estimation (MLE) to estimate the parameters of the log-linear model. To overcome the overfitting, we follow the common solution that modifies the objective function to include a regularization term.

4.4 Applications in OOV Translation

In this study, we integrate the results of our proposed Uyghur loanword identification model in OOV translation in NMT with following two methods:

Training data extend: we extend the training data with loanword pairs (as parallel sentences) directly.

Bilingual dictionary extend: we first extend the bilingual dictionary with our loanword pairs; then, we follow (Luong et al., 2014) to annotate the training data with explicit information that to enables the NMT system to emit, for each OOV word, a pointer to its corresponding word in the source sentence. The information is later used in post-processing to translate the OOVs words using the extended bilingual dictionary.

Table 1: Statistic of Corpus.

5 Experiments

To evaluate the effectiveness of our proposed approach, we conducted two groups of experiments: loanword identification and OOV translation. In loanword identification experiments, we try to detect loanwords in Uyghur in four donor languages: Chinese, Persian, Russian, and Arabic; the details can be found in Table 2. In OOV translation experiments, we trained several NMT models on eight translation directions, all of them with serious OOV problems due to the limited training data sets. We integrated the results of the loanword identification experiments into OOV translation.

5.1 Datasets

We applied two types of data in our experiments: comparable and bilingual. The details of these corpora can be found in Table 1:

BilCorp4MT:This set includes bilingual corpora for training and developing NMT translation models. We collected these corpora from Wikipedia, websites, government documents and several other resources. Also, we generated bilingual lexicons on training data in this sets. The test set of the Uyghur part was annotated manually, which include loanword information in four donor languages. Therefore, we used the test set both for evaluation of loanword identification and NMT.

CompCorp4Train:We used these data sets to train word embedding models, and apply them in cross-lingual word embedding based loanword candidate list generation approach. We extract some loanword pairs (100) to train transliteration models.

5.2 Settings

Loanword identification experiments We compared our method with other three previous proposed models for loanword identification. Before that, we finished transliteration based on Moses[3] with default settings.

MutilShlFeats:(Multiple shallow features based model): which was proposed by (Mi et al., 2014), which use pronunciation similarity, common substring to build a loanword detection model in Uyghur.

NNBased: (Neural Network based model): This method was described by (Mi et al., 2016), which relied on pronunciation similarity and a small annotated corpus to build a loanword identification model.

Ours: We applied the open source toolkit word2vec[4] to train our cross-lingual word embeddings. We set the window size as 5 and negative sampling parameter as 5. We merged the documents based on method described in section 4.2. We implemented the PRED and language model tools by ourselves.

Chinese	0.58	**0.79**	0.75	0.72	0.67	0.63	0.56	0.54	0.40	0.38
Persian	0.43	0.52	0.65	0.74	**0.80**	0.72	0.62	0.48	0.32	0.24
Russian	0.49	0.67	0.70	0.71	**0.79**	0.64	0.55	0.51	0.45	0.39

Table 3: Evaluation the affection of threshold value ρ (in **CdbCLE** model) on the precision of Uyghur loanword identification model.

The differences between our proposed model and previous studies are: 1) we used a transliteration model to obtain character mapping table for pronunciation similarity computation between two writing systems and a fixed mapping rule table was used in previous work; 2) previous loanword identification models mainly relied on large-scale annotated corpora and some rules. Our model based on a cross-lingual embedding model and loanword candidates were extracted from monolingual corpora.

OOV translation experiments

We conducted OOV translation experiments on NMT. Based on loanword identification results, we built loanword dictionaries for Uyghur-Chinese, Uyghur-Arabic, Uyghur-Russian and Uyghur-Persian. We extended bilingual corpus with these dictionaries.

NMT:We conducted NMT experiments using the open source Nematus toolkit[5]. Nematus has been used to build top-performing submissions to shared translation tasks at WMT and IWSLT. In this study, we use the default settings: the word embedding dimension was 620 and the size of a hidden layer was 1000, the vocabulary size was 30K, the batch size was 80, the maximum sequence length was 50, and the beam size for decoding was 10. Default dropout was applied. Each NMT model was trained for 80 batches by using AdaDelta optimizer (Zeiler, 2012).

5.3 Results and Analysis

Corpora	Size (word pair)			
	Uyghur-Arabic	Uyghur-Chinese	Uyghur-Persian	Uyghur-Russian
Dictionary	62,820	77,592	54,902	80,367
Dictionary (extend)	**63,652** (+832)	**78,342** (+750)	**55,408**(+506)	**81,065**(+698)

Table 4: Size of bilingual dictionaries (before and after extend).

Language pair	BLEU			OOV rate		
	sys1	**sys2**	**sys3**	**sys1**	**sys2**	**sys3**
Uyghur-Russian	15.94	16.71	**16.93**	18.25	17.08	**16.94**
Uyghur-Persian	17.88	18.25	**18.47**	18.63	17.27	**17.10**
Uyghur-Chinese	22.50	22.94	**23.15**	18.05	17.48	**17.29**
Uyghur-Arabic	19.79	20.03	**20.31**	18.69	18.25	**17.84**
Russian-Uyghur	13.51	13.84	**14.07**	19.07	18.69	**18.52**
Persian-Uyghur	16.14	16.59	**16.80**	18.92	18.73	**18.56**
Arabic-Uyghur	17.82	18.23	**18.52**	19.97	19.45	**19.29**
Chinese-Uyghur	19.26	19.85	**20.03**	19.32	18.74	**18.61**

Table 5: Experiment results on OOV translation of different language pairs. **sys1** indicates the BPE based model (baseline), **sys2** means BPE based model with loanword pairs in training data, **sys3** means BPE based model with loanword pairs in post-processing step (Section 4.4).

In Table 2, we present loanword identification results in Uyghur. We find that across the four donor languages, our proposed method achieves the best performance compares with other three models. One important reason is that our method combines both semantic similarity (cross lingual word embedding) and pronunciation similarity (edit distance and language model). Among different donor languages, experimental results show that Persian loanwords in Uyghur can be identified more effectively compared with Arabic, Chinese and Russian. This is because Uyghur and Persian share much more words and has the most similar word formation. The loanword identification of Arabic also performs well compare with Russian and Arabic, the most possible reason is that many loanwords entered the language directly through Islamic literature. Although many loanwords of Europe origin have reached Uyghur through Russia's influence, the results of Russian loanword identification cannot outperform others. We believe that relatively fewer corpora lead to this situation. Due to the significant different word formation, the Chinese loanword detection achieves the worst results.

We find that the precision of our proposed model rely on threshold value heavily (Table 3). There are two possible reasons lead to this situation: size of data and diversity of languages. Since we have different size of data for each language pairs and the performance of cross-lingual embedding model usually based on the data, our model achieves best precision of four donor languages in different thresholds (0.55 and 0.70). Another reason is diversity of languages. We can easily find that Arabic, Persian and Russian are all achieves best results when ρ is **0.70**, only Chinese achieves its best precision score when ρ is **0.55**. After analysis, we know that Russian, Arabic and Persian have the similar word formation system with Uyghur, which is very different from Chinese.

We evaluate translation quality both with the BLEU score and OOV rate in NMT experiments (Table 5). We find that in all NMT tasks, models optimized by our loanword identification experiments received significant improvements compared with baseline methods. After extending the bilingual corpus by our loanword identification results, the OOV rates decrease significantly. Since BPE has achieved many state-of-the-art results in recent studies, we choose the BPE based model as the baseline (**sys1**). Due to the extend size of data sets, systems with loanword pairs are all outperform the baseline model, but with different BLEU improvements. For **sys2** (BPE+loanwordpairs+train), we use the loanword pairs in model training as other parallel sentences. Therefore, some OOV may not translate due to data spareness. **sys3** overcome this problem through translate OOV words in post-processing step with extended dictionaries Table 4. So the sys3 achieves best performance among all three translation systems in all language pairs.

6 Conclusion

In this study, we try to identify loanwords in low-resource languages (Uyghur) to extend bilingual corpus. In our proposed method, we first use the cross-lingual word embeddings as the core feature to generate semantically related candidates based on large comparable corpora and a small bilingual lexicon; then,

a log-linear model which combines several shallow features is explored to predict the final results. Results of loanword identification suggest that our proposed model outperforms other baseline methods significantly. Also, we conduct experiments on OOV translation in NMT. Experimental results show that loanword pairs can help reduce OOV rates in several low-resource language pairs.

In future work, we plan to import transfer learning into our model to further improve the performance.

Abstract

In the popular sequence to sequence (seq2seq) neural machine translation (NMT), there exist many weighted sum models (WSMs), each of which takes a set of input and generates one output. However, the weights in a WSM are independent of each other and fixed for all inputs, suggesting that by ignoring different needs of inputs, the WSM lacks effective control on the influence of each input. In this paper, we propose adaptive weighting for WSMs to control the contribution of each input. Specifically, we apply adaptive weighting for both GRU and the output state in NMT. Experimentation on Chinese-to-English translation and English-to-German translation demonstrates that the proposed adaptive weighting is able to much improve translation accuracy by achieving significant improvement of 1.49 and 0.92 BLEU points for the two translation tasks. Moreover, we discuss in-depth on what type of information is encoded in the encoder and how information influences the generation of target words in the decoder.

1 Introduction

Recent advances in neural machine translation (NMT) have achieved remarkable success over the state-of-the-art of statistical machine translation (SMT) on various language pairs (Bahdanau et al., 2015; Jean et al., 2015; Luong et al., 2015; Wu et al., 2016; Vaswani et al., 2017). In the neural networks of seq2seq models, either RNN-based (Bahdanau et al., 2015), CNN-based (Gehring et al., 2017), or full attention-based (Vaswani et al., 2017), there exist many scenarios in both encoder and decoder where a weighted sum model (WSM) takes a set of inputs and generate one output. As shown in Eq. 1, the WSM first combines k inputs $(x_1, \cdots, x_k)$ with k respective weights $(w_1, \cdots, w_k)$ and then non-linearizes it through an activation function f, such as $\tanh$, *sigmoid function*, $ReLU$, and so on. In this paper we omit bias terms to make the equations less cluttered.

$$o = f\left(\sum_{i=1}^{k} w_i x_i\right) \tag{1}$$

Note that the above weights $(w_1, \cdots, w_k)$ are independent of each other and once the model is tuned, the weights are fixed for all inputs, suggesting that by ignoring different needs of the inputs, the WSM lacks effective control on the influence of each input.

Let us take a concrete scenario in seq2seq model as an example. Figure 1(a) shows a typical illustration of generation of t-th target word where the decoder takes three inputs, i.e., source context c_t, previous target word y_{t-1} and current target state s_t while generating one output y_t via output state o_t. However, the study in Tu et al. (2017) suggests that different target words require inconsistent contributions from source context (c_t) and target context (i.e., y_{t-1} and s_t). For example, to generate translation *Xinhua News Agency , Hong Kong*, the first word y_1 *xinhua* is highly related to its source context c_1 while the

Santa Fe, New Mexico, USA, August 20-26, 2018.

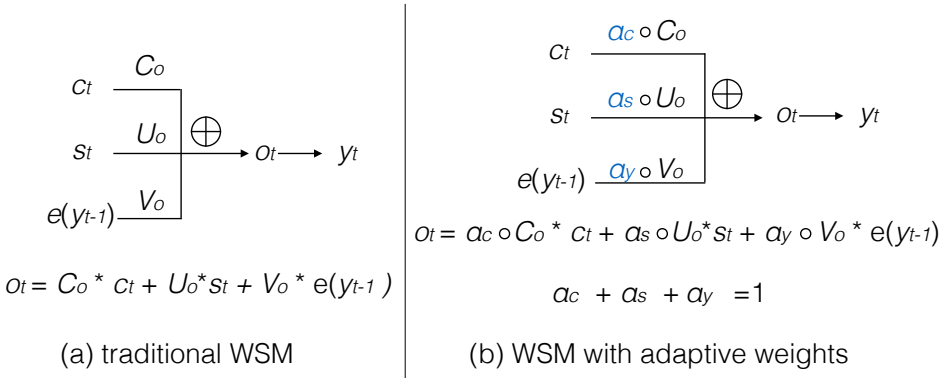

Figure 1: Illustration of generation of t-th translation word.

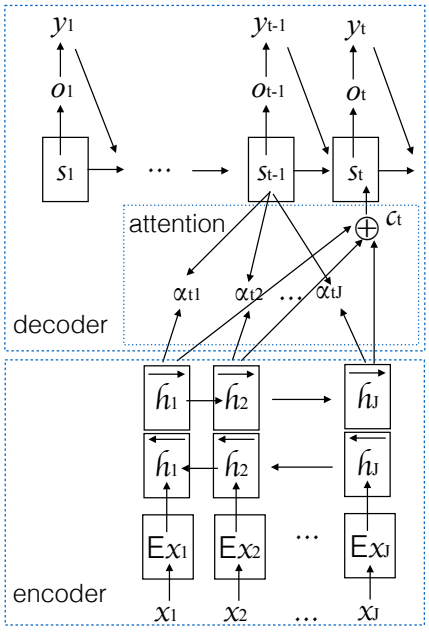

Figure 2: NMT model with attention mechanism.

second and third words y_2 *news* and y_3 *agency* are mainly influenced by target context due to the well-formed saying *Xinhua News Agency*. Similarly, y_5 *Hong* and y_6 *Kong* are mainly influenced by source context and target context, respectively.

In this paper, we propose adaptive weighting to dynamically control the contribution of each input in a WSM that has a set of inputs. Unlike the conventional weights that are independent of each other, adaptive weights are learned to be dependent on each other and more importantly be able to dynamically select the amount of input information. Specifically, we use gate mechanism to incorporate adaptive weights in GRU and in computing the output states. Experimentation on both Chinese-to-English and English-to-German translation tasks demonstrates that NMT systems with adaptive weighting are able to much improve the translation accuracy. Moreover, through adaptive weights we discuss in-depth on what type of information encoded in the encoder and how information influences the generation of a target word.

2 NMT with Attention Mechanism

In this section, we review NMT model with attention mechanism. Encoder-decoder model with attention mechanism is one of the most popular frameworks for NMT (Bahdanau et al., 2015), which consists of

an encoder and a decoder, as shown in Figure 2. In the following, m refers to the embedding size of both source and target sides, and n the hidden state size of the two sides. E_{x_j} returns the word embedding for source word x_j while $e(y_t)$ returns the word embedding for target word y_t.

Encoder: Given a source sentence $\mathbf{x} = (x_1, \cdots, x_J)$, the encoder first converts each word x_j into a real-valued m-dimensional vector E_{x_j} via the embedding matrix $E \in \mathbb{R}^{m \times |V_s|}$, where V_s is the source-side vocabulary. Then the encoder uses bidirectional RNN: the forward RNN reads the input sequence from left to right and outputs a forward sequence of hidden states $(\overrightarrow{h_1}, \cdots, \overrightarrow{h_J})$ by $\overrightarrow{h_j} = RNN(\overrightarrow{h_{j-1}}, E_{x_j})$; likewise the backward RNN operates from right to left and outputs a backward sequence $(\overleftarrow{h_1}, \cdots, \overleftarrow{h_J})$. Each source word x_j is represented as h_j (also referred to as word annotation vector): the concatenation of hidden states $\overrightarrow{h_j}$ and $\overleftarrow{h_j}$. Such bidirectional RNN encodes not only the word itself but also its left and right context, which can provide important evidence for its translation.

Decoder: The decoder is also an RNN that predicts a target sequence $\mathbf{y} = (y_1, \cdots, y_T)$. It defines a probability over the translation $\mathbf{y}$ by decomposing the joint probability into the ordered conditionals:

$$p(\mathbf{y}) = \prod_{t=1}^{T} p(y_t | y_1, \cdots, y_{t-1}, \mathbf{x}) \tag{2}$$

$$p(y_t | y_1, \cdots, y_{t-1}, \mathbf{x}) = softmax\left(\mathbf{W}_o f(o_t)\right) \tag{3}$$

where $\mathbf{W}_o \in \mathbb{R}^{|V_t| \times m}$ is a weight matrix, and V_t is the target-side vocabulary. o_t is the **output state**, defined as:

$$o_t = \mathbf{U}_o s_t + \mathbf{V}_o e(y_{t-1}) + \mathbf{C}_o c_t \tag{4}$$

$$s_t = RNN(s_{t-1}, e(y_{t-1}), c_t) \tag{5}$$

where $\mathbf{U}_o \in \mathbb{R}^{n \times n}$, $\mathbf{V}_o \in \mathbb{R}^{n \times m}$, $\mathbf{C}_o \in \mathbb{R}^{n \times 2n}$ are weight matrices. s_t is the hidden state of the decoder. c_t is the context vector, which is calculated as the summation vector weighted by a_{tj}:

$$c_t = \sum_{j=1}^{J} a_{tj} h_j \tag{6}$$

where a_{tj} is the weight of h_j, defined as

$$a_{tj} = \frac{exp(e_{tj})}{\sum_{k=1}^{J} exp(e_{tk})} \tag{7}$$

where $e_{tj} = a(s_{t-1}, h_j)$ is an alignment model, measuring the degree of matching between the *j*-th source hidden unit h_j and the *t*-th target hidden unit s_t.

Training: The whole model is jointly trained to maximize the conditional log-likelihood of the training data containing I sentence pairs.

$$L(\Theta) = \max_{\Theta} \frac{1}{I} \sum_{i=1}^{I} \log p_\Theta(\mathbf{y}_i | \mathbf{x}_i) \tag{8}$$

where Θ is the set of all parameters, and $(\mathbf{x}_i, \mathbf{y}_i)$ is the i-th sentence pair in the training set.

3 Adaptive Weighting for NMT

In this section, we propose adaptive weighting for NMT. Our goal is to enable a WSM dynamically selects the amount of input information when there exist two or more inputs. Specifically, we apply the above idea into the attention-based seq2seq model from two perspectives: (1) adaptive weighting for GRU; and (2) adaptive weighting for the output state o_t as in Figure 1.

3.1 Gated Recurrent Unit

Gated recurrent unit (GRU) (Cho et al., 2014a; Cho et al., 2014b) is a type of hidden unit of RNN which makes each recurrent unit to adaptively capture dependencies of different time scales. A GRU has two gates called reset gate r_t and update gate z_t, which control the amount of information will "flow through" the network. r_t and z_t are computed as follows:

$$r_t = \sigma(\mathbf{W}_r Ex_t + \mathbf{U}_r h_{t-1}) \tag{9}$$

$$z_t = \sigma(\mathbf{W}_z Ex_t + \mathbf{U}_z h_{t-1}) \tag{10}$$

where $\sigma(\cdot)$ is a logistic sigmoid function. Ex_t and h_{t-1} are the input and the previous hidden state. $\mathbf{W}_r, \mathbf{W}_z \in \mathbb{R}^{n\times m}$, $\mathbf{U}_r, \mathbf{U}_z \in \mathbb{R}^{n\times n}$ are model parameters which are learned. The new hidden unit h_t is computed by

$$\tilde{h_t} = tanh(\mathbf{W}Ex_t + \mathbf{U}(r_t \circ h_{t-1})) \tag{11}$$

$$h_t = z_t \circ h_{t-1} + (1 - z_t) \circ \tilde{h_t} \tag{12}$$

where $tanh(\cdot)$ is a hyperbolic tangent activation function, and $\circ$ is an element-wise multiplication. $\mathbf{W} \in \mathbb{R}^{n\times m}$, $\mathbf{U} \in \mathbb{R}^{n\times n}$ are model parameters.

3.2 Adaptive Weighting for GRU

As shown in Section 3.1, recurrent unit is critical in GRU. Both the reset gate r_t and the update gate z_t control the amount of previous state h_{t-1} and current input Ex_t being carried over to the current hidden state h_t. However, the gate itself either r_t or z_t, is uniformly set via fixed weights $\mathbf{W}_r$ (or $\mathbf{W}_z$) and $\mathbf{U}_r$ (or $\mathbf{U}_z$) for all inputs of Ex_t and all previous states of h_{t-1}. To dynamically select the amount of Ex_t and h_{t-1}, we define a hyper-gate g_t to control the flow of information between Ex_t and h_{t-1} explicitly, as shown in Eq. 13.

$$g_t = \sigma(\mathbf{W}_g Ex_t + \mathbf{U}_g h_{t-1}) \tag{13}$$

where $\mathbf{W}_g \in \mathbb{R}^{n\times m}$ and $\mathbf{U}_g \in \mathbb{R}^{n\times n}$ are parameters to be learned. Then we add g_t to the standard GRU to control how much information from previous hidden state is preserved at current time step explicitly. Accordingly, we update Eq. 9 $\sim$ 12 with the following equations.

$$r_t = \sigma((1 - g_t) \circ \mathbf{W}_r Ex_t + g_t \circ \mathbf{U}_r h_{t-1}) \tag{14}$$

$$z_t = \sigma((1 - g_t) \circ \mathbf{W}_z Ex_t + g_t \circ \mathbf{U}_z h_{t-1}) \tag{15}$$

$$\tilde{h_t} = tanh((1 - g_t) \circ \mathbf{W}Ex_t + g_t \circ \mathbf{U}(r_t \circ h_{t-1})) \tag{16}$$

$$h_t = g_t \circ z_t \circ h_{t-1} + (1 - z_t) \circ \tilde{h_t} \tag{17}$$

As shown in Eq.14, for example, the input Ex_t and the previous state h_{t-1} are now controlled by weights $(1-g_t)\circ\mathbf{W}_r$ and $g_t\circ\mathbf{U}_r$, respectively, which are dependent on each other and further controlled by the hyper-gate g_t.

Note that the NMT model adopts GRU in both encoder and decoder to generate the source side hidden states (i.e., h_t) and the target side hidden states (i.e., s_t), respectively. Therefore, we incorporate adaptive weights for GRUs in both encoder and decoder.

3.3 Adaptive Weighting for Output State

As shown in Figure 1 (b), the decoder iteratively takes three inputs, i.e., source context c_t, previous target word y_{t-1} and current target state s_t and generates one output y_t via intermediate state o_t. In order to dynamically select the amount of c_t, y_{t-1}, and s_t, we update Eq. 4 with the following:

$$o_t = \alpha_s \circ \mathbf{U}_o s_t + \alpha_y \circ \mathbf{V}_o e(y_{t-1}) + \alpha_c \circ \mathbf{C}_o c_t \tag{18}$$

where α_s, α_y, α_c can be either scalars or vectors. Together with $\mathbf{U}_o$, $\mathbf{V}_o$ and $\mathbf{C}_o$, they control the amount of s_t, y_{t-1} and c_t being carried forward, respectively. In this work, we define them as vectors, and α_s, for example, is computed as:

$$\alpha_s = \frac{exp(e_s)}{exp(e_s) + exp(e_y) + exp(e_c)} \tag{19}$$

$$e_s = f(\tilde{o}_t, s_t) \tag{20}$$

$$\tilde{o}_t = \mathbf{U}_c s_t + \mathbf{V}_c e(y_{t-1}) + \mathbf{C}_c c_t \tag{21}$$

where f is a feed-forward neural network. $\mathbf{U}_c \in \mathbb{R}^{n \times n}$, $\mathbf{V}_c \in \mathbb{R}^{n \times m}$, and $\mathbf{C}_c \in \mathbb{R}^{n \times 2n}$ are parameters to be learned. Similarly, e_y and e_c can be computed, and consequently α_y and α_c.

4 Experiments

To test our approach, we carry out experiments on the tasks of Chinese-to-English (ZH-EN) and English-to-German (EN-DE) machine translations. All source code is available on github. [1]

4.1 Dataset and Evaluation Metrics

ZH-EN Translation. Our training data for ZH-EN translation consists of 1.25M sentence pairs extracted from LDC corpora, with 27.9M Chinese words and 34.5M English words respectively. NIST MT 06 (1664 sentence pairs) is chosen as the development set while NIST MT 02, 03, 04, 05, and 08 datasets (878, 919, 1788, 1082 and 1357 sentence pairs, respectively) are used as our test sets. We use the case-insensitive 4-gram NIST BLEU score (Papineni et al., 2002) for validation and evaluation, measured by mteval-v11b.pl script.

EN-DE Translation. The EN-DE training data is provided by the standard benchmark ACL WMT 2017 [2], which consists of 5.85M sentence pairs with 141.42M English words and 134.83M German words respectively. We combine news-test-2012 and news-test-2013 as development set (6003 sentence pairs), and use news-test-2014 (News14), news-test-2015 (News15) and news-test-2016 (News16) as test sets (3003, 2169, and 2999 sentence pairs, respectively). Following Barone et al. (2017), we use the validation cross-entropy to choose the best model on the development set and use the case-sensitive 4-gram BLEU score for evaluation on test sets, measured by multi-bleu.perl script.

4.2 Training Details and Systems

We train each model with sentences of length up to 50 words for ZH-EN and 60 words (tokens) for EN-DE. The source and target word embedding dimension is 620. The size of the hidden layer is 1000. We use Adam (Kingma and Ba, 2014) to optimize model parameters with a learning rate of 0.0002, and the mini-batch size of 80.

For efficient training the neural networks, in ZH-EN translation we limit the source and target vocabularies to the most frequent 30K words, covering approximately 97.7% and 99.3% of the data in the two languages respectively. All out of vocabulary words are mapped to a special token *UNK*. For EN-DE translation, we apply byte-pair encoding (BPE) [3] (Sennrich et al., 2016) for better handling unknown words and set the vocabulary size as 30K.

We compare the performance of the following NMT systems:

- baseNMT: We use the open source toolkit dl4mt as our baseline attention-based NMT system (Bahdanau et al., 2015) [4] with most default parameter settings kept the same. For translation, a beam search with size 10 is employed.
- +Adaptive GRU: On baseNMT, we leverage adaptive weighting for GRU, as described in Section 3.2.

[1] https://github.com/liyc7711/weighted-nmt
[2] http://data.statmt.org/wmt17/translation-task/preprocessed/de-en/
[3] https://github.com/rsennrich/subword-nmt
[4] https://github.com/nyu-dl/dl4mt-tutorial

- +Adaptive Output: On baseNMT, we leverage adaptive weighting for the output state, as described in Section 3.3.
- +Both: On baseNMT, we leverage adaptive weighting for both GRU and the output state.

System	MT06	MT02	MT03	MT04	MT05	MT08	All	Params (M)
baseNMT	35.29	39.28	36.69	38.68	36.13	25.69	35.46	89.7
+Adaptive GRU	36.29‡	40.14†	36.99	39.96‡	36.91†	**27.15**‡	36.62‡	97.5
+Adaptive Output	35.72	40.38‡	37.29	39.31†	36.47	25.98	35.93‡	93.1
+Both	**36.52**‡	**40.87**‡	**38.04**‡	**40.41**‡	**37.42**‡	27.07‡	**36.95**‡	100.9

Table 1: BLEU scores of ZH-EN translation. †/‡: significant over baseline at 0.05/ 0.01, tested by bootstrap resampling (Koehn, 2004).

4.3 Experimental Results: ZH-EN Translation

Table 1 shows the performance of ZH-EN translation measured in BLEU score. From the table, we have the following observations.

- NMT models are benefited from adaptive weighting for either GRU or the output state. Moreover, the system of Adaptive GRU outperforms the system of Adaptive Output (i.e., 36.62 vs. 35.93 on all test sets).
- Fortunately, the improvements from adaptive weighting for GRU and the output state have little overlap. Combining the two types of adaptive weighting leads to more improvement on all test sets with the only exception of MT 08. Compared to baseNMT, the system *+Both* yields significant improvement of 1.49 BLEU scores, suggesting the positive effect of dynamically controlling the amount of input information being carried forward.

4.4 Experimental Results: EN-DE Translation

The results on English-German translation are presented in Table 2. It shows that leveraging adaptive weighting for GRU and the output state leads to significant improvement of 0.92 BLEU scores over all test sets. Overall, the performance trend over the proposed systems is consistent with that of ZH-EN translation.

System	News14	News15	News16	All
baseNMT	23.61	25.22	28.79	25.97
+Adaptive GRU	24.26‡	25.71†	29.63‡	26.53 ‡
+Adaptive Output	23.65	25.33	29.34†	26.11
+Both	**24.26**‡	**26.15**‡	**29.98**‡	**26.89**‡

Table 2: BLEU scores of EN-DE translation.

4.5 Parameters and Training Speed

As shown in Table 1, the proposed models introduce new parameters in different ways. [5] The baseline system has 89.8M parameters. The Adaptive GRU system introduces additional 7.8M parameters. The Adaptive output system introduces additional 3.4M parameters.

When running on a single GPU GeForce GTX 1080, the baseline model speeds 1.1 second per batch with 150K updates for ZH-EN, and 600K updates for EN-DE tasks, while the improved system (+Both) only increases the training time by about 12%.

[5]The parameters of the systems for EN-DE translation tasks are same as those for ZH-EN.

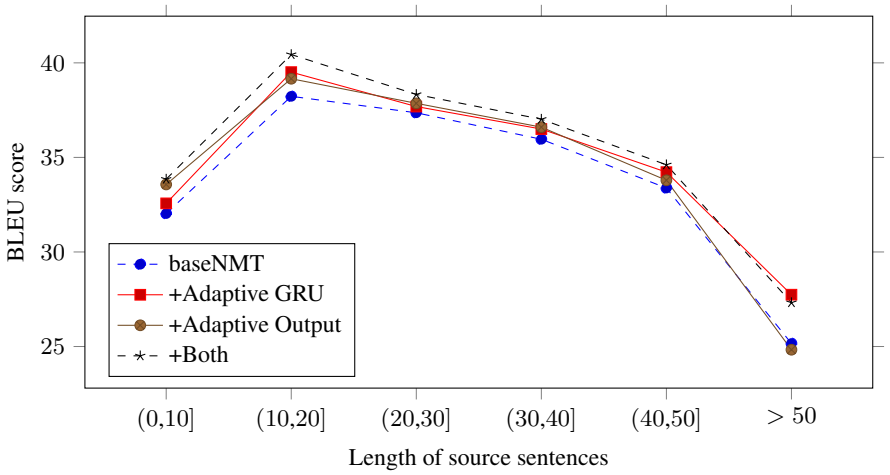

Figure 3: BLEU scores of translation with respect to the lengths of the input sentences.

5 Discussion

In this section, we further look at the *+Both* system and the *baseNMT* system to explore more on how adaptive weighting help in ZH-EN translation.

5.1 Analysis on Word Alignment

In the encoder, the Adaptive GRU uses adaptive weights to control the information flow of previous state and the current input. Thus, it has a direct impact on word representation vectors (i.e., hidden states) of source words. We conjecture that better word representation will help the decoder be able to attend to appropriate source words in decoding. To test this hypothesis, we carry out experiments of the word alignment task on the evaluation dataset from Liu and Sun (2015), which contains 900 manually aligned Chinese-English sentence pairs. We force the decoder to output reference translations, as to get automatic alignments between input sentences and their reference translations. To evaluate alignment performance, we report the alignment error rate (AER) (Och and Ney, 2003) and the soft AER (SAER) (Tu et al., 2016) in Table 3. It shows that adaptive weighting improves the attention model.

System	AER	SAER
baseNMT	43.0	55.7
+Both	**40.9**	**54.6**

Table 3: Evaluation of word alignment for ZH-EN translation. The lower the AER or SAER, the better the alignment quality.

5.2 Effects on Long Sentences

Following Bahdanau et al. (2015), we group sentences of similar lengths together and compute BLEU scores. Figure 3 presents the BLEU scores over different lengths of input sentences. It shows that systems with adaptive weighting consistently outperform baseNMT on all sentence lengths. It also shows that the performance drops substantially when the length of input sentences increases from 20. This performance trend over the length is consistent with the translation output in (Wang et al., 2017; Tu et al., 2016; Li et al., 2017).

5.3 Quantitative Analysis

Due to the continuous representations and non-linearity of neural networks. It is difficult to interpret the internal workings of NMT model (Ding et al., 2017). Fortunately, adaptive weights provide a mechanism to analyze what inputs of a WSM are more important than others. Next, we make insights on what type of

information encoded in the encoder and what types of information has a greater impact on the generation of a target word.

Table 5: Averaged α_s, α_c and α_y scores in computing the intermediate state o_t for different target words.

Analysis on encoder. In GRU, g_t in Eq. 14 $\sim$ 16 indicates that the importance of h_{t-1}. The lower g_t is, the more important the word content itself x_t and the less important the previous state h_{t-1}. To obtain word representation vectors, the encoder uses a forward GRU and a backward GRU to read an input sentence in two directions. Table 4 presents the average g_t values in the forward GRU and the backward GRU. Interestingly, as shown in the table, the two GRUs behave differently in choosing amount of input word x_t and previous hidden state h_{t-1}. There also exists a consistent trend in the two GRUs that as expected, content words usually have lower g_t than function words, indicating that the encoder focuses more on the words themselves while encoding content words.

Analysis on decoder. In the output states, we assign α_s to control the current hidden state s_t, α_y to the previously generated word y_{t-1} and α_c to the source context c_t. Table 5 lists their average values for a few typical target words in the development set MT06. From it, we observe that:

- Generally speaking, the decoder pays more attention to the current hidden states s_t than either source context c_t or previous target word y_{t-1}.
- As expected, the decoder works differently in selecting how much source context to generate different types of target words. For example, *comma*, *period* and the end of sentence token *EOS* have the lowest α_c scores in that they are mainly decided by the translation content itself and less influenced by source context. This explains why it is surprising that target side *EOS* aligns to source side *EOS* in low frequency (e.g., 20%).
- Similarly, function words, including prepositions (e.g., *of*, *to*, *on*) and auxiliary words (e.g., *is*, *has*) have low α_c scores too, indicating that their generation is less decided by source context.
- Compared to function words, content words (e.g., *US*, *China*, *president*) are opt to have higher α_c scores, suggesting the decoder considers more on source context to generate target side content words.
- However, there are also scenarios that some target content words are less influenced by source context. In 1-to-many translation where a source content word aligns to multiple target content words (i.e., 新华社/Xinhua News Agency, 香港/Hong Kong, and 纽约/New York), the first target content word usually has higher α_c score while the others have lower α_c scores. Figure 4 illustrates the changes of α_s, α_c, and α_y in a real translation *Xinhua News Agency, Hong Kong*. Apart from α_s, it shows a very obvious trend that *Xinhua* and *Hong* have higher α_c scores while *News*, *Agency*, and *Kong* have lower ones.

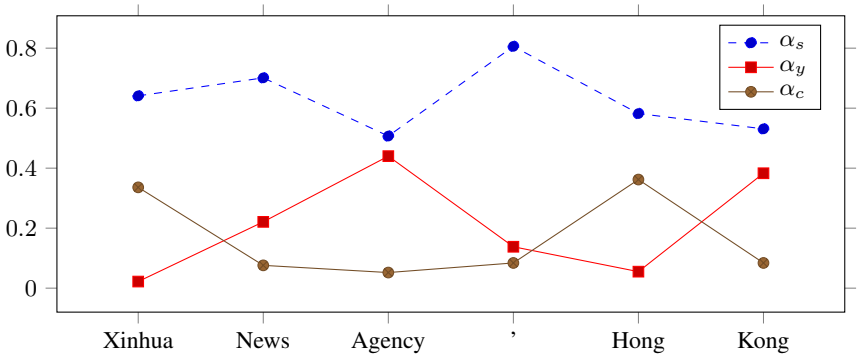

Figure 4: α_s, α_y and α_c scores in a real translation "新华社 香港 / Xinhua News Agency , Hong Kong". In it, there exist two 1-to-many correspondences, i.e., 新华社/Xinhua News Agency, and 香港/Hong Kong.

6 Related Work

We describe related work from two perspectives.

Gate mechanism. Our work is partially inspired by studies of gate mechanism for neural networks. Following the success of LSTM (Hochreiter and Schmidhuber, 1997) and GRU (Cho et al., 2014a; Cho et al., 2014b), the gate mechanism has become standard components in RNN. Recently, Srivastava et al. (2015) employ gate units to regulate information flow, called highway networks. The most relevant work to ours is Tu et al. (2017), in which they propose context gate to control the ratios of the source context (i.e., c_t) and target context (i.e., y_{t-1} and s_{t-1}) for computing next target state s_t. On the contrary, we use gate units to regulate information flow in computing the output state o_t. Moreover, we propose adaptive weighting for GRU through gate units.

Interpretation for neural networks. Attention mechanism (Bahdanau et al., 2015; Lin et al., 2017; Vaswani et al., 2017) offers a way of understanding the contribution of every source words to the generation of a target word. Ding et al. (2017) propose to use layer-wise relevance propagation (LRP) to

interpret the internal workings of NMT and analyze translation errors. Moreover, Karpathy et al. (2015) and Li et al. (2016) propose to visualize and understand RNNs for natural language processing. In this work, we use the proposed gates in both encoder and decoder to analyze what types of information encoded in the encoder and what types of information influences the generation of a target word.

7 Conclusion

In this paper, we present an approach to regulate the information flow in neural machine translation model explicitly. This is done by employing adaptive weights through gate units. We apply adaptive weighting for both GRU and the output intermediate state. Experimental results on Chinese-to-English and English-to-Germany translation tasks show that the proposed approach achieves better translation performance and alignment quality over baseline NMT system.

Generic refinement of expressive grammar formalisms with an application to discontinuous constituent parsing

Kilian Gebhardt
Department of Computer Science
Technische Universität Dresden
D-01062 Dresden, Germany
kilian.gebhardt@tu-dresden.de

Abstract

We formulate a generalization of Petrov et al. (2006)'s split/merge algorithm for interpreted regular tree grammars (Koller and Kuhlmann, 2011), which capture a large class of grammar formalisms. We evaluate its effectiveness empirically on the task of discontinuous constituent parsing with two mildly context-sensitive grammar formalisms: *linear context-free rewriting systems* (Vijay-Shanker et al., 1987) as well as *hybrid grammars* (Nederhof and Vogler, 2014).

1 Introduction

Probabilistic grammars are a standard model for language processing tasks. Their fundamental principle is a rewriting process in which nonterminals are repeatedly unfolded in accordance to rewrite rules until a structure consisting solely of terminals is obtained. Context-free independence assumptions imply that the applicability as well as the probability of a rewrite step depend only on the nonterminal that is unfolded but not on the context or history in which the nonterminal occurs.

The independence assumptions allow for tractable algorithms when processing data with these grammars. Then again, the expressiveness of such a grammar is constrained by the number of its nonterminals. This is why it was found beneficial to refine naturally emerging sets of nonterminals (such as syntactic categories). Strategies of refinement of *context-free grammars* (CFGs) involve for instance *Markovization*, i.e., the encoding of limited context into the nonterminals (Collins, 1999; Klein and Manning, 2003), and automatic state-splitting by means of latent annotations (Matsuzaki et al., 2005; Petrov et al., 2006). An important observation is that these refinements are *latent*, i.e., they are not observed in the predictions that the CFG is supposed to provide. Automatic state-splitting has been successfully applied also to tree-substitution grammars (Shindo et al., 2012) and tree-adjoining grammars (Ferraro et al., 2012).

Koller and Kuhlmann (2011) proposed *interpreted regular tree grammars* (IRTGs) as a uniform way to describe a large class of grammar formalisms that share the context-free rewriting mechanism. IRTGs decouple the derivational process, in which derivation trees are generated by a (probabilistic) *regular tree grammar* (RTG), from the interpretation of derivation trees in one or multiple algebras. IRTGs enable the development of generic algorithms for binarization (Büchse et al., 2013), parsing and decoding (Groschwitz et al., 2016; Teichmann et al., 2017), and estimation techniques (Teichmann et al., 2016).

The central hypothesis of this article is that Petrov et al. (2006)'s *split/merge algorithm* (a) can be transferred from CFGs to a large class of grammar formalisms and (b) that its application improves the probabilistic behavior of a given grammar for parsing and decoding tasks.

The first contribution of our paper is a generic version of Petrov et al. (2006)'s *split/merge algorithm* in the IRTG framework. We choose IRTGs because the separation of the derivational process in an RTG from the interpretation in algebras implies that (i) only one algorithm needs to be formulated to capture a large class of grammar formalisms and that (ii) the nonterminals cannot be observed in the generated structures. Because of (ii) nonterminals of IRTGs may be viewed as already being latent, i.e., with IRTGs latent annotations *come for free*. We also transfer objectives for efficient parsing and decoding as proposed

Proceedings of the 27th International Conference on Computational Linguistics, pages 3049–3063
Santa Fe, New Mexico, USA, August 20-26, 2018.

by Matsuzaki et al. (2005) and Petrov and Klein (2007) into the IRTG framework. An implementation of the generic algorithms is provided.

Then, for a case study of (b) we apply the generalized split/merge algorithm and the different parsing objectives to both *linear context-free rewriting systems* (LCFRSs) (Vijay-Shanker et al., 1987; Kallmeyer and Maier, 2013) and *hybrid grammars* (Nederhof and Vogler, 2014) on the task of discontinuous constituent parsing. This choice is relevant because the application of the split/merge algorithm to either grammar formalism has been supposed by Evang and Kallmeyer (2011) and Gebhardt et al. (2017), respectively, but to our knowledge not yet been performed. We find that the split/merge algorithm improves the parsing accuracy of the grammars by up to 14.5 points in labeled F1. However, the grammars do not reach the accuracy of recent transition-based discriminative parsers.

2 Preliminaries

Let A, B, and C be sets and $f\colon A \to B$ and $g\colon B \to C$ be functions. The *powerset of* A is denoted by $\mathcal{P}(A)$. We extend f in the natural way to $f\colon \mathcal{P}(A) \to \mathcal{P}(B)$ and $f^{-1}\colon \mathcal{P}(B) \to \mathcal{P}(A)$. We call f *surjective*, if for each $b \in B$, there exists $a \in A$ with $f(a) = b$. We let $g \circ f\colon A \to C$ denote the composition of f and g. We identify a singleton set $\{a\}$ with its element a.

2.1 Interpreted regular tree grammars

An interpreted regular tree grammar generates an object a of some domain A in two phases: firstly a derivation tree ξ is generated and secondly ξ is interpreted in an algebra $\mathcal{A}$ to a. Figure 1 shows two derivation trees ξ_1 and ξ_2 over *operator symbols* f_0, f_1 and f_2. Each operator symbol admits a fixed number of arguments called its *rank*, e.g., the ranks of f_0, f_1, and f_2 are 0, 1, and 2, respectively. A finite, non-empty set of operator symbols constitutes a *signature* Σ. The set of *derivation trees over* Σ, denoted by T_Σ, is the smallest set U where for any $f \in \Sigma$ of rank k and $\xi_1, \ldots, \xi_k \in U$ we have $f(\xi_1, \ldots, \xi_k) \in U$. Let $\xi = f(\xi_1, \ldots, \xi_k)$ be in T_Σ. The set of *positions* of ξ is $\mathrm{pos}(\xi) = \{\varepsilon\} \cup \{i\pi \mid 1 \le i \le k, \pi \in \mathrm{pos}(\xi_i)\}$. The *operator symbol at the position* π *in* ξ, denoted by $\xi(\pi)$, is f if $\pi = \varepsilon$ and $\xi_i(\pi')$ if $\pi = i\pi'$.

Next, we describe the interpretation of a derivation tree from T_Σ by a Σ-algebra. A Σ-*algebra* $\mathcal{A}$ consists of a set A (*domain*) and, for each operator symbol f in Σ of rank k, an *operation* $f^{\mathcal{A}}\colon A^k \to A$. Each derivation tree $f(\xi_1, \ldots, \xi_n)$ in T_Σ can be *evaluated in* $\mathcal{A}$ to an element $[\![f(\xi_1, \ldots, \xi_k)]\!]_{\mathcal{A}} = f^{\mathcal{A}}([\![\xi_1]\!]_{\mathcal{A}}, \ldots, [\![\xi_k]\!]_{\mathcal{A}})$ in A. Let $\Sigma_{\mathrm{ex}} = \{f_0, f_1, f_2\}$. Figure 1 shows the operations of the Σ_{ex}-algebras $\mathcal{A}_s$ and $\mathcal{A}_t$ with the set of strings and parse trees as domains, respectively. Also, it shows the evaluation of $\xi_1, \xi_2 \in T_{\Sigma_{\mathrm{ex}}}$ in $\mathcal{A}_s$ to the string $s = bbb$ and the evaluation of ξ_1 and ξ_2 in $\mathcal{A}_t$ to the parse trees t_1 and t_2, respectively.

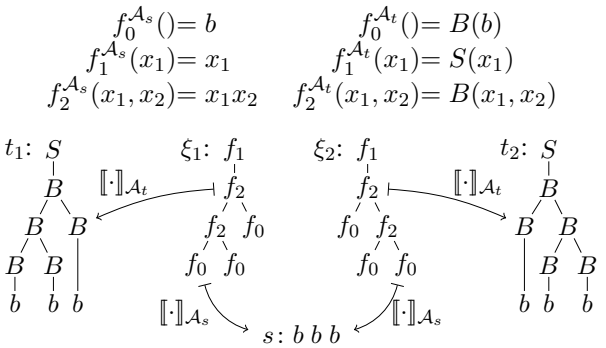

Figure 1: Operations of the Σ_{ex}-algebras $\mathcal{A}_s$ and $\mathcal{A}_t$, derivation trees ξ_1 and ξ_2, and evaluation of ξ_1 and ξ_2 in $\mathcal{A}_s$ and $\mathcal{A}_t$.

Regular tree grammars are useful to describe formal languages of derivation trees. A *regular tree grammar* (RTG) (Brainerd, 1969) over Σ is a tuple $G = (N_G, S_G, R_G)$. The finite set N_G is disjoint from Σ and contains *nonterminals*. S_G in N_G is the *start nonterminal*. The set R_G is a finite subset of the set of prototypical rules $R[N_G, \Sigma]$. $R[N_G, \Sigma]$ contains each *rule* of the form $B \to f(B_1, \ldots, B_k)$ where $f \in \Sigma$ is of rank k and $B, B_1, \ldots, B_k$ are in N_G. Figure 2a shows the rules of $G_{\mathrm{ex}} = (\{S, B\}, S, R_G)$ over Σ_{ex}.

An RTG G generates a derivation tree $\xi \in T_\Sigma$ if it has a valid run on it: A *run of* G *on* ξ is a mapping $r\colon \mathrm{pos}(\xi) \to N_G$. The *rule at position* π *of* r is $\mathrm{rule}_r^\pi = r(\pi) \to \xi(\pi)(r(\pi 1), \ldots, r(\pi k))$ where k is the rank of $\xi(\pi)$. We call r *valid* if $r(\varepsilon) = S_G$ and r is *consistent with* R_G, i.e., for every $\pi \in \mathrm{pos}(\xi)$, we require that $\mathrm{rule}_r^\pi \in R_G$. We denote the set of all valid runs of G on ξ by $\mathrm{runs}_G^v(\xi)$. The *language of* G is $L(G) = \{\xi \in T_\Sigma \mid \mathrm{runs}_G^v(\xi) \neq \emptyset\}$. Moreover, we let $\mathrm{runs}_G^v = \{(\xi, r) \mid \xi \in T_\Sigma, r \in \mathrm{runs}_G^v(\xi)\}$.

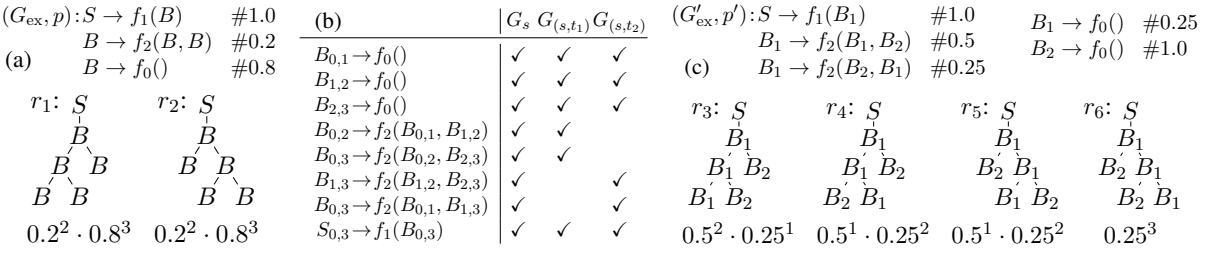

Figure 2: (a) and (c): Prob. RTGs (G_{ex}, p) and (G'_{ex}, p') with runs and probabilities (below). (b): Charts.

Figure 2a shows the only valid runs r_1 and r_2 of G_{ex} on the derivation trees ξ_1 and ξ_2, respectively, in tree-like form.

Interpreted RTGs. An *interpreted RTG* (IRTG) (Koller and Kuhlmann, 2011) is a tuple $\mathbb{G} = (G, \mathcal{A}_1, \ldots, \mathcal{A}_l)$ where G is an RTG over Σ and each $\mathcal{A}_j$ is a Σ-algebra[1]. Given an object $a = (a_1, \ldots, a_l)$ from the *domain* $A = A_1 \times \ldots \times A_l$, the parsing problem for IRTG is to compute $\text{parses}_{\mathbb{G}}(a) = \{\xi \in L(G) \mid \forall j : [\![\xi]\!]_{\mathcal{A}_j} = a_j\}$. This set is equal to the intersection of all sets $D_{a_j} = \{\xi \in T_\Sigma \mid [\![\xi]\!]_{\mathcal{A}_j} = a_j\}$ and $L(G)$. If, for each $a_j \in A_j$, there is an RTG whose language is D_{a_j}, then $\mathcal{A}_j$ is called *regularly decomposable*. In the following we consider only such algebras. Since the languages of RTGs are closed under intersection, we can construct RTGs G_{a_j} with $L(G_{a_j}) = D_{a_j} \cap L(G)$ and the RTG G_a with $L(G_a) = \bigcap_j L(G_{a_j}) = \text{parses}_{\mathbb{G}}(a)$. We call G_{a_j} and G_a the *chart of* a_j and the *chart of* a, respectively.

As a running example we extend the RTG G_{ex} to an IRTG $\mathbb{G}_{\text{ex}} = (G_{\text{ex}}, \mathcal{A}_s, \mathcal{A}_t)$. Then $\mathbb{G}_{\text{ex}}$ is equivalent to a CFG where $\mathcal{A}_s$ specifies the generation of strings and $\mathcal{A}_t$ describes the corresponding parse trees. Figure 2b depicts the rules of the charts G_s, $G_{(s,t_1)}$, and $G_{(s,t_2)}$ where the nonterminals were annotated with spans as usual and the start nonterminal is $S_{0,3}$.

Grammar morphisms. In order to relate two RTGs G' and G (e.g., G' could be a chart G_a), we consider mappings $\varphi\colon N_{G'} \to N_G$ between the respective sets of nonterminals. We lift φ to $\varphi\colon R[N_{G'}, \Sigma] \to R[N_G, \Sigma]$ by setting $\varphi(B' \to f(B'_1, \ldots B'_n)) = \varphi(B') \to f(\varphi(B'_1), \ldots, \varphi(B'_n))$. If $\varphi^{-1}(S_G) = \{S_{G'}\}$ and $\varphi(R_{G'}) \subseteq R_G$, then we call φ a *grammar morphism from G' to G*. Intuitively, φ has to establish a correspondence between the grammars' start nonterminals and rules.

For instance, we can choose any set M and any mapping $\varphi\colon N_G \to M$ that satisfies $\varphi^{-1}(\varphi(S_G)) = \{S_G\}$ and construct a new RTG $\varphi(G)$ from G: we set $\varphi(G) = (\varphi(N_G), \varphi(S_G), \varphi(R_G))$. Obviously, φ is a grammar morphism from G to $\varphi(G)$.

For each chart G_a we assume a grammar morphism φ_a from G_a to G that gives rise to a one-to-one correspondence between the valid runs of G_a and the valid runs of G for derivations trees of a. Formally, for each $\xi \in \text{parses}_{\mathbb{G}}(a)$ we require that $\bar{\varphi}_a\colon \text{runs}^v_{G_a}(\xi) \to \text{runs}^v_G(\xi)$ where $\bar{\varphi}_a(r) = \varphi_a \circ r$ is a bijection. For instance, φ_s, $\varphi_{(s,t_1)}$, and $\varphi_{(s,t_2)}$ strip the spans from each nonterminal, e.g., $\varphi_s(B_{i,j}) = B$.

2.2 Extending IRTGs with probabilities

RTGs and IRTGs can be equipped with probabilities in the *standard* way: A *weight assignment for an RTG* G is a mapping $p\colon R_G \to [0, 1]$. We define the weight of a run r on a derivation tree ξ as $W_{(G,p)}(\xi, r) = \prod_{\pi \in \text{pos}(\xi)} p(\text{rule}^\pi_r)$ and the weight of a derivation tree ξ as $W_{(G,p)}(\xi) = \sum_{r \in \text{runs}^v_G(\xi)} W_{(G,p)}(\xi, r)$. We call p *proper* if, for every $A \in N_G$, we have $1 = \sum_{\varrho = (A \to f(B_1, \ldots, B_k)) \text{ in } R_G} p(\varrho)$. If $1 = \sum_{\xi \in T_\Sigma} W_{(G,p)}(\xi)$, then we call p *consistent*. In this case we may write $P(\xi, r \mid G, p)$ and $P(\xi \mid G, p)$ for $W_{(G,p)}(\xi, r)$ and $W_{(G,p)}(\xi)$, respectively, and call (G, p) *probabilistic RTG*. Let G' be an RTG and φ be a grammar morphism from G' to G. Then $p \circ \varphi\colon R_{G'} \to [0, 1]$ is a weight assignment for G'.

Given an IRTG $\mathbb{G} = (G, \mathcal{A}_1, \ldots, \mathcal{A}_l)$ and a proper and consistent weight assignment p for G, we define a probability distribution on A by $P(a \mid \mathbb{G}, p) = \sum_{\xi \in \text{parses}_{\mathbb{G}}(a)} W_{(G,p)}(\xi)$. Using the chart G_a the same quantity can be obtained: $P(a \mid \mathbb{G}, p) = \sum_{\xi \in L(G_a)} W_{(G_a, p \circ \varphi_a)}(\xi)$ (see Appendix A.1).

[1] For ease of notation, we omit the homomorphism that is originally associated to each algebra. We note that the methods we develop in the following are agnostic of the algebras and, thus, applicable to the original definition as well.

Considering $\mathbb{G}_{\text{ex}}$ and the probability assignment p for G in Figure 2a, we get that $P((s,t_1) \mid \mathbb{G}_{\text{ex}}, p) = P((s,t_2) \mid \mathbb{G}_{\text{ex}}, p)$ because r_1 and r_2 have the same probability. In contrast, G'_{ex} in Figure 2c has two runs (r_3/r_4 and r_5/r_6, respectively) on each of ξ_1 and ξ_2. Taking the sum of their probabilities yields $P((s,t_1) \mid \mathbb{G}'_{\text{ex}}, p') > P((s,t_2) \mid \mathbb{G}'_{\text{ex}}, p')$ for the IRTG $\mathbb{G}'_{\text{ex}} = (G'_{\text{ex}}, \mathcal{A}_s, \mathcal{A}_t)$.

Inside and outside weights are a tool for efficient calculation of probabilities during training and parsing. The *inside weight* $\beta(B)$ and the *outside weight* $\alpha(B)$ of a nonterminal $B \in N_G$ are defined as

$$\beta(B) = \sum_{\varrho = B \to f(B_1,\ldots,B_k) \in R_G} p(\varrho) \cdot \beta(B_1) \cdot \ldots \cdot \beta(B_k) \quad \text{and} \quad \alpha(B) = \delta_B^S + \sum_{\substack{\varrho = C \to f(B_1,\ldots,B_k) \text{ in } R_G \\ 1 \le i \le k\colon B_i = B}} \alpha(C) \cdot p(\varrho) \cdot \prod_{j \neq i} \beta(B_j) \ ,$$

respectively, where $\delta_B^S = 1$ if $B = S$ and 0 otherwise.

The sum of the probabilities of all runs of an RTG G equals $\beta(S_G)$. Hence, an efficient way to obtain $P(a \mid \mathbb{G}, p)$ is computing $\beta(S_{G_a})$. The expected frequency with which a nonterminal B occurs in a run of G is obtained by $\alpha(B) \cdot \beta(B)/\beta(S_G)$ (Nederhof and Satta, 2004). For any rule ϱ of the form $B \to f(B_1, \ldots, B_k)$, we let $\alpha(\varrho) = \alpha(B)$ and $\beta(\varrho) = \beta(B_1) \cdot \ldots \cdot \beta(B_k)$.

2.3 A parsing or decoding problem

Suppose we want to employ $\mathbb{G}_{\text{ex}}$ for syntactic parsing (for clarity we write G instead of G_{ex}). This can be framed as a decoding problem: for a given string s, the chart G_s is computed, from which we obtain the set $T = [\![L(G_s)]\!]_{\mathcal{A}_t}$ of parse trees of s (i.e., $T = \{t_1, t_2\}$ in our example). If the IRTG is equipped with a probability assignment, then, alternatively, one can ask for the *best* parse tree $\hat{t}$, which may be formalized as

$$\hat{t} = \arg\max_{t \in T} \quad \sum_{\xi \in L(G_s)\colon [\![\xi]\!]_{\mathcal{A}_t} = t} \quad P(\xi \mid G, p) \ . \tag{1}$$

Computing this expression turns out to be infeasible in general because maximizing the sum over the potentially infinite set of derivation trees and the sum over the exponential number of runs over each derivation tree resists dynamic programming. A tractable option is to compute the Viterbi run $\hat{r}$ of the grammar (Knuth, 1977; Nederhof, 2003), defined as

$$(\hat{\xi}, \hat{r}) = \arg\max_{(\xi,r) \in \text{runs}^v_{G_s}} P(\xi, r \mid G, p) \tag{2}$$

or, with a small overhead, the n-best runs (Huang and Chiang, 2005).

For a given derivation tree $\xi \in T_\Sigma$, we can efficiently compute or approximate $P(\xi \mid G, p)$ by restricting G to ξ, which yields an RTG G_ξ, and computing $\beta(S_{G_\xi})$. Likewise, for a given parse tree t, we can compute $P(t \mid s, G, p) = \beta(G_{(s,t)})/\beta(G_s)$.

2.4 Expectation/Maximization training

The expectation/maximization (EM) algorithm (Dempster et al., 1977) in the inside-outside variant (Lari and Young, 1990) carries over to IRTGs. We recall it for sake of completeness. During the *expectation* step, we compute a corpus $c\colon R_G \to \mathbb{R}_{\ge 0}$ over rules given a corpus $c_A\colon A \to \mathbb{R}_{\ge 0}$ over the domain such that

$$c(\varrho) = \sum_{a \in A} c_A(a) \cdot \sum_{\varrho' \in \varphi_a^{-1}(\varrho)} \frac{\alpha(\varrho') \cdot p(\varrho') \cdot \beta(\varrho')}{\beta(S_{G_a})} \ .$$

In the *maximization* step the probability assignment p is updated to match the empirical distribution of $c(\varrho)$. Both steps are iterated until p changes only slightly or until the likelihood of a validation set drops.

3 Refinement of IRTGs with the split/merge algorithm

Probabilistic context-free grammars with latent annotation (PCFG-LAs) were introduced by Matsuzaki et al. (2005) as a way to tackle the too strong independence assumptions of probabilistic CFG. Instead of assigning each CFG rule just a single probability, different probabilities are assigned depending on the substate which is annotated to each nonterminal. These substates are *latent*, i.e., when calculating

the probability of a parse tree, any assignment of substates to nonterminals is considered. The work of Petrov et al. (2006) extends the PCFG-LA approach by a procedure that adaptively refines the latent state set. Petrov et al. (2006) start from a binarized PCFG-LA where each nonterminal has just one substate. In multiple cycles each such substate is split in two and the resulting grammar is trained with the EM algorithm. Then 50% of the splits are undone depending on how much likelihood gets lost and the grammar is trained with EM again. Finally, the rule weights are smoothed and trained once more.

The idea of latent annotated grammar states can be easily formalized in the IRTG framework: The probabilistic behavior of the IRTG depends only on the nonterminals and the applied rules of its RTG G. However, in the derivation trees in $L(G)$ and their interpretations, the nonterminals of G are no longer visible. To calculate the probability of a derivation tree ξ, we have to consider any valid run r on ξ and its weight. Thus, the latent states of a PCFG-LA naturally correspond to the nonterminals of the RTG G.

We reformulate the split/merge algorithm by Petrov et al. (2006) for an arbitrary IRTG $\mathbb{G} = (G, \Sigma, \mathcal{A}_1, \ldots, \mathcal{A}_l)$. In the process a (fine) probabilistic RTG (G', p') is constructed from the (coarse) probabilistic RTG (G, p), while Σ and the algebras are not changed. The refinement from N_G to $N_{G'}$ allows defining a more subtle probabilistic behavior in (G', p'). Thus, $L(G) = L(G')$, however $W_{(G,p)}$ and $W_{(G',p')}$ may differ. In analogy to the original algorithm, each nonterminal is split in two by an inverse grammar morphism μ_{sp}^{-1} yielding an intermediate grammar G^f. The probabilities of the rules of G^f are tuned by EM training. Afterwards, splits that turn out less useful are reversed by a grammar morphism μ_Δ yielding the grammar G'. The probabilities of this grammar are trained again and smoothed.

The grammar morphisms between the grammars G, G^f, and G', also imply the existence of grammar morphisms between the charts of these grammars. Consequently, charts can be easily transformed (sparing recomputation from scratch) which increases the efficiency of EM training and parsing (cf. Section 3.4).

3.1 Splitting and merging

We define the splitting and merging of nonterminals in a generic way by (inverse) grammar morphisms. Let (G, p) be a probabilistic RTG. For splitting the nonterminals of (G, p) we consider a surjective mapping $\mu\colon N' \to N_G$ where N' is a finite set (fine nonterminals) and $\mu^{-1}(S_G)$ is a singleton set. Splitting corresponds to applying the *inverse* of μ to G, i.e., $\mu^{-1}(G) = (N', \mu^{-1}(S_G), R')$ where $R' = \mu^{-1}(R) = \{\varrho' \in R[N', \Sigma] \mid \mu(\varrho) \in R\}$. The corresponding weight assignment for $\mu^{-1}(G)$ is $p \circ \mu$, which may be normalized to obtain a genuine probability assignment.

For merging the nonterminals of (G, p) we consider a surjective mapping $\mu\colon N_G \to M$ where M is a finite set (merged nonterminals) and $\mu^{-1}(\mu(S_G)) = \{S_G\}$. Merging is as simple as applying μ to G, i.e., computing $\mu(G) = (M, \mu(S_G), \mu(R))$. In order to construct a probability assignment $\mu(p)$ for $\mu(G)$, we let for every $\hat{\varrho} \in \mu(R)$:

$$(\mu(p))(\hat{\varrho}) = \textstyle\sum_{\varrho \in \mu^{-1}(\hat{\varrho})} p(\varrho) \cdot \dfrac{\alpha(\varrho) \cdot \beta(\varrho)}{\sum_{\varrho' \in \mu^{-1}(\hat{\varrho})} \alpha(\varrho') \cdot \beta(\varrho')} \quad ,$$

where α and β are computed with respect to (G, p).

Two instances. We give two instances for grammar morphisms in reminiscence of Petrov et al. (2006). For splitting we consider a grammar morphism μ_{sp} that splits every nonterminal B of G but the start nonterminal into B_1 and B_2. Formally, $\mu_{\mathrm{sp}}\colon N' \to N_G$ where $N' = \{B_q \mid B \in N_G, B \neq S, q \in \{1, 2\}\} \cup \{S\}$ and

$$\mu_{\mathrm{sp}}(B') = \begin{cases} B & \text{if } B' = B_1 \text{ or } B' = B_2 \\ B' & \text{if } B' = S \end{cases}$$

In order to partially reverse the split of μ_{sp}, we define the grammar morphism μ_Δ that merges each pair B_1 and B_2 back to B based on a utility measure $\Delta(B_1, B_2)$. Formally, $\mu_\Delta\colon N' \to M$ where

$$\mu_\Delta(B') = \begin{cases} B & \text{if } B' = B_q \text{ for } B \in N_G,\ q \in \{1, 2\},\ \text{and } \Delta(B_1, B_2) > \eta \\ B' & \text{otherwise.} \end{cases}$$

We chose M to be the largest subset of $N_G \cup N'$ such that μ_Δ is surjective.

The function Δ is meant to approximate the quotient of likelihood after and before merging. This approximation, introduced by Petrov et al. (2006), uses inside and outside weights of charts, which were precomupted during EM training, to simulate merging of single instances of B_1 and B_2 in one chart. A generalization of Δ can be defined for arbitrary IRTG as long as each nonterminal of some chart occurs at most once in a run (App. A.2). The parameter η is set dynamically such that 50% of the splits are merged.

3.2 The complete split/merge cycle

Splitting, merging, the EM training of Section 2.4, and a tie-breaking and smoothing step, yet to be defined, is composed to a complete *split/merge cycle* in Algorithm 3.1. Multiple split/merge cycles are iteratively applied to a *base grammar* G_0 until the resulting grammar G_i reaches the desired level of refinement. For every refined grammar G_i, there exists a grammar morphism μ_i from G_i to G_0. During *tie-breaking* each rule's probability obtains a small random perturbation. During *smoothing* the probability of a rule ϱ is set proportional to $\gamma \cdot p(\varrho) + (1-\gamma) \cdot u$ where u is the sum of probabilities of rules $\varrho' \in \mu_i^{-1}(\mu_i(\varrho))$. Intuitively, the probability of different refinements of the same rule from the base grammar is slightly aligned. Following Petrov et al. (2006), we set γ to 0.9 for rules without nonterminals on the right-hand side. Otherwise, we set γ to 0.99.

Algorithm 3.1 Split/merge cycle

Input: IRTG $\mathbb{G} = (G, \mathcal{A}_1, \ldots, \mathcal{A}_l)$, prob. ass. p
corpus $c_A \colon A \to \mathbb{R}_{\geq 0}$
Output: IRTG $\mathbb{G}'$, prob. assignment p'

1: $(G^f, p^f) \leftarrow (\mu_{\text{sp}}^{-1}(G), p \circ \mu_{\text{sp}})$
2: $p^f \leftarrow \textsc{BreakTies}(p^f)$
3: $p^f \leftarrow \textsc{EM-Training}(G^f, p^f, \mathcal{A}_1, \ldots, \mathcal{A}_l, c_A)$
4: $(G', p') \leftarrow (\mu_\Delta(G^f), \mu_\Delta(p^f))$
5: $p' \leftarrow \textsc{EM-Training}(G', p', \mathcal{A}_1, \ldots, \mathcal{A}_l, c_A)$
6: $p' \leftarrow \textsc{Smooth}(G', p')$
7: $p' \leftarrow \textsc{EM-Training}(G', p', \mathcal{A}_1, \ldots, \mathcal{A}_l, c_A)$
8: **output** $(G', \mathcal{A}_1, \ldots, \mathcal{A}_l), p'$

3.3 Efficient refinement of a chart

Let G^c be a coarse grammar, $a \in A$ be in the domain, and the chart G_a^c be already computed. We assume that G^c was refined to $G^f = \mu^{-1}(G^c)$ and that we want to compute the chart G_a^f. Due to the definition of splitting and merging, we do not need to compute G_a^f from scratch. Instead we construct (a grammar that is isomorphic to) G_a^f via the grammar morphisms φ'_a and μ' such that the diagram on the right commutes. Let $N' = \{(B, q) \mid B \in N_{G_a^c}, q \in \mu^{-1}(\varphi_a(B))\}$, and for every $(B, q) \in N'$, set $\varphi'_a(B, q) = q$ and $\mu'(B, q) = B$. We define $G_a^f = {\mu'}^{-1}(G_a^c)$.

$$\begin{array}{ccc} G_a^f & \xrightarrow{\varphi'_a} & G^f \\ {\scriptstyle \mu'}\downarrow & & \downarrow{\scriptstyle \mu} \\ G_a^c & \xrightarrow[\varphi_a]{} & G^c \end{array}$$

3.4 Parsing objectives and weight projections

In order to apply a refined IRTG to parsing, we return to the question on how to substitute Equation 1. We consider alternative parsing objectives inspired by Matsuzaki et al. (2005). In the following we refer to the base RTG and the one resulting from several iterations of Algorithm 3.1 by G^c and G^f, respectively. Also, we consider charts of a string s and assume grammar morphisms φ_s, φ'_s, μ, and μ' as in Section 3.3.

The $\hat{t}$ of Equation 1 is sometimes called *most probable parse*. A subproblem that is in general still infeasible is finding the parse tree corresponding to the *most probable derivation tree*, i.e.,

$$\hat{t} = [\![\arg\max_{\xi \in L(G_s^f)} P(\xi \mid G^f, p^f)]\!]_{\mathcal{A}_t} \ .$$

For usual PCFG(-LA) this objective coincides with the most probable parse because derivation trees and parse trees are in a one-to-one correspondence.

The parse corresponding to the *viterbi derivation tree* is $\hat{t} = [\![\hat{\xi}]\!]$ where $(\hat{\xi}, \hat{r})$ is computed according to Equation 2 for $(G_s^f, p^f \circ \varphi'_s)$. This objective is tractable but reported to yield suboptimal parses for PCFG-LA in terms of the usual bracket scoring metric (Matsuzaki et al., 2005; Petrov et al., 2006).

A combination of coarse-to-fine parsing with n-best parsing yields the *base-n-rerank* objective: n-best runs of the base grammar are computed and the corresponding derivation trees are reranked according to the refined grammar. Formally, we compute $\hat{t} = [\![\hat{\xi}]\!]_{\mathcal{A}_t}$ with

$$(\hat{\xi}, \hat{r}) = \arg\max_{(\xi, r) \in n\text{-best-runs}(G_s^c, p^c \circ \varphi_s)} P(\xi \mid G^f, p^f) \ .$$

$\text{SQ} \to \text{yf}_1(\text{MD}, \text{VP}, \text{NP})$	$\text{yf}_1^{\mathcal{A}_s}(x_1, (x_2, x_3), x_4) = (x_2 x_1 x_3 x_4)$	$\text{yf}_1^{\mathcal{A}_t}(x_1, x_2, x_3) = \text{SQ}(x_1, x_2, x_3)$
$\text{VP} \to \text{yf}_2(\text{WHNP}, \text{VB})$	$\text{yf}_2^{\mathcal{A}_s}((x_1), (x_2)) = (x_1, x_2)$	$\text{yf}_2^{\mathcal{A}_t}(x_1, x_2) = \text{VP}(x_1, x_2)$
$\text{WHNP} \to \text{yf}_3()$	$\text{yf}_3^{\mathcal{A}_s}() = (\text{What})$	$\text{yf}_3^{\mathcal{A}_t}() = \text{WHNP}(\text{What})$
$\text{MD} \to \text{yf}_4()$	$\text{yf}_4^{\mathcal{A}_s}() = (\text{should})$	$\text{yf}_4^{\mathcal{A}_t}() = \text{MD}(\text{should})$
$\text{NP} \to \text{yf}_5()$	$\text{yf}_5^{\mathcal{A}_s}() = (\text{I})$	$\text{yf}_5^{\mathcal{A}_t}() = \text{NP}(\text{I})$
$\text{VB} \to \text{yf}_6()$	$\text{yf}_6^{\mathcal{A}_s}() = (\text{do})$	$\text{yf}_6^{\mathcal{A}_t}() = \text{VB}(\text{do})$

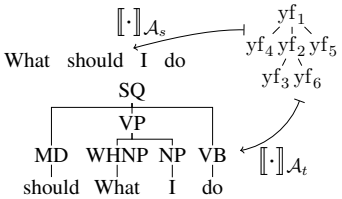

Figure 4: Rules of an LCFRS and the evaluation of a derivation tree in $\mathcal{A}_s$ and $\mathcal{A}_t$.

Parsing by weight projection. Matsuzaki et al. (2005) propose an alternative parsing objective, where a new weight assignment q for G_s^c is computed based on $(G_s^f, p^f \circ \varphi'_s)$ such that the KL-divergence of $P(\xi \mid G_s^c, q)$ to $P(\xi \mid s, G^f, p^f)$ is minimized. Precisely, $q = \mu'(p^f \circ \varphi'_s)$. Subsequently the parse tree $\hat{t}$ corresponding to the Viterbi derivation tree is computed using q, i.e., $\hat{t} = [\![\hat{\xi}]\!]_{\mathcal{A}_t}$ with

$$(\hat{\xi}, \hat{r}) = \arg\max_{(\xi,r) \in \text{runs}^v_{G_s^c}} P(\xi, r \mid G_s^c, q) \ .$$

An empirically superior way to define q called *max-rule-product* is due to Petrov and Klein (2007). They intent to optimize for "the tree with greatest chance of having all rules correct, under the (incorrect) assumption that the rules correctness are independent." To this end, each rule is assigned the sum of the expected frequencies of its refinements, i.e., $q(\varrho)$ is set to $\sum_{\varrho' \in \mu'^{-1}(\varrho)} \alpha(\varrho') \cdot (p^f \circ \varphi'_s)(\varrho') \cdot \beta(\varrho') / \beta(S_{G_s^f})$. Hence, the value $q(\varrho)$ does not have to be in the interval $[0, 1]$ and max-rule-product (as well as *max-rule-sum* – where the weight of a run is the sum of rule weights rather than the product) is in theory a potentially non-monotonic and, thus, ill-defined objective (cf. Appendix A.3).

4 Grammars for discontinuous parsing

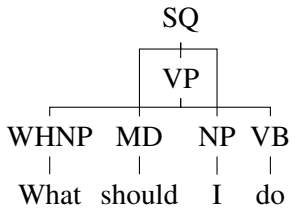

Figure 3: A discontinuous phrase structure.

String-rewriting *linear context-free rewriting systems* (LCFRSs) (Vijay-Shanker et al., 1987) generalize CFGs and can account for discontinuous constituent trees such as the one in Figure 3. Each nonterminal B derives instead of a single string an m_B-tuple of strings. The integer $m_B \geq 1$ is called *fanout* of B. Each rule of an LCFRS consists of a left-hand side nonterminal B, any number of right-hand side nonterminals $B_1, \ldots, B_k$, and a *yield function* yf. The latter specifies how the components of the string tuples generated by $B_1, \ldots, B_k$ are concatenated with new terminal symbols to form the string tuple of B. The rewriting is *linear*, that is, each input to yf is used at most once. Parsing of binary LCFRS is in $\mathcal{O}(n^{3m})$ where n is the sentence length and m is the maximum fanout of nonterminals of the LCFRS (Seki et al., 1991).

We use the following straightforward representation of LCFRSs as IRTGs: Σ is the set of yield function symbols, A_s is the set of tuples over strings, and the string algebra $\mathcal{A}_s$ interprets each yield function symbol by the respective yield function. To obtain the corresponding parse tree, the derivation tree is interpreted in an algebra $\mathcal{A}_t$. Figure 4 depicts an LCFRS with start nonterminal SQ and the interpretation of a derivation tree.

In a *LCFRS/sDCP-hybrid grammar* (Nederhof and Vogler, 2014; Gebhardt et al., 2017) (short: hybrid grammar), an LCFRS is coupled with a tree generating device called *simple definite clause program* (sDCP) (Deransart and Małuszynski, 1985). An object in the domain of a hybrid grammar is a *hybrid tree*, i.e., a string and a tree together with a linking between sentence positions and tree positions. Hybrid trees (and hybrid grammars) are suitable to model (formal languages of) discontinuous constituent structures. Figure 5 depicts a hybrid grammar in IRTG notation and the evaluation of the derivation tree ξ_3 in the algebra $\mathcal{A}_h$ to the hybrid tree h. The algebra $\mathcal{A}_s$ is a copy of the string component of $\mathcal{A}_h$ and evaluates ξ_3 to "What should I do". We observe that the structure of ξ_3 deviates notably from the structure of the tree component of h. In fact, the hybrid grammar generates a discontinuous tree although its string component is equivalent to a CFG.

Nederhof and Vogler (2014) present an algorithm that induces an LCFRS/sDCP-hybrid grammar $\mathbb{G}$ given a corpus of phrase structure trees. The algorithm is parametrized by an integer $k \geq 1$ that limits the maximum fanout of the LCFRS component of $\mathbb{G}$ to k. A second parameter of the algorithm is one of two nonterminal labeling schemes called *child labeling* and *strict labeling* of which the former is coarser. Drewes et al. (2016) present an algorithm that computes the chart G_h in time polynomial in the size of some hybrid tree h. Computing G_s, given a string s, inherits the parsing complexity of LCFRSs.

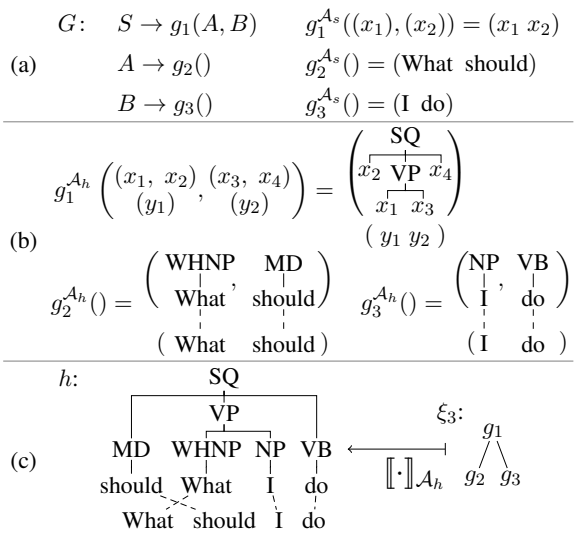

Figure 5: (a,b): An LCFRS/sDCP-hybrid grammar $(G, \mathcal{A}_s, \mathcal{A}_h)$ in IRTG notation. (b): $\mathcal{A}_h$ interprets each function symbol g_i by a function on synchronized tuples over trees (top) and tuples over strings (bottom). (c): Interpretation of ξ_3 in $\mathcal{A}_h$ to a hybrid tree h.

5 Experimental evaluation

We implemented[2] the generic split/merge algorithm and the parsing objectives in `C++` with bindings to `python3`. We evaluate it with LCFRSs and hybrid grammars for discontinuous phrase structure parsing. We use the TiGer corpus (Brants et al., 2004) and employ the split of the SPMRL shared task (Seddah et al., 2014) (TiGerSPMRL) and the one of Hall and Nivre (2008) (TiGerHN08). TiGer contains ca. 50k annotated sentences of German news text, exhibits discontinuity, and is predominantly used for evaluation in recent literature on discontinuous parsing. Evaluation with other languages is subject of further research. Part-of-speech (POS) tags for the TiGerHN08 test set are predicted using the `MATE` tagger (Björkelund et al., 2010), which we trained on the training and development section of TigerHN08.

The base LCFRS is induced from the treebank following Maier and Søgaard (2008). For each rule we remember the grammatical function symbol of the left-hand side nonterminal to its parent in the algebra $\mathcal{A}_t$. We binarize the LCFRS either right-to-left ($\text{LCFRS}_{\text{r2}\ell}$) or head-outward ($\text{LCFRS}_{\text{ho}}$) (cf. Kallmeyer and Maier, 2013) and apply Markovization ($v = 1$, $h = 1$). The base LCFRS/sDCP-hybrid grammar is induced according to a modified version of the algorithm by Nederhof and Vogler (2014) where we include only the POS tag in the sDCP component of a lexical rule but no additional unary categories. Also, we include syntactic function labels into the rules' sDCP component. We restrict the fanout to 2 and use strict and child labeling (abbreviated $\text{hybrid}_{\text{strict}}$ and $\text{hybrid}_{\text{child}}$, respectively). The numbers of nonterminals and all/lexical rules of either grammar, and the coverage of trees from the development set are given in the table on the right for TiGerHN08.

	nont.	rules / lex.	cover.
LCFRS_{ho}	767	50,153 / 28,080	78.3%
$\text{LCFRS}_{\text{r2}\ell}$	817	49,297 / 28,080	76.5%
$\text{hybrid}_{\text{child}}$	288	39,123 / 28,080	82.9%
$\text{hybrid}_{\text{strict}}$	32,281	108,957 / 28,080	50.0%

The LCFRSs and hybrid grammars are refined by 5 and 4 split/merge cycles, respectively. We stop EM training if the likelihood of the covered trees in the development set decreases. Then we apply the grammars in some of the ways outlined in Section 3.4 for parsing unseen sentences. Each sentence is a tokenized string s over pairs of words and (gold) POS tags. For both LCFRSs and hybrid grammars we have to carry out an LCFRS parsing step on s, for which we employ the implementation[3] of van Cranenburgh et al. (2016, see Sec. 6.4). Precisely, a pruned version of the chart G_s is computed via a coarse-to-fine pipeline that utilizes a PCFG approximation of the probabilistic LCFRS. Once a best parse has been selected, we compare it to the gold tree by computing F1 and exact match (EM) for labeled brackets, F1 for discontinuous labeled brackets, and F1 including function tags (F1-fun) using *disco-dop*[3].

[2]The implementation is freely available at `https://github.com/kilian-gebhardt/panda-parser`.

[3]*disco-dop* can be obtained from `https://github.com/andreasvc/disco-dop`. For evaluation on TiGerHN08 we use the `proper.prm` parameters. For TiGerSPMRL we also report F1 with `spmrl.prm`.

Objective	F1 (disc)	EM	F1-fun	F1 (disc)	EM	F1-fun	F1 (disc)	EM	F1-fun	F1 (disc)	EM	F1-fun

Table 1: Results on the TiGerHN08 development set with gold POS tags for sentences up to length 40.

The results on the TiGerHN08 development set are depicted in Table 1. The refined grammars notably improve over the respective base grammars by up to 14.50 points in F1. If we fix a base grammar but alter the parsing objectives, then we observe the following variations in F1 and EM: Reranking the 500-best derivations of the base grammar gives worse results than the Viterbi objective on the refined grammar. The weight projection approaches again improve over the Viterbi objective by up to 2.85 and 1.13 points in F1 for LCFRSs and hybrid grammars, respectively, where max-rule-product is consistently superior to variational. We do not observe an instance where max-rule-product is ill-defined in our experiments. Figure 6 shows that the F1 decreases for longer sentences by the example of LCFRS_{ho}/max-rule-product. $\text{LCFRS}_{\text{r2}\ell}$ is superior to LCFRS_{ho} with the Viterbi objective but the opposite holds for the projection-based objectives. $\text{Hybrid}_{\text{strict}}$, which suffers from 165 parse failures, produces worse results than $\text{hybrid}_{\text{child}}$ (12 parse failures) except for the reranking objective. For the discontinuous F1 and the F1-fun we find that $\text{LCFRS}_{\text{r2}\ell}$ performs better than LCFRS_{ho} in all cases but one. Also $\text{hybrid}_{\text{strict}}$ outperforms $\text{hybrid}_{\text{child}}$ with respect to discontinuous F1 but not for F1-fun. Overall, LCFRSs outperform hybrid grammars in terms of F1. The best F1 of 79.44 and 77.69 are obtained by LCFRS_{ho} and $\text{hybrid}_{\text{child}}$, respectively, with max-rule-product.

We parse the test set with LCFRS_{ho} and $\text{hybrid}_{\text{child}}$ using the max-rule-product objective. We present the results and compare to other discontinuous constituent parsers of the recent literature in Table 2. Most of these parsers are discriminative. The parsers by Hall and Nivre (2008), Fernández-González and Martins (2015), and Corro et al. (2017) employ different forms of dependency representation which are converted into constituent structures (dep2const). In contrast, Maier (2015), Maier and Lichte (2016), Coavoux and Crabbé (2017), and Stanojević and Garrido Alhama (2017) employ transition systems (SR-swap, SR-gap, SR-adj-gap) that can produce discontinuous constituent structures directly. Lastly, the chart-based parser of van Cranenburgh et al. (2016) is a generative model that enhances LCFRSs to discontinuous tree substitution grammars where tree fragments are learned according to the *data-oriented parsing* (DOP) paradigm. The results on the HN08 test set are close to the one on the development set. The F1 on the SPMRL test set is more than 4 points lower than in the HN08 split. Other parsers exhibit the same phenomenon that is probably caused by a shift in the distribution to longer sentences. Using predicted POS tags decreases the F1 by 2.38 and 2.00 points for the LCFRS and the hybrid grammar, respectively.

Discussion. The results indicate a strong influence of the granularity of the base grammar's nonterminals. A low granularity results in a higher coverage but also decreases the performance of the base grammar. For instance, for hybrid grammars we see that, despite many parse failures, strict labeling outperforms child labeling with the reranking objective. The drastically lower scores of the reranking objective for $\text{LCFRS}_{\text{r2}\ell}$, LCFRS_{ho} and $\text{hybrid}_{\text{child}}$ in light of the small difference with $\text{hybrid}_{\text{strict}}$ are likely caused by the base grammars being too coarse and, thus, assigning higher probabilities to bad candidates. Moreover, we suppose that including some context in the base grammars' nonterminals helps to guide the split/merge algorithm and avoids overfitting: For $\text{hybrid}_{\text{child}}$ the accuracy drops if we run more than 4 split/merge cycles. Also, in early experiments we observed worse performance if the conditioning context of Markovization for LCFRSs is further restricted. It will be interesting to study hybrid grammars whose base grammars have slightly finer nonterminals than with child labeling.

The EM algorithm is prone to overfitting to the training corpus. In fact, in our experiments we observed that the validation likelihood decreased after some epochs of training whereas the smoothing step counteracted this trend. To improve robustness, we plan to investigate changes in the training regime,

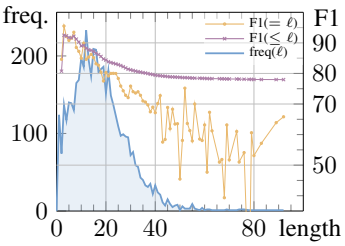

Figure 6: Frequency of sentence length ℓ, F1 for sentences of length ℓ, and F1 of sentences of length $\leq \ell$ on TiGerHN08 dev. set with LCFRS_{ho}/max-rule-product.

e.g., adding a prior on probability assignments or merging a higher percentage of nonterminal splits.

It is not surprising that the best results are obtained with the projection-based parsing objectives: the loss function of EM training does not guarantee that the probability mass of one derivation is concentrated in a single run. That max-rule-product outperforms the variational approach in terms of F1 and EM is in accordance with the findings and interpretations of Petrov and Klein (2007). For hybrid grammars the improvements of the projection-based methods are smaller than for LCFRSs which may be explained by the additional layer of spurious ambiguity (i.e., multiple derivation trees for one hybrid tree) they exhibit.

The F1 on discontinuous brackets is much lower than the overall F1 where the discontinuous recall is particularly low. Each grammar predicts only between 631 and 989 discontinuous brackets where there are 1837 in the gold standard. This could be affected by the way we approximate the PCFG in the coarse-to-fine pipeline which penalizes discontinuous rules. Most discontinuous brackets are predicted with the reranking objective but, as the lower discontinuous F1 indicates, these brackets are often incorrect.

Table 2 shows that the systems proposed in the literature exhibit a higher F1 than our grammars. This holds in particular for the systems that employ discriminative (and sometimes global) features, which are not available in our system. On the other hand, also van Cranenburgh et al. (2016)'s DOP-based parser is superior to our system in the predicted POS tag scenario. One reason might be error propagation due to wrong POS tags predicted by the external tagger that we use. In contrast, in van Cranenburgh et al. (2016) POS tags are predicted during parsing. Also, the probability assignment that we obtained by EM training may be less robust than the rule probabilities obtained according to the DOP paradigm.

Conclusion. The state refinement method considerably improves over the baseline grammars, which confirms our hypothesis that the usefulness of the split/merge algorithm goes beyond parsing with CFGs. However, at least with the used version of EM training, the initial granularity of the nonterminal set has a decisive impact on the quality of the resulting grammar and should be chosen carefully. When considering the task of discontinuous parsing, the results fall behind recent advances in the literature. This holds in particular for the discriminative deterministic transition-based systems where the representable discontinuity is not restricted by grammar constants, non-local features may be considered, and the parsing is much faster. One remedy to the lower accuracy and speed could be the enhancement of our chart-based method with a discriminative classifier to guide the pruning of the chart (Vieira and Eisner, 2017). In the future one may advance the understanding of the split/merge algorithm by applying it to other IRTGs such as synchronous hyperedge replacement grammars for graph parsing (Peng et al., 2015) or in a task different from parsing like syntax-based machine translation with synchronous grammars (Chiang, 2007).

Acknowledgements

The author thanks the anonymous reviewers for many helpful comments, Markus Teichmann for contributing to the implementation, Heiko Vogler and Tobias Denkinger for feedback on a draft of this paper, and Andreas van Cranenburgh and Toni Dietze for helpful discussions. The implementation utilizes *disco-dop* by Andreas van Cranenburgh, *treetools* by Wolfgang Maier, and the *Eigen* template library.

A Appendix

In this appendix we provide auxiliary calculations and definitions, an example in which the max-rule-product parsing objective is ill-defined, and choices of hyperparameters and preprocessing steps used during the experiments.

A.1 Computing the probability of an object using its chart

In Section 2.2 we state that $P(a \mid \mathbb{G}, p) = \sum_{\xi \in L(G_a)} W_{(G_a, p\circ\varphi_a)}(\xi)$. This follows from:

$$\begin{aligned}
\sum_{\xi \in \mathrm{parses}_{\mathbb{G}}(a)} W_{(G,p)}(\xi) &= \sum_{\xi \in \mathrm{parses}_{\mathbb{G}}(a)} \sum_{r \in \mathrm{runs}^v_G(\xi)} \prod_{\pi \in \mathrm{pos}(\xi)} p(\mathrm{rule}^\pi_r) \\
&= \sum_{\xi \in L(G_a)} \sum_{r' \in \mathrm{runs}^v_{G_a}(\xi)} \prod_{\pi \in \mathrm{pos}(\xi)} p(\mathrm{rule}^\pi_{\varphi_a \circ r'}) \\
&= \sum_{\xi \in L(G_a)} \sum_{r' \in \mathrm{runs}^v_{G_a}(\xi)} \prod_{\pi \in \mathrm{pos}(\xi)} (p \circ \varphi_a)(\mathrm{rule}^\pi_{r'}) \\
&= \sum_{\xi \in L(G_a)} W_{(G_a, p\circ\varphi_a)}(\xi)
\end{aligned}$$

A.2 Approximation of the likelihood loss.

Let G^c be the RTG at the beginning of a particular split/merge cycle and $G^f = \mu_{\mathrm{sp}}^{-1}(G^c)$ be the RTG after splitting. We describe how $\Delta(B_1, B_2)$ is computed for a pair B_1 and B_2 of nonterminals in G^f that are candidates for merging. Similar to Section 3.3, for each $a \in A$ we assume grammar morphisms $\mu'_{\mathrm{sp}} \colon G^f_a \to G^c_a$, $\varphi_a \colon G^c_a \to G^c$, and $\varphi'_a \colon G^f_a \to G^f$ which satisfy $\varphi_a \circ \mu'_{\mathrm{sp}} = \mu_{\mathrm{sp}} \circ \varphi'_a$.

Firstly, we compute *merge factors* p_1 and p_2 based on the relative frequency of B_1 and B_2 where

$$p_i = \frac{\mathrm{freq}(B_i)}{\mathrm{freq}(B_1) + \mathrm{freq}(B_2)} \ .$$

To compute the expected frequency of B_i ($i \in \{1, 2\}$), we sum over the expected frequency of each occurrence B'_i of B_i in some chart G^f_a:

$$\mathrm{freq}(B_i) = \sum_{a \in A} c_A(a) \cdot \sum_{B'_i \in {\varphi'_a}^{-1}(B_i)} \frac{\alpha(B'_i) \cdot \beta(B'_i)}{\beta(S_{G^f_a})} \ .$$

Secondly, we consider pairs (B'_1, B'_2) of occurrences of B_1 and B_2 in some chart G^f_a such that $\mu'_{\mathrm{sp}}(B'_1) = \mu'_{\mathrm{sp}}(B'_2)$. For each such pair, we introduce a hypothetical nonterminal B' which symbolizes merging just B'_1 and B'_2. Its inside and outside weight is obtained by $\alpha(B') = \alpha(B'_1) + \beta(B'_2)$ and $\beta(B') = p_1 \cdot \beta(B'_1) + p_2 \cdot \beta(B'_2)$, respectively.

Using these hypothetical nonterminals, we approximate the loss in likelihood due to merging B_1 and B_2 by accumulating likelihood losses due to merging pairs of occurrences:

$$\Delta(B_1, B_2) = \prod_{\substack{a \in A \\ (B'_1, B'_2) \text{ in } G^f_a}} \left(\frac{\beta(S_{G^f_a}) \ + \ \alpha(B') \cdot \beta(B') - \left(\sum_{i \in \{1,2\}} \alpha(B'_i) \cdot \beta(B'_i) \right)}{\beta(S_{G^f_a})} \right)^{c_A(a)} .$$

In the above formula, the numerator shall express the probability of the chart after merging and the denominator expresses the probability before merging. If a nonterminal A' occurs more than once in a run of the chart, then the sum of the probability of all runs that contain A' is not equal to its expected frequency $\alpha(A') \cdot \beta(A')$. Thus, the above formula is reasonable under the assumption that each nonterminal A' in N_{G_a} occurs at most once in a run on a derivation tree in $L(G^f_a)$. This assumption is violated if, e.g., the chart contains a chain rule $A' \to f(A')$.

A.3 The max-rule-product objective can be ill-defined

We give an example of a CFG with chain rules where max-rule-product is an ill-defined parsing objective. Consider the refined CFG G^f with nonterminals $\{S, A_1, A_2, A_3\}$, terminals $\{a\}$, and rules with probabilities:

$$\begin{aligned} S \to A_i \quad & \#1.0 \text{ if } i = 1 \quad \text{else } 0.0 \\ A_i \to A_j \quad & \#1.0 \text{ if } j = i + 1 \text{ else } 0.0 \\ A_i \to a \quad & \#1.0 \text{ if } i = 3 \quad \text{else } 0.0 \end{aligned}$$

Consider the chart G^f_a for the string a which is isomorphic to G^f. The inside and outside weight of each nonterminal of G^f_a is 1.0. If we merge A_1, A_2, and A_3 to A and project weights according to the max-rule-product principle, then we obtain the CFG G^c_a with weights

$$\begin{aligned} S \to A \ \ & \#1.0 \\ A \to A \ \ & \#2.0 \\ A \to a \ \ & \#1.0 \end{aligned}$$

Now the weight of some parse tree of G^c_a is exponential in the number of occurrences of the chain rules $A \to A$ it contains. Consequently, there cannot be a best tree.

A.4 Hyperparameters and preprocessing

The TiGer corpus is preprocessed before grammar induction. Specifically, punctuation tokens are attached to lower nodes in order to reduce the number of discontinuous brackets using *disco-dop*. Also, we replace words with less than 4 occurrences in the training corpus by a fresh "UNKNOWN" symbol. In addition, the training set and the validation set are enriched by copies of the constituent trees where every word is replaced by the "UNKNOWN" symbol. These copies get assigned frequency 0.1 in either set.

During the split/merge algorithm EM training is applied as follows. The probability assignment p_i of the i-th epoch ($m \leq i \leq 20$) with the best validation likelihood is selected as result. We set $m = 2$ after smoothing and $m = 5$ otherwise. Also, we skip all remaining EM epochs, if validation likelihood dropped in 6 consecutive epochs. When computing validation likelihood, we ignore trees with probability 0 except after smoothing.

Double Path Networks for Sequence to Sequence Learning

Abstract

Encoder-decoder based Sequence to Sequence learning (S2S) has made remarkable progress in recent years. Different network architectures have been used in the encoder/decoder. Among them, Convolutional Neural Networks (CNN) and Self Attention Networks (SAN) are the prominent ones. The two architectures achieve similar performances but use very different ways to encode and decode context: CNN use convolutional layers to focus on the local connectivity of the sequence, while SAN uses self-attention layers to focus on global semantics. In this work we propose Double Path Networks for Sequence to Sequence learning (DPN-S2S), which leverage the advantages of both models by using double path information fusion. During the encoding step, we develop a double path architecture to maintain the information coming from different paths with convolutional layers and self-attention layers separately. To effectively use the encoded context, we develop a cross attention module with gating and use it to automatically pick up the information needed during the decoding step. By deeply integrating the two paths with cross attention, both types of information are combined and well exploited. Experiments show that our proposed method can significantly improve the performance of sequence to sequence learning over state-of-the-art systems.

1 Introduction

Sequence to Sequence learning (S2S) (Cho et al., 2014; Sutskever et al., 2014) is one of the challenging tasks in artificial intelligence, which covers machine translation, document summarization and question answering, etc. It has attracted more and more attention in recent years due to the success of deep learning. Sequence to sequence learning is usually developed based on a general encoder-decoder framework: The encoder reads the source sequence and generates a set of representations. After that, the decoder estimates the conditional probability of each target token given the source representations and its preceding tokens.

Different network architectures for sequence to sequence modelling have been designed based on this framework. Long Short-Term Memory (LSTM) based model (Cho et al., 2014) is the most popular. In the LSTM based model, the tokens are encoded/decoded using LSTM units, which can effectively summarize the temporal information of the sentences in source/target domains. However, because of its recurrent nature, the LSTM based model is difficult to parallel, so the training efficiency becomes the major challenge. Recently, Convolutional Neural Network (CNN) based (Gehring et al., 2017a) and Self Attention Network (SAN) based (Vaswani et al., 2017) models have been proposed, which achieved significant improvements in accuracy. Both models replace the recurrent structure with networks that are easy to parallelize, leading to training time acceleration.

CNN based and SAN based sequence to sequence models encode and decode information in very different ways. CNN based model treats the sequences similar with images: The convolutional layer is used to summarize information for a local region of the sequence, which corresponds to a subsequence

This work was done when K. Song was an Intern at Microsoft Research

Proceedings of the 27th International Conference on Computational Linguistics, pages 3064–3074
Santa Fe, New Mexico, USA, August 20-26, 2018.

of tokens. Different from CNN based model, SAN based model uses self-attention layer to abstract the context based on semantic meanings: In each layer, for each token, the similarity between the token and all other tokens in the sequence are computed. Then the contexts are weighted combined based on the global semantic similarity. By stacking multiple convolutional layers or self-attention layers, the two models obtain the whole contextual information during the encoding and decoding step.

As we can see, the convolutional layer focuses more on abstracting information according to local connectivity, while self-attention layer focuses more on using global semantics. Both models achieve similar accuracy on several sequence to sequence learning tasks. Then a natural question raises: is there any way to integrate the two methods together to achieve a higher accuracy? This is exactly the purpose of the paper.

In this work, we investigate the possibility to combine the two models into a unique framework and develop efficient architecture to leverage both advantages. In particular, we propose Double Path Networks for Sequence to Sequence learning (DPN-S2S), which contain a convolutional path and a self-attention path with attention information fusion between the encoder and the decoder. In the encoding step, we use the convolutional path and self-attention path independently. Thus we can summarize the context of the source sequences from different aspects. In the decoding step, we develop a cross attention module with gating to automatically select appropriate context, and use the context in a similar double path structure. As there is no recurrent structure in convolutional layers and self-attention layers, the model is still easy to parallelize. Since we abstract the hidden representation from different ways, the contexts we obtain are more diverse, making it possible to achieve higher accuracy under the same parameter number.

Experimental results show that our proposed approach can achieve significant improvements than single path based S2S framework. The results are summarized as follows:

- With a similar number of parameters, our model outperforms CNN based, SAN based model. More specifically, on Nist Chinese-English translation task, we outperform the strong CNN based baseline by 0.46-2.96 BLEU, SAN based baseline by 0.74-0.99 BLEU respectively in different Nist test sets. Furthermore, our model also achieves state-of-art BLEU/ROUGE score on IWSLT14 German-English translation task and English Gigaword text summarization task.

- Through ablation studies and analyses we show that both the CNN and SAN path are important in the encoder and the decoder. Removing any part would cause performance drop, which demonstrates the effectiveness of our model.

2 Background

2.1 Encoder-Decoder Framework

Denote $x = (x_1, x_2, ..., x_m)$ and $y = (y_1, y_2, ..., y_n)$ as the sentence pair, in which x_i and y_t are the i-th and t-th tokens for sequences x and y, m and n are the lengths of the sequences. The sequence to sequence model learns to estimate the conditional probability $P(y|x)$. Denote the model parameter as θ and denote the training corpus as S. One of the most popularly used objective functions is the log likelihood function:

$$L(\theta; S) = \frac{1}{|S|} \sum_{(x,y)\in S} \log P(y|x; \theta). \tag{1}$$

According to the probability chain rule, we have:

$$P(y|x; \theta) = \prod_{t=1}^{n} P(y_t|y_{<t}, x; \theta), \tag{2}$$

where $y_{<t}$ is the sequence of proceeding tokens before position t. To model the conditional probability, an encoder-decoder framework is usually employed (Cho et al., 2014; Bahdanau et al., 2015). In the encoding phase, $(h_1, h_2, \cdots, h_m)$ is learnt as the representations of the source sequence:

$$(h_1, h_2, \cdots, h_m) = f(x_1, x_2, ..., x_m). \tag{3}$$

where $f(\cdot)$ can be implemented as RNN, CNN or SAN. During the decoding phase, the decoder generates the target token y_t at position t using the previous generated tokens $y_{<t}$ and the source representations $(h_1, h_2, \cdots, h_m)$.

An attention mechanism is usually adopted to choose the places in the source representations to focus on. There are several types of attention used in the literature, such as dot, $concat$ and $general$ (Luong et al., 2015; Bahdanau et al., 2015). In this paper, we mainly adopt the dot type which is formulated as the q-k-v form:

$$Attention(q, k, v) = softmax(qk^T)v, \tag{4}$$

where $softmax$ function computes the attention coefficient which evaluates how well the source representations k matches the target query q. q is usually the hidden state in the current decoder layer and k, v are usually the same as source representation h.

2.2 CNN based Encoder-Decoder

CNN based Encoder-Decoder framework (Gehring et al., 2017b) typically uses one-dimensional convolution in each layer to perform nonlinear transformation. Denote h_i^l with dimension d as the i-th hidden state in the l-th CNN layer and set $h_i^0 = e_i$, where e_i is the input embedding of the sequence. The hidden state h_i^l is computed by the convolution operation:

$$h_i^l = v([h_{i-r/2}^{l-1}, ..., h_{i+r/2}^{l-1}]W^l + b_w^l) + h_i^{l-1}, \tag{5}$$

where $W^l \in \mathcal{R}^{rd \times 2d}$ is the convolution filter with kernel size r, $b_w^l \in \mathcal{R}^{2d}$ is the bias and d is the hidden dimension. The convolution input is the concatenation of r elements in the lower layer with hidden dimension d. We use Gated Linear Units (GLU) (Dauphin et al., 2017) as the activation function v, with $2d$ input vector and d output vector.

2.3 SAN based Encoder-Decoder

SAN system is first proposed by Vaswani et al. (2017). Each single self-attention layer has two sublayers: a multi-head self-attention layer and a feed forward network. Both sublayers are stacked using residual connection (He et al., 2016) and layer normalization (Ba et al., 2016). The multi-head self-attention layer $MH(\cdot)$ is formulated as follows:

$$\begin{aligned} MH(q, k, v) &= Concat_{i=1}^{s} h_i(q, k, v), \\ h_i(q, k, v) &= Att(\frac{qW_i^q}{\sqrt{d_s}}, kW_i^k, vW_i^v). \end{aligned} \tag{6}$$

Each head uses weights W_i^q, W_i^k and W_i^v to linearly transform the input q, k, v and then performs $Att(\cdot)$ which is equal to Equation 4. W_i^q, W_i^k and $W_i^v \in \mathcal{R}^{d \times d_s}$, where d_s is a scale factor, which equal to d/s, d is the hidden size of q, and s is the number of heads.

For the feed forward network, we use a simple two-layer, fully connected network with ReLU activation function in the middle layer:

$$FeedForward(x) = f_2(Max(0, f_1(x))), \tag{7}$$

where $f_1(\cdot)$ and $f_2(\cdot)$ are both feed forward network. The feed forward network applies the non-linear transformation on each position identically and separately.

3 Double Path Networks

In our work, we introduce double path networks which incorporate CNN and SAN for sequence to sequence learning. A detailed model structure is shown in Figure 1.

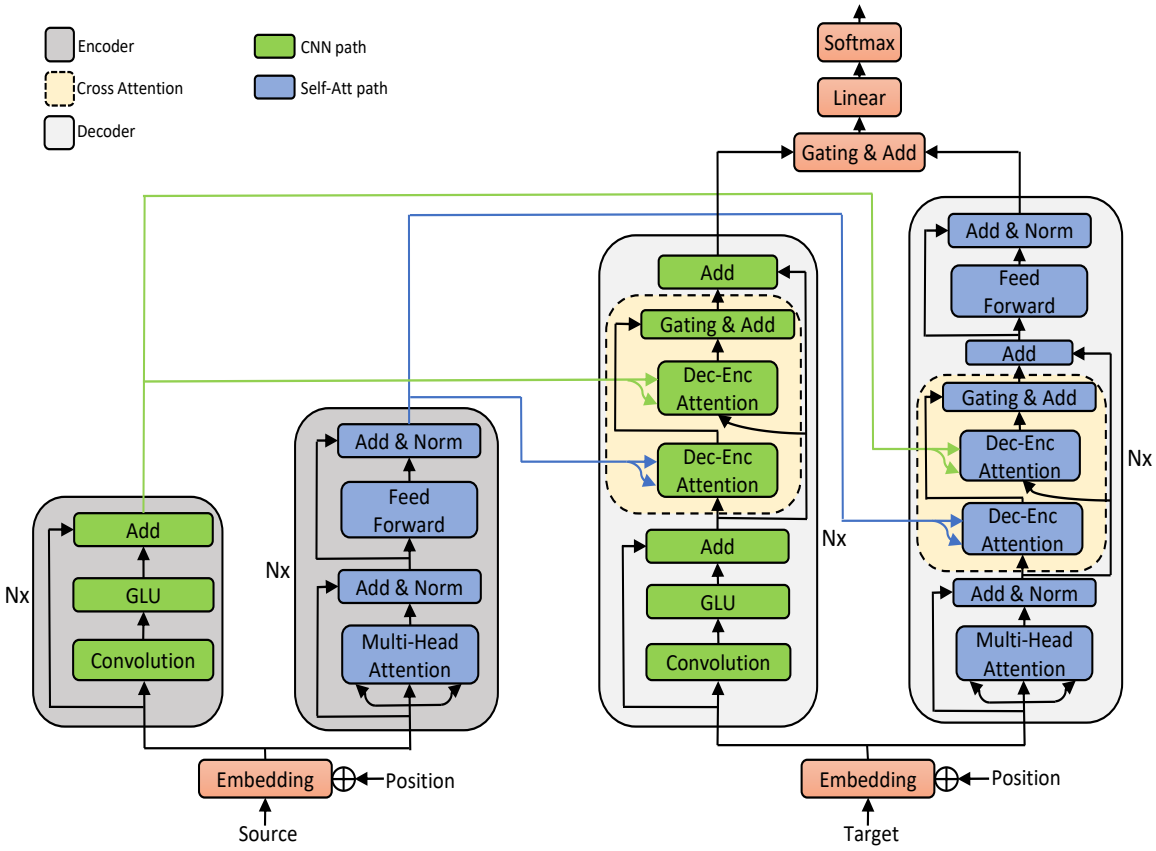

Figure 1: DPN-S2S architecture. The CNN and SAN path are depicted with green and blue module, respectively. The encoder part is colored with dark grey, attention fusion part with light yellow, and decoder part with light grey. The blue and green line show the information flow from encoder to decoder.

3.1 Double Path Encoder

To leverage the advantage of CNN and SAN layer, we design an encoder which includes a CNN and SAN path, introduced in Section 2.2 and 2.3 respectively. We sum up the position embedding $\mathbf{p} = (p_1, ..., p_m)$ and word embedding $\mathbf{w} = (w_1, ..., w_m)$ as the input of encoder, to give the model a sense of the token's position in the sentence. For each path, we employ residual connections to stack multiple layers for deeper network. Consequently, we can collect two various context representations from encoder.

3.2 Cross Attention with Gating

Between the encoder and the decoder, we develop a cross attention module with gating fusion, to automatically pick up the information needed to decode target word. As shown in Figure 1, the attention fusion module consists of two submodules: $Dec - Enc\ Attention$ and $Gating\ \&\ Add$. We now give detailed descriptions of the two submodules.

Each path in the decoder take encoder's double-path outputs as context to make attention. Thus, there are four types of information flows through encoder to decoder. The $Dec - Enc\ Attention$ module in the decoder takes Eq. (4) to compute attention results, which is denoted as:

$$\begin{aligned} ctx^{cc} &= Attention(q^c, k^c, v^c), \quad ctx^{ca} = Attention(q^c, k^a, v^a), \\ ctx^{ac} &= Attention(q^a, k^c, v^c), \quad ctx^{aa} = Attention(q^a, k^a, v^a). \end{aligned} \tag{8}$$

For example, $ctx^{ca} \in \mathcal{R}^d$ means the attention result with attention query q^c from CNN path in the decoder and attention key k^a and value v^a from SAN path in the encoder.

In order to fully exploit the information captured by different encoder paths, we design a gating mechanism to fuse them for balancing information usage between local connectivity and global semantics.

This fusion gate is shown as the $Gating\ \&\ Add$ module in the right side of Figure 1, formulated as follows:

$$\begin{aligned} g^c &= sigmoid([ctx^{cc}, ctx^{ca}]W^c + b^c), \\ g^a &= sigmoid([ctx^{aa}, ctx^{ac}]W^a + b^a), \\ ctx^c &= ctx^{cc} \cdot (1 - g^c) + ctx^{ca} \cdot g^c, \\ ctx^a &= ctx^{aa} \cdot (1 - g^a) + ctx^{ac} \cdot g^a, \end{aligned} \tag{9}$$

where g^c and g^a are scalar attention gates for CNN context and SAN context; $[\cdot, \cdot]$ is an element concatenate operation; W^c and $W^a \in \mathcal{R}^{2d}$ are the weight matrices; b^c and b^a are the scalar biases of the attention gates; and ctx^c and ctx^a are the fusion context vectors for the current CNN layer and SAN layer. For the gate g^c and g^a, both the two attention results are used as inputs to the gating computation.

3.3 Double Path Decoder

The decoder is illustrated in the right side of Figure 1. It is similar to the encoder except for the decoder-to-encoder attention. Each layer in CNN and SAN contains two decoder-to-encoder attention modules, which is denoted in last subsection. We also need remove the future information in the convolution and self-attention operations in order to be consistent with decoding phase, for target sentence is generated sequentially, without any prior knowledge about next word.

We also apply a gating mechanism to combine the outputs of the two decoder paths and feed the combined result into the $softmax$ layer to generate next word:

$$\begin{aligned} g^o &= sigmoid([z^c, z^a]W^o + b^o), \\ z^o &= z^c \cdot (1 - g^o) + z^a \cdot g^o, \\ P(y) &= softmax(z^o W^s + b^s), \end{aligned} \tag{10}$$

where z^c and z^a are the outputs of CNN and SAN path, respectively. z^o is the fusion output and W^s, b^s are linear transform weights and biases before $softmax$.

4 Experiment Settings

In this section, we introduce the datasets used in experiments, model settings, and training details.

4.1 Datasets

We evaluate our proposed method on two neural machine translation tasks and one abstractive text summarization task. The datasets are described as follows:

IWSLT2014 German-English We use the dataset of IWSLT14 German-English machine translation track (Cettolo et al., 2014) for training and evaluation. We tokenize the data which come from TED and TEDx talks. After preprocessing, the dataset remains 160K training sentences and 7K development sentences[1]. We concatenate dev2010, tst2010, tst2011 and tst2012 as the test set. We consider a joint source and target byte-pair encoding (BPE) with 10K types (Sennrich et al., 2016).

Nist Chinese-English We use the corpus consisting of 1.25M sentence pairs extracted from LDC corpora [2]. This dataset contains 27.9M Chinese words and 34.5M English words respectively. We learn a 25K subwords dictionary based on BPE for source and target languages separately. After tokenization, we get a source vocabulary with 37K words and a target vocabulary with 25K words. We choose Nist-2003 as the development set, and Nist-{2004, 2005, 2006, 2008, 2012} as the test sets.

[1] https://github.com/facebookresearch/fairseq-py/blob/master/data/prepare-iwslt14.sh

[2] The corpora includes LDC2002E18, LDC2003E07, LDC2003E14, Hansards portion of LDC2004T07, LDC2004T08 and LDC2005T06.

Text Summarization We use the Gigaword corpus (Graff et al., 2003) and follow the processing as Rush (2015). We obtain 3.8M training samples and 190K validation samples. We evaluate our approach on Gigaword dataset, which is a widely used test set with 2000 article-title pairs. Similar to Gehring (2017a), we use source and target vocabulary both with 30K words. Follow Gehring (2017a), we require the length of generated sequence is at least 14 words.

4.2 Model Settings

IWSLT14 German-English For CNN path, we adopt 4 idential convolutional layers with 256 neurons in both the encoder and the decoder. As one self-attention layer is comprised of 2 sublayers, we set 2 layers for SAN to guarantee the depth consistency of network. The hidden size and the filter size of SAN block are set as 256 and 1024 respectively. The word embedding dimension is 256. And the dropout rate is set as 0.1. In order to demonstrate the efficiency of our method, we compare our method with four following baselines: (i) *Deeper CNN Model*, a standard CNN based model with 8 layers of 256 neurons. (ii) *Wider CNN Model*, a standard CNN based model with 4 layers of 512 neurons. (iii) *Wider SAN Model*, a standard SAN based model with 2 layers of 512 neurons. (iv) *Deeper SAN Model*, a standard SAN based model with 4 layers of 256 neurons. Besides, we also list some related works for comparison.

Nist Chinese-English We perform a deep model on Nist Chinese-English translation task. This model adopts 12 stacked layers for the CNN path and 6 stacked layers for SAN path in the encoder and decoder respectively. The hidden size of both CNN/SAN layers are both set as 256 and the filter size of SAN layer is 1024. We set 256 neurons for the word embedding. The dropout rate is set as 0.2. For the purpose of comparison, We choose two model settings as baselines: (i) *CNN Model*, a CNN based model with 12 stacked layers of 512 neurons (ii) *SAN Model*, a SAN model with 6 stacked layers of 512 neurons and the filter size of layer is 2048. These model settings contain approximately similar number of parameters in contrast to our model. We also list some previous works for comparison.

Text Summarization We follow the same model setting as described in IWSLT14 German-English translation task. For this task, We adopt the models including RNN MRT (Ayana et al., 2016), WFE (Suzuki and Nagata, 2017) and ConvS2S (Gehring et al., 2017a) as the baselines.

4.3 Training and Evaluation

We adopt Nesterov Accelerated Gradient (NAG) (Bengio et al., 2012) as training optimizer. The initial learning rate is set as 0.25 for IWSLT14 German-English and text summarization, and 0.50 for Nist Chinese-English, with a decay schedule that shrinking by 10 when the validation loss stops decreasing. Each training batch contains approximately 4000 source and target tokens. During inference, we set beam size as 5 for IWSLT14 German-English and text summarization, and 10 for Nist Chinese-English. All models are implemented in PyTorch based on *fairseq-py*[3]. We use one Nvidia Titan x Pascal GPU for IWSLT14 German-English and text summarization, and 4 GPUs for Nist Chinese-English.

5 Results

In this section, we report our results on translation and summarization tasks. In addition, we also conduct a series of extensive analyses for a better understanding of our model.

Table 2: Performance of different systems on Nist Chinese-English translation task.

5.1 IWSLT2014 German-English

We evaluate the translation accuracy by BLEU [4] (Papineni et al., 2002). Table 1 shows the experiment results on German-English translation task. We list the results of the wider network, deeper network and some related works for a comparison. The results can be summarized as follow:

When compared with wider network, DPN-S2S achieves an improvement of 1.36 BLEU and 0.70 BLEU over CNN and SAN model. When compared with deeper network, DPN-S2S achieves an improvement of 1.29 BLEU and 0.56 BLEU over CNN and SAN model. Generally, we note that DPN-S2S can produce better performance than wider or deeper networks with fewer parameters. In addition, we choose two methods which used an actor-critic algorithm (Bahdanau et al., 2016) and a phrased-based model with an auxiliary language model (Huang et al., 2017) separately. We find our method also outperforms these approaches. All of these comparsions indicate the effectiveness of our method.

5.2 Nist Chinese-English

Table 2 lists the results about our model on each Nist Chinese-English test set, together with several NMT baselines. These baselines are RNNSearchs with some well acknowledged techniques including: 1) Using multi-channel information into encoder (MC-NMT) (Xiong et al., 2018); 2) Incorporating word reorder information into NMT (NMT+Distortion) (Zhang et al., 2017); 3) An attention mechanism with a directed-syntax (SD-NMT) (Chen et al., 2017). We can observe that our method surpasses SAN and CNN baseline by 0.74-0.99 and 0.46-2.96 BLEU score in different test sets. In addition, we also compare our results with some related works, and our model outperforms MC-NMT by 0.47-4.27 BLEU, NMT+Distortion by 0.74- 4.31 BLEU and SD-NMT by 1.44-4.38 BLEU in Nist test sets. These results on Nist Chinese-English dataset prove that our model can also achieve improvement in large dataset.

	Gigaword		
	RG-1 (F)	RG-2 (F)	RG-L (F)
RNN MRT (Ayana et al., 2016)	36.54	16.59	33.44
WFE (Suzuki and Nagata, 2017)	36.30	17.31	33.88
ConvS2S (Gehring et al., 2017a)	35.88	17.48	33.29
DPN-S2S	**36.92**	**17.91**	**34.32**

Table 3: Accuracy on Gigaword text summarization task in terms of ROUGE-1 (RG-1), ROUGE-2 (RG-2), and ROUGE-L (RG-L). F stands for F1-score.

5.3 Text Summarization

We employ three variants of ROUGE (Lin, 2004) as evaluation metrics for text summarization: ROUGE-1 (unigrams), ROUGE-2 (bigrams), and ROUGE-L (longest-common substring).

[4] https://github.com/moses-smt/mosesdecoder/blob/master/scripts/generic/multi-bleu.perl

We compare our model with some previous work including RNN MRT (Ayana et al., 2016) which adopts RNNSearch on this task, WFE (Suzuki and Nagata, 2017) which addresses the problem of repeated sequence generation, and ConvS2S (Gehring et al., 2017a). Table 3 shows the text summarization results on the Gigaword dataset. DPN-S2S outperforms all the three models by 0.43-1.04 ROUGE-1, 0.43-1.32 ROUGE-2 and 0.64-1.23 ROUGE-L in terms of F1 score.

5.4 Ablation Study

To understand to what extent each path in the encoder/decoder can affect the model performance, we conduct some experiments for ablation study. For conciseness we just choose one task (IWSLT14 German-English) for this study. Table 4 shows the experiment settings and results. All the models are of the same dimensions for hidden states and word embedding. Note that model M9 is our proposed DPN-S2S. We have the following observations.

ID	Encoder CNN	Encoder SAN	Decoder CNN	Decoder SAN	BLEU
M1	Δ		Δ		30.38
M2	Δ			Δ	31.00
M3	Δ		Δ	Δ	31.26
M4		Δ	Δ		29.80
M5		Δ		Δ	30.63
M6		Δ	Δ	Δ	31.11
M7	Δ	Δ	Δ		31.03
M8	Δ	Δ		Δ	31.43
M9	Δ	Δ	Δ	Δ	**31.99**

Table 4: Ablation studies of DPN-S2S on IWSLT14 German-English. Δ means the model contains this component.

- Comparing model M4 with M7, M5 with M8, and M6 with M9, we can see that adding the CNN encoder leads to 0.80-1.23 BLEU gain.
- Comparing model M2 with M3, M5 with M6, and M8 with M9, we observe that adding the CNN decoder leads to 0.26-0.56 BLEU gain.
- Comparing model M1 with M7, M2 with M8, and M3 with M9, we find that adding the SAN encoder results in 0.43-0.73 BLEU improvement.
- Similarly comparing model M1 with M3, M4 with M6, and M7 with M9, we see 0.88-1.31 BLEU gain by adding the SAN decoder.

These results suggest that both the CNN path and the SAN path make positive contributions to the overall architecture, and they are needed in both the encoder and decoder.

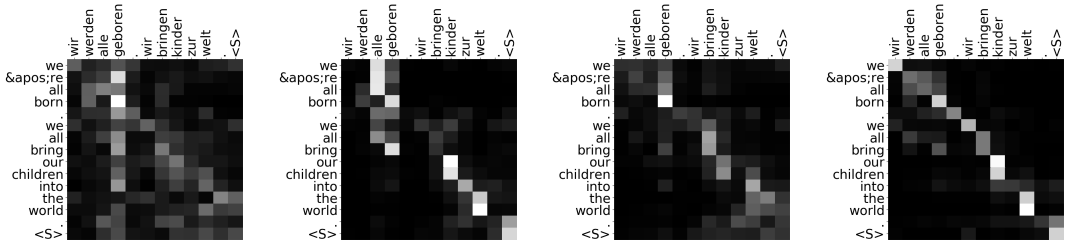
5.5 Attention Visualization

To demonstrate the different characteristics of the CNN and SAN path, we analyze the alignments (attention coefficients) from the four types of decoder-to-encoder attention. The alignments are computed by $Softmax(qk^T)$ from Eq. (4), and the alignments from each token in decoder form a distribution. We use the entropy of the distribution $-\sum_i x_i log x_i$ to depict to what extent the target token focuses on the source tokens. Small entropy means less uncertainty, i.e., the attention is more concentrated.

Encoder \ Decoder	CNN	SAN
CNN	2.208	1.406
SAN	1.886	1.377

Table 5: The entropy of the alignments of CNN/SAN decoder to CNN/SAN encoder on IWSLT14 German-English.

We choose the 6750 sentences in the German-English test set and calculate the entropy of each target token's alignments distribution, averaged by target token in the sentence and then averaged by sentence, as shown in Table 5. The entropy of alignments from both paths in decoder to CNN path in encoder (the first row of the table) is larger than that of SAN path in encoder. This is consistent with our intuitions: CNN focuses more on local information, and so the decoder needs to attend to multiple hidden states



(a) CNN to CNN (b) CNN to SAN (c) SAN to CNN (d) SAN to SAN

Figure 2: The alignments of CNN/SAN decoder to CNN/SAN encoder from DPN-S2S. The x-axis and y-axis of each plot correspond to the words in the source language and target language. Each pixel shows the alignment scores of the target word to source word.

	Translation
Source (De)	das ist die linke hlfte, die die logische seite ist und dann die rechte hälfte, die die intuitive seite ist.
Target (En)	there 's *the left half*, which is the logical side, and then *the right half*, which is the intuitive.
CNN	this is *half the left half*, which is the logical side, and then *half the rights* that is the intuitive side.
SAN	that's the left half, which is the logical side , and then *half*, that 's the intuitive side.
DPN-S2S	that's *the left half*, which is the logical side, and then *the right half*, which is the intuitive side.

Table 6: A German-English translation case to demonstrate DPN-S2S outperforms CNN and SAN in terms of translation accuracy.

of the CNN path in the decoder to extract necessary information for target word generation; in contrast, each hidden state in the SAN path has already included global semantics, and so the decoder only needs to focus on a small number of hidden states of the SAN path in the encoder, resulting in more focused alignments and smaller entropy (the second row of the table).

For an intuitive understanding, we visualize the alignments of a sentence pair in Figure 2. Comparing Figure 2b with 2a, we can see that the attention from the CNN path of the decoder to the SAN path of the encoder is more focused than that to the CNN path of the encoder. The same phenomenon can be found for attention from the SAN path of the decoder to the encoder, by comparing Figure 2d with 2c.

5.6 Case Study

To better understand the advantage of DPN-S2S over single path models, Table 6 shows a case from the German-English test set. We list the generated target sentence by CNN based model, SAN based model and DPN-S2S, respectively. As can be seen, CNN based model generates detailed words such as "half the left half" and "half the rights", without a global view to correctly organize these local meanings. SAN based model misses the local details about the "the right half" information. Our DPN-S2S well combine the local information from the CNN based path and the global information from the SAN based path, resulting in a better translation.

6 Conclusion

In this paper, we have proposed double path networks for sequence to sequence learning, named *DPN-S2S*, which uses a cross attention module to leverage the advantages of two different models, and achieves the state-of-art performance in several sequence to sequence tasks.

We plan to explore the following directions in the future. First, we will test the new model on more language pairs for neural machine translation and other sequence to sequence tasks. Second, it is interesting to investigate how to design better structures for information fusion. Third, we would like to extend the current double path model to multiple paths.

Abstract

Syntactic parsing plays a crucial role in improving the quality of natural language processing tasks. Although there have been several research projects on syntactic parsing in Vietnamese, the parsing quality has been far inferior than those reported in major languages, such as English and Chinese. In this work, we evaluated representative constituency parsing models on a Vietnamese Treebank to look for the most suitable parsing method for Vietnamese. We then combined the advantages of automatic and manual analysis to investigate errors produced by the experimented parsers and find the reasons for them. Our analysis focused on three possible sources of parsing errors, namely limited training data, part-of-speech (POS) tagging errors, and ambiguous constructions. As a result, we found that the last two sources, which frequently appear in Vietnamese text, significantly attributed to the poor performance of Vietnamese parsing.

Title and Abstract in Vietnamese

Khám phá dựa trên thực nghiệm các kiểu lỗi trong phân tích cú pháp tiếng Việt

Phân tích cú pháp đóng vai trò then chốt trong việc cải thiện chất lượng các hệ thống xử lý ngôn ngữ tự nhiên. Mặc dù đã có một vài dự án nghiên cứu về phân tích cú pháp tiếng Việt, chất lượng của những công trình này thấp hơn nhiều so với các nghiên cứu trên các ngôn ngữ phổ biến như tiếng Anh và tiếng Trung Quốc. Trong bài báo này, chúng tôi đánh giá các phương pháp phân tích cú pháp tiêu biểu trên ngân hàng cây cú pháp tiếng Việt để tìm ra phương pháp phân tích cú pháp phù hợp nhất cho tiếng Việt. Sau đó, chúng tôi kết hợp những ưu điểm của phân tích tự động và phân tích thủ công để khám phá các kiểu lỗi mà những phương pháp phân tích cú pháp được thực nghiệm mắc phải và tìm nguyên nhân cho những lỗi đó. Phân tích của chúng tôi tập trung vào ba nguồn chính gây ra lỗi, cụ thể là dữ liệu huấn luyện ít, lỗi trong việc gán nhãn từ loại, và các cấu trúc nhập nhằng. Kết quả cho thấy rằng lỗi trong việc gán nhãn từ loại và cấu trúc nhập nhằng là hai nguyên nhân chính gây ra hiệu suất thấp trong phân tích cú pháp tiếng Việt.

1 Introduction

Syntactic parsing plays a crucial role in improving the quality of natural language processing (NLP) applications and speech processing. Parsing has been broadly studied for languages such as English and Chinese, which leads to the development of many parsing methods. For example, Klein and Manning (2003), Matsuzaki et al. (2005), and Petrov and Klein (2007) improved probabilistic context-free grammar (PCFG) parsing by enriching contextual information, Finkel et al. (2008) and Hall et al. (2014) employed feature-based conditional random fields (CRFs), Zhu et al. (2013) and Coavoux and Crabbé (2017) employed shift-reduce algorithms, while Durrett and Klein (2015) and Dyer et al. (2016) used neural networks.

The parsing problem has not been studied thoroughly enough for Vietnamese. Since a Vietnamese Treebank was built by Nguyen et al. (2009), a few researchers have adapted available constituent parsers

[*]This work was carried out while the first author was a PhD student at The Graduate University for Advanced Studies (SOKENDAI), Japan.

Proceedings of the 27th International Conference on Computational Linguistics, pages 3075–3089
Santa Fe, New Mexico, USA, August 20-26, 2018.

to construct a parser for Vietnamese; e.g., AC. Le et al. (2009) modified the Bikel's parser (Bikel, 2004) and Le-Hong et al. (2012) modified the LTAG parser developed by LORIA laboratory[1]. However, the parsing accuracies were far lower than the performances reported in English, Chinese, and French.

It is hard to parse Vietnamese text due to difficulties that result from characteristics of the Vietnamese language[2]. Vietnamese does not have word delimiters and inflectional morphemes in comparison to English. While similar problems also occur in Chinese (Xia et al., 2000), parsing Vietnamese may be more difficult because the modern Vietnamese writing system is based on Latin characters, which represent the pronunciation but not the meanings of words. As a result, there are many polysemous expressions in Vietnamese, i.e., expressions having the same surface form with different interpretations. Difficulties in Vietnamese parsing are also caused by word orders. Although Vietnamese is a subject-verb-object (SVO) language like English and Chinese, its word orders are different from these languages. For example, the word order in Vietnamese noun phrases (*NPs*) is exactly the same as those in simple sentences, which leads to ambiguities in labelling these two types of expressions. In addition, other problems, such as word omission, contribute to many complications in parsing Vietnamese texts.

Another possible reason for difficulties in Vietnamese parsing is treebank design[3]. For example, syntactic categories in the Vietnamese Treebank by Nguyen et al. (2016) are similar to those in the Penn Treebank, e.g., *NP* for noun phrases and *VP* for verb phrases. These categories were not fine-grained enough to distinguish various syntactic constructions in Vietnamese. In addition, there are ambiguous constructions that have the same tag sequences (including POS tags and phrase tags), but are bracketed in different ways. For instance, the sequence of POS tags *Nn Vv* can be bracketed as a noun phrase (*NP*) in which *Vv* is a modifier of the head noun *Nn*. The sequence can also be bracketed as a simple sentence where *Nn* is the subject and *Vv* is the predicate.

A worthwhile effort would be to analyze parsing errors to improve the quality of parsers. Based on this analysis, we can consider how to modify parsing models such that they can capture the necessary syntactic information. Several researchers (Levy and Manning, 2003; Hara et al., 2009) have manually investigated parsing errors. Manual investigations can help us find reasons for parsing errors that are specific to languages. However, this method cannot be applied to a large amount of parsing outputs and is also limited to a few syntactic phenomena. Kummerfeld et al. (2012) developed a tool to automatically classify English parsing errors within a set of predefined error types such as NP attachment and VP attachment. However, based on these analyzing results, we cannot specify any reasons to explain why the error types occurred, which is important clues to improve parsers.

In this paper, we firstly evaluated representative parsing models on the Vietnamese Treebank. We then investigated three possible sources of errors produced by parsers, viz., limited training data, confusing POS tags, and ambiguous constructions. Our analysis method combined an automatic tool and manual analysis. We used Kummerfeld et al. (2012)'s tool in the automatic phase to quantify how often the types of errors occurred in the experimented parsers. By comparing the results obtained from this analysis, we could identify which types of errors could be solved by different parsers as well as which errors were difficult for parsers to address. We manually investigated parsing errors in the second phase based on the results obtained from the analysis in the first phase to find the reasons for each error type.

2 Parsing evaluation

We applied six representative parsers in the literature in English and Chinese to the Vietnamese Treebank. For each parser, we used parameter settings that had the best accuracy in English.

Stanford-Unlex (Klein and Manning, 2003) is an unlexicalized probabilistic context free grammar (PCFG) parser where the coarse categories of PCFG, such as *NP* for noun phrases, are enriched by several simple structural annotations, e.g., markovization before splitting several symbols according to a manual grammar.

Stanford-RNN (Socher et al., 2013) is a combination of a PCFG with a recursive neural network,

[1] http://www.loria.fr

[2] An example illustrating Vietnamese charateristics is presented in Appendix C.

[3] Vietnamese Treebank's POS tags and constituent tags are described in Appendices A and B.

Parsers	Tagging accuracy	R	P	F
Stanf-Unlex	89.92	52.15	56.38	54.18
Stanf-RNN	91.83	63.66	66.15	64.88
Berkeley	93.94	70.38	73.48	71.90
Epic-CRF	93.15	72.20	72.96	72.58
Epic-NeuralCRF	93.85	71.68	72.42	72.05
RNNGs-D	94.65	71.94	72.45	72.19
RNNGs-G	**94.65**	**71.71**	**74.21**	**72.94**

Table 1: PARSEVAL scores on the test set for all parsers in our experiments.

which reranks the outputs of Stanford-Unlex. Phrase representations in this model are learned via a recursive neural network that is conditioned on the coarse PCFG.

Berkeley parser (Petrov et al., 2006) is an unlexicalized PCFG parser where the PCFG is automatically enriched and generalized by using informative latent annotations.

Epic-CRF (Hall et al., 2014) is a CRF parser in which the anchored rules are scored by using sparse features of the surface spans. The base grammar in this parser employs parent annotations, a subset of annotations in Stanford-Unlex.

Epic-NeuralCRF (Durrett and Klein, 2015) is also a CRF parser but the anchored rules are scored using dense features that are computed via a feedforward neural network.

RNNGs (Dyer et al., 2016) is a top-down transition-based neural model in which a recurrent neural network conditions on a full input sentence to parameterize decisions. The RNNGs parser supports two models, i.e., discriminative (RNNGs-D) and generative models (RNNGs-G).

We used the Vietnamese Treebank developed by Nguyen et al. (2016) which includes 10,377 sentences (containing 232,838 words and 280,505 syllables). We randomly selected 1,000 sentences for the development (dev) set, 1,000 sentences for the test set, and the rest, including 8,377 sentences, was used for training. We used the input data with gold word segmentation[4] and predicted POS tags (PredictedPOS)[5].

Table 1 summarizes the PARSEVAL results of each parser on the test set. We can see from this table that RNNGs-G, which is a top-down transition-based neural model, achieved the best accuracy on the Vietnamese Treebank, while the differences among the RNNGs-G, RNNGs-D, Epic-CRF, and Epic-NeuralCRF were not very significant. This indicates that parsing models based on CRF and neural networks are equally good for Vietnamese. However, these parsers still achieved far less accuracy in comparison to that in English. One possible reason is that although each of the parsing models had its own advantages, these were insufficient to address all Vietnamese constructions.

Although Stanford-Unlex and Stanford-RNN also enriched the coarse categories of PCFG with contextual information, they achieved far less accuracy in comparison with the RNNGs parser, Berkeley parser, Epic-CRF, and Epic-NeuralCRF. The main reason for this is that Stanford-Unlex and Stanford-RNN usually split tags into subcategories in response to linguistic trends in the English Penn Treebank. For example, determiners are distinguished from demonstratives, or the POS tag of *IN* is divided into six subcategories. It was difficult to apply these parsers to the Vietnamese Treebank because many linguistic trends occurring in the English Penn Treebank are not found in the Vietnamese Treebank.

In comparison with Stanford-Unlex and Stanford-RNNs, the Berkeley parser, Epic-CRF, and Epic-NeuralCRF obtained far higher accuracies. The reason is that the Berkeley parser, Epic-CRF, and Epic-NeuralCRF used automatic methods to enrich contextual information, which were easy to apply to other languages including Vietnamese. This also indicated that enriching contextual information is beneficial for Vietnamese parsing. Contextual information can be fine-grained categorizations or features extracted from the surface spans of anchor rules[6]. However, it seems that the contextual information extracted on the basis of CFG rules did not sufficiently capture Vietnamese constructions. While RNNGs modeled

[4]We used gold word segmentation for all experiments in this research.

[5]The POS tags were predicted by the parsers. In the case of RNNGs, since the parser cannot predict POS tags, we trained a Vietnamese POS tagger with the method of Nghiem et al. (2008), using the same training data as the parsers. This POS tagger achieved an accuracy of 94.65% on the test set.

[6]An anchor rule consists of the first and last words of spans, span lengths, span shape descriptions, and the start, stop, and split indexes where the rules are anchored.

Parser	F-score	1-Word Phrase	Unary	VP Attach	NP Attach	PP Attach	Clause Attach	NP Int.	Mod Attach	Diff Label	Co-ord	XoverX Unary	Other
Stanford-Unlex	53.49	1.33	0.86	**2.23**	**1.86**	1.80	1.06	0.68	0.78	0.92	0.06	0.03	4.06

Table 2: Average number of bracket errors per sentence on the development set of Vietnamese Treebank.

sequences based on the full input sentences, which helps it find more useful contextual information.

Our evaluation of representative parsing models on the Vietnamese Treebank provided an overall sense of parsing accuracy in the Vietnamese language. While RNNGs-G achieved the highest accuracy, this was still far less than that reported in English or Chinese. In the following sections, we will explain how we investigated parsing errors to find reasons for the poor accuracy of Vietnamese parsing. This investigation was a valuable step toward improving the quality of Vietnamese parsing.

3 Investigating behaviors of parsers

This investigation was aimed at clarifying two main issues: (1) what are the most frequent errors in Vietnamese parsing?; and (2) which errors can be addressed by different parsing methods? To answer these two questions, we used a tool developed by Kummerfeld et al. (2012)[7] to classify the parsing errors into error types such as VP and NP attachments. We then computed the average number of bracket errors per sentence for each error type. The results on the development set of the Vietnamese treebank are presented in Table 2[8].

By comparing eleven types of errors produced by the parsers (columns from "1-Word Phrase" to "XoverX Unary" in Table 2), we can see that bracket errors caused by VP attachments are the most frequent, while the ones caused by NP and PP attachments are the second most. The table also indicates how the errors can be addressed by different parsing methods. For example, RNNGs-G is the best method that could address most error types in Vietnamese parsing.

In comparison to English parsing errors (Kummerfeld et al., 2012), errors in Vietnamese have the following attributes. (i) Most error types that appeared in English parsing also appeared in Vietnamese parsing. However, the average errors per sentence in Vietnamese parsing were much larger than those in English, except for co-ordination. (ii) PP-attachment was the most problematic constructions in English but it was not in Vietnamese (it was ranked at the third position). (iii) VP attachment was the most frequent error type in Vietnamese parsing while it did not occur in English parsing.

Kummerfeld et al. (2013) also analyzed Chinese parsing errors but we did not directly compare with them because our method of error classification is different from their method. Nevertheless, we drew three main conclusions from our analysis results: (i) the NP internal structure is the most problematic construction in Chinese parsing, while it is rare in Vietnamese parsing. (ii) Although VP, NP, and PP attachments are the top three difficult constructions in Vietnamese parsing, they are not frequent errors in Chinese parsing; no NP attachment errors were even detected in Chinese parsing. (iii) One-word phrases are the most problematic constructions in both languages.

Apart from containing the same complex constructions as English and Chinese such as PP attachments, Vietnamese parsing has its own constructions, e.g., VP attachments, that cannot be solved with the current parsing methods. A new parsing method to address such specific issues in the Vietnamese language is required. By quantifying error types produced by different parsing methods, our investigation provided an orientation for improving the quality of Vietnamese parsing. For example, solving the most frequent errors, such as VP attachment, NP attachment, and PP attachment errors can significantly improve the parsing performance. However, we could not find reasons of error types from this investi-

[7]This tool was designed to classify English parsing errors. We found about 20.1% of errors were identified as the "Other" type by directly applying this tool to Vietnamese parsing output (this ratio is about 11.3% for English). Several errors in the "Other" class could be classified into existing types such as clause and VP attachments.

[8]The types of errors reported in this paper are the same as those in Kummerfeld et al. (2012).

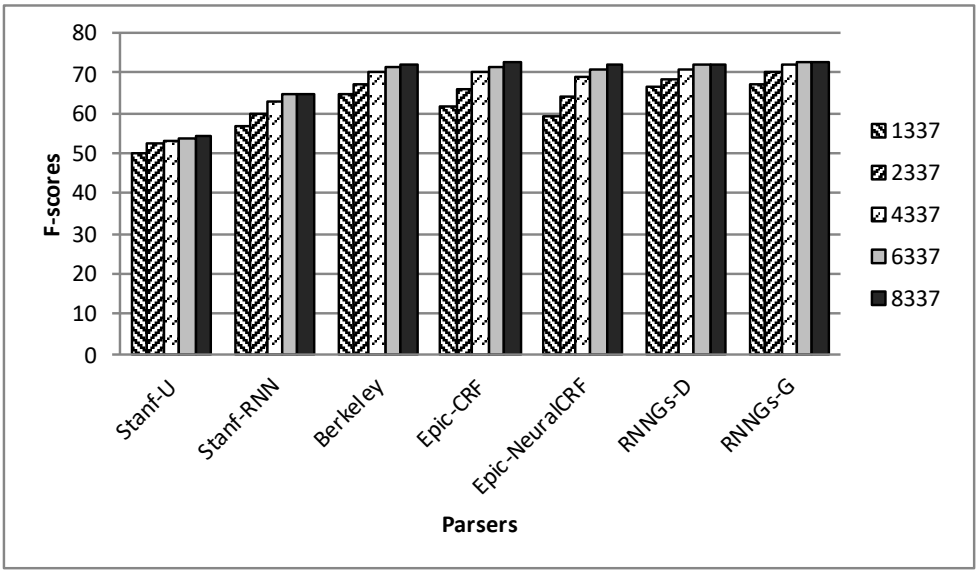

Figure 1: Parsing results from the parsers with different amounts of training data.

gation, which are very important clues to solving errors. We therefore conducted another investigation on three possible sources for the poor performance of Vietnamese parsing in the following sections, viz., the impact of training data size (Section 4), impact of POS tagging errors (Section 5), and impact of ambiguous constructions (Section 6).

4 Impact of training data size

Our training data consisted of 8,337 sentences, which were much fewer than the data used for English and Chinese parsing. To verify whether the small size of training data was a reason for the poor accuracy of the parsers, we evaluated them on different amounts of training data including 1,337, 2,337, 4,337, 6,337, and 8,337 sentences. The parsing results (F_1) on the test set of the Vietnamese Treebank are presented in Figure 1. The figure shows that the parsers' performance was improved when we eventually increased the training data from 1,337 to 6,337. However, the F-score is almost saturated when the number of sentences was increased from 6,337 to 8,337 sentences. These observations indicated that we could not expect a significant improvement in accuracy by simply increasing the amount of data. Consequently, the amount of training data was not the main reason for the poor performance of the parsers.

5 Impact of tagging errors

Figure 2 presents the PARSEVAL evaluations (F-scores) on two different versions of the test set, *PredictedPOS*, i.e., POS tags were automatically produced, and *GoldPOS*, i.e., gold POS tags were used. These results indicate that using gold POS tags could improve the accuracies of the parsers. The F-score of RNNGs-G especially achieved 78.2%, which was improved by 5.26% points in comparison with the use of an automatic POS tagger (*PredictedPOS*). However, this figure does not indicate the error types that could be solved by improving POS tagging.

To find how the gold POS tags affected parsing errors, we compared the error types produced by the best parser, RNNGs-G, on two different versions of the development set: (1) *Gold*: by using gold word segmentation and POS tags and (2) *Pred.*: by only using gold word segmentation. Results in Table 3 reveal that the occurrence of some error types was reduced when gold POS tags were used. However, it should be noted that the reductions were not significant, especially in the cases of VP and NP attachments. Therefore, enhancing POS tagger would somehow improve the performance of Vietnamese parsing but the improvement would not be radical since VP and NP attachments are the most frequent errors.

We used the same method as Kummerfeld et al. (2013) to find how an ambiguous POS pair impacted

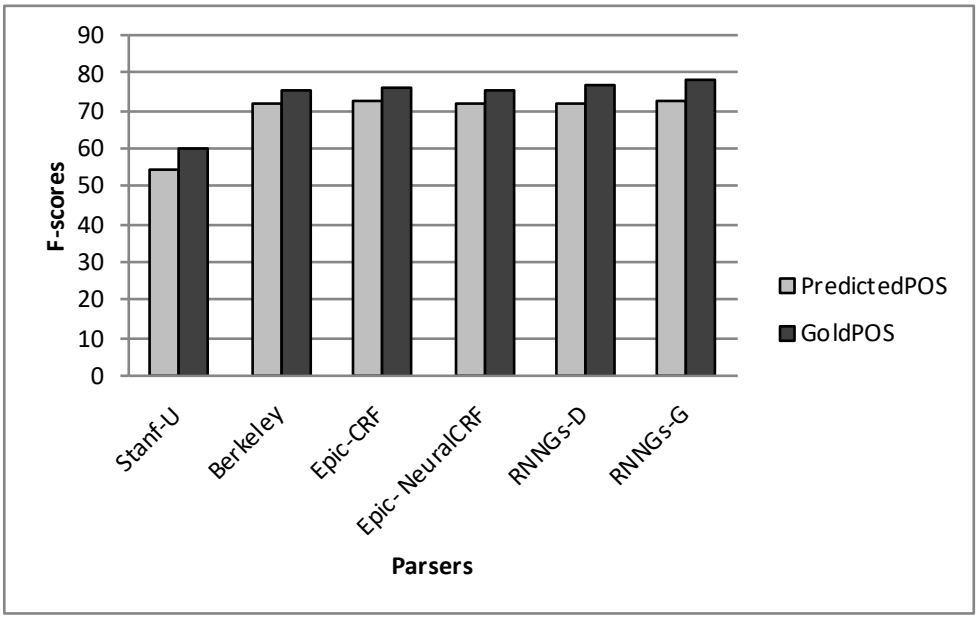

Figure 2: Results from the parsers on two different versions of test set, PredictedPOS and GoldPOS.

parsing errors. We began from *Gold*, and replaced the gold tags with tags predicted by the automatic tagger (semi-gold input). We then parsed the semi-gold input by using RNNGs-G and obtained the results from the PARSEVAL evaluation and automatic analysis. The impacts of the top four confusing POS pairs on overall bracketing errors and the F-scores are presented in Table 4. We can see that all of these four confusing POS pairs were potential contributors to bracketing errors that caused significant decreases in F-scores. However, this table also indicates that the frequency of confusing POS pairs was not directly proportional to the contributions they made to parsing errors. For example, although *Aa/Vv* was the third most confusing POS pair, it contributed most to parsing errors and caused the highest decrease in F-scores (2.58). While occurrences of *Nn/Vv* were highest (106 times), they caused the lowest decrease in F-scores (1.94).

Table 5 summarizes the impact that the top four confusing POS pairs had on each error type. The positive and negative numbers correspond to the number of bracketing errors that were created or reduced in parsing output when we replaced gold POS tags with predicted POS tags. Analysis based on four of the most frequent error types of VP, NP, PP, and clause attachments revealed the following.

VP and NP attachments: As previously explained, improving POS tagger did not assist in preventing VP and NP attachment errors. We can see from Table 5 that bracketing errors caused by VP attachment increased when we replaced the gold tag of *Vv* with predicted tags of *Nn* or *Aa*. Bracketing errors caused by NP attachment also increased when we revised the gold tag of *Aa* with the predicted tag of *Vv*. This indicated that gold POS tags were helpful in these cases. However, using predicted POS tags was better for some constructions, e.g., using the predicted tag of *Vv* instead of the gold *Nn* reduced 65 bracketing errors that were caused by NP attachment errors. These observations have revealed that the gold POS tags are important for solving VP and NP attachment errors. However, it is possible that the current 33 POS tags of the Vietnamese Treebank are not good enough for disambiguating constructions.

PP attachments: All four confusing POS pairs caused these types of parsing errors. However, *Aa/Vv* was the major contributor to parsing errors

Clause attachments: *Aa/Vv* was the major contributor to these types of parsing errors. In addition, ambiguous POS pairs, such as *Nn/Vv* and *Vv/Aa*, also created significant numbers of bracketing errors.

In summary, the quality of Vietnamese parsing could be improved by about 5% points through enhancing the Vietnamese POS tagging. We also found that all frequent ambiguous POS pairs contributed to parsing errors, in which *Aa/Vv* was the major contributor. Our analysis results indicated that improving POS tagging was beneficial for some constructions, such as PP and clause attachments. However,

Error type	Occurrences		Node errors		Node errors per sentence		Gain
	Pred.	Gold	Pred.	Gold	Pred.	Gold	
1-Word Phrase	765	517	857	544	0.86	0.54	0.32
Unary	475	386	475	386	0.48	0.39	0.09
VP Attach	392	373	1362	1368	1.36	1.37	-0.01
PP Attach	415	345	936	837	0.94	0.84	0.10
Diff label	350	157	700	314	0.70	0.31	0.39
NP Attach	333	339	1104	1101	1.10	1.10	0.00
Clause Attach	327	277	814	696	0.81	0.70	0.11
Mod Attach	216	182	381	362	0.38	0.36	0.02

Co-ord	34	44	34	44	0.03	0.04	-0.01
XoverX Unary	24	25	24	25	0.02	0.03	0.01
Other	969	729	1779	1435	1.78	1.44	0.34
Sum	4545	3585	8845	7436			

Table 3: Statistics on errors produced by RNNGs-G on two different versions of the development set, *Pred.* and *Gold*. "Gain" represents gain (positive number) and loss (negative number) of errors per sentence when replacing automatically predicted POS tags with gold POS tags (i.e., Errors per sentence (Pred.) - Errors per sentence (Gold)).

Confusing tags	Occurrences	Bracketing errors	F1	Δ F1
Nn/Vv	106	7694	76.26	-1.94
Vv/Nn	87	7764	76.15	-2.05
Aa/Vv	77	7897	75.62	-2.58
Vv/Aa	69	7749	76.07	-2.13
Gold		7436	78.20	

Table 4: The most frequently confusing POS tag pairs in Vietnamese POS tagging. Δ F1 indicates the decreases in F-scores when gold POS tags were replaced with predicted POS tags. Meanings of POS tags are: *Nn*: common nouns, *Vv*: common verbs, and *Aa*: adjectives. For each confusing POS pair *x/y*, *x* is the gold POS, and *y* is the predicted one.

not all gold tags are helpful for solving the parsing errors, which means that the current 33 POS tags of the Vietnamese Treebank are not good enough for disambiguating constructions. We therefore should improve the tag set (e.g., splitting tags) or find more features to address the parsing errors, especially VP and NP attachments—the two most frequent error types.

6 Ambiguous constructions in Vietnamese

This section aims to investigate parsing errors caused by ambiguous constructions in Vietnamese. Our investigation was carried out on the *Gold* data set parsed by the RNNGs-G model trained on 8,337 sentences. By doing that, we could eliminate the impacts of limited training data, word segmentation errors, and confusing POS tags from the parsing output.

We randomly selected 100 sentences from the parsing output for this investigation. We then classified

Error type	Nn/Vv	Vv/Nn	Aa/Vv	Vv/Aa
Single Word Phrase	80	70	66	68
Unary	16	22	52	38
VP Attachment	-26	44	-45	17
NP Attachment	-65	-45	37	-43
PP Attachment	27	51	83	48
Clause Attachment	75	26	103	70
NP Internal Structure	69	21	50	30
Modifier Attachment	11	25	-11	-14
Different label	42	44	32	22
Co-ordination	-21	-14	-14	-21
XoverX Unary	-1	-1	-2	-1
Other	51	85	110	99

Table 5: Gains and Losses in bracket errors when gold POS tags were replaced with predicted ones.

Ambiguous construction	Error type	Frequency
Nx|Vv|Aa|Cs Vv|Aa|Nx VP	VP attachment	19/34
Vv|Nx Vv|Aa|Nx NP	NP attachment	25/39
Nx|Vv Nx|Vv PP	PP attachment	17/29
NP VP NP VP	Clause attachment	10/26
NP|VP NP|VP VP	Clause attachment	6/26
Cs NP VP	Clause attachment	4/26

Table 6: Several frequent ambiguous constructions in Vietnamese parsing.

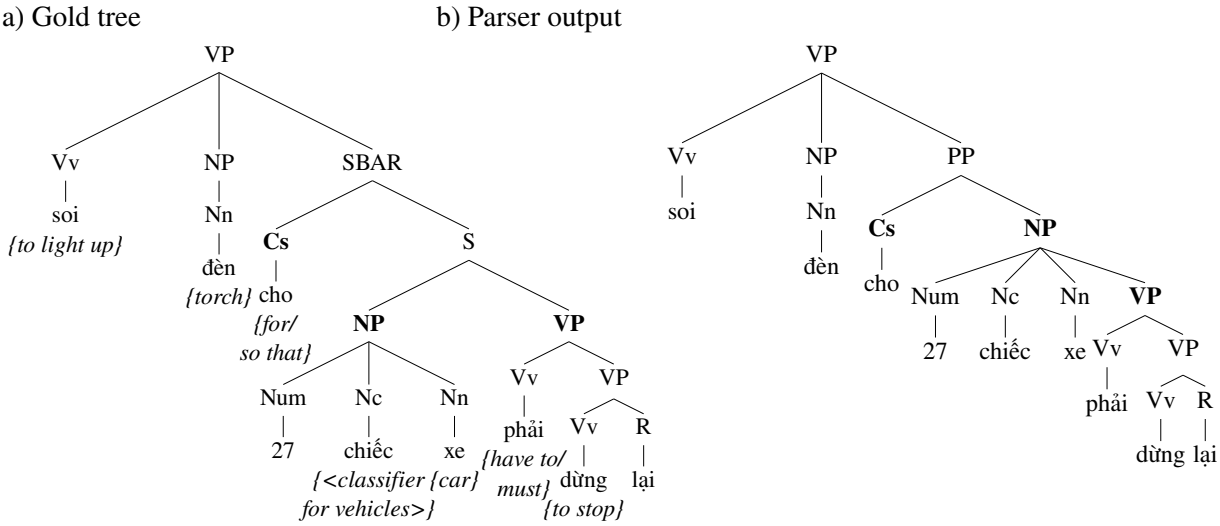

Figure 3: Examples illustrating an VP attachment error that is caused by ambiguous construction *Cs NP VP* in Vietnamese.

parsing errors into error types by applying the automatic analysis tool (Kummerfeld et al., 2012) to the selected sentences. Next, we manually investigated the reasons for each error type. Since individual error types were probably caused by particular constructions, finding reasons for parsing errors according to their error types would provide precise orientations for solving the errors.

Table 6[9] presents several frequent ambiguous constructions[10] in Vietnamese parsing that were found in this manual investigation. The column "Ambiguous construction" in this table presents frequent ambiguous tag sequences in Vietnamese. Error types caused by ambiguous tag sequences are indicated in the column "Error type". For example, tag sequences in the first row, such as *Cs Nx VP*, are candidates for VP attachment errors. For each pair of *x/y* in the column "Frequency", *x* represents the number of times that each ambiguous tag sequence caused errors in 100 investigated sentences; while *y* denotes the frequency of each error type in 100 investigated sentences. For instance, 19/34 in the first row means that we found 34 VP attachment errors in 100 investigated sentences, in which 19 errors were caused by the ambiguous constructions listed in the first column.

These ambiguous constructions are caused by the characteristics of the Vietnamese language, such as lack of inflectional morphemes, polysemous words, word order in which modifying lexical words follow the head word, and word omission.

Figure 3[11] illustrates an ambiguity attributed by most of the above-mentioned linguistic features. In

[9] *Nx* in Table 6 represents a noun that can be *Nn* (a common noun), *Nc* (a classifier noun), or *Ncs* (a special classifier noun). Each component of the tag sequence can be generalized as a phrase, e.g., instead of *Nn*, a noun phrase with head word *Nn* can be placed in the position of *Nn*.

[10] Refer to Appendix D for more details about the ambiguous constructions in Vietnamese parsing.

[11] Underscore "_" is used to link syllables of Vietnamese multi-syllabic words. English translations of Vietnamese words are provided as subscripts. If a Vietnamese word does not have a translatable meaning, the subscript is blank. The translation for the Vietnamese sentence is provided in braces below the original text.

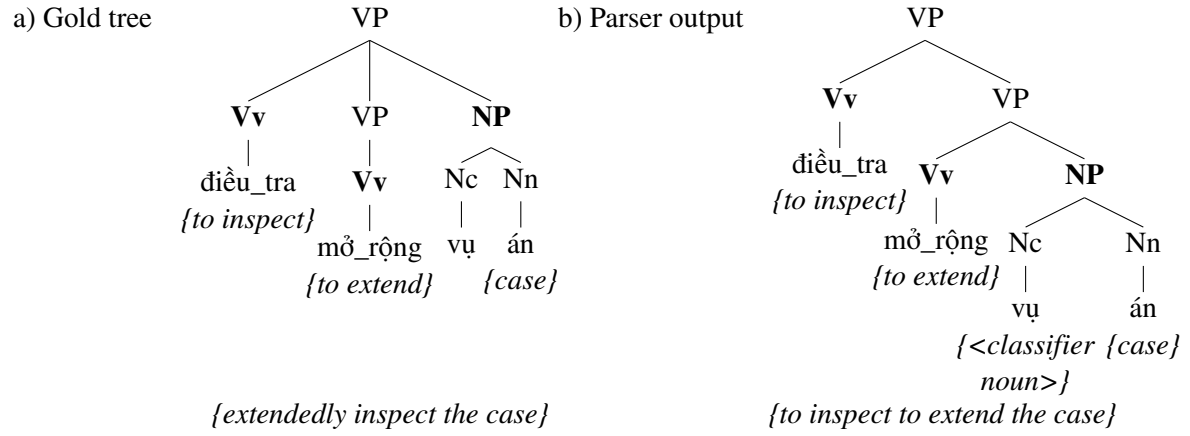

Figure 4: Examples illustrating an NP attachment error that is caused by ambiguous construction *Vv Vv NP* in Vietnamese.

the figure, the bold *NP VP* should be considered as a simple sentence (gold tree—Figure 3a) where *VP* is a predicate, but the parser labelled the whole construction as a noun phrase (*NP*) in which *VP* is an attachment (parser output—Figure 3b). A reason for that is the lack of inflectional morphemes in Vietnamese, in which a verb can (1) modify a noun, a verb, or an adjective, or (2) be the main verb of a sentence, without changing the word form. In addition, modifying verbs, adjectives, etc. follow the head words in Vietnamese noun phrases, which makes the word order in noun phrases identical to that in simple sentences. Polysemous words are also a possible reason for such parsing errors. In the figure, the word *"cho"* has two different interpretations. It means *"so that"* in the case it precedes a clause as shown in the gold tree. When it precedes a noun phrase, it means *"for"* as shown in the parser output. It is difficult for RNNGs-G to parse this case because both constructions *"cho S"* and *"cho NP"* occur in the Vietnamese Treebank.

Figure 4 presents the ambiguous construction of *Vv Vv NP* (row 2 in Table 6), a candidate for the NP attachment error in Vietnamese parsing. The *NP* in this construction can be annotated as the modifier of the first verb (gold tree) or the modifier of the second verb (parser output). This ambiguity is also caused by the common word order in Vietnamese, where modifying lexical words follow the head word. In addition, this also results from the lack of inflectional morphemes. We can see from the figure that this is not an ambiguous construction in English (or Chinese) parsing because cases like *"mở_rộng$_{\textit{to extend}}$"* are expressed by adverbs that appear before the head verb and cannot be combined with a noun. However, Vietnamese does not have adverbs; verbs and adjectives are used in such contexts. It is confusing to bracket these constructions because a noun phrase can be the modifier of both previous words.

Statistics on the top four frequent error types, i.e., VP, NP, PP, and clause attachments, revealed that about 63% of attachment errors were caused by ambiguous constructions in Vietnamese. Although RNNGs-G considered the full input sentence in its model, the contextual information was only found based on the coarse non-terminal symbols and surface forms of the words, which were not enough to address ambiguous constructions.

We found in Section 2 that non-neural Berkeley and Epic parsers perform competitively to RNNGs-G. This might suggest that these two parsers have their own advantages, and a possible direction for the future development of Vietnamese parsers is to integrate the idea of these parsers with the modern strong neural parsers. For example, although RNNGs represent each constituent in a continuous space, explicit, symbolic distinction among categories as done in the Berkeley and Epic parsers would still be useful for Vietnamese parsing. In the Vietnamese treebank, subordinate conjunctions that introduce a clause and a noun phrase are both annotated with the same POS tag of *Cs*. This caused ambiguous constructions in which a relative clause and a prepositional phrase have the same tag sequence of *Cs NP VP*. Symbol splitting might help for resolving this ambiguity. For example, we can refine the POS tag for *"cho"* mentioned in Figure 3 as *Cs-SBAR* and *Cs-PP*, depending on whether it precedes a sentence or a noun

phrase, with manual refinements as in Stanford and Epic parsers, or automatic refinements as in the Berkeley parser. We therefore expect that one possible approach for future research is a hybrid approach that combines the advantages of different parsers.

7 Conclusion

We have evaluated representative parsing models on the Vietnamese Treebank and found that parsing models based on CRF and neural networks are good for Vietnamese. Contextual information is very beneficial for improving the parsing performance. We have also investigated the errors produced by the parsers. This investigation has revealed the frequent errors in Vietnamese parsing: VP attachment, NP attachment, PP attachment, and clause attachment. Although POS tagging errors have significantly contributed to many parsing errors such as PP attachment and clause attachment errors, they are not an essential reason for the top two error types, VP attachment and NP attachment.

In addition, our investigation on parsing errors has found that ambiguous constructions are the major contributor to the errors in Vietnamese parsing, which are resulted from the characteristics of the Vietnamese language. Our goal in future work is to develop a parser that can overcome the challenges found by the analysis in this paper, and one possible direction is a hybrid approach that combines the advantages of different parsing models investigated in the paper.

Appendix A The POS tags designed for the Vietnamese Treebank

No.	POS tag	Meaning of tag	No.	POS tag	Meaning of tag
1	SV	Sino-Vietnamese syllable	17	NA	Noun-adjective
			18	Vcp	Comparative verb
2	Nc	Classifier noun	19	Vv	Other verb
3	Ncs	Special classifier noun	20	An	Ordinal number
4	Nu	Unit noun	21	Aa	Other adjective
5	Nun	Special unit noun	22	Pd	Demonstrative pronoun
6	Nw	Quantifier indicating the whole	23	Pp	Other pronoun
			24	R	Adjunct
7	Num	Number	25	Cs	Preposition or conjunction introducing a clause
8	Nq	Other quantifier			
9	Nr	Proper noun	26	Cp	Other conjunction
10	Nt	Noun of time	27	ON	Onomatopoeia
11	Nn	Other noun	28	ID	Idioms
12	Ve	Exitting verb	29	E	Exclamation word
13	Vc	Copula "là" verb	30	M	Modifier word
14	D	Directional verb	31	FW	Foreign word
15	VA	Verb-adjective	32	X	Unidentified word
16	VN	Verb-noun	33	PU	Punctuation

Appendix B The constituency tags designed for the Vietnamese Treebank

No.	Tag	Explanation
1	NP	Noun phrase
2	QP	Quantitative phrase
3	VP	Verb phrase
4	ADJP	Adjective phrase
5	PP	Prepositional phrase
6	RP	Adjunct phrase
7	CONJP	Conjunction phrase
8	UCP	Unlike coordinated phrase
9	QNP	Questioning noun phrase
10	QRP	Questioning adjunct phrase
11	QPP	Questioning prepositional phrase
12	QADJP	Questioning adjective phrase
13	MDP	Modal phrase
14	S	Simple/compound declarative sentence
15	SQ	Question
16	SPL	Special sentence
17	SBAR	Subordinate clause
18	XP	Unknown phrase

Appendix C Examples illustrating Vietnamese characteristics

Figure 5 represents an example illustrating two characteristics of Vietnamese, viz., lack of inflectional morphemes and the word orders. We can see from English translations in this figure that the noun *establishment* (Figure 5a) and the past tense verb *established* (Figure 5b) can be distinguished on the basis of inflectional morphemes *"-ment"* and *"-ed"*. However, Vietnamese does not have such clues because Vietnamese is a non-inflected language. This leads to the situation that the verbs $thiết\_lập_{to\ establish}$ have the same surface forms in both syntactic roles, i.e., the modifier of the noun $thủ\_tục_{procedure}$

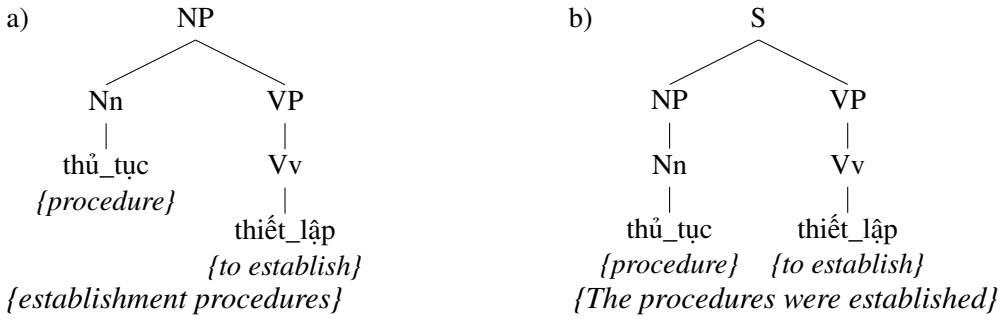

Figure 5: Examples illustrating Vietnamese characteristics.

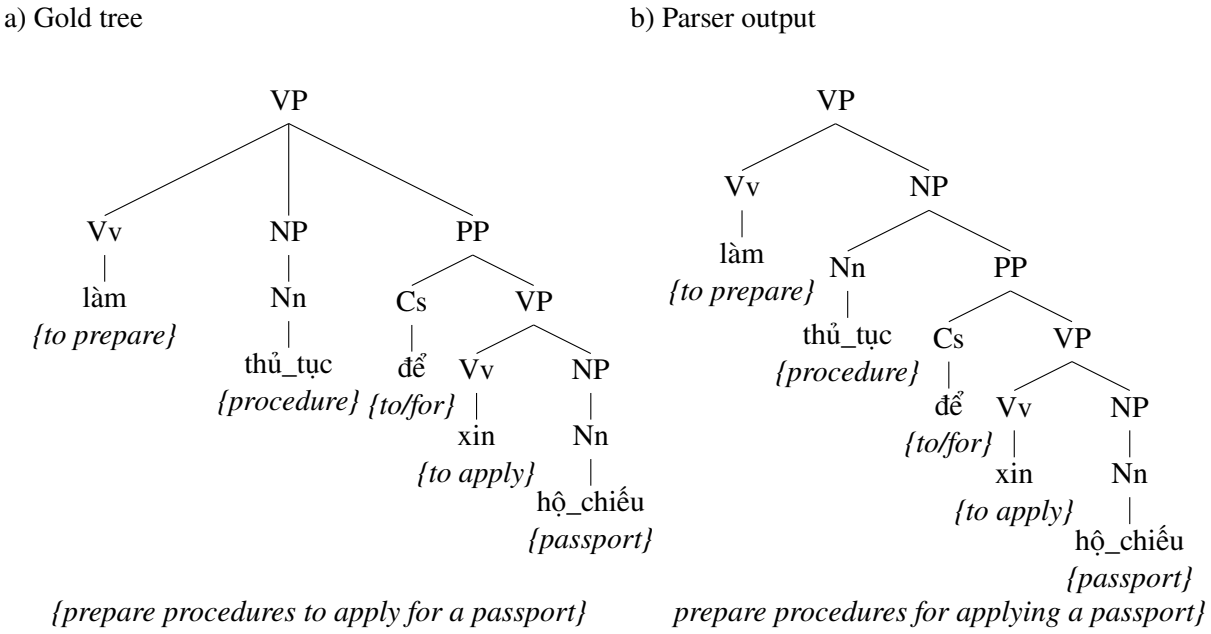

Figure 6: Examples illustrating the PP attachment error in Vietnamese parsing.

(Figure 5a) and the predicate of the simple sentence (Figure 5b). In addition, the modifying verb follows the head noun in a Vietnamese noun phrase (as shown in Figure 5a). This word order is the same as that in a simple sentence (Figure 5b). Parsing noun phrases and simple sentences is ambiguous because they have the same construction of *Nn Vv*.

Appendix D Examples illustrating several error types in Vietnamese parsing

As mentioned in the main content of the paper, we applied the error detection tool proposed by Kummerfeld et al. (2012) to Vietnamese. Therefore, our error types are the same as those in Kummerfeld et al. (2012). Follows are more details about the top four frequent error types in Vietnamese parsing.

D.1 VP attachment error

Constructions in which *VPs* are moved, viz., the incorrect bracket over an *VP* or incorrect attachment in noun phrases, verb phrases, adjective phrases, and prepositional phrases (an example was given in Section 6).

D.2 NP attachment error

Constructions in which *NPs* are moved (an example was given in Section 6).

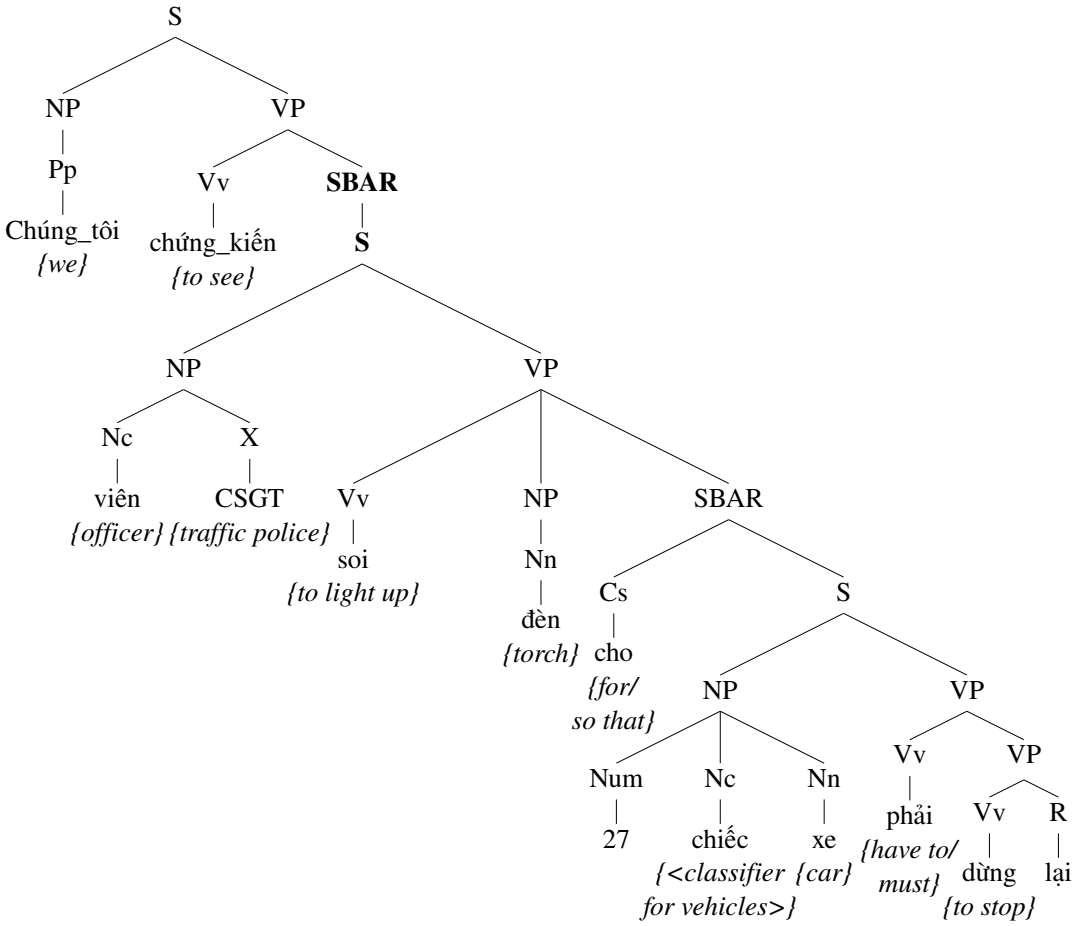
D.3 PP attachment error

Constructions in which *PPs* are moved. For example, Figure 6 represents an PP attachment error caused by the ambiguous construction *Vv Nn PP*. The *PP* in this example should be annotated as a modifier of the previous verb $làm_{to\ prepare}$ (gold tree), rather than attached to the previous noun $thủ\_tục_{procedure}$ (parser output).

D.4 Clause attachment error

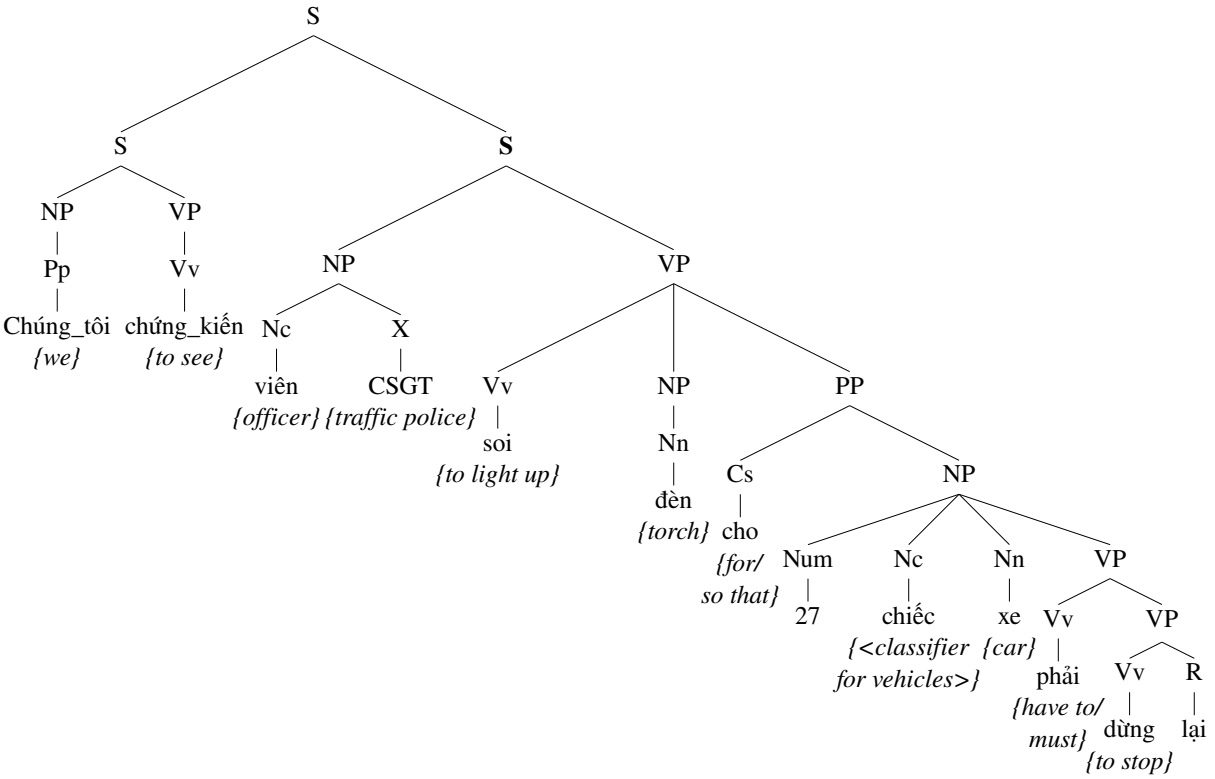
Constructions in which *Ss* or *SBARs* are moved. Figure 7 represents an example of clause attachment error caused by the ambiguous construction of *NP VP NP VP*. We can see that the later *NP VP* should be considered as an *SBAR* modifying the previous verb $chứng\_kiến_{to\ see}$ (gold tree). However, it was attached as the second clause of a compound sentence (parser output).

a) Gold tree



{We saw that the traffic police officer lighted up the torch so that 27 cars have to stop}

b) Parser output



{We saw the traffic police officer lighted up the torch for 27 cars to stop}

Learning with Noise-Contrastive Estimation: Easing training by learning to scale.

Matthieu Labeau and **Alexandre Allauzen**
LIMSI, CNRS, Univ. Paris-Sud, Université Paris-Saclay, 91405 Orsay, France
{matthieu.labeau,alexandre.allauzen}@limsi.fr

Abstract

Noise-Contrastive Estimation (NCE) is a learning criterion that is regularly used to train neural language models in place of Maximum Likelihood Estimation, since it avoids the computational bottleneck caused by the output softmax. In this paper, we analyse and explain some of the weaknesses of this objective function, linked to the mechanism of *self-normalization*, by closely monitoring comparative experiments. We then explore several remedies and modifications to propose tractable and efficient NCE training strategies. In particular, we propose to make the scaling factor a trainable parameter of the model, and to use the noise distribution to initialize the output bias. These solutions, yet simple, yield stable and competitive performances in either small and large scale language modelling tasks.

1 Introduction

In many tasks, such as machine translation and speech recognition, statistical language models[1] play a key role. Neural models (Bengio et al., 2003; Mikolov et al., 2010; Józefowicz et al., 2016) have recently shown great improvement. However most of them share a common issue: a large output vocabulary implies a prohibitive computation time, due to the output normalization, along with a prediction challenge in a such high dimensional space. A workaround is to reduce the vocabulary size by considering sub-word units like morphemes or even characters. For several applications, this is an efficient solution, though the main issue is not directly addressed. Other trends consist in changing the output structure by using *shortlists* (Schwenk, 2007) or *hierarchical softmax* (Morin and Bengio, 2005; Mnih and Hinton, 2009; Le et al., 2011), while *self-normalisation* techniques (Devlin et al., 2014; Andreas et al., 2015; Chen et al., 2016) partially solve the issue at test time. Finally, sampling-based techniques like *Importance sampling* (Bengio and Sénécal, 2003; Jean et al., 2015), and *Noise-Contrastive Estimation* or NCE (Mnih and Teh, 2012) are also promising alternatives.

In this work, we focus on NCE, which uses a discriminative objective that approximates negative log-likelihood. Its main advantage is to consider the model as *un-normalized* instead of trying to approximate its normalization. With this objective function the model is explicitly learnt to estimate *un-normalized* probability distributions, while the partition function (or the scaling factor) is parametrized separately. While this method is very appealling in theory, empirical issues arise in large vocabulary applications: training divergence and instability, along with poor performance when compared to similar approaches, notably Importance Sampling. The contributions of this paper are twofold: first an empirical exploration of the NCE allows us to better explain the estimation process and why it sometimes fails; then we propose and explore several remedies yielding to tractable and efficient NCE training strategies.

While section 2 reviews two widely used training criteria for un-normalized model, Importance Sampling and NCE, section 3 provides an empirical analysis of the NCE. This algorithm is theoretically proven to converge when the partition function is parametrized separately. However, the scaling parameter

[1]Neural Machine Translation and Speech Recognition can be seen as a language model where the sequence probability is conditioned on a source sentence or a speech signal.

Proceedings of the 27th International Conference on Computational Linguistics, pages 3090–3101
Santa Fe, New Mexico, USA, August 20-26, 2018.

is usually fixed and the *un-normalized* model therefore *self-normalizes*, as a side effect of the training procedure. We show experimentally that the training instability is tied to the difficulty of the model to self-normalize. After analysing the consequences of these issues, we experiment (section 4) with various solutions, including smoothing the sampling distribution or using the recent application of *Negative sampling* to language modelling (Melamud et al., 2017). Moreover, we propose to jointly learn the scaling parameter with the model and show that this approach yields a practical and efficient training strategy. We also propose to initialize the output bias to the logarithm of the noise distribution, which diminishes greatly the impact of the issues described in section 3.

2 Training objectives and partition function

For neural language models (NLMs), the main computational burden lies in the summations over the (very large) vocabulary $\mathcal{V}$. Indeed, a NLM parametrized by θ, outputs, for an input context H, a conditional distribution P_θ^H for the next word, over $\mathcal{V}$. This conditional distribution is defined using the *softmax* activation function:

$$P_\theta(w|H) = \frac{e^{s_\theta(w,H)}}{\sum\limits_{w' \in \mathcal{V}} e^{s_\theta(w',H)}} = \frac{e^{s_\theta(w,H)}}{Z_\theta(H)} \tag{1}$$

Here, $s_\theta(w, H)$ is a scoring function which depends on the network architecture. The denominator is the *partition function* $Z_\theta(H)$, which is used to ensure that for each input context H, output scores are normalized into a probability distribution. Then, each model can be written as an *un-normalized* model divided by the partition function. The natural objective is to minimize the negative log-likelihood of this conditional distribution for each tuple of input context and following word $(H, w) \in \mathcal{D}$, where $\mathcal{D}$ is the training set:

$$NLL(\theta) = -\sum_{(H,w)\in\mathcal{D}} \log P_\theta(w|H) \tag{2}$$

Using the Stochastic Gradient Descent (SGD) to train this objective implies taking the objectives gradient to make the parameter updates. For one training example (H, w), the gradient of the log-probability will be computed as follows:

$$\frac{\partial}{\partial\theta} \log P_\theta(w|H) = \frac{\partial}{\partial\theta} s_\theta(w, H) - \sum_{w' \in \mathcal{V}} P_\theta(w'|H) \frac{\partial}{\partial\theta} s_\theta(w', H). \tag{3}$$

The first term tends to increase the conditional log-likelihood of the word w, whereas the second term lowers probabilities for all the other words in the vocabulary. Unfortunately, the partition function $Z_\theta(H)$ is necessary to compute both $P_\theta(w'|H)$ at test time, and the parameter gradients are necessary to update the model during the training process. In (Gutmann and Hyvärinen, 2013), the authors detail why knowing the partition function, which represents the *'scale'* of the model, is essential to compute the likelihood[2]. Parametrizing separately the partition function (as a scaling parameter) would give irrelevant results, since we could minimize the negative log-likelihood independently of the data. Following this reasoning, we focus on objectives that allow for the estimation of un-normalized models. In the language modelling literature, methods based on Importance Sampling (IS) and NCE are the most widely used.

2.1 IS: approximating the partition function

As detailed in (Bengio and Sénécal, 2003), the idea is to rewrite the gradient described in equation 3 as an expectation that we estimate using importance sampling. We choose a distribution P_n from which it is easy to sample, and obtain the following gradient approximation:

[2]Beyond the fact that the concept of likelihood only applies to probability density functions, which are normalized.

$$\frac{\partial}{\partial\theta}\log P_\theta(w|H) \approx \frac{\partial}{\partial\theta}s_\theta(w,H) - \frac{1}{k}\frac{1}{Z_\theta(H)}\sum_{\substack{i=1\\ \hat{w}_i\sim P_n}}^{k}\frac{e^{s_\theta(\hat{w}_i,H)}}{P_n(\hat{w}_i)}\frac{\partial}{\partial\theta}s_\theta(\hat{w}_i,H) \tag{4}$$

While we replaced one summation over $\mathcal{V}$, the partition function remains. Rewriting it as an expectation, we can apply importance sampling a second time, using the same distribution P_n:

$$Z_\theta(H) = \mathbb{E}[e^{s_\theta(w,H)}] \approx \frac{1}{k}\sum_{\substack{i=1\\ \hat{w}_i\sim P_n}}^{k}\frac{e^{s_\theta(\hat{w}_i,H)}}{P_n(\hat{w}_i)} \tag{5}$$

And thus, by approximating the partition function, we obtain a biased estimator for the maximum likelihood gradient. Both its bias and variance can be reduced by increasing the sample size k. In order to limit this growth, (Bengio and Sénécal, 2008) investigates on adapting P_n during training.

2.2 NCE: avoiding normalization

NCE was first described in (Gutmann and Hyvärinen, 2010), as a way of estimating a parametric probabilistic model from data in the case where the probability function of the model is un-normalized. Considering the partition function as a separate parameter, the objective function mimics maximum-likelihood estimation by learning to discriminate between true examples from data or generated from a *noise distribution*. This method has been applied to language modelling in (Mnih and Teh, 2012): considering a mixture of the data and noise distributions, for each example $(H, w) \in \mathcal{D}$, we draw k noise samples from a noise distribution P_n. The posterior probability of the class C associated to the sample can be estimated ($C = 1$ if the sample comes for the data and $C = 0$ from the noise). Since the goal is to approximate the data distribution with a model parametrized by θ, the conditional class distribution is defined as $P(w|C = 1, H) = P_\theta(w|H)$ and $P(w|C = 0, H) = P_n(w)$, which gives the posterior class probabilities:

$$P(C=1|w,H) = \frac{P_\theta(w|H)}{P_\theta(w|H)+kP_n(w)} \quad \text{and} \quad P(C=0|w,H) = \frac{kP_n(w)}{P_\theta(w|H)+kP_n(w)} \tag{6}$$

If σ denotes the sigmoid function, these equations can be rewritten as a logistic regression problem:

$$P(C=1|w,H) = \sigma\left(\log\frac{1}{k}\frac{P_\theta(w|H)}{P_n(w)}\right) \tag{7}$$

The reformulation obtained in equation 7 shows that training a classifier based on a logistic regression will estimate the log-ratio of two distributions: this allows the learned distribution to be un-normalized, and the partition function to be parametrized separately[3]. However, the partition function is context-dependent. In (Mnih and Teh, 2012), the authors argue that these context-dependent scaling parameters can be put to one, and that given the number of free parameters, the output scores $e^{s_\theta(w,H)}$ will self-normalize for each context. In what follows, we adopt this trick and for clarity denote $p_\theta(w|H) = e^{s_\theta(w,H)}$ the un-normalized model score. Since the class labels are by assumption Bernoulli distributed and independent, the classification objective is given by maximizing the log-likelihood of the true examples to belong to class $C = 1$ and the noise samples $(\hat{w}_i)_{1\leq i\leq k}$ to $C = 0$, which is, for one example (H, w) from $\mathcal{D}$:

$$J_\theta^H(w) = \log\frac{p_\theta(w|H)}{p_\theta(w|H)+kP_n(w)} + \sum_{i=1}^{k}\log\frac{kP_n(\hat{w}_i)}{p_\theta(\hat{w}_i|H)+kP_n(\hat{w}_i)} \tag{8}$$

The gradient update is the following:

[3] (Pihlaja et al., 2012) and (Gutmann and Hirayama, 2011) show the NCE to be a particular case of larger classes of objective functions, with which the model learns to match a ratio of data and noise samples instead of directly matching the data samples, which allows un-normalized model estimation

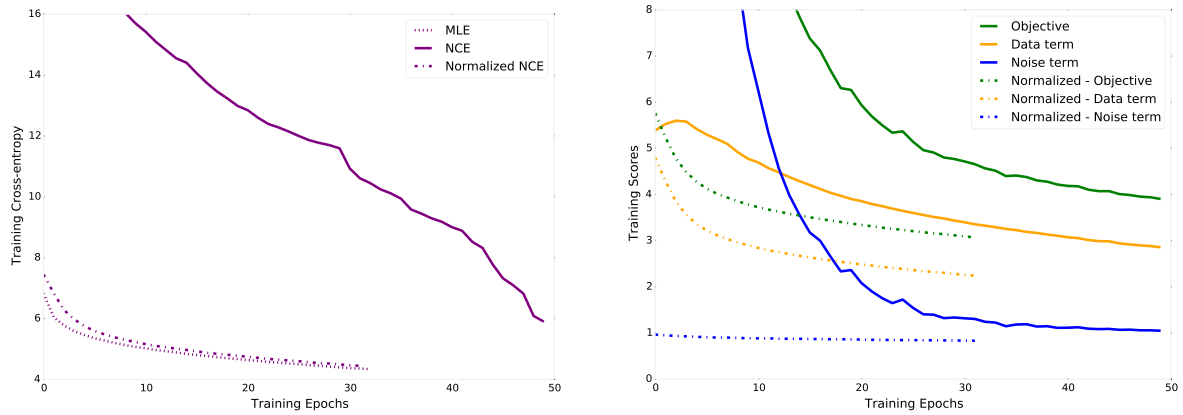

Figure 1: *Left*: Training cross-entropy curves on PTB with Maximum-Likelihood estimation, NCE on an un-normalized model and a model normalized before application of the NCE. *Right*: Training scores (see equation 10) of the same un-normalized and normalized models trained with NCE

$$\frac{\partial}{\partial\theta}J_\theta^H(w) = \frac{kP_n(w)}{p_\theta(w|H) + kP_n(w)}\frac{\partial}{\partial\theta}\log p_\theta(w|H) - \sum_{i=1}^{k}\left[\frac{p_\theta(\hat{w}_i|H)}{p_\theta(\hat{w}_i|H) + kP_n(\hat{w}_i)}\frac{\partial}{\partial\theta}\log p_\theta(\hat{w}_i|H)\right] \tag{9}$$

It is worth noting that this gradient converges to the Maximum-Likelihood Estimation (MLE) gradient as the number of samples k grows. Concerning the choice of the noise distribution, the estimation error of parameters θ is asymptotically independent of P_n when the ratio of noise samples by example k coming from the data is large enough. It is also shown that having both a noise distribution close to the data distribution and a high number of samples k lower the estimation error. (Mnih and Teh, 2012) compared using the uniform and unigram distribution in their experiments, finding the unigram distribution to give far more accurate results. In the literature, NCE was then mainly used in the context of machine translation: (Vaswani et al., 2013; Baltescu and Blunsom, 2015) report results with the unigram distribution, while (Zoph et al., 2016) used an uniform noise. However, despite strong theoretical guarantees, (Chen et al., 2016) highlighted the inconsistency of NCE training when dealing with very large vocabularies, showing very different perplexity results for close loss values. In another work (Józefowicz et al., 2016), NCE was shown far less data-efficient than IS.

3 Training behaviour of NCE

To understand these instabilities, the training process of the same language model is monitored, varying only the training criterion, *i.e* MLE and NCE. For a better understanding, we also consider an '*intermediate*' model denoted as *NCE normalized*. This model is trained using NCE; however, we normalize the scores $p_\theta(w|H) = e^{s_\theta(w,H)}$ into $P_\theta(w|H)$ right before computing the objective. While it is without any practical interest, this model will allow us to better assess the impact of the normalization process. We train the 3 models on the Penn Tree Bank (PTB) with a full vocabulary and $k = 100$ noise samples drawn from the unigram distribution for NCE. We use classic SGD[4]. To reduce the impact of the training criterion, models are learnt for a minimum of 30 epochs. Beyond that limit, we backtrack the epoch when no progress has been made on the validation set perplexity, stopping training after 10 consecutive backtrackings[5].

3.1 The objective and partition functions

The training cross-entropy for the 3 models are drawn in the top graph of figure 1. When trained with MLE or NCE, the normalized model exhibits similar learning curves. However, the un-normalized model

[4]Hyperparameters are the same than those used in (Melamud et al., 2017), except the vocabulary, i.e $\approx 44K$ words, instead of $10K$, to consider a more realistic learning situation for NCE.

[5]For the sake of clarity, backtrakings are discarded from the graphs, keeping only the epochs used to obtain the final model.

trained with NCE takes far longer to reach a comparable cross-entropy, ending with a higher value. In the bottom graph we can observe, for the normalized and un-normalized models trained with NCE, the values of minus the objective function[6], and both of its terms (the first, data-dependent, and the second, containing the noise samples):

$$-J_\theta = \sum_{H,w\in\mathcal{D}} -\log \frac{p_\theta(w|H)}{p_\theta(w|H)+kP_n(w)} - \sum_{H,w\in\mathcal{D}}\sum_{i=1}^{k} \log \frac{kP_n(\hat{w}_i)}{p_\theta(\hat{w}_i|H)+kP_n(\hat{w}_i)} \tag{10}$$

We can observe a small decrease of the second term for the normalized model, whereas for the un-normalized, it starts with high values and decreases to become closer to the normalized one. Moreover, the gap between the two data-dependent terms stays high at the end of training. For a deeper analysis, we study the values of the partition function during training. For both the normalized and the un-normalized models, the partition function $Z_\theta(H)$ associated to each training context H is computed and the results over an epoch are summarized with an histogram. Each bin represents a range of values, and its height represent the fraction of training contexts whose partition function belongs to this range. For a better readability, both range values and bin heights are in log-scale. These histograms are shown in figure 2 for different epochs. While the repartition of the partition function values for the normalized model does not change much - which is logical, since the model is always integrated to 1 - we observe that these values for the un-normalized model are chunked together and are decreasing during learning (epochs 5, 10 and 15). However, this trend seems to slow down towards the end of training, since, at epoch 30, the repartition resemble to the one of the normalized model, only shifted to smaller values (which are still quite high).

3.2 Self-normalisation is crucial for NCE

Considering these results, we dissect what happens during the training of the un-normalized model. Let us rewrite the objective J_θ as function of the following ratio:

$$r_\theta(w|H) = \frac{p_\theta(w|H)}{kP_n(w)}, \text{ then } -J_\theta = \sum_{H,w\in\mathcal{D}} -\log \frac{r_\theta(w|H)}{r_\theta(w|H)+1} - \sum_{H,w\in\mathcal{D}}\sum_{i=1}^{k} \log \frac{1}{r_\theta(\hat{w}_i|H)+1} \tag{11}$$

[6]Since the objective J_θ^H is negative, we minimize $-J_\theta^H$.

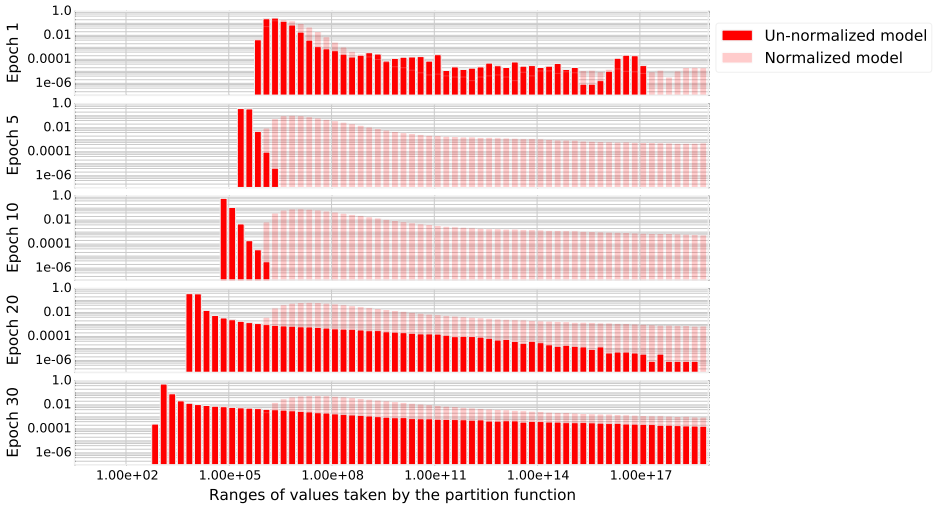

Figure 2: Repartition of the values of the partition function $Z_\theta(H)$ for all examples (H, w) during specific epochs of training on PTB with NCE. The fully coloured bars represent the repartition for the un-normalized model, while the faded bars represent the repartition for the normalized model. Both scales are logarithmic.

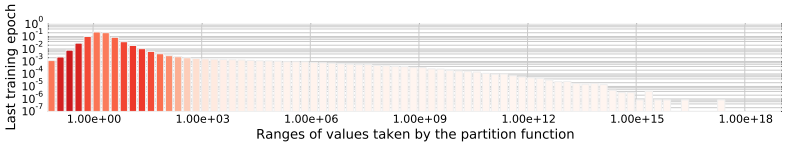

Figure 3: Repartition of the values of the partition function $Z_\theta(H)$ for all training examples (H, w), during the last epoch of training with NCE on PTB. For both this figure and figure 4, the colour of a bin indicates the proportion of training examples (H, w) for which the word w is one of the 10 most frequent according to the noise distribution P_n: the lighter the colour is, the higher is that proportion. Both scales are logarithmic.

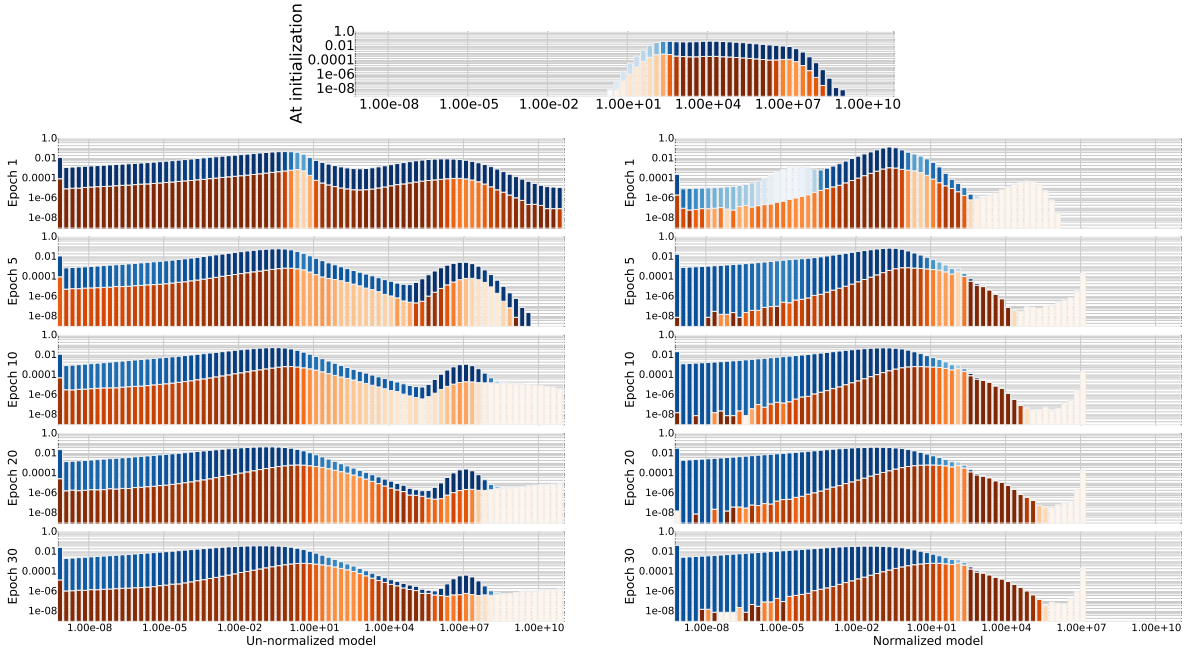

Figure 4: Repartition of the values of the ratio $r_\theta(w|H)$ for all positive training examples (H, w) in orange, and associated noise sample $(\hat{w}_i)_{i=1}^k$, in blue, at initialization (top) and during several training epochs with NCE on PTB. On the left, the model is un-normalized, while on the right it is normalized.

The second term of $-J_\theta$ is very high for large values of r_θ. Since values of P_n are always smaller than 1 and $k = 100$, and knowing the partition function at the beginning of training is large for all contexts, we can assume that $r_\theta(\hat{w}_i|H)$ will be large for a least part of the set of noise samples $(\hat{w}_i)_{i=1}^k$. Thus, this second term is the largest part of the objective, whose minimization leads to a decrease of the model scale. However, this is done at the expense of the data-dependent term, since its score increases a little during the first few epochs. If we look at its gradient, we see from equation 9 that it is always scaled by the weight $1/(r_\theta(w|H) + 1)$, which means that the objective will learn nearly nothing from data as long as the model scale has not decreased to a reasonable value. This shows that this 'self-normalization' mechanism is crucial for NCE, but we still need to understand what makes a scaling value 'reasonable'.

3.3 Impact of the noise distribution P_n

While the un-normalized model underperforms its normalized counterpart, its cross-entropy is not that far off. Let us explore the repartition of the partition function values during the last epoch of training. In particular, we expect an impact of the P_n values. The histogram is shown in figure 3: each bin is coloured according to the proportion of examples associated to the highest values of P_n it contains[7]. We clearly observe that while the majority of the partition functions have values under ≈ 100, functions associated

[7]Since we use the unigram distribution, it indicates here the examples who are among the 10 most frequent words.

with the words with the higher values of P_n - which are also the most sampled words - can take values that are far larger. To understand why, consider the weight of the gradient of the data-dependent term:

$$\frac{1}{r_\theta(w|H)+1} = \frac{kP_n(w)}{p_\theta(w|H)+kP_n(w)}.$$

Having higher values of P_n means that the model does not need to scale back the partition function as much to be able to learn from data. Besides, if the noise distribution is correlated with the data distribution, an example with a high value of P_n tends to be more frequent. Therefore the model will be able to learn first from words w with the higher values of $P_n(w)$. However, the lower $P_n(w)$ is, the more difficult it will be for the model to learn about w. And the associated partition function will have to be closer to 1 for the data-term gradient to be meaningful. To visualize how learning is affected, we study histograms showing the repartition of the values of r_θ during a training epoch. They are presented in figure 4. Again, we show histograms for both models, at epochs 1, 5, 10, 20, and 30, while on top is a histogram of the initial repartition (before learning). Similarly, they are in log-scale. On the right are histograms for the normalized model. For epoch 1, there is a peak of data examples with higher values of P_n - frequent words - that have higher values of r_θ, while for noise samples, the repartition still follows the initial one - samples with higher P_n have a smaller r_θ. As learning progresses, a clear trend appears: values of r_θ for data examples, seemingly ordered by values of P_n, become well-separated of the values of r_θ for noise samples. On the left are the repartition of values for the un-normalized model. While they are ordered by values of P_n, a clear separation between data examples values and noise samples values takes far more time to appear, and a cluster of high values of r_θ for noise samples still remains visible at epoch 30 - these high values correspond to small values of P_n: in our case, rare words.

These observations show us that an higher discrepancy between high and low P_n leads to a more difficult learning procedure with NCE. As a consequence, and because of the Zipfian distribution of word frequencies, using the unigram distribution will be harder as the size of the vocabulary grows.

4 Practical solutions and learning to scale

As discussed in section 3, two quantities strongly impact NCE training: first, the noise distribution (and the number k of noise samples); then, the partition function. To evaluate different training strategies, we provide training cross-entropy curves in figure 5. As a comparison point, results with importance sampling are also reported since it is nowadays the best choice to train large language models. To verify the validity of our analysis on the PTB, we also report results on a larger corpus, the 1 Billion Word Benchmark[8] (Chelba et al., 2014). In this case, the vocabulary contains $64K$ words, which renders normalized models not competitive[9]. We trained the models for at least one epoch, and up to a second if models made progress on the validation set perplexity. Final perplexity results are presented in table 1.

4.1 Acting on the noise distribution P_n

As the number of noise samples k increases, the estimation error reduces, along with the necessity for the model to downscale the partition function. With $k = 500$, we can observe indeed a faster convergence with a lower final perplexity. On the large corpus, the conventional NCE model doesn't even reach a perplexity under the size of the vocabulary, whereas augmenting k to 500 is not enough to reach a suitable perplexity. However, increasing k reduces the computational benefit of NCE, even with k far inferior to the vocabulary size. There is a trade-off in the choice of P_n: the closer P_n is to the data distribution, the lower is the estimation error; however the Zipfian distribution of word frequencies implies too few updates for rare words if P_n is the usual unigram distribution. Therefore P_n is often distorted into P_n^α, with a parameter $0 \leq \alpha \leq 1$. This smoothing helps reducing the range of values of P_n, and α is usually set to 0.75. With this choice, convergence is indeed faster, but the final perplexity is not that better[10]. However,

[8] We also used the same hyperparameter settings than in (Melamud et al., 2017)

[9] Besides the computation time constraints, the batch size is rapidly limited by the GPU memory, while a smaller batch size also increases the computation time.

[10] We should note that for both these experiments, convergence being faster would imply reducing the number of epochs without backtracking, which we didn't do here.

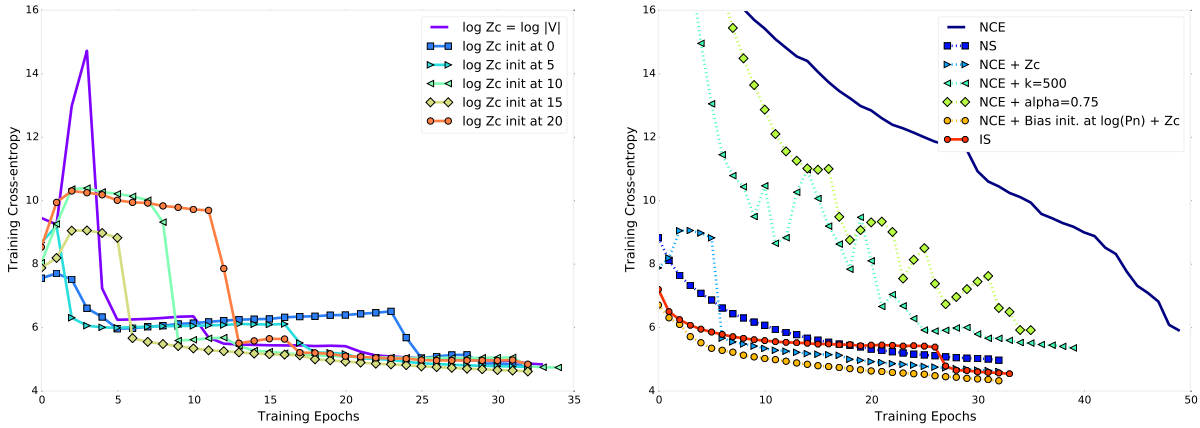

Figure 5: *Left*: Training cross-entropy curves on PTB for un-normalized models trained with NCE while fixing, then learning a parameter Z_c that shifts the partition function, depending on the initial value of Z_c, as presented in section 4.2. *Right*: Training cross-entropy curves on PTB for un-normalized models trained with Importance Sampling, NCE and alternative additions presented in section 4

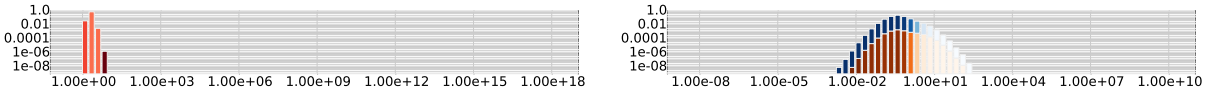

Figure 6: Repartition of the values of the partition function $Z_\theta(H)$ (*left*) and ratio $r_\theta(w|H)$ (*right*) for all training examples (H, w) at initialization, for a model whose output bias is initialized with $\log P_n$.

on the large corpus, this solution fails to stabilize training.

4.2 Shifting the partition function and learning to scale

Following a method introduced by (Chen et al., 2015), we could simply shift all values of the partition function by a fixed value Z_c. In practice, it means we set

$$p_\theta(w|H) = \frac{e^{s_\theta(w,H)}}{Z_c}.$$

Another similar workaround consists in initializing the output bias to $-\log|\mathcal{V}|$ (Vaswani et al., 2013; Melamud et al., 2017). It has the same effect as fixing $Z_c = |\mathcal{V}|$ and initializing the bias to 0. In (Chen et al., 2015) this value is set to $\log Z_c = 9$. In this paper we propose to learn the best shifting value by adding Z_c to the model parameters θ. In this case Z_c can be seen as an extra bias term that learns a normalizing constant. The left graph of figure 5 shows training cross-entropy curves depending on the initial value of Z_c, revealing its impact. On both corpora, learning to scale allows the model to achieve a better perplexity than fixing it to an arbitrary *e.g.* $|\mathcal{V}|$.

4.3 The case of Negative sampling

The *Negative Sampling* (NS) algorithm was popularized by the skip-gram embedding algorithm (Mikolov et al., 2013), and while closely linked to NCE, is not able to directly optimize the likelihood of a language model and learn conditional probabilities, as detailed in (Dyer, 2014). Recently, (Melamud et al., 2016; Melamud et al., 2017) showed Negative Sampling to be viable for language modelling. As previously, we use k samples $(\hat{w}_i)_{1\leq i\leq k}$ from the unigram distribution. The objective maximizes the likelihood of a logistic regression that discriminates true examples from noise samples. However, here, the model directly parametrizes the log-odds, since $P(C = 1|w, H) = \sigma\left(s_\theta^{NS}(w, H)\right)$, which gives the scoring function:

$$J_\theta^H(w) = \log\sigma(s_\theta^{NS}(w, H)) + \sum_{i=1}^{k} \log\sigma(-s_\theta^{NS}(\hat{w}_i, H)) \tag{12}$$

Training method	PTB	1BW Benchmark
MLE	150.2	-
Normalized NCE	159.3	-
NCE	306.0	X
NCE + $\alpha = 0.75$	277.0	X
NCE + $k = 500$	231.9	X
Importance Sampling	168.3	80.2
NS	228.3	99.0
NS + $\alpha = 0.75$	195.8	96.1
NCE + $Z_c = \|\mathcal{V}\|$	178.6	79.2
NCE + $Z_c \in \theta$	172.3	76.6
NCE + Bias init. at $\log(P_n)$	151.8	76.0
NCE + Bias init. at $\log(P_n)$ + $Z_c \in \theta$	148.4	74.7

Table 1: Best testing perplexities obtained on PTB with a full vocabulary, and on the 1 Billion Word Benchmark with a $64K$ words vocabulary. '-' indicates that the models were not trained due to technical limitations, and 'X' indicates that the model did not converge to a perplexity value under $|\mathcal{V}|$.

Therefore, this objective function corresponds to the log-ratio $\log r_\theta(w|H)$ for the NCE. Indeed, we can get back an estimation of the conditional probability using the model score and the noise distribution:

$$\hat{P}(w|H) \propto P_n(w) \exp\left(s_\theta^{NS}(w|H)\right) \tag{13}$$

The model directly learns what is, in the NCE, the ratio of the data and noise distribution, without knowing the values of P_n. The initial values of $r_\theta(w|H) = e^{s_\theta^{NS}(w,H)}$ simply depend on the model initialization, and the initial values of the partition function are close to 1. While the final perplexity values are not among the best[11], we can observe on the bottom graph of figure 5 a far smoother learning curve than that the ones for methods previously presented. More precisely, we avoid the initial increase in cross-entropy that is visible when we fix or learn Z_c (on the top graph). We believe this is due to having an initial model distribution very close to P_n, which is a consequence of multiplying final scores by P_n, as showed in equation 13. To verify this, we trained a NCE model for which we initialized the output bias with values of $\log P_n(w)$. It gave great results, especially on the smaller corpus. By looking at the repartitions of the values of the ratio and partition function at initialization, showed in figure 6, we can check that having $p_\theta(w|H) \approx P_n(w)$ mitigates the main issues described in section 3: first, our distribution is far closer to be normalized; then, the values of $r_\theta(w|H)$ are bundled together around $\frac{1}{k+1}$. This method clearly helps learning; furthermore, when used in complement to learning Z_c, it gives the best model on the PTB. It is however less impactful on the larger corpus. We believe it is due to the fact that the vocabulary is cut at $64K$ words and is thus very small for a corpus of this size: the frequency distribution does not have the Zipfian long tail of rare words, which mitigates the issue we try to solve with this initialization strategy.

4.4 Summary of training recommendations

To have a clearer idea of which solution to use depending on the size of the corpus and of the vocabulary, we experiment with the solutions presented earlier on smaller parts of the 1 Billion Word Benchmark, and with different vocabulary sizes. Testing cross-entropy curves are shown in figure 7. The top figure shows the experiments whose results we presented in table 1, with the full corpus and with $|\mathcal{V}| = 64K$. The two leftmost figures show experiments with 10 and 100 times less data, while the center and rightmost figures show experiments with smaller and larger vocabularies on the full corpus. The main noticeable result is that learning Z_c as a parameter is not working well when we have less data - in this case, initializing the output bias to $-\log|\mathcal{V}|$ is far more efficient, while initializing output bias with values of $\log P_n(w)$ gives even better results. However, this last method loses efficiency when the vocabulary becomes very

[11] Given the recommendation given in (Mikolov et al., 2013) on using $\alpha = 0.75$ with Negative Sampling, we suppose smoothing the noise distribution has an important impact, and added corresponding results, which are indeed better, to table 1.

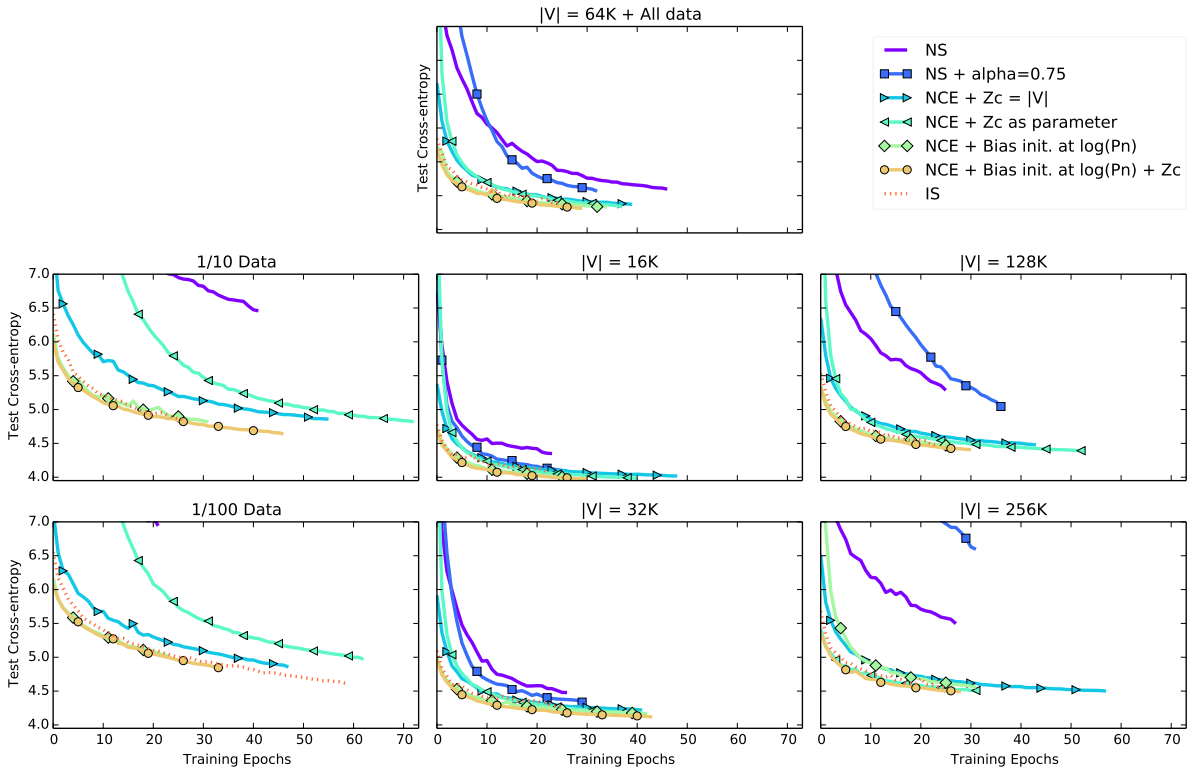

Figure 7: Testing cross-entropy curves on 1BW for un-normalized models trained with Importance Sampling, and NCE-based alternative additions presented in section 4 The seven figures show experiment with various vocabulary sizes $|\mathcal{V}|$ and quantities of Data.

large (here, for $|\mathcal{V}| = 256K$. Finally, combining this initialization scheme and the learning of Z_c as a parameter gives the best results accross all configurations.

5 Conclusion

Training neural language models with large output vocabularies is still challenging. Noise contrastive estimation is one of the most promising training criterion but was empirically shown to be unstable. In this paper, we carried out an extensive analysis of the training process of NCE. We showed how setting the scaling parameters to 1 yields an implicit self-normalization step which necessarily precedes actual learning from data examples. The difficulty of this process depends on the value range of the noise distribution P_n. Given the Zipfian distribution of word frequencies texts, learning with an unigram distribution is getting harder as the vocabulary size grows. This is quite inconsistent with the motivation of this learning criterion. However, we also explored several remedies and showed that when including the scaling parameter in the parameters of the model, the scaling process can be both stable and efficient. Additional improvements can be obtained by initializing the bias of the output layer according to the noise distribution. Combining this 'learning to scale' approach with the adapted initialization scheme yields a very competitive, yet simple, training strategy for neural language models with large vocabularies.

Abstract

In this paper, we describe an attempt towards the development of parallel corpora for English and Ethiopian Languages, such as Amharic, Tigrigna, Afan-Oromo, Wolaytta and Ge'ez. The corpora are used for conducting a bi-directional statistical machine translation experiments. The BLEU scores of the bi-directional Statistical Machine Translation (SMT) systems show a promising result. The morphological richness of the Ethiopian languages has a great impact on the performance of SMT specially when the targets are Ethiopian languages. Now we are working towards an optimal alignment for a bi-directional English-Ethiopian languages SMT.

1 Introduction

The advancement of technology and the rise of the internet as a means of communication led to an ever increasing demand for Natural Language Processing (NLP) applications. NLP applications are useful in facilitating human-machine and human-human communications. One of the NLP applications which facilitates human-human communication is Machine Translation (MT). MT refers to a process by which computer software is used to translate a text or speech from one language to another (Koehn, 2009). In the presence of high volume digital text, the ideal aim of machine translation systems is to produce the best possible translation with minimal human intervention (Hutchins, 2005).

The translation of natural language by machine becomes a reality, for technologically favored languages, in the late 20^{th} century although it is dreamt in seventieth century (Hutchins, 1995). Various approaches to MT have been and are being used in the research community, that can broadly classified as rule-based and corpus based (Koehn, 2009). The rule based machine translation demands various kinds of linguistic resources such as morphological analyzer and synthesizer, syntactic parsers, semantic analyzers and so on. On the other hand, corpus based approaches (as the name implies) require parallel and monolingual corpora. Since corpus based approaches do not require deep linguistic analysis of the source and target languages, it is the preferred approach for under-resourced languages of the world, including Ethiopian languages.

1.1 Machine Translation For Ethiopian Languages

Research in the development of MT has been conducted for technologically favored and economically as well as politically important languages of the world since the 17^{th} century. As a result, notable progress towards the development and use of MT systems has been made for these languages. However, research in the area of MT for Ethiopian languages, which are under-resourced as well as economically and technologically disadvantaged, has started very recently. Most of the

Proceedings of the 27th International Conference on Computational Linguistics, pages 3102–3111
Santa Fe, New Mexico, USA, August 20-26, 2018.

researches on MT for Ethiopian languages are conducted by graduate students (Tariku, 2004; Sisay, 2009; Eleni, 2013; Jabesa, 2013; Akubazgi, 2017), including two PhD works: one that tried to integrate Amharic into a unification based machine translation system (Sisay, 2004) and the other that investigated English-Amharic Statistical Machine Translation (Mulu, 2017). Beside these, Michael and Million (2017) attempted a bi-directional Amharic-Tigrigna SMT experiement using word and morpheme as translation units.

Due to unavailability of linguistic resources and since the most widely used MT approach is statistical, most of these researches have been conducted using SMT, which requires large bilingual and monolingual corpora. However, as there were no such corpora for SMT experiments, the researchers had to prepare small size corpora. This in turn, affects the results that they obtain.

In addition, since there is no standard corpora for conducting replicable and consistent experiment for performance evaluation, it is difficult to know the progress made in the area for local languages. Moreover, since the researchers spend their time on corpora preparation, they usually have limited time for experimentation, exploration and development of MT systems.

1.2 Motivation of this paper

African languages, which contribute around 30% (2139) of the world languages, highly suffer from lack of sufficient language resources (Simons and Fennig, 2017). This is true for Ethiopian languages as well. On the other hand, Ethiopia being multilingual and multiethnic country, its constitution decrees that each citizen has the right to speak, write and develop in his/her own language. However, a lot of written documents, brochures, text books, magazines, advertisements and other information in the web are being produced in technological favored and economically important languages such as English.

In order to enable Ethiopians to use the documents and information produced in technologically favored languages, the documents need to be translated. Since manual translation is expensive, a promising alternative is the use of machine translation, particularly SMT as Ethiopian languages suffer from lack of basic linguistic resources such as morphological analyzer, syntactic analyzer, morphological synthesizer, etc. The major and basic resource required for SMT is parallel corpora, which are not available for Ethiopian languages. The collection and preparation of parallel corpora for Ethiopian languages is, therefore, an important endeavor to facilitate future MT research and development. Corpus acquisition for SMT is actually one of the recommendations of Saba and Sisay (2006).

We have, therefore, collected and prepared parallel corpora for English and Ethiopian Languages that fall under the Semitic, Cushitic and Omotic language families. We have considered Amharic, Tigrigna and Ge'ez from the Semitic, Afan-Oromo from the Cushitic and Wolaytta from Omotic language families. This paper, therefore, describes an attempt that we have made to collect and prepare English-Ethiopian languages parallel corpora and the SMT experiments conducted using the corpora.

2 Nature of the language pairs

The language pairs in the corpora belong to Semitic (Ge'ez, Amharic and Tigrigna), Cushitic (Afan-Oromo) and Omotic (Wolaytta) language families. Except Ge'ez, these languages have native speakers. Presently, Ge'ez does not have native speakers. Ge'ez functions as a liturgical language of Ethiopian Orthodox Church. It is thought as a second language in traditional schools of churches and given as a course in different Universities. There is a rich body of literature in Ge'ez. It is not only literature but also philosophical, medical and astrological documents were written in Ge'ez. Because of this, there is a big initiative in translating those documents written in Ge'ez. On the other hand, Amharic is spoken by more than 27 million people which makes it the second most spoken Semitic language. Tigrigna is spoken by 9 million people. Afan-Oromo and Wolaytta are spoken by more than 34 million and 2 million speakers, respectively (Simons

and Fennig, 2017).

The writing systems of these language pairs are Ge'ez or Ethiopic script and Latin alphabet. Ge'ez, Amharic and Tigrigna are written in Ge'ez script whereas both Afan-Oromo and Wolaytta are written in Latin alphabet. It is believed that the earliest known writing in the Ge'ez script dated back to the 5^{th} century BC. The writing system is syllabry where each character represents a consonant and vowel. The basic features of the writing system is that each character gets its basic shape from the consonant of the syllable, and the vowel is represented through a systematic modifications of these basic shapes. The script is used to write other languages like Amharic, Tigrigna, Argoba, etc.

The Ethiopian languages considered in the project have got different functions in the country. Amharic for instance is the working language of the Federal Government of Ethiopia. It also serves as regional working language of some other regional states. It facilitates inter-regional communication as well. Tigrigna and Afan-Oromo are working language in Tigray and Oromiya regional administrations, respectively. Some of the governmental websites are available in Amharic, Tigrigna and Afan-Oromo. Apart from this, they serve as medium of instructions in primary and secondary schools. These languages are available in electronic media like news, blogs and social media except Ge'ez. Currently, Google offers a searching capability using Amharic, Tigrigna and Afan-Oromo. Further, Google also included Amharic in its translation service recently.

2.1 Morphological features

As in other Semitic language morphology, Ge'ez (Dillman, 1907), Amharic (Leslau, 2000; Teferra and Hudson, 2007) and Tigrigna (Mason, 1996; Yohannes, 2002), make use of the root and pattern system. In these languages, a root (which is called a radical) is set of consonants which bears the basic meaning of the lexical item whereas a pattern is composed of a set of vowels inserted between the consonants of the root. These vowel patters together with affixes results in derived words. Such derivational process makes these language to be morphologically complex languages.

In addition to the morphological information, some syntactic information are also expressed at word level. Furthermore, an orthographic word may attach some syntactic words like prepositions, conjunctions, negation, etc. which make word forms to be very varied (Gasser, 2010; Gasser, 2011). In these languages, nominals are inflected for number, gender, definiteness and case whereas verbs are inflected for person, number, gender, tense, aspect, and mood.

As we may observe in the Semitic languages, nominals are inflected for number, gender, case and definiteness and verbs are inflected for person, number, gender, tense, aspect and mood (Griefenow-Mewis, 1995). Essentially, unlike the Semitic languages which allow prefixing, Afan-Oromo allows suffixing. Most functional words like pospositions are also suffixed. However, there are some prepositions written as a separate word.

Wolaytta like Afan-Oromo is a suffixing language in which words can be generated from root words recursively by adding suffixes only. Wolaytta nouns are inflected for number, gender and case whereas verbs are inflected for person, number, gender, aspect and mood (Wakasa, 2008).

2.2 Syntactic Features

Ethiopian languages that are under our consideration follow Subject-Object-Verb (SOV) word-order except Ge'ez which allows the verb to come first. In Ge'ez, the basic word-order is Verb-Subject-Object (VSO). On the contrary, English language uses Subject-Verb-Object (SVO) word-order.

3 Challenges of SMT

Statistical machine translation is greatly affected by the linguistic features of the target languages. The challenges ranges from the writing system to that of word ordering and morphological complexity.

3.1 Writing System

Semitic language writing system are represented by a consonant vowel (CV) sequence and the basic shape of each character is determined by the consonant, which is modified for the vowel. These language script has inherited its writing system from Ge'ez (ግእዝ) /gə'əzə/ using a grapheme based writing system called fidel /fidälə/ which is written and read from left to right being the classical and ecclesiastical language of Ethiopia. Unlike the Semitic languages, The Cushitic (Afan-Oromo) and Omotic (Wolaytta) languages use a latin based writing system.

3.2 Word Ordering

Semitic languages like Amharic, Tigrigna and Ge'ez are morphologically rich where words are required to be further segmented or a single word from these languages would be aligned with as big as handful of words in languages like English. The languages under consideration have different word order. With this respect, Amharic, Afan-Oromo, Tigrigna and Wolaytta have SOV, Ge'ez has VSO and English has SVO topology. The different word orders used in these languages is major challenge for Multilingual machine translation system.

Another challenge is the existence of flexibility in word order. For instance, even though Afan-Oromo follows SOV word order format, nouns can be changed based on their role in a sentence which makes the word order to be flexible. Although the major word order of Ge'ez is VSO, it also follows free word order. Such flexibilities will pose another challenge for translation from source to Afan-Oromo and Ge'ez languages.

3.3 Morphological Complexity

While word alignment could be done automatically or with supervision, morphological agreement between words in the source and target are crucial. For instance, Amharic and Ge'ez have subject agreement, object agreement and genitive (possessive) agreement. Each of which are expressed as bound morphemes which should be aligned or translated as independent words in English. In Amharic, for the word **ገደልክ** /you killed/ the English subject "you" is represented by the suffix "+**ክ**" while the same subject is represented as "+**ከ**" in the Ge'ez (**ቀተልከ** /you killed/). Likewise, the definite marker for Amharic and English are quite different in their representation. While it is a bound morpheme in Amharic, it is a word (free morpheme) in English. Most of the local languages under consideration falls into this group.

4 Parallel Corpus preparation

The development of machine translation more often uses statistical approach because it requires very limited computational linguistic resources compared to the rule-based approach. Nevertheless, the statistical approach relies to a great extent on parallel corpora of the source and target languages.

The research team has applied different techniques to collect parallel corpora for the selected Ethiopian languages paired with English. The collected data fall under the religious, historical and legal domains.

The religious domain include Holy Bible and different documents written in spiritual theme and collected from Jehovah's Witnesses (JW[1]), Ethiopicbible[2], Ebible[3] and Ge'ez experience[4] which are freely available websites.

The historical domain is from one source which is the handbook of Africa ("African Almanac"). The source is griped from admase ethiopia github[5].

The legal domain includes documents collected from Ethiopian constitution, Proclamation and Regulation documents which are available for different period of time and languages (Amharic,

[1]available at `https://www.jw.org`
[2]available at `https://www.ethiopicbible.com`
[3]available at `http://ebible.org`
[4]available at `https://www.geezexperience.com`
[5]Corpus available at https://github.com/admasethiopia/parallel-text/

Tigrigna and Afan-Oromo aligned with English). The documents are taken from Ethiopian legal brief website.

Legal and historical domain data collected from sources specified above are available in text and pdf format. For the sources in pdf, a pdf miner tool is used for extracting texts.The contents in the pdf files are stored in multiple columns with a language per column. By using a Unicode range of characters, the contents in each column were extracted without distorting the sentence sequence. For the corpus in the religious domain, a simple web crawler was used to extract parallel text from targeted websites.

Python libraries such as requests and BeautifulSoup were used to analyze the structure of the website, extract texts and combine to a single text file. To collect the bible data, we have generated the structure of the URL so that it shows the book names, chapters and verse numbers of Bible in each language.

For the daily text which is published at Jehovah Witnesses (JW), we tried to use the date information to generate URL for each language. The page was requested to extract the data we are interested in. Finally, we organized and merged the data to a single UTF-8 text files for each language.

We could have all these domains only for a language pair Amharic-English. The Tigrigna-English and Afan Oromo-English corpora are in legal and religious (both bible and other religious collections) domains. The Wolaytta-English and Ge'ez-English language pairs are from the religious domain only. However, the Ge'ez-English corpius is only from Bible while the Wolaytta-English consists of Bible and other religious collections.

4.1 Preprocessing

Data preprocessing is an important and basic step in preparing bilingual and multilingual parallel corpora. Since the collected parallel data have different formats and characteristics, it is very difficult and time-consuming to prepare manually. To produce parallel corpus there is a need to analyze the structure of collected raw data by applying different techniques.

During preprocessing the following tasks have been performed: character normalization, sentence tokenization and alignment.

4.1.1 Character Normalization

There are characters in Amharic that have similar roles and are redundant. Characters ሀ, ሐ and ኀ; ሠ and ሰ; አ and ዐ as well as ጸ and ፀ are variants along with their orders. These characters are used interchangeably. To avoid words with the same meaning from being taken as distinct words due to these character variants, we have replaced a set of characters with similar function into a single most frequently used character.

As a result of normalizing character variants in Amharic text , reduction in the number of word types (vocabulary) has been obtained. Table 1 presents the vocabulary reduction of training, development and testing dataset. As can be seen from the table, the vocabulary size reduced by 15.78 % for training, 10.53% for development and 11.95% for testing from a total of 40,726 sentence (132,723 Token of 628,474 type).

	Word Normalization		**Percentage reduction**
	Before	**After**	
Training	98,784	83,196	15.78 %
development	23,701	21,207	10.53%
Testing	24,142	21,258	11.95%

Table 1: Amharic text corpus before and after character normalization.

4.1.2 Sentence Tokenization and Alignment

Lines that contain multiple sentences in both source and target languages are tokenized. The team have set two criteria to check whether the aligned sentences are correct or not. The first criterion is counting and matching the number of sentences in the source and target languages. The second criterion is mapping the sentence end marker in source and destination languages. For example, after sentence tokenization is applied the number of new sentences and sentence end marker of the source is compared with that of the target. If both criteria are fulfilled, the new sentence list is used as a parallel corpus.

For the English–Ge'ez[6] parallel corpus, the source language contain multiple verses in a single line while on the target side, each line contains a single verse. To align the two corresponding language pairs, we tried to merge verses to produce the desired parallel verse. In addition, removing unnecessary links, numbers, symbols and foreign texts in each language has been done.

4.2 Corpus Size and Distribution of tokens and vocabulary

The corpus has been analyzed to see the relationship between English and each one of the considered Ethiopian languages. As it can be seen from Table 1 to Table 5 and the corresponding Figures (Figure 1 to 5), there is a significant difference between the morphology of English and the Ethiopian languages. Due to this difference, the same number of sentences in these language pairs is tokenized into significantly different number of tokens and vocabularies in all the available domains.

The Figures clearly show that English vocabulary is much lower than vocabulary of all the considered Ethiopian languages. On the contrary, the English token is significantly higher than tokens of the Ethiopian languages. It is clear, therefore, that such differences between the languages in a language pair makes SMT difficult because it aggravates data scarcity and results into a weakly trained translation model. The morphological complexity of the Ethiopian languages also challenges the SMT towards them because it results into a poorly trained language model.

5 SMT Experiments and results

In this study, bi-directional SMT systems are developed to check the validity of the collected parallel corpora for English and the four Ethiopian languages.

5.1 Experimental setups

In the experimental setup, Moses is used along with GIZA++ alignment tool (Och and Ney, 2003) for aligning words and phrases. SRILM toolkit was used to develop language models using semi-automatically prepared corpora from the training and tuning corpora of target languages.

Table 7 shows the sentence length, the number of words, the total number of tokens and the average sentence length found in the corpora for the four Ethiopian languages with respect to English.

To carry out the experiments, each parallel corpus is divided into three partitions; 80% as a training set where a large subset of the whole corpus is used to train the language and translation models, 10% for tuning (useful to adjust the weights of the model combination) and 10% as a tes tset for evaluating the final bi-direction statistical machine translation system of each language pair.

Automatic metrics and subjective evaluation are the two most widely used techniques or methods for MT system evaluation. In this research, BiLingual Evaluation Under Study (BLEU)

		Sentence	Token	Type	Average word
Language Pairs	English	40,726	66,400	969,345	23
	Amharic		132,723	628,474	15
	English	35,378	50,217	849,878	19
	Tigrigna		98,157	561,376	14
	English	14,706	29,076	264,790	20
	Afan-Oromo		37,773	268,035	17
	English	30,232	35,012	760,075	21
	Wolaytta		69,332	509,163	14
	English	11,663	15,260	303,546	26
	Ge'ez		33,894	160,662	13

Table 7: Sentence and word distribution of Ethiopian languages and English text.

is used for automatic scoring. Table 8 presents the experimantal results of bi-directional English-Ethiopian languages SMT.

Language pair	BLEU	Language pair	BLEU
English-Amharic	13.31	Amharic-English	22.68
English-Tigrigna	17.89	Tigrigna-English	27.53
English-Afan Oromo	14.68	Afan Oromo-English	18.88
English-Wolaytta	10.49	Wolaytta-English	17.39
English-Ge'ez	6.76	Ge'ez-English	18.01

Table 8: Experimental results of bi-directional English-Ethiopian languages SMT

As shown in Table 8, the English-Amharic translation shows a BLEU score of 13.31 while the Amharic-English has a 22.68. Similarly, the English-Tigrigna and Tigrigna-English have BLEU scores of 17.89 and 27.53, respectively. Likewise, English-Afaan Oromo has a 14.68 BLEU and Afan Oromo-English has 18.88 BLEU score. In a similar way, the English-Wolaytta translation has BLEU of 10.49 while Wolaytta-English has 17.39. Finally, The English-Ge'ez and Ge'ez-English translation has BLEU score of 6.67 and 18.01, respectively.

Figure 6 presents summary of BLEU score registered for bi-directional English-Ethiopian languages using statistical approach.

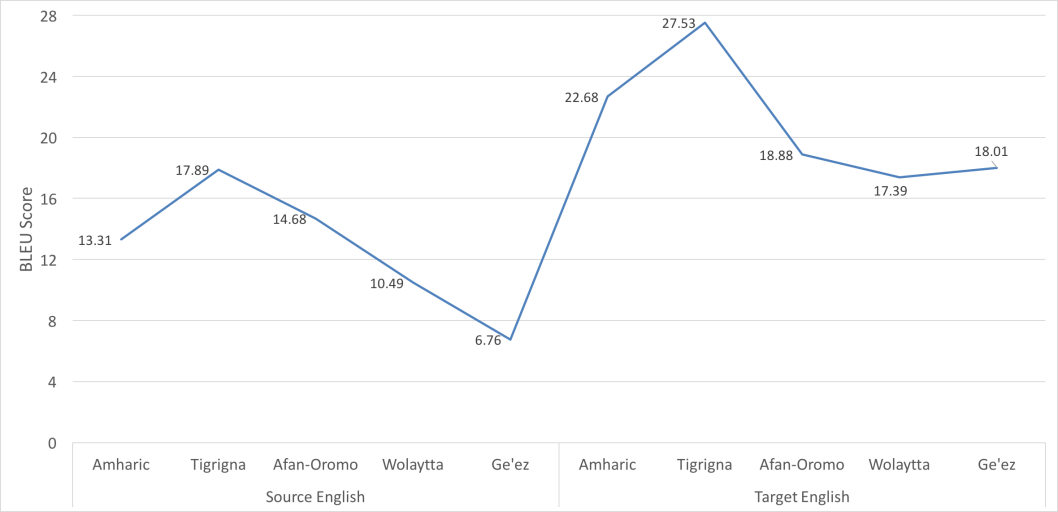

Figure 6: Comparison of Bi-directional English to Ethiopian language translation results

The BLEU score of Amharic-English translation system is lower than the Tigrigna-English translation system although the size of the Amharic-English parallel corpus is bigger than the Tigrigna-English one. This might be due to the number of domains considered in the corpora. The Amharic-English corpus covers all the three domains whereas the Tigrigna-English corpus is from only two domains.

Despite the size of the data, the English-Ethiopian languages SMT systems have less BLEU scores than that of Ethiopian languages-English ones. This is because of the fact that when the Ethiopian languages are used as a target language, the translation from English as a source language is challenged by many-to-one alignment. On the other hand, better performance is registered when the target language is English since the alignment is one-to-many taking each Ethiopian language as a source. In addition to this, the language model data favours the English language than that of Ethiopian languages due to the complexity of the morphology of these languages.

6 Conclusion and future work

This paper presents the attempt made in preparing standard parallel corpora for English and Ethiopian languages. The text data have been collected from the web in history, legal and religious domains. Then, the data are further pre-processed and normalized in preparing a bilingual parallel corpora for SMT task. Using the corpora, bi-directional statistical machine translation experiments have been conducted. The experimental results show that a translation from Ethiopian languages to English resulted in better BLEU score than that of the English to Ethiopian languages. The morphological richness of the Ethiopian languages greatly affect the performance of SMT specially when they are target languages.

To further see the impact, there is a need to conduct additional experiments with the objective of identifying an optimal one-to-many and many-to-one alignment when either of them used as a target language. Moreover, further research is needed to identify the exact reason behind the low performance of English to Ethiopian languages translation systems. Investigating the effect of domains on SMT performance is one of the future work we will work on.

Abstract

Multilingual machine translation addresses the task of translating between multiple source and target languages. We propose task-specific attention models, a simple but effective technique for improving the quality of sequence-to-sequence neural multilingual translation. Our approach seeks to retain as much of the parameter sharing generalization of NMT models as possible, while still allowing for language-specific specialization of the attention model to a particular language-pair or task. Our experiments on four languages of the Europarl corpus show that using a target-specific model of attention provides consistent gains in translation quality for all possible translation directions, compared to a model in which all parameters are shared. We observe improved translation quality even in the (extreme) low-resource zero-shot translation directions for which the model never saw explicitly paired parallel data.

1 Introduction and Motivation

Multilingual machine translation is the task of building a system capable of translating between more than just a single source and target language. The approach is motivated by the idea that learning to translate between one pair of languages can help to improve the translation quality of related language pairs. Multilingual MT can be divided into three main types according to the support for source and target languages: (i) single source, multiple target (ii) multiple source, single target, and (iii) multiple source, multiple target. Our work focuses on improving the quality of fully n-way multilingual NMT models that can translate between multiple source and target languages.

Multinational organizations and companies increasingly publish content in a variety of languages. In addition to exploiting multiple sources of parallel data and leveraging similarities across different languages, multilingual translation can considerably simplify deployment. Directly supporting all possible translation directions for a set of n languages would require $n(n-1)$ sets of parallel data and trained models. This is an expensive proposal, from both a data and deployment perspective. The number of required systems can be reduced to n if translation by bridging is used. In contrast, a fully n-way multilingual system can be trained to translate between all known language pairs using a single model. It is even possible to translate between language pairs that were never explicitly paired in the parallel training data, so called zero-shot translation (Johnson et al., 2017).

Neural machine translation (NMT) (Bahdanau et al., 2014; Sutskever et al., 2014) has recently become the standard model of translation due to the high levels of fluency and accuracy that it can achieve (Koehn and Knowles, 2017). NMT is an excellent choice for multilingual translation since the neural architecture is language-agnostic and capable of capturing translation properties, such as long-distance re-ordering, between even highly dissimilar languages. One of the main advantages of NMT is that the model is able to learn useful linguistic representations for many languages, and to share parameters and leverage similarities in the abstractions learned by the embeddings and hidden layers of the model. Exploiting multilingual data and representations is of particular interest in improving the quality of translation for low-resource (or even zero-resource) language pairs.

Proceedings of the 27th International Conference on Computational Linguistics, pages 3112–3122
Santa Fe, New Mexico, USA, August 20-26, 2018.

In this paper, we describe a simple but effective extension to the attentional model of neural machine translation that improves the quality of multilingual NMT. We seek to retain as much of the parameter sharing of NMT models as possible, while allowing for language-specific specialization of the attention model to a particular task. Our experiments on the Europarl corpus show that multilingual translation quality is improved for all tested language pairs, with the largest improvements in the (extreme low-resource) zero-shot directions.

The architecture of our sequence-to-sequence neural machine translation system is described in Section 2. An overview of related work in multilingual machine translation and multi-task learning is provided in Section 3. In Section 4, we introduce three task-specific attention model variants that can be used to improve the quality of multilingual NMT. Our experimental framework, implementation and results are described in Section 5, followed by an analysis and example translations with attention plots in Section 6. We conclude with a discussion of possible future work in Section 7.

2 Sequence to Sequence Translation with Attention

Our NMT system is based on the sequence-to-sequence model of translation described by Bahdanau et al. (2014), consisting of a recurrent neural network encoder and decoder with an attention mechanism.

The encoder uses bi-directional gated recurrent units (GRU) (Cho et al., 2014) to encode a source sequence $\mathbf{x} = (x_1, \ldots, x_l)$, where x_i is the embedding vector for the i-th word of the source sentence and l its length. The encoded form of the complete sentence is defined by the sequence of hidden states $\mathbf{h} = (h_1, \ldots, h_l)$, where each h_i is computed as

$$h_i = \begin{bmatrix} \overleftarrow{h}_i \\ \overrightarrow{h}_i \end{bmatrix} = \begin{bmatrix} \overleftarrow{f}(x_i, \overleftarrow{h}_{i+1}) \\ \overrightarrow{f}(x_i, \overrightarrow{h}_{i-1}) \end{bmatrix}, \tag{1}$$

and $\overleftarrow{f}$ and $\overrightarrow{f}$ denote the operations of the right-to-left and left-to-right GRU cells, respectively.

Given the encoded representation of the source sentence $\mathbf{h}$, the decoder produces the target translation $\mathbf{y}$ by computing the sequence $\mathbf{y} = (y_1, \ldots, y_m)$, where m is the target sentence length. At each time-step t, the probability of target word y_t is computed as

$$p(y_t|\mathbf{h}, y_{t-1}, \ldots, y_1) = g(s_t, y_{t-1}, H_t), \tag{2}$$

where g is a feed-forward network over the current decoder hidden state s_t, the word embedding of the previously predicted target word y_{t-1}, and a context vector H_t, followed by a softmax to predict the probability distribution over the output vocabulary. The decoder states are updated according to

$$s_t = q(s_{t-1}, y_{t-1}, H_t), \tag{3}$$

where q implements the conditional GRU with attention of Sennrich et al. (2017) and H_t is an attention-weighted representation of the encoded source sequence $\mathbf{h}$. The attention-weighted source representation at time-step t is defined as the weighted sum

$$H_t = \begin{bmatrix} \sum_{i=1}^{l}(\alpha_{t,i} \cdot \overleftarrow{h}_i) \\ \sum_{i=1}^{l}(\alpha_{t,i} \cdot \overrightarrow{h}_i) \end{bmatrix}, \tag{4}$$

where the normalized weights $\alpha_{t,i}$ indicate the relative importance of the vector representation of each source position h_i when producing the next target word at time-step t. The weights are computed using a two-layer feed-forward network r:

$$\alpha_{t,i} = \frac{\exp\{r(s_{t-1}, h_i, y_{t-1})\}}{\sum_k \exp\{r(s_{t-1}, h_k, y_{t-1})\}}. \tag{5}$$

3 Related Work

Early phrase-based approaches to multilingual MT focused on multi-source translation. Och and Ney (2002) used a simple product or max rule to select at the sentence-level the single best hypothesis with the highest translation score from multiple decoders. There is no sharing of parameters. Consensus network decoding (Matusov et al., 2006) can also be used to combine the word-level output of translations from multiple source languages. Such system combination techniques allow sharing of the words in the candidate translations, but still require training individual models for each language pair of interest.

Training multilingual MT systems capable of translating between multiple languages can be considered an instance of multi-task learning (Caruana, 1997), which is the idea of solving synergistic tasks while maximizing the number of shared parameters. Sharing parameters may be useful when attempting to solve different tasks, since we can minimize representation bias by learning a more regularized representation (Baxter, 2000). The flexibility nature of neural architectures allows for selection of the components of the model that are to be shared and those which are not.

Sequence to sequence models with attention are no exception. Each set of parameters provides different levels of generalization (Reimers and Gurevych, 2017), which is evidenced in the synergistic task of training multilingual translation models. For example, Dong et al. (2015) jointly train decoders while the rest of the parameters are task-specific; Zoph and Knight (2016) jointly train the encoders while the rest of the parameters are task-specific, and Johnson et al. (2017) train both encoders and decoders jointly with language-specific tokens to guide learning as in (Ammar et al., 2016). These latter approaches are the ones that we build on. We augment our decoder with a task-specific attention mechanism intended to better capture word order and language-specific nuances while continuing to share the rest of the model parameters (including token embeddings).

4 Task-Specific Attention Models

Fully n-way multilingual NMT systems need to support multiple source and target languages in the encoder and decoder GRUs. Our work focuses on improving the use of attention in the decoder. At each time-step t, the decoder computes the attention model weights $\alpha_{t,i}$ of Equation (5) in order to quantify the relative importance of the encoder states corresponding to each source position. To the extent that attention can be considered an analogue of word alignment, we would expect to see different patterns of attention for language-pairs with different word order and word-level alignments. Multilingual models restricted to a single shared attention will struggle when decoding multiple languages with different word orders, since the parts of the source sentence that should be attended to depend on the source and target languages of the translation task.

Our task-specific attention models can be used to address this issue. We train and empirically evaluate three task-specific attention model variants: *target-specific* attention, *source-specific* attention, and *paired* attention which is associated with a particular language pair (i.e. translation direction). Each of our models introduces conditioning on the weights and biases used to compute the attention coefficients. They differ only in the choice of the key used for conditioning attention:

- *Target-specific*: separate attention weights and bias for each target language
- *Source-specific*: separate attention weights and bias for each source language
- *Paired*: separate attention weights and bias for each source + target pair

Our multilingual NMT system follows Johnson et al. (2017) in using special tokens to indicate the desired target language. These tokens can be considered to define the 'task' from a multi-task learning perspective as shown in (Ammar et al., 2016; Kann et al., 2018). Since the encoder states are composed from bi-directional GRUs, we augment the source side of our parallel training data with both prefix and suffix task tokens. This ensures that the task token is not attenuated in the left-to-right encoder GRU. Such tokens are sufficient to ensure that the multilingual decoder produces words in the correct target language[1]. A French source sentence that is to be translated into English would be augmented as follows:

[1]We tried explicit softmax decoding constraints on the target vocabulary, but found them to be unnecessary.

target-specific	<ToEn>, <ToFr>, <ToEs>, <ToDe>
source-specific	<FromEn>, <FromFr>, <FromEs>, <FromDe>
paired	<FrEn>, <EnFr>, <EsEn>, <EnEs>, <DeEn>, <EnDe>

Table 1: Valid source-side task tokens for task-specific attention model training and decoding.

target-specific	<ToFr> w_1 w_2 ... w_l <ToFr>
source-specific	<FromFr> <ToEn> w_1 w_2 ... w_l <ToEn>
paired	<FrEn> w_1 w_2 ... w_l <FrEn>

Table 2: Source side training data augmented with task-specific attention model tokens.

<ToEn> Guide des industries canadiennes : <ToEn>

During training and decoding, we dynamically construct the computation graph using the parameters for each task. Table 1 defines the valid task tokens for target-specific, source-specific and paired attention models, given the four languages supported by our multilingual model. See Section 5 for full details of our experimental framework and supported language pairs.

The augmented source sides of the parallel training data for our three model variants take the abstract forms shown in Table 2. The target-specific and paired attention models simply add the desired target language or language pair prefix and suffix tokens. For the source-specific attention model, we want to continue to allow for run-time selection of the desired target language so we introduce a second prefix token to indicate the selection of the specific attention parameters. The first token for the source-specific models is used only to select the parameters and stripped from the source sentence before using it in training or decoding. This allows us to dynamically select the source-specific attention parameters associated with translation from French, while (i) still allowing run-time selection of the target language, (ii) supporting zero-shot directions, and (iii) ensuring that the multilingual model sees exactly the same sequence of tokens as the target-specific model.

Note that only the target-specific and source-specific model variants enable zero-shot translation. The paired form of attention model trains separate attention weights and biases for each of the translation directions observed in the training data. It would be possible to use a separate prefix token for the attention key (in a similar manner to that of source-specific attention), but there is no explicit set of attention parameters that should be used for the zero-shot directions. The prefix token could specify that the attention parameters associated with either the source or target language of the zero-shot direction should be used.

All three of our task-specific attention model variants still share most of their encoder and decoder parameters. The task-specific attention models require only a very small increase in the total number of parameters. For hidden state dimensionality d, we add one additional set of attention weights ($d \times d$ parameters) and bias (d parameters) for each supported task. For the neural network topology used in our experiments (see Section 5, below), a target-specific attention model with support for four distinct target languages (i.e. tasks) requires only a 1.2% increase in the total number of model parameters, compared to the shared-attention version of the model.

5 Experiments

We evaluate the quality of our multilingual translation models using training data from the Europarl Corpus[2], Release V7. Our experiments focus on three primary language pairs: French-English, Spanish-English and German-English. We include German with SOV-type word order to contrast the SVO-type word order of the other languages. The source and target sides of the parallel training data are processed with the standard tokenizer included in the Moses SMT Toolkit (Koehn et al., 2007). For

target (BPE)	35.3k	35.2k	35.1k	80.0k

Table 4: Source and target vocabulary sizes for single-data baselines and n-way multilingual models.

training multilingual systems, we merge the parallel data for all available directions. The parallel data for each language pair is thus included twice, once in each direction.

In order to support experiments on many-to-many multilingual translation using a single model, we apply a jointly-learned set of 80k Byte-Pair Encoding (BPE) rules (Sennrich et al., 2015) obtained from the merged source and target sides of the training data for all three language pairs. This ensures that all experiments, including the single-language baselines, share exactly the same tokenization and sub-word vocabularies. Tokenized corpus statistics for the parallel training data are summarized in Table 3, while Table 4 compares the vocabulary sizes obtained from BPE processed data for the single-data baseline and fully n-way multilingual models.

The Europarl evaluation data set dev2006 is used as our validation set, while devtest2006 and test2007 are our blind test sets. We also evaluate the out-of-domain News Commentary test sets nc-dev2007 and nc-devtest2007 in order to demonstrate the robustness of our approach to different kinds of data. Case-sensitive single-reference BLEU scores (Papineni et al., 2002) are computed using the `multi-bleu.perl` script included with Moses. Reimers and Gurevych (2017) have shown that reporting a single metric score can sometimes be misleading for many neural architectures. For this reason, all BLEU scores reported in the tables are obtained by averaging the decoding results from five separate models initialized with distinct random seeds.

5.1 Implementation Details

Our sequence-to-sequence NMT model with task-specific attention is implemented in C++ using DyNet[3] (Neubig et al., 2017a). We use DyNet since the computation graph can be efficiently modified on a batch-by-batch basis during training and decoding, allowing for the runtime selection of attention weights and bias parameters according to the desired task.

We utilize the auto-batching feature (Neubig et al., 2017b) of DyNet for efficient matrix computations, but the parallel training data must still be separated into batches[4] such that each batch consists of sentences for a single task, e.g. `<ToEn>` for a batch of sentences that all use the same target-specific attention model for translating into English. The entire training data and batches are shuffled at the beginning of each epoch so that the order of tasks seen during training is random and that they occur in proportion to their distribution in the training data.

We use 256 dimensions for our source and target word embeddings, and 256 dimensions for the hidden states. A single recurrent layer is used for the encoder and decoder. The model parameters are optimized using an unbiased Adam[5] stochastic optimizer (Kingma and Ba, 2014) in order to minimize perplexity on a held-out validation set. The validation set for the single-data baseline systems is simply the dev2006 portion of the official Europarl evaluation data for that language pair, e.g. dev2006.fr and dev2006.en for

[3] `http://dynet.io/`

[4] Each batch contains a combined maximum of 5000 source and target tokens.

[5] We use a learning rate of 0.001.

Table 6: BLEU scores for single-data baseline and task-specific attention model variants: En-to-xx

French-to-English translation. For multilingual systems, we want the model to work well in all possible directions so we merge the dev2006 data for all directions of interest. Combining all six directions gives a validation set with a total of $6 \times 2000 = 12000$ sentences.

5.2 Task-Specific Attention Model Decoding Results

Tables 5 and 6 show decoding results for the Foreign-to-English (xx-to-En) and English-to-Foreign (En-to-xx) directions, respectively. In all six translation directions, the single-data baseline systems obtain the highest overall BLEU scores. We expect these baseline models to perform well on their respective test sets since the translation direction (i.e. task) of the test set exactly matches the parallel data and validation set used to train the models.

The fully n-way multilingual system with a shared attention model shows degradations of up to -2.0 BLEU score, exhibiting a similar pattern to previously reported multilingual NMT results (Johnson et al., 2017). When the encoder and decoder both support multiple languages, a single shared attention model is harmful. Our multilingual NMT model with target-specific attention mitigates much of this degradation. We observe gains of between +0.5 and +0.9 BLEU, with respect to the single attention model shared across all language pairs.

Source-specific attention is also better than the shared attention model, but not as good as target-specific attention. Paired attention (i.e. a separate set of attention weights and biases for each of the six translation directions with explicitly paired parallel data) shows little change compared to the standard shared attention model. The paired attention model has more tasks than the other models (6 for paired attention vs. 4 for both target-specific and source-specific attention). It has therefore seen less data for each task and benefits from no sharing of attention-related parameters. The paired model probably lacks sufficient training data to learn a good separate attention for all tasks.

Table 7 shows BLEU scores on the out-of-domain News Commentary nc-dev2007 and nc-devtest2007 test sets. Our task-specific attention model again provides gains of between +0.6 to +1.2 BLEU showing that the technique is robust even for test sets less closely matched to the parallel training data.

5.3 Zero-Shot Decoding Results

Table 8 shows decoding results for the six zero-shot translation pairs, i.e. those directions (such as French-to-Spanish) never explicitly paired in the parallel data. Although the absolute numbers are lower (as expected for zero-shot pairs), our target-specific attention model gives gains of between +1.0 and +1.5 BLEU over the model that shares attention parameters across all languages. Source-specific attention does not work well for zero-shot translation.

	Fr-En		Es-En		De-En

Table 8: BLEU scores for multilingual NMT 'zero-shot' translations comparing the baseline shared attention model to target-specific and source-specific attention models.

No single-data baseline exists for zero-shot translation since we have no parallel data for those pairs. However, we can pivot by data (i.e. find new parallel sentence pairs $x : z$ from existing data $x : y$ and $y : z$, with common y) or translate by bridging (translate from x to y, and then from y to z) for the zero-shot pairs. Pivoting by data is possible since there is a high degree of overlap amongst the various languages of the Europarl Corpus.

Although our multilingual NMT model has not seen explicitly paired data in the zero-shot directions, the encoder and decoder have seen many of the source or target sentences paired with other languages. Our zero-shot experiments are designed to test the hypothesis that the target-specific attention model is better than a model which shares attention parameters for all languages. Any benefit due to source or target data similarity applies equally to each of these multilingual models.

6 Analysis and Examples

Learning curves for the shared attention and target-specific attention model variants are shown in Figure 1. The plot includes five curves for each model variant, corresponding to different random initializations. Our target-specific attention model achieves much higher BLEU scores on the validation set in earlier epochs. There is also considerably less variance. The first few times the validation set is decoded with the shared attention model, the gap with respect to the target-specific attention model can be as large as 10 points BLEU. Our validation set contains sentences from all six translation directions so it is not surprising that a model with a single set of shared attention weights and biases performs poorly when applied to the 'wrong' task. Even after a full epoch of training (11.8m sentence pairs), the shared attention model continues to lag behind the target-specific attention model by almost one BLEU point.

The following example shows German-to-English translations obtained using a multilingual NMT system with a shared or target-specific attention model. This is an interesting example since the model must attend to the distant German source words "angesprochen worden ist" when producing the English trans-

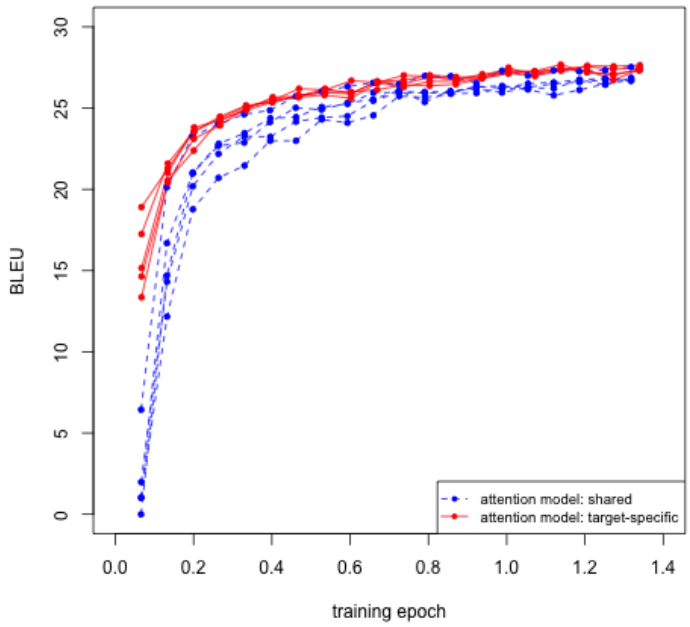

Figure 1: Multilingual validation set BLEU scores obtained during training for five different randomly initialized seeds using a shared or target-specific attention model.

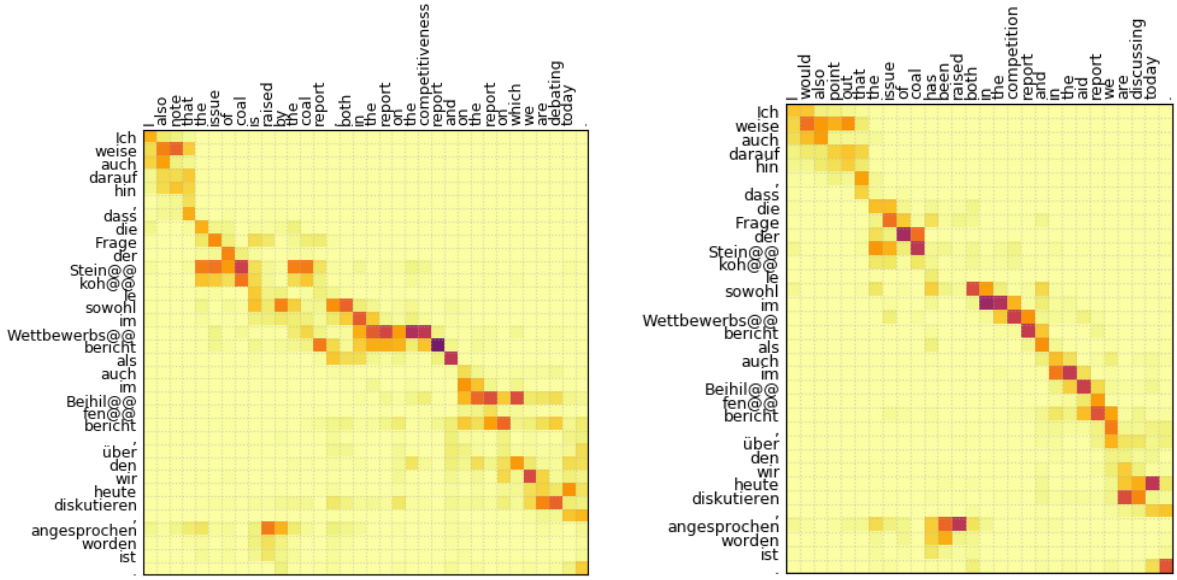
lation. The multilingual NMT system with a shared model of attention produces a deficient translation, containing multiple repetitions of the word 'report' and omitting the important content word 'aid':

source	Ich weise auch darauf hin , dass die Frage der Stein@@ koh@@ le sowohl im Wettbewerbs@@ bericht als auch im Beihil@@ fen@@ bericht , ber den wir heute diskutieren , angesprochen worden ist .
reference	I would also draw your attention to the fact that the coal issue is raised both in the competition report and in the subsidy report that we are discussing today .
shared	I also note that the issue of coal is raised by the coal report , both in the report on the competitiveness report and on the report on which we are debating today .
target-specific	I would also point out that the issue of coal has been raised both in the competition report and in the aid report we are discussing today .

The attention matrices computed during decoding for the shared and target-specific model variants are shown in Figure 2. Rows correspond to the words of the German source sentence and columns to the words of the English target translation. The target-specific attention model results in a sharper and less diffuse attention over the words of the source sentence, especially at the beginning and end of the sentence, and for the translation of the passive German construction "angesprochen worden ist" which requires long-distance re-ordering.

For this example, the shared attention model leads to diffuse alignments since a single set of attention weights and biases must be used to align the words of many target languages with disparate word orders. Our target-specific attention model leads to more accurate alignments since the decoder is conditioned for a single target language (as indicated by the 'task' token prefix). Given the target-specific set of attention weights and biases, and the initialization of the decoder state using the RNN encoded source, the decoder is able to more accurately attend to the correct source words when producing the words of the target sentence at each time-step.



(a) Attention model: shared

(b) Attention model: target-specific

Figure 2: Attention plots obtained while decoding a German-to-English sentence pair in the test set. Rows correspond to source words and columns to each target position. Target-specific attention results in less diffuse alignments.

7 Conclusions and Future Work

We have described a simple but effective technique for improving the quality of multilingual NMT. Our technique mitigates much of the loss that occurs when multiple source and target languages are supported in a system with a single encoder and decoder. It is particularly effective in the zero-shot (i.e. extreme low-resource) translation directions.

Our approach extends the use of target language prefix tokens described by Johnson et al. (2017) to select a task-specific set of attention weights and biases for each task of interest. For NMT, where attention can be considered an analogue of word alignment, the use of separate attention weights and biases for language pairs with different word orders leads to improved BLEU scores in our multilingual decoder. Our results show that multilingual NMT works best with a target-specific attention model, i.e. a distinct set of attention weights and bias parameters for each supported target language. Our improved model handles all possible translation directions with only a small increase in the total number of parameters, compared to the single-data baseline or standard shared attention model systems.

In future work, we plan to apply our multilingual techniques to true low-resource language pairs, with the goal of augmenting low-resource poor quality translation systems with knowledge obtained on languages with richer resources. Given our results for zero-shot translation, we expect our approach to work well. Our attention model variants can also be applied to multi-task learning frameworks, e.g. to improve the quality of translation using knowledge learned from a variety of other natural language processing tasks such as POS tagging and dependency parsing (Kiperwasser and Ballesteros, 2018). Recent work on learning and unsupervised induction of multilingual word representations (Upadhyay et al., 2016; Zhang et al., 2017) could also be used to improve multilingual translation since the models share a single vocabulary for all source and target languages of interest.

Combining Information-Weighted Sequence Alignment and Sound Correspondence Models for Improved Cognate Detection

Johannes Dellert
Seminar für Sprachwissenschaft
Universität Tübingen
johannes.dellert@uni-tuebingen.de

Abstract

Methods for automated cognate detection in historical linguistics invariably build on some measure of form similarity which is designed to capture the remaining systematic similarities between cognate word forms after thousands of years of divergence. A wide range of clustering and classification algorithms has been explored for the purpose, whereas possible improvements on the level of pairwise form similarity measures have not been the main focus of research. The approach presented in this paper improves on this core component of cognate detection systems by a novel combination of information weighting, a technique for putting less weight on reoccurring morphological material, with sound correspondence modeling by means of pointwise mutual information. In evaluations on expert cognacy judgments over a subset of the IPA-encoded NorthEuraLex database, the combination of both techniques is shown to lead to considerable improvements in average precision for binary cognate detection, and modest improvements for distance-based cognate clustering.

1 Introduction

The inference of cognate sets, i.e. sets of words which are related by being inherited from a common ancestor, is a central problem of historical linguistics. In the classical comparative method, the detection of cognates is an elementary preprocessing step for establishing sound laws, reconstructing the original forms in proto-languages, and thereby ultimately showing that groups of languages are related by common ancestry. In computational historical linguistics, cognacy-encoded datasets are the most common input format for modern methods of phylogenetic inference as pioneered by Gray and Jordan (2000). While in classical historical linguistics, a sharp distinction is made between cognates connected purely by inheritance, and words which are related due to borrowing, the common usage in the computational field refers to both types of relations as cognacy, with the understanding that the primary distinction is whether words are etymologically related, and the decision whether they are related by inheritance or borrowing will be made at a later refinement stage. Since this paper deals with automated cognate detection, the term will be used in the broader sense.

This paper builds on Dellert and Buch (to appear), where we introduced a segment-wise information content model as a technique for alignment and comparison of IPA strings. Information content is used to focus the string distance judgment on the parts of the word forms that are distinctive with respect to all the other words in the language. The main benefit for cognate detection is that it weakens distorting effects older approaches were faced with when dealing with lexical forms that were not reduced to stems.

In this paper, I take the next step of combining information weighting with the more established idea of inferring specialized segment similarity matrices for each language pair, with the goal of capturing some of the regularity in sound correspondences caused by sound laws, and therefore making cognates at a higher timedepth more similar.

In order to evaluate the resulting form distances independently of the choice of clustering algorithm, I continue to work primarily on the level of pairwise cognacy judgments. This allows performance to

Proceedings of the 27th International Conference on Computational Linguistics, pages 3123–3133
Santa Fe, New Mexico, USA, August 20-26, 2018.

be measured in terms of precision and recall for each threshold that could be used to separate cognates from non-cognates. The average precision across all possible threshold values provides a criterion for assessing the quality of form distances that is independent of the clustering algorithm. To assess whether improvements in average precision do indeed lead to improved cognate sets after inferring clusters from the distances, B-cubed precision and recall scores are compared in a second step.

As in previous work, our recently published NorthEuraLex database (Dellert and Jäger, 2017) is used for the experiments. NorthEuraLex is a data collection effort aiming to cover a large slice of the basic vocabulary (more than 1,000 concepts) across all sufficiently well-documented languages of Northern Eurasia. At the current stage, dozens of languages from the well-studied Uralic and Indo-European language make it a useful source of cross-family lexicostatistical data. The unique advantage of NorthEuraLex among deep-coverage databases is that it provides a full set of (mostly automatically generated) IPA transcriptions which adhere to a single unified set of conventions across more than 100 languages from a range of families. The disadvantage is that expert cognate annotations are currently only available for a small subset. What is available was produced by intersecting NorthEuraLex with the data present in the most recent online version of IELex (Dunn, 2015), a cognacy-annotated database covering about 200 concepts across more than 120 Indo-European languages.

The Java code implementing the entire toolchain described in this paper, from the NorthEuraLex dump file to the different form distances, as well as the evaluation code, is available under a GPL license in a public repository[1] for other researchers to inspect and build upon.

2 Cognate Detection

In its simplest form, cognate detection is the task of deciding for word forms a from a language L_a and b from a language L_b whether a and b can be traced back to a single proto-word from which both forms derive on different paths of regular sound shifts and borrowing.

On the algorithmic level, cognate detection can be approached directly as a binary classification problem. For instance, machine learning algorithms can be applied to training data in the form of pairwise cognate judgments in order to let a system learn to make correct binary cognacy decisions for pairs of words. Early work in this direction is summarized by Rama (2015), who trains a Support Vector Machine (SVM) over a feature representation that encodes shared subsequences, and shows that this feature set outperforms earlier SVM-based attempts. Moving to non-linear classifiers, Rama (2016) trains a convolutional neural network (CNN) on handcrafted representations of ASJP data, a large database by Wichmann et al. (2016) which covers 40 concepts across more than 5,000 languages in an approximate phonetic transcription. The trained network proves to be quite successful at deciding cognacy between pairs of words from families of limited timedepth.

2.1 Form Distances

A variety of string distance measures has been proposed and tested as a basis for cognate detection. Measures proposed can be as simple as the number of shared bigrams, the longest common subsequence, or even just a binary distinction where strings are judged as similar if there is a match of very coarse-grained equivalence classes assigned to the first two consonants, and as dissimilar otherwise (Turchin et al., 2010). Kondrak (2005) systematically evaluates the potential of some of these simple measures, and shows that they achieve acceptable results on the cognate detection task, albeit on small testsets covering only closely related languages.

However, as shown by List et al. (2017b), more elaborate measures are needed to arrive at state-of-the-art performance. The most widely used non-trivial string distance measure is the Levenshtein distance or edit distance (Levenshtein, 1965), which counts the minimal number of elementary editing operations (deletions, insertions, or replacements) needed to transform the one string into the other. The Levenshtein distance on either the orthography or some coarse-grained sound-class model tends to lead to a workable first approximation to phonetic form distance. In this paper, the **normalized edit distance (NED)**, the edit distance divided by the length of the longer string, will be used as a baseline for IPA-encoded data.

[1] `https://github.com/jdellert/iwsa`

Since assessing the usefulness of different sound class schemes would add an additional dimension to our evaluation, we are using NED on full IPA with the expectation that it will perform very badly, as in the absence of a notion of sound similarity, very small differences in pronunciation between e.g. [ɑ] and [ɒ], will be weighted just as much as e.g. the difference between a vowel and a consonant.

The major step improving on edit distance has been to estimate a similarity score for each pair of phonemes, and to count replacement of similar phonemes by only a fraction of a full replacement in distance computation. For instance, when assessing the similarity of English orthographic strings, changing an *o* to a *u* should be much better than changing an *l* to an *n*. This natural extension to the Levenshtein distance leads to the algorithm first presented by Needleman and Wunsch (1970), another dynamic programming approach which maximizes the similarity score between strings by introducing gaps. Variants of the Needleman-Wunsch algorithm are a very popular method for computing string distances in distance-based phylogenetics.

2.2 Clustering

Since the results of binary classification will typically not lead to a consistent result (as the cognacy relation is transitive, whereas binary decisions taken in isolation will typically not be), the output of a system trained for binary classification needs to be combined with an additional clustering stage in order to arrive at a partition into cognate sets. This approach is exemplified by Jäger and Sofroniev (2016), who train an SVM to predict pairwise probabilities of non-cognacy from phonetic distances, overall language distance, and average word length, and combine the result with UPGMA clustering (Sokal and Michener, 1958) to derive the cognate sets.

The **LingPy** system (List et al., 2017a) is an actively maintained and user-friendly suite of tools for computational historical linguistics. One of its core components is the **LexStat** module (List, 2012) which still provides state-of-the-art performance for cognate clustering, and has become the standard benchmark for the more recent cognate detection systems. For instance, Jäger and Sofroniev compare their system to LexStat in terms of the B-Cubed F-score measure of clustering quality, finding that it only slightly outperforms LexStat, an advantage which seems to hinge mostly on improved clustering methods. In LexStat, IPA input sequences are first converted into sound classes and annotated with sonority profiles. Segment similarity scores are then inferred for each language pair by comparing how often segments are mapped to each other when aligning candidate cognate pairs as opposed to semantically unrelated word pairs, and the Needleman-Wunsch algorithm is applied on these scores. The resulting scores are converted into pairwise form distances (**LexStat distances**), and these distances are used to infer cognate sets based on standard clustering algorithms like UPGMA and InfoMap.

Rama et al. (2017) combine distance scores based on pointwise mutual information (PMI) with InfoMap clustering, and evaluate the resulting system on a range of datasets against LexStat distances, as well as an alternative distance score derived from Pair Hidden Markov Models (PHMM). On a range of testsets, they find that PMI scores trained in an unsupervised fashion using online expectation-maximization, in combination with the Needleman-Wunsch algorithm and InfoMap clustering, beat LexStat by a small margin on a number of datasets.

List et al. (2017b) compare the performance of UPGMA clustering on various older form distance measures with UPGMA on LexStat distances as well as the more advanced InfoMap clustering on LexStat distances, finding that the two LexStat-based approaches clearly perform best, whereas InfoMap clustering only leads to a very small improvement over much simpler UPGMA. This means that the influence of the quality of form similarity scores on the quality of automatically inferred cognate sets seems to be much greater than that of the clustering method used on top of them, motivating the focus of this paper on improving and evaluating form similarity scores.

Whichever clustering method is used, all state-of-the-art cognate detection methods are ultimately based on form similarity or distance scores, whether they are computed from weighted edit distances, PHMMs, or stochastic models. The quality of these scores can (and should) be assessed independently of the clustering method on the level of pairwise cognacy judgments, since any improvement on this level is likely to increase the performance of all clustering methods explored in the literature.

There are quite a few interesting alternative approaches to cognate detection for which no implementations are available. Older approaches like Kondrak (2005) have tended to be evaluated only on very small wordlists from closely related languages. Some newer approaches would be interesting to compare because they provide very general models (Berg-Kirkpatrick and Klein, 2011), or even integrate cognate detection with phylogenetic inference and reconstruction in a comprehensive statistical model (Bouchard-Côté et al., 2013), but their source code remains unavailable, and the system descriptions do not contain all the necessary details for exact reimplementations.

3 Alignment-Based Form Distances

In bioinformatics, the Needleman-Wunsch algorithm is used on standardized and well-tested similarity matrices which encode current knowledge about the different probabilities for each nucleotide base to turn into a different one due to mutation. Unfortunately, no such standard matrix exists so far for phonemes, due to the absence of a global inventory of attested sound changes. One might try to derive such a matrix from phonological knowledge, but methods which estimate a distance matrix from large amounts of data consistently fare better in practice than such attempts, due to the impossibility for a human to assign an intuitive meaning to the distance weights. In practice, phoneme similarity distances are therefore always estimated from large datasets.

Estimation of phoneme similarity builds on observation of segment pairs which are likely to be equivalent given the context. Any method which uses dynamic programming to compute string similarity implicitly constructs an **alignment**, i.e. a separation of the two or more aligned strings into columns of equivalent segments. A binary alignment specifies which phonemes are cognate in a pair of cognate word, providing pairs of observations which can be counted and correlated to build models of phoneme distances. The procedure used in the toolchain for this paper to extract phoneme similarity scores from the NorthEuraLex database is detailed in Section 6.

4 Information Weighting for IPA Sequences

This section revisits the information weighting model which we proposed in Dellert and Buch (to appear), and adds some additional examples and considerations to motivate the changes that were necessary to handle pairwise correspondences. Assume we are faced with the task of assessing the closeness of the English word "to freeze" and its German equivalent "gefrieren". The NorthEuraLex IPA representations of the words are [friiz] and [gəfʁiiʁən], respectively. The NED between these forms is 0.667, which is clearly too high for a pair of cognates from closely related languages. Assuming that we use alignment weights, and that our global similarity matrix additionally tells us that [ɾ] and [ʁ] are a good fit, and (optimistically) that sound correspondence detection will have determined that English [z] clearly coincides with German [ʁ] in some contexts, we would still be left with distance of at least 0.444, i.e. only slightly better than, say, the distance between *sink* [sɪŋk] and *song* [sɔŋ].

The reason for the problems is, of course, that there is some additional material in the German form which would traditionally need to be stripped in order to only map the core portion, the stem *frier-*, to *freeze*. If we cannot extract the stems manually because it would require too much time, or because too little is known about the languages in question (which is frequently the case for languages where automated methods might yield new results), a mathematical model is needed to tell us which bits to ignore, and then a way to incorporate this information into the sequence distance computation.

4.1 Gappy Trigram Models

An important criterion for mathematical models of relevance is that the irrelevant material will be predictable. For instance, the infinitive ending *-ć* is present at virtually every Polish verb, so seeing it at the end of a verbal lexeme is completely unsurprising. Put differently, using the information-theoretic notion of surprise as high information, we will generally find the low-information segments to be more justified to ignore when comparing lexical material across languages. The most direct way to model predictability builds on the probability of seeing the item in question given the knowledge we already have. In phonetic strings, the knowledge we have are the surrounding symbols. If the probability of seeing a segment given

the neighboring segments is very high, this implies low information content. These considerations lead to the use of language-specific (gappy) n-gram models for modeling information content.

Depending on the context, I will use the terms **gappy trigram** and **extended bigram** interchangeably for trigrams where one of the three symbols (the "gap") is a wildcard, i.e. can be replaced by any symbol. For instance, the gappy trigram Xbc represents any of the trigrams abc, bbc, cbc, dbc, etc. A gappy trigram aXb with the gap in the middle could also be called a 1-skip-bigram in the terminology of e.g. Guthrie et al. (2006), but the other two types of extended bigrams are not skip bigrams.

Writing c_{abc}, c_{abX}, c_{Xbc}, c_{aXc} for the trigram and extended bigram counts extracted from all word forms of a language L, the **information content** of a segment c in its five-segment context $abcde$ is defined as

$$I_L(c, [ab\_de]) := -\log \left\{ \frac{c_{abc} + c_{bcd} + c_{cde}}{c_{abX} + c_{bXd} + c_{Xde}} \right\}$$

In words, one combines the number of times c was observed together with the two segments before it, the two segments after it, and its immediate neighbors, and compares this number of observations with the analogous count for the gappy bigrams. It is easy to show that these fractions define a probability distribution over segments in the context $[ab\_de]$, which implies that the negative logarithm does indeed define a measure of surprisal in the information-theoretic sense.

To also be able to define information content values for segments at the start and the end of an IPA representation, the word boundary symbol # is used for expanding a string a of length k to the positions a_{-1}, a_{-0}, a_{k+1}, and a_{k+2}. On these padded strings, no special definition is needed for the trigram and extended bigram counts involving peripheral segments. For instance, the counts for the affricate [t͡ɕ] in Polish *dać* [dat͡ɕ] "to give" are $c_{\text{dat͡ɕ}}$ = 13, c_{daX} = 30, $c_{\text{at͡ɕ\#}}$ = 132, $c_{\text{daX\#}}$ = 339, $c_{\text{t͡ɕ\#\#}}$ = 350, and $c_{\text{X\#\#}}$ = 1124. After smoothing, the information content of [t͡ɕ] in this word is I_{pol}(t͡ɕ,[da_##]) = 1.287. For comparison, an information content I_{pol}(d,[##_at͡ɕ]) = 3.306 is inferred for the first segment.

5 Information-Weighted Sequence Alignment

The next step is to define how the segment-wise information content values are used during alignment. Our solution, first presented in Dellert and Buch (to appear), is to use information content in a modified Needleman-Wunsch algorithm which we call **Information-Weighted Sequence Alignment (IWSA)**.

The modified dynamic programming procedure for computing the raw sequence similarity score $sc(a, b) := M(m, n)$ for two IPA strings $a \in L_a$ of length m and $b \in L_b$ of length n is defined by the following recursion:

$$\begin{array}{lcl} M(0,0) & := & 0 \\ M(i,0) & := & M(i-1,0) + w(a_i, \epsilon) \cdot I^2_{L_a,L_a}(a_i, a_i) \\ M(0,j) & := & M(0,j-1) + w(\epsilon, b_j) \cdot I^2_{L_b,L_b}(b_j, b_j) \\ M(i,j) & := & min \left(\begin{array}{c} M(i-1,j-1) + w(a_i, b_j) \cdot I^2_{L_a,L_b}(a_i, b_j), \\ M(i-1,j) + w(a_i, \epsilon) \cdot I^2_{L_a,L_a}(a_i, a_i), \\ M(i,j-1) + w(\epsilon, b_j) \cdot I^2_{L_b,L_b}(b_j, b_j), \end{array} \right) \end{array} \quad (1)$$

For the $w(a_i, b_j)$, any segment similarity score can be used. My choices for these scores, and their motivation, are described in Section 6. $I^2_{L_a,L_b}(a_i, b_j)$ is defined as the quadratic mean of information weights assigned to the segments:

$$I^2_{L_a,L_b}(a_i, b_j) := \sqrt{\frac{I_{L_a}(a_i, [a_{i-2} \ldots a_{i+2}])^2 + I_{L_b}(b_j, [b_{j-2} \ldots b_{j+2}])^2}{2}}$$

In the cases of insertion and deletion, the score combinations are equivalent to the information content of the segment that was matched to a gap. The quadratic mean is used because it remains high for similar segments with equally high information content, while not penalizing alignment of dissimilar low-information segments, but that of high-information with dissimilar low-information segments. These three properties combine into a focus on matching stems (high-information regions), while discounting differences in low-information parts such as frequently recurring affixes.

In Dellert and Buch (to appear), we only used a single globally inferred phoneme similarity matrix for IWSA. The Needleman-Wunsch scores $sc(a, b)$ were normalized through division by the average self-similarity of both word forms, leading to the following formula for deriving form distance values from similarity scores:

$$d(a, b) := 1 - \frac{2 \cdot sc(a, b)}{sc(a, a) + sc(b, b)}$$

When moving beyond the global similarity matrix and inferring pair-specific phoneme similarity scores in the style of LexStat, this definition turns out to be problematic. If we infer a separate model for each language pair, this leads to very high self-similarity scores because all words can be perfectly aligned with themselves. This causes distance values to be close to 1 for any pair of longer words, even if they are actually very similar. On the other hand, simply using the global similarity scores instead leads to negative distance values, because a specialized model will of course lead to higher $sc(a, b)$ values than the global one. I therefore normalize each similarity score by the length of the relevant sequence:

$$d(a, b) := 1 - \frac{2 \cdot \frac{sc(a,b)}{\max\{n,m\}}}{\frac{sc(a,a)}{m} + \frac{sc(b,b)}{n}}$$

The resulting scores will still often lie beyond the interval $[0, 1]$, but at least there are only very few negative distances, and distances can easily be scaled to the interval if necessary.

6 Inferring Phoneme Similarity Scores

We now turn to the problem of inferring good phoneme similarity matrices. Any model which attempts to estimate such matrices will quickly run into problems if too many parameters are to be estimated from too little data. For many language pairs where we would like to estimate correspondences (e.g. members from different branches of the same family), we often need to get by on little more than 100 cognate pairs. List (2012) reduces the number of similarity scores to estimate by internally reducing IPA (which LingPy accepts as input) to 28 equivalence classes, over which it is easy to estimate sound correspondences even based on only 100 or 200 cognate pairs. On the NorthEuraLex data, where about a thousand word pairs are available for each language pair, we can operate directly on the tokenized and simplified IPA representations in NorthEuraLex, which distinguish 105 IPA symbols.

Most work on phoneme similarity has been based on **pointwise mutual information (PMI)**, which is defined as the logarithm of the observed number of co-occurrences of two events divided by the number of co-occurrences we would expect if both events were independent. Pointwise mutual information has successfully been applied in many areas of computational linguistics. Treating the occurrences of segments in IPA strings as observations of a variable, the pointwise mutual information of two segments x and y would be defined as

$$i(x, y) := \log \frac{p(x, y)}{p(x)p(y)} \tag{2}$$

The problem of PMI scores for sound correspondences is that due to the non-random nature of phoneme sequences (e.g. a preference for the consonant-vowel pattern CVCVCV over CCCVVV), there will always be non-zero mutual information between any pair of consonants and vowels, even if the languages the correspondences are inferred for are completely unrelated. It is unclear how one could correct for this effect in an explicit parametrization of the expected probabilities.

The decisive idea which successfully addresses this problem goes back to Kessler (2001). The similarity scores $w(x, y)$ for IPA segments x and y are PMI scores based on the probability $p(x, y)$ of x being aligned with y in cognate pairs based on counts for a large set of likely cognate pairs, compared to an estimate $\hat{p}(x, y)$ of that probability on non-cognate words:

$$w_{glo}(x, y) := \log \frac{p(x, y)}{\hat{p}(x, y)} \tag{3}$$

6.1 Global Similarity Scores

The interesting decisions are now hidden behind the symbols p and $\hat{p}$. In our architecture, we stay within the framework of aligning randomly chosen wordpairs, and only modify the counting procedure in the case where information weights are used. Our implementation of this in the NWD case is very similar to LexStat, except that LingPy uses multiple-sequence alignments instead of only pairwise alignments to increase consistency. Due to the additional weighting factor, it is not obvious how IWSA could be generalized to multiple-sequence alignment in a consistent way, but as we shall see, this disadvantage does not appear to negatively impact performance.

The distribution $\hat{p}(x, y)$ to compare $p(x, y)$ against is derived by randomly sampling as many word pairs (of any meaning) from random language pairs as there are form pairs of identical meaning in the dataset, aligning each pair in the same way that the cognacy candidates are aligned, and then counting the number of times each pair of phonemes occurred in one column in the resulting alignments. 20% of the overall observation mass is redistributed for Laplace smoothing of the phoneme pair distributions.

$\hat{p}(x, y)$ is kept constant throughout each iteration of re-estimating $p(x, y)$ from a refined set of cognate candidates. Cognate candidates are selected based on an NED threshold (< 0.35) in the initial step, and on a threshold on the Needleman-Wunsch scores (< 1.2) for the current matrix in each subsequent iteration. Due to the large amounts of data in NorthEuraLex, three iterations were enough to derive very stable values for $\hat{c}(x, y)$. Also, no special treatment was needed for the gap symbol, which occurs in correspondences whenever insertions or deletions were inferred in the optimal alignment, and models the costs for inserting or deleting the respective phoneme in the inferred matrices.

In the information-weighted case, our implementation diverges from previous approaches in a crucial way. The probabilities are not directly based on counts of the number of times each symbol pair was aligned, but each instance in a candidate cognate pair only counts with its combined information content. Using the notation $al(a, b)$ for the optimal information-weighted alignment of a word pair (a, b) according to the current segment distances, $sc(a, b)$ for the corresponding Needleman-Wunsch score, and $al(a, b).a$ and $al(a, b).b$ to refer to the individual strings (with gap symbols) in which positions can be indexed by subscripts, this way of counting pairs of aligned segments can be written in one expression as follows:

$$c(x, y) := \sum_{L_1, L_2 \in \mathcal{L}} \sum_{\substack{(a,b) \in lex(L_a, L_b), \\ sc(a,b) < 1.2}} \sum_{\substack{1 \leq i \leq \max\{m,n\}, \\ al(a,b).a_i = x, \\ al(a,b).b_i = y}} I^2_{L_a, L_b}(a_i, b_i) \tag{4}$$

I will call the distance measure based on Needleman-Wunsch scores over the resulting global phoneme similarity matrix **Needleman-Wunsch Distance (NWD)**, whereas the variant using information weighting both for inferring the phoneme similarity scores and during alignment will be called **Information-Weighted Distance (IWD)**. NWD can thus be seen as a special case of IWD where all information weights $I_L(c, [ab\_de])$ are set to 1.

6.2 Pairwise Correspondences for NorthEuraLex

In the same way that global similarity scores were estimated, it is possible to infer specialized scores from the data for any pair of languages. These will tend to assign low costs to sound pairs which are equivalent across many alignments, and can therefore be interpreted as encoding some of the sound correspondences the comparative method operates with. For instance, given enough examples such as *water*/*Wasser*, *street*/*Straße*, and *foot*/*Fuß*, the alignment costs of English [t] and German [s] will be rather low, encoding the consequence of a part of the High German consonant shift.

To infer sound correspondence models for each pair of languages (leading to what I will call **local similarity scores**), we repeat the procedure that we used for inferring the global segment similarities on cognate pairs for that language pair. The values for $\hat{p}(x, y)$ are estimated based on 100,000 random word pairs sampled independently of the associated concepts. Like in LexStat, the inferred similarity scores will be based on a mixture of global and local PMI scores, because the local models for some pairs of unrelated languages will otherwise include some very strong correspondences that are only due to

random noise. To keep the mixture interpretable as an information measure, some weighted mean of both scores needed to be chosen. In order to avoid overfitting the method to the dataset, we based our decision for the proportions between local and global PMI scores on inspection of the resulting correspondences for a small subset of language pairs, and not on optimization. It turned out that one of the simplest option, the arithmetic mean of the local and global PMI scores, already resulted in convincing PMI scores for the inspected language pairs, leading the following definition of local similarity scores:

$$w_{L_1,L_2}(x,y) := \frac{w_{glo}(x,y) + \log \frac{p_{L_1,L_2}(x,y)}{\hat{p}_{L_1,L_2}(x,y)}}{2} \tag{5}$$

Again, using information weighting for the observation counts is crucial for getting good information-weighted alignments. If information weighting is not used for the counts, the local similarity scores will be influenced by reoccurring phonological material, leading to spurious low scores which are then applied across the board. For instance, the frequent mapping of the Persian infinitive ending [æn] to Ukrainian [tɪ] will result in an erroneous high local similarity score [æ] and [t], leading to unwanted small form distances between such pairs as Persian [ælæf] and Ukrainian [trɑwɑ] "grass". More generally, information content weighting of counts will diminish the effect of reoccurring morphological material in non-stemmed data.

I will call the extension of IWD by local similarity scores **Information-Weighted Distance with Sound Correspondences (IWDSC)**. Analogously, the combination of NWD with local similarity scores will be called **Needleman-Wunsch Distance with Sound Correspondences (NWDSC)**.

7 Evaluation

7.1 Test Data

To evaluate whether information weighting does indeed help to better separate cognate from non-cognate word pairs, all five methods were applied to a large IELex-based cognate pair testset which is available as part of the supplementary materials[2] to my dissertation (Dellert, 2017). For this testset, the 6,106 word forms which exist in both IELex and NorthEuraLex were manually mapped to each other, allowing the expert judgments contained in IELex to be added as annotations to the corresponding entries in NorthEuraLex. The resulting testset covers 185 concepts across 36 languages. At a size of 100,156 pairwise judgments, this is one of the largest expert-annotated testsets for cognacy detection currently available.

All the methods that are compared in this evaluation were run on the full version of NorthEuraLex 0.9 (121,615 forms covering 1,016 concepts across 107 languages), including the inference of global and pairwise sound similarity scores. The resulting distance values and clusterings were then reduced to the testset for evaluation. The numbers that will be reported are thus computed on the testset, whereas the dataset used for inference was about 20 times larger. Evaluation in previous literature on cognate detection has relied on testsets that are much smaller in terms of the number of concepts covered, and therefore do not include enough data for building high-quality language-specific information models as needed for information-weighted alignment.

7.2 Results

Using the form distances for pairwise cognate detection boils down to picking a single threshold value θ such that a word pair (a, b) is considered a pair of cognates if and only if $d(a, b) \leq \theta$. For any given threshold, each word pair annotated as cognates in the IELex-based gold standard is counted as a true positive if their distance is below the threshold, and as a false negative if it is not. Analogously, pairs which are considered non-cognates due to a distance above the threshold, are classified into true negatives and false positives depending on the gold standard. This makes it possible to compute precision and recall values for each value of θ.

[2] http://www.sfs.uni-tuebingen.de/~jdellert/pubs/jdellert-diss-supplements.tar.gz

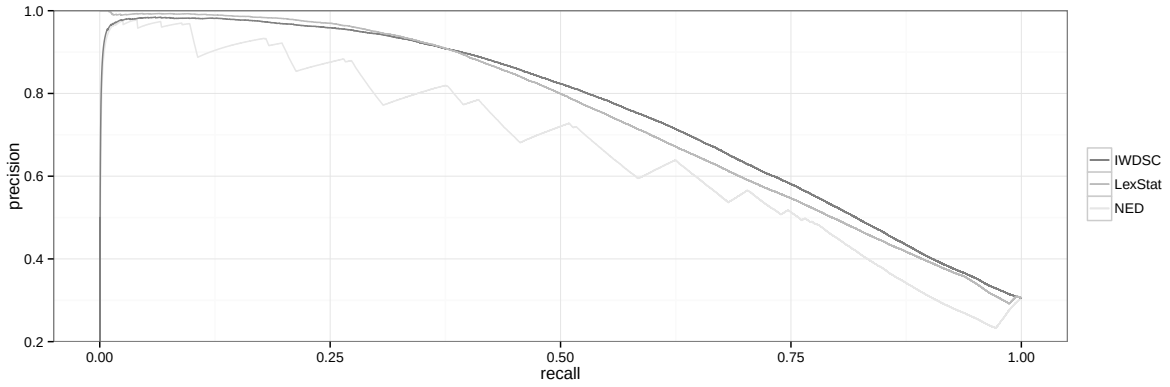

Figure 1: Precision-recall curves for form distance measures in cognacy detection.

As a threshold-independent performance measure, I use the **average precision**, defined as the precision integrated over all possible recall values. To approximate this integral, one simply orders the precision-recall pairs by recall, and then sums up the precision values weighted by the distance between the current recall value and the last, which approximates the area under the precision-recall curve as a sum of rectangles. For illustration, Figure 1 shows the curves for the three most important distance measures in my comparison. In this visualization of the tradeoff between precision and recall, the curve for the NED baseline is jagged and does not drop monotonously. The reason for this is that to ensure a fair comparison, all tied values (of which there are of course many in a distance based on counting edit operations) need to be ordered in the worst-case fashion, i.e. all non-cognate pairs need to be counted as if they had slightly lower distances, followed by the cognate pairs.

Between the smooth curves for LexStat and IWDSC, we observe that in the low-recall range (i.e. for the easy cases), LexStat is slightly better, but its precision decays more quickly with higher recall, showing that information weighting leads to improvement especially for the more difficult instances. The curve already suggests that IWDSC will have a global advantage at desirable recall values of more than 50%, and the average precision values will substantiate this impression.

Table 1 shows the average precision values for all the distance measures discussed in this paper. As already suggested by the curve, IWDSC distances clearly outperform LexStat distances at a gain in average precision of 4.3 percentage points, which in this case corresponds to an average reduction of the false discovery rate by 15.8%.

Method	**NED**	**LexStat**	**NWD**	**NWDSC**	**IWD**	**IWDSC**
Average Precision	0.604	0.727	0.741	0.747	0.764	**0.771**
Maximum F-score	0.599	0.631	0.652	0.654	0.673	**0.679**
Precision at max. F-score	0.639	0.652	0.666	0.660	0.696	**0.706**
Recall at max. F-score	0.564	0.611	0.639	0.648	0.652	**0.654**

Table 1: Quantitative comparison of form distance methods on pairwise cognacy testset.

To evaluate whether this advantage carries over to clustering results, and to maintain comparability with the previous literature, we now turn to the evaluation in terms of B-Cubed F-score for the full cognate detection task, i.e. in terms of the cognate clusters inferred over the testset. For this, the IWDSC values were squared to enhance the differences in the upper range, and then divided by 1.5 (with cutoff at the same value) to scale them to the interval $[0, 1]$ before clustering. To ensure a fair comparison, the main clustering parameter (a single threshold value) was varied with a step size of 0.05 in order to find a near-optimal value for the testset without overfitting. This emulates the usage of LingPy in practice, where on a new dataset, the user is encouraged try other threshold values instead of the default 0.6.

As the numbers in Figure 2 show, the advantage of IWDSC turns out to be far less prominent on the full task than it was for the pairwise cognacy judgments. In combination with UPGMA, IWDSC

does lead to better cognate clusters than LexStat, but only by about 1 percentage point in B-Cubed F-score. Regarding the comparison of clustering algorithms, the NorthEuraLex dataset does not confirm the superiority of InfoMap over much simpler UPGMA found by List et al. (2017b) on their testsets.

Method	Best Threshold	Precision	Recall	F-score
LexStat + InfoMap	0.70	0.757	0.612	0.677
LexStat + UPGMA	0.80	0.763	0.616	0.681
IWDSC + UPGMA	0.75	0.790	0.613	**0.690**

Table 2: B-Cubed measures for LexStat and IWDSC on the NorthEuraLex/IELex testset.

7.3 Discussion

To understand which of the differences between IWDSC and LexStat contributes most to the improvement in average precision, we consider the result figures for the other measures in Table 1. We see that about a fourth of the difference already appears in the comparison between LexStat and our implementation of NWD. This is likely due to the difference in the segment model (with full IPA vs. a reduction to equivalence classes in LexStat), since a test for the only other major difference (the normalization by length during the score-to-distance transformation) did not lead to a lower average precision score.

The performance gain from pairwise segment similarity matrices is of almost exactly the same size for NWD and IWD. This increases my confidence that the small improvement by little more than half a percentage point is a meaningful difference, establishing that there is a gain due to sound correspondences that is orthogonal to and can be combined with the improvements coming from information weighting.

Information weighting alone appears to account for about half of the difference between LexStat and IWDSC, a difference which persists whether we additionally infer sound correspondences (NWDSC vs. IWDSC) or not (NWD vs. IWD). This orthogonality to other improvements makes it a useful technique for inclusion in cognate detection systems.

The small improvement for the full cognacy task is of a similar size to the ones reported by Jäger and Sofroniev (2016) and List et al. (2017b), once more confirming the difficulty to achieve substantial gains over LexStat. To explain how the much more pronounced gain in average precision fits into this picture, the most obvious hypothesis is that while better for pairwise comparisons, the IWDSC distances are not more consistent within cognate sets than LexStat distances, making it difficult to transfer the clear advantage in pairwise judgments to the level of clusters.

8 Conclusion and Future Work

This paper has shown that information weighting and pair-specific phoneme similarity matrices can be used independently to increase the quality of pairwise form distances for automated cognate detection, and that a combination of both techniques improves the Needleman-Wunsch scores for this task.

A large part of the improvement appears due to the use of information weights already for counting the observations that the similarity matrices are based on, whereas the advantage of modeling sound correspondences in the form of local similarity scores turned out to lead to only small additional gains.

The reasons for the small size of the improvement on the full cognate detection task as opposed to the quality of pairwise form distances, and possible remedies, will be a focus of future work. Also, it will be interesting to apply IWSA to other language families as soon as cognacy-annotated databases for other subsets of the lexical data covered by NorthEuraLex (or possible future databases of similar coverage) become available.

Tailoring Neural Architectures for Translating from Morphologically Rich Languages

Peyman Passban, Andy Way, Qun Liu
ADAPT Centre
School of Computing
Dublin City University, Ireland
firstname.lastname@adaptcentre.ie

Abstract

A morphologically complex word (MCW) is a hierarchical constituent with meaning-preserving subunits, so word-based models which rely on surface forms might not be powerful enough to translate such structures. When translating *from* morphologically rich languages (MRLs), a source word could be mapped to several words or even a full sentence on the target side, which means an MCW should not be treated as an atomic unit. In order to provide better translations for MRLs, we boost the existing neural machine translation (NMT) architecture with a double-channel encoder and a double-attentive decoder. The main goal targeted in this research is to provide richer information on the encoder side and redesign the decoder accordingly to benefit from such information. Our experimental results demonstrate that we could achieve our goal as the proposed model outperforms existing subword- and character-based architectures and showed significant improvements on translating from German, Russian, and Turkish into English.

Title and Abstract in Farsi (Persian)

بهبود معماری مدل‌های مبتنی بر شبکه‌های عصبی برای ترجمه از زبان‌های باساختار مورفولوژیکی پیچیده

کلمات با الگوهای پیچیده مورفولوژیکی همانند ساختارهای سلسله مراتبی با واحد (زیربخش) های معنادار هستند، لذا مدل‌های مبتنی بر کلمات که هر کلمه را یک واحد تجزیه‌ناپذیر در نظر می‌گیرند گزینه‌های مناسبی برای پردازش چنین ساختارهای سلسله مراتبی نمی‌باشند. به هنگام ترجمه از یک زبان با ساختارهای پیچیده مورفولوژیکی (ترکی) به یک زبان ساده‌تر از نظر ساختار (انگلیسی)، یک کلمه پیچیده می‌تواند به چندین کلمه و یا حتی یک جمله کامل در زبان مقصد نگاشت (ترجمه) شود، و این پدیده تایید کننده این ضرورت است که کلمات پیچیده نباید همانند واحدهای تجزیه‌ناپذیر درنظر گرفته شوند. در این پژوهش، به منظور تولید ترجمه‌های با کیفیت بهتر، ما سعی کردیم تا معماری متداول (Encoder-Decoder) در مدل‌های ترجمه ماشینی مبتنی بر شبکه‌های عصبی را تغییر دهیم. در معماری پیشنهادی بجای یک کانال در قسمت انکودر دو کانال به صورت همزمان فعال هستند تا اطلاعات غنی‌تری از سمت مبدا را فراهم کنند؛ در سمت دکودر نیز واحد تمرکز (Attention mechanism) موجود با واحد دیگری با ساختار پیچیده‌تر جابجا شده است. هدف اصلی از انجام این پروژه بهبود کیفیت ترجمه و بدست آوردن بازنمایی بهتری از سمت مبدا بود که نتایج آزمایشات انجام شده مؤ ید این دستاورد هستند. نتایج مطالعات نشان می‌دهد که مدل پیشنهادی قادر است عملکرد بهتری از دیگر مدل‌های موجود داشته باشد و در ترجمه از سه زبان مورد مطالعه ما یعنی آلمانی، روسی، و ترکی به انگلیسی موفق‌تر و با دقت بیشتری عمل می‌کند.

1 Introduction

In this paper we propose a neural architecture which is designed to deal with morphological complexities on the source side. In such scenarios the neural model and specifically the encoder should be able to handle morphologically complex inputs. It is hard (or even impossible) to benefit from all subunit information within an MCW when it is treated as an atomic unit, e.g. the Turkish word '*ev.de.ki.ler.de.ki*' meaning '*one of those (things/people) at home*' clearly demonstrates that there are meaningful subunits within the word which should be processed separately. Expecting a neural model to learn such intra-word relations by itself complicates the whole process drastically as it requires powerful neural structures which may not lead to the desired result. Accordingly, we believe that there should be an architectural design (manipulation) inspired by the nature of this particular problem, which is able to decompose MCWs or process them in decomposed forms.

Subword-level NMT models are the most preferred alternatives to translate from MRLs, which can be discussed in two main categories. One group of models does not change the neural architecture but manipulates data by decomposing words into their subunits. In this approach either linguistically motivated morphological analyzers such as Morfessor (Smit et al., 2014) or purely statistical models such as the byte-pair encoding (*bpe*) model (Sennrich et al., 2016) are applied to process words. This approach, by its very nature, seems to be a promising solution as it changes the sparse surface form-based vocabulary set into a much smaller set of fundamental subunits. The size of a set including atomic subunits, especially for MRLs, is considerably smaller than that of the vocabulary set. Moreover, this solution partially solves the out-of-vocabulary word problem, as the chance of facing an unknown surface form is much higher than the chance of facing an unknown subunit.

The aforementioned approach could help generate better translations, but there is a potential problem with its single encoder shared among all different types of subunits. In the Morfessor-based segmentation (or any other linguistically motivated segmentation models) the NMT model is fed by stems and affixes instead of words, but all those subunits are processed with a single encoder. Clearly, this is not the best way of learning/representing source-side information, as stems and affixes are different constituents and should be processed separately. The same problem also applies to statistical models such as *bpe*, because although the difference between different subunits might not be obvious (as that of stems and affixes), it does not mean that they are the same types and should be treated equally. Furthermore, there could be another issue raised by the type of the neural architecture. The encoder-decoder architecture (Cho et al., 2014; Sutskever et al., 2014) employed in this approach was originally designed to work at the word level but is instead used for subwords, which might produce some problems, e.g. a sequence of subwords can be considerably longer than a sequence of words. Long sequences are usually hard to remember for neural models and this can affect NMT model's performance. Considering all positive and negative aspects of subword-based models, we still believe that such models are truly beneficial but our main concern is their architecture which we demonstrate can be improved to work with subwords.

As we previously mentioned, there are two main categories of models proposed to tackle the problem of translating from MRLs. We already explained the first group and its advantages and disadvantages. Unlike the first group, the second one focuses more on the neural architecture rather than data preprocessing (word segmentation), and boosts the network with character-based encoders. In such models words are consumed character by character. Usually, there is a convolutional module after the input layer to read characters, connect them to each other, and extract inter-character relations. This approach is helpful as it requires no preprocessing step, but there are two main problems with that. Similar to the previous group, the length of the input sequences could be an issue as by segmenting words into characters an input sequence with a limited number of words is changed to a long sequence of characters. Furthermore, the convolutional computation over characters could be quite costly, e.g. Lee et al. (2017) use 200 convolutional filters of width 1 along with 200 filters of width 2, 250 filters of width 3, and continue up to a filter size of 300 with width 8 to extract useful information on the source side. This amount of computation is carried out only in one layer (for one word), so in addition there are max-pooling

layers followed by 4 highway layers (Srivastava et al., 2015), and then recurrent layers on top. This is a complex architecture which is determined by the type of the input data (a sequence of characters).

Considering both groups of approaches, we assert that there is a need for a third one, for two main reasons: i) models from the first approach work at the subword level but the neural architecture they use is not designed for this purpose; and ii) systems from the second approach use complex architectures to be able to learn character-level information but (it seems) the complex mechanism is not completely effective as results reported from different studies demonstrate that character-based models usually fail to compete with other architectures.[1] Our experimental results also confirm this (see Table 2). The main issue we try to point out by studying these approaches is that existing models may provide state-of-the-art results but they are not designed based on the nature of the problem at hand. Rather, they are just powerful models with recurrent, convolutional, and highway layers which work with simplified (segmented) inputs. They might improve translation quality or partially address the problem, but do not resolve, in a meaningful way, the challenge of handling morphological (subword-level) complexities on the source side.

In this paper we propose a new architecture to address the shortcomings of these previous approaches which is our main contribution. We prefer to work with subwords not characters, because we might lose useful information when we segment structures into characters, or might not be able to extract desired information via the character-based architecture. Related characters are already grouped and connected to each other in subwords, so there is no need to decompose and then glue them back together. Therefore, our basic unit for translation is a morpheme (subword). As mentioned earlier, it seems that existing architectures can be improved further to work with subwords. Accordingly, we propose a novel neural architecture which relies on subwords and is supposed to outperform other character- and subword-based counterparts. In the next section, we first review similar models which tackle the same problem with different approaches, then we explain our own solution. The comparison between our model and others confirms that our hypothesis on designing the neural architecture according to the nature of the problem is true and directly affects performance.

2 Related Work

The problem of morphology and dealing with MCWs is an important issue in the field of sequence modeling as it directly affects the model's architecture and its performance. There is a fair amount of research carried out to address this problem, which can be discussed in two main categories. One group of models tries to cope with the problem on the encoder side where the goal is to understand the rich morphology of the source language. Kim et al. (2016) proposed a convolutional module to process complex inputs for the problem of language modeling. Costa-jussà and Fonollosa (2016) and Lee et al. (2017) adapted the same convolutional encoder to NMT. Luong and Manning (2016) designed a hybrid character- and word-based encoder to try to solve the out-of-vocabulary problem. Vylomova et al. (2016) tackled the problem by comparing the impact of different representation schemes on the encoder. Similarly, Burlot et al. (2017) investigated the impact of different word representation models in the context of factored NMT. Our work is also an example of models which try to provide richer information when the source side is an MRL.

Models reviewed so far address the problem of morphology on the source side. In contrast, there is a group of models which study the same problem for the target side. Huck et al. (2017) compared different word-segmentation models, including linguistically motivated as well as statistical techniques, to find the most appropriate segmentation scheme when translating into MRLs. Chung et al. (2016) tried to design a suitable architecture when the target language is an MRL. They benefit from using a character-based decoder which partially resolves the problem. Passban et al. (2018) proposed a similar approach in which they equipped the character-based decoder with an additional morphology table to inform the decoder with the target language's morphological structures.

[1] Comparing translation results generated by different word-, subword-, and character-based architectures on different language pairs shows that there is no character-based model which is able to outperform its word- and/or subword-based counterparts. Please see results at `http://matrix.statmt.org/?mode=all`

Apart from these models, there are others that do not directly address the problem of morphology but their solutions could be quite useful to translate MRLs. Jean et al. (2015) proposed a model to handle very large vocabularies. Luong et al. (2015) addressed the problem of rare and unseen words with the help of a post-translation phase to exchange unknown tokens with their potential translations. Dalvi et al. (2017) did not propose a new model but studied the impact of morphological information in NMT. They evaluated the behaviour of an encoder-decoder model to see what sort of morphological information is learned via the model and how the model deals with complex structures. Passban (2018) extensively discussed the problem of morphology at the word and sequence level and proposed solutions for modeling and translating sequences in monolingual and bilingual settings.

3 Proposed Approach

We propose an NMT architecture with a double-source encoder and double-attentive decoder for translating from MRLs. Our neural architecture is inspired by models proposed in Firat et al. (2016) and Zoph and Knight (2016). It takes inputs from two different channels: one channel which is referred to as the *main* channel sends stem information (main input), and the other one (the *auxiliary* channel) sends affix information. If the input is $w_0, w_1, ..., w_n$ for the (original) encoder-decoder model, our proposed architecture takes two sequences of $\varsigma_0, \varsigma_1, ..., \varsigma_n$ and $\tau_0, \tau_1, ..., \tau_n$ through the main and auxiliary channels, respectively, where w_i shows the surface form of a word whose stem is ς_i, and affix information associated with w_i is given by τ_i.

Our new neural architecture is based on a hypothesis which assumes the *core semantic unit* is the stem. The translation generated on the target side could appear in different surface forms but it should convey the core meaning dictated by source-side stems. Therefore, to generate a translation the minimum requirement is stem information. Defining the translation process based on stems considerably simplifies the problem, because we no longer need to work with complex surface forms. The sentence representation generated based on stems provides the decoder with high-level source-side information. While it could steer the decoder toward potentially correct target tokens, the decoder needs more than this to generate precise translations. Accordingly, stem information is accompanied with auxiliary information supplied by the affix channel.

There are two main motivations underpinning this type of modelling. We can have different words on the target side (morphologically naive) which could be translations of a single stem. The reason they differ from one another and appear in different forms is because the source-side stem collocates with different affixes. By having different input channels we can model these combinations to help the decoder with the generation of the translation. The double-channel encoder can understand such combinations better, as it separately processes the stem and its affixes. This is the first motivation for our design. Moreover, the neural model is not totally able to extract all information preserved in MCWs when it works with surface forms, but we can simplify the process by explicitly showing subword units to the network, which is a novel point in our architecture. This is the second reason why we process stems and affixes separately.

3.1 The Double-Channel Architecture

Our neural model is an extension to the encoder-decoder model of Cho et al. (2014) with some fundamental changes. In our architecture, given an input sequence $w_1, w_2, ..., w_n$, words are segmented into their stems (ς) and affix tokens (τ). Regarding the structure of the input data, our encoder should process two tokens (stem and affix) instead of one (word) at each time step, so the neural architecture is adapted to the new data structure. To this end, we have two encoders where the stem encoder reads stems one after another and the other one (affix encoder) reads affix tokens. The process can be formulated as in (1):

$$\begin{aligned} s_t &= f(s_{t-1}, \varsigma_t^e) \\ a_t &= f(a_{t-1}, \tau_t^e) \end{aligned} \tag{1}$$

where s_t and a_t are the hidden states of the stem and affix encoders, respectively, at time step t. ς_t^e indicates the embedding of the t-th word's stem, and τ_t^e is the embedding of the affix token for the same

word.

When the final time step is reached for an input sentence of length n, we have two vectors that represent the summary of stem and affix sequences. The decoder should be informed about source-side information to start sampling/generation, for which we place a fully connected layer with a transformation matrix between the encoder and decoder to map both source vectors to the first hidden state of the decoder, as in (2):

$$h_0 = tanh\big(W_{\varsigma\tau}[s_n \bullet a_n]\big) \tag{2}$$

where h_0 is the decoder's hidden state at the beginning, *tanh* applies non-linearity, $W_{\varsigma\tau} \in \mathbb{R}^{(|s_n|+|a_n|)\times|h_0|}$ is the transformation matrix, and $\bullet$ indicates the concatenation operation.

At each time step the decoder samples a token from the target vocabulary. In the simple encoder-decoder model, the decoder conditions the prediction on its hidden state h_t, the last predicted token y_{t-1}, and a dedicated context vector $\mathbf{c}_t$ generated by the attention mechanism (Bahdanau et al., 2014) over the encoder's hidden states. In our case, we have two sets of source-side hidden states and the decoder pays attention to both (instead of one). This process is simply formulated as in (3):

$$y_t = g(h_t, y_{t-1}, \mathbf{c}_t^{\varsigma}, \mathbf{c}_t^{\tau}) \tag{3}$$

Our decoder benefits from a double-attentive mechanism instead of the simple attention model. $\mathbf{c}_t^{\varsigma}$ is the stem-based context vector and provides information about source stems, and $\mathbf{c}_t^{\tau}$ is the affix context vector which informs the decoder about morphological properties of the input sequence.

In order to construct the stem-based context vector $\mathbf{c}_t^{\varsigma}$, we use exactly the same attention model proposed by Bahdanau et al. (2014), as in (4):

$$\begin{aligned} \mathbf{c}_t^{\varsigma} &= \sum_{t'=1}^{n} \alpha_{tt'} s_{t'} \\ \alpha_{tt'} &= \frac{\exp(e_{tt'}^{\varsigma})}{\sum_{k=1}^{n} \exp(e_{tk}^{\varsigma})} \\ e_{tt'}^{\varsigma} &= \mathbf{a}_{\varsigma}(s_{t'}, h_{t-1}) \end{aligned} \tag{4}$$

where $\mathbf{a}_{\varsigma}$ is a simple feed-forward connection. The equation shows that the decoder tries to select relevant stems at each time step which can help it sample better tokens. $\mathbf{c}_t^{\varsigma}$ summarizes all source stems and informs the decoder about the impact of each stem. For the affix context vector, the attention model has a slightly different mechanism whose detail is shown in (5):

$$\begin{aligned} \mathbf{c}_t^{\tau} &= \sum_{j=t'}^{n} \beta_{tt'} a_{t'} \\ \beta_{tt'} &= \frac{\exp(e_{tt'}^{\tau})}{\sum_{k=1}^{n} \exp(e_{tk}^{\tau})} \\ e_{tt'}^{\tau} &= \mathbf{a}_{\tau}(a_{t'}, [h_{t-1} \bullet \mathbf{c}_t^{\varsigma}]) \end{aligned} \tag{5}$$

Affix tokens are weighted given the hidden state of the decoder together with the stem context vector. We know that affixes associate with their stems, so to select the best affix we need to consider both the impact of stems and the decoder's information. Experimental results show that this combination obtains better performance (see Section 4). Figures 1 and 2 visualize our double-attentive attention module. They provide a comparison between simple and double-attentive attention models. It should be noted that for simplicity our figures only show connections associated with the attention module (and exclude others).

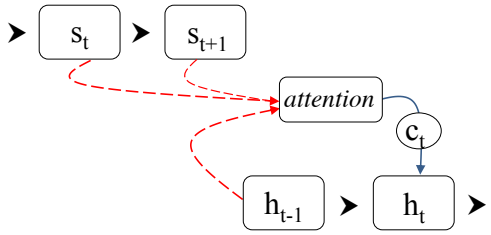

Figure 1: This figure shows the original attention mechanism where the source side-encoder consumes one word at each time step and updates its hidden state s_t. The decoder constructs the context vector $\mathbf{c}_t$ based on the decoder's previous hidden state and all source-side hidden states. The context vector is used along with the (current) hidden state h_t to generate the output.

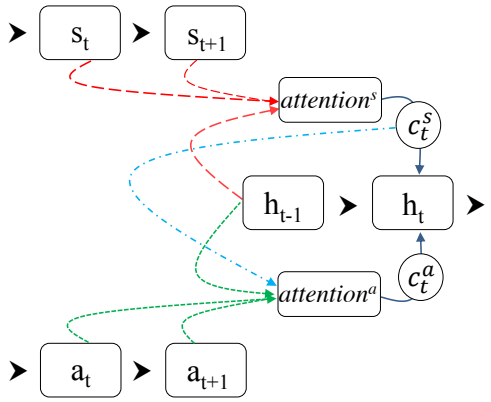

Figure 2: This figure illustrates the double-source encoder, where the stem encoder takes one stem at each time step and updates s_t, and the affix encoder updates a_t after consuming the t-th affix token. The stem-based context vector is depicted by $\boldsymbol{c}_t^s$. The affix-based context vector is constructed using information provided by all of the affix-encoder's hidden states, the decoder's previous hidden state, and the stem context vector.

4 Experimental Study

Our NMT model is an encoder-decoder model with gated recurrent units (GRUs) (Cho et al., 2014). On the encoder side we have two encoders, one for stems and the other for affix tokens. Both encoders include two GRU layers where the first layer is a bidirectional layer and the second layer is a unidirectional layer. Stems and affix tokens are represented with 512-dimensional embeddings. On the decoder side, we have the double-attentive attention module and two GRU layers. The GRU size for both the encoder and decoder is 1024. Similar to input tokens, target tokens are also represented with 512-dimensional embeddings. The network was trained using stochastic gradient descent with Adam (Kingma and Ba, 2015). The mini-batch size is 80, the beam search width is 20, and the norm of the gradient is clipped with the threshold 1.0.

4.1 Data Preparation

Our models are trained to translate from German (De), Russian (Ru), and Turkish (Tr) into English (En). For German and Russian, we used `WMT-15` datasets,[2] where the De–En corpus includes 4.5M parallel sentences and the size of the Ru–En corpus is 2.1M. The `newstest-2013` and `newstest-2015` datasets are used as the development and test sets, respectively. For Tr–En, we used the `OpenSubtitle2016` collection (Lison and Tiedemann, 2016).[3] We randomly selected 3K sentences for each of the development and test sets, and 4M for training.

	English–German		English–Russian		English–Turkish	
	En	**De**	**En**	**Ru**	**En**	**Tr**
Sentence	4.2M		2.1M		4.0M	
Token	103,692,553	96,235,845	43,944,989	39,694,475	24,875,286	17,915,076
Type	103,574	143,329	70,376	119,258	108,699	178,672
Stem	21,223	26,301	15,964	19,557	15,714	17,419
Affix	13,410	24,054	9,320	17,542	7,112	8,041
Prefix	3,104	5,208	2,959	3,324	1,211	753
Suffix	3,285	4,974	2,219	3,460	1,766	2,701
Char	355	302	360	323	189	231

Table 1: *Sentence* is the number of parallel sentences in the corpus. *Token* is the number of words. *Type* shows the number of unique words. *Stem*, *Prefix*, *Suffix*, and *Affix* show the number of unique stems, prefixes, suffixes, and affix tokens in the corpus. *Char* is the number of unique characters appeared in the corpus.

We segment input words with Morfessor. The longest subunit is selected as the stem. What appears before the stem is the prefix and what follows the stem is considered as the suffix. We do not postprocess Morfessor's output, e.g. Turkish is a suffix-based language with no prefixes, but Morfessor extracted some prefixes for this language. We use segmented units as they are and do not change them. Table 1 summarizes some statistics about our training corpora.

It is clear what the stem encoder takes as its input, but for a word we may have none (null), one or many prefixes and suffixes, whose combination constructs the affix token in our setting. For the affix encoder we have a look-up table which includes prefix and suffix embeddings. The encoder retrieves associated prefix and suffix embeddings at each time step, combines them (via vector summation) and sends the combined vector to the encoder. This architecture is referred to as *pre+suf* in our experiments. If a word has more than one prefix/suffix the encoder retrieves all of them, and if it has none the encoder uses a *null* embedding.

In the *pre+suf* setting, what the affix encoder receives as its input is a vector which has some information about morphological properties of the associated stem (word), but it is possible to provide the encoder with richer information, so we propose the *affix* extensions (*affix*-$\mathbf{c}^\tau$ and *affix*-$\mathbf{c}^\varsigma\mathbf{c}^\tau$).[4] In this new setting we combine the surface form of all prefixes and suffixes to generate a new affix token, e.g if $word_i = prefix_i^1.stem_i.suffix_i^1.suffix_i^2$, the affix token τ_i would be $prefix_i^1.suffix_i^1.suffix_i^2$. We assign a unique embedding for this new combination. Clearly, the embedding of the new affix token is different from the summation of the embeddings of the prefix(es) and suffix(es) and introduces a new token.

A real example can show the difference between the *pre+suf* and *affix* extensions. If the given word is *pre.process.ing*, in the first extension *pre+suf*, the stem encoder takes the embedding of *process* and the affix encoder takes the summation of the embeddings of *pre* and *ing*. In the second extension (either *affix*-$\mathbf{c}^\tau$ or *affix*-$\mathbf{c}^\varsigma\mathbf{c}^\tau$), the stem token is the same but the affix encoder takes an embedding which is exclusively defined for *pre.ing*.

The embedding of the affix token is a new unit which preserves information about: i) morphological properties of its associated word, ii) morphological properties of other words appearing in the sentence, and iii) the collocation and order of different prefixes and suffixes, at the word and sentence level. It seems that the simple combination of prefix and suffix embeddings as in the *pre+suf* extension cannot preserve this amount of information, because the role of each suffix/prefix is clear and their summation will provide us with specific information, while in the second extension we can expect the neural network to learn our desired information. Basically, by defining the affix token we try to introduce an additional cell of memory, in which the NMT model and the affix encoder store the useful information it has learned

[4]In these two extensions everything is the same but the attention mechanism. Equations (5) and (6) explain the attention mechanisms for *affix*-$\mathbf{c}^\varsigma\mathbf{c}^\tau$ and *affix*-$\mathbf{c}^\tau$, respectively.

(in addition to stem).

4.2 Experimental Results

The results obtained from our experiments are reported in Table 2. The numbers in the table are BLEU scores (Papineni et al., 2002) of different neural models. We compare our models to all existing models which translate from MRLs or reported experimental results on our datasets. The first row of the table shows an encoder-decoder model where the decoder works at the character level and uses the architecture proposed in Chung et al. (2016). The first row can be considered as a baseline for all other models reported in the table, as it does not use any complicated neural architecture on the source side. For each word it simply sums stem, prefix, and suffix embeddings together and sends the summed vector as the word-level representation to the GRU-based encoder. Although the model is quite simple, it is able to generate comparable results to other more complex architectures, which reinforces our claim that existing neural architectures are not suitable to work at the subword level. If we find a better way to provide the neural model with subword information, we will be able to improve translation quality still further. For all other models we use the same neural architecture where we keep the character-based decoder unchanged and only change the encoder to compare the capacity of different encoders in modeling morphological information.

Model	Source	Target	De→En	Ru→En	Tr→En
Baseline	ς+*pre*+*suf*	*char*	22.11	22.79	22.98
Costa-jussà and Fonollosa (2016)	*word*	*word*	18.83	-	-
	char	*word*	21.40	-	-
Firat et al. (2016)	*bpe*	*bpe*	24.00	22.44	-
Lee et al. (2017)	*bpe*	*char*	25.27	22.83	-
	char	*char*	25.83*	22.73	-
Sennrich and Haddow (2016)$\star$	$\varsigma \bullet \tau$	*char*	22.41	23.01*	23.14*
Our model					
pre+*suf*	$[\varsigma]^1$ [*pre*+*suf*]^2	*char*	26.11	22.95	23.62
affix-$\mathbf{c}^{\varsigma}\mathbf{c}^{\tau}$	$[\varsigma]^1$ $[\tau]^2$	*char*	**26.74**	**23.44**	**23.81**
affix-$\mathbf{c}^{\tau}$	$[\varsigma]^1$ $[\tau]^2$	*char*	26.29	23.40	23.74

Table 2: Source and Target indicate the data type for the encoder and decoder, respectively. ς is the stem, pre is the prefix and suf is the suffix. τ is the affix token. The bold-faced score is the best score for the direction and the score with * shows the best performance reported by other existing models. According to paired bootstrap re-sampling (Koehn, 2004) with $p = 0.05$, the bold-faced number is significantly better than the score with *. Brackets show different channels and the + mark indicates the summation, e.g. $[\varsigma]^1$ [*pre*+*suf*]^2 means the first channel takes a stem at each step and the second channel takes the summation of the prefix and suffix of the associated stem. $\bullet$ is the concatenation operation and $\star$ indicates that results were produced in our experimental setting using our re-implementation of the original model.

The second row shows the model proposed by Costa-jussà and Fonollosa (2016), in which a complicated convolutional module is used to model the relation between characters and build the word-level representation. It shows that the character-level modeling works better than the word-level model but the simple baseline engine still outperforms both settings. The third row belongs to Firat et al. (2016) which is a multi-way multilingual NMT model. The fourth row shows a fully character-level NMT model (Lee et al., 2017) where both the encoder and decoder are designed based on characters. As previously discussed, this model has quite a complicated architecture.

The fifth row reports results from the model of Sennrich and Haddow (2016) that is a suitable model to cope with the problem of complex structures on the source side. The idea behind the model is to enrich input words via additional annotations such as part-of-speech and/or morphological tags. The embedding of the additional annotation(s) is concatenated to the embedding of the word/stem. The idea of attaching

auxiliary information to words/stems was successful and our experimental results also confirm this. In their original model the training data is tagged with external tools which show the need for annotated training sets. We borrowed the same idea and tried to evaluate that architecture in our setting. In the original model, proper morphological tags are defined for input words/stems whereas in our case we consider the affix token as the morphological tag of each stem and we do not need a morphological tagger. The embedding of the affix token is concatenated to the stem embedding and sent to the encoder. Accordingly, the NMT engine is an extension to the baseline model in which the encoder is fed by concatenated structures and the decoder still has the same character-based architecture. This simple concatenation provides better results than the summation applied in the baseline model, which approves affix and subword level information is useful but we only need to find an optimal way to explore it.

The last block shows 3 variations of our model. In the *pre+suf* model the encoder has two encoding channels, one for stems and the other for prefixes and suffixes. At each time step, the stem encoder takes one stem embedding. On the other channel, the affix encoder takes an embedding which is the summation of the prefix and suffix embeddings of the word whose stem is processed by the stem encoder at the same time step. *pre+suf* employs our novel double-attentive attention mechanism. This new architecture enables the NMT engine to perform better than the complicated fully character-based model, which is an indication that the character-level representation does not necessarily provide a better representation. We think that our model outperforms the character-based model because its architecture is more compatible with the nature of MRLs. The impact of the compatible neural architecture becomes more important when we compare the baseline and *pre+suf* models. The input format is exactly the same for both, but the baseline model simply sums stem, prefix, and suffix embeddings, whereas *pre+suf* has two separate channels to process stem and affix information.

The *affix*-$\mathbf{c}^{\varsigma}\mathbf{c}^{\tau}$ variation is the best model among our double-channel models. As previously discussed, assigning a unique embedding to the combination of prefixes and suffixes instead of summing their embeddings generates better results and provides richer information.

The third and last variation, *affix*-$\mathbf{c}^{\tau}$, shows the impact of our architecture on the decoder side. As we modeled in Equation (5), attention weights assigned to the affix-encoder's hidden states are computed based on the decoder's hidden state and the stem context vector. As affix tokens provide complementary information to stem information, the affix context vector should be aware of the content of the stem context vector, so we proposed the model explained in Equation (5). If we only consider the decoder's information to compute affix weights, the equation will be revised as in (6):

$$\begin{aligned} \mathbf{c}_t^{\tau} &= \sum_{j=t'}^{n} \beta_{tt'} a_{t'} \\ \beta_{tt'} &= \frac{\exp(e_{tt'}^{\tau})}{\sum_{k=1}^{n} \exp(e_{tk}^{\tau})} \\ e_{tt'}^{\tau} &= \mathbf{a}_{\tau}(a_{t'}, h_{t-1}) \end{aligned} \tag{6}$$

In the *affix*-$\mathbf{c}^{\varsigma}\mathbf{c}^{\tau}$ version, the energy between the decoder's (t-1)-th state and the affix-encoder's t'-th state was computed by $e_{tt'}^{\tau} = \mathbf{a}_{\tau}(a_{t'}, [h_{t-1} \bullet \mathbf{c}_t^{\varsigma}])$, whereas this version simplifies the computation by estimating $e_{tt'}^{\tau}$ with $\mathbf{a}_{\tau}(a_{t'}, h_{t-1})$. The model described in Equation (6) is implemented in the *affix*-$\mathbf{c}^{\tau}$ extension. Results obtained from this extension show that, although the architecture is also successful compared to other exiting models, its performance is worse than the model which (additionally) involves the stem context vector to compute affix weights.

5 Conclusion and Future Work

In this paper we focused on morphological complexities on the source side in the NMT task and equipped the encoder to handle complex inputs. The proposed model includes two separate channels to consume both stem and affix tokens. This novel two-channel solution can improve performance in two ways, which can be discussed from linguistic and computational perspectives. In terms of linguistic issues,

when the first channel deals with stems instead of words, it is asked to process considerably fewer constituents as the number of stems are much fewer than the number of words. The network is trained to translate simple stem forms instead of complex words. This simplification is usually helpful when translating (from/into) MRLs (Sennrich and Haddow, 2016). Furthermore, there is another channel which preserves morphological information. Every time that the first channel is not able to provide precise translations or needs auxiliary information, the second channel completes it with morphological information.

The proposed architecture can also be studied from mathematical and computational points of view. Defining a secondary channel means adding extra neural modules and parameters (weights). Increasing the number of neural parameters increases the learning capacity of the network and gives a higher possibility to achieve better results. Experimental results confirm that this happens in practice and the extra channel is helpful.

Existing subword-based models segment MCWs using Morfessor, *bpe*, and other models, and feed the translation engine with simplified units. Character-based models also try to facilitate the process by working with characters. Both approaches are useful and improve performance but the improvement is somewhat random, as we do not exactly know what/where the origin of this improvement is. By proposing our double-channel architecture we address this problem and feed the network in a more structured way, in the expectation that we can represent the impact of morphological information. While we are still far from the goal of modeling morphological information for NMT, this research is an important step toward our goal.

Along with these useful properties of our approach, it also has some deficiencies which we plan to address in future work. Our affix information is extracted via Morfessor which could be noisy. Affix tokens are supposed to provide morphological information but we are not sure that our interpretation matches what actually happens in reality. According to experimental results, affix tokens are useful but we are not sure if they preserve real morphological information. In our future work we plan to linguistically enrich our pipeline with more precise and relevant information. As another plan, we also tend to focus on the decoder.

Abstract

Predicting Machine Translation (MT) quality can help in many practical tasks such as MT post-editing. The performance of Quality Estimation (QE) methods has drastically improved recently with the introduction of neural approaches to the problem. However, thus far neural approaches have only been designed for word and sentence-level prediction. We present a neural framework that is able to accommodate neural QE approaches at these fine-grained levels and generalize them to the level of documents. We test the framework with two sentence-level neural QE approaches: a state of the art approach that requires extensive pre-training, and a new light-weight approach that we propose, which employs basic encoders. Our approach is significantly faster and yields performance improvements for a range of document-level quality estimation tasks. To our knowledge, this is the first neural architecture for document-level QE. In addition, for the first time we apply QE models to the output of both statistical and neural MT systems for a series of European languages and highlight the new challenges resulting from the use of neural MT.

1 Introduction

Quality Estimation (QE) (Blatz et al., 2004; Specia et al., 2009) aims at predicting the quality of machine translation (MT) without human intervention. Most recent work has focused on QE to predict sentence-level post-editing (PE) effort, i.e. the process of manually correcting MT output to achieve publishable quality (Bojar et al., 2014; Bojar et al., 2015; Bojar et al., 2016a; Bojar et al., 2017). In this case, QE indicates to what extent a MT sentence needs post-editing. Document-level QE, on the other hand, scores or ranks documents according to their quality for fully automated MT usage scenarios where no post-editing can be performed, e.g. MT for gisting of news articles online.

Recently, neural methods have been successfully exploited to improve QE performance. These methods mostly rely on either complex architectures, require extensive pre-training, or need some feature engineering (Patel and M, 2016; Kim et al., 2017a; Martins et al., 2017a; Jhaveri et al., 2018). In addition, these methods have only been developed for word, phrase and sentence-level QE. These cannot be directly used for document-level QE since this level requires to take into account the content of the document in its entirety. State-of-the-art document-level QE solutions still rely on non-neural methods, and extensive feature engineering (Scarton et al., 2016).

In this paper we propose a neural framework that is able to accommodate any QE approach at a fine-grained level (e.g. a sentence-level approach), and to generalize it to learn document-level QE models. We test the framework using a state of the art neural sentence-level QE approach (Kim et al., 2017b), which uses a complex architecture and requires resource-intensive pre-training, and a light-weight neural approach employing simple encoders and no pre-training. Our sentence-level prediction approach leads to comparable or better results than the state of the art at a much lower cost. Additionally, the document-level framework improves over previous work by a large margin. To our knowledge, this is the first attempt at document-level QE using purely neural methods.

Proceedings of the 27th International Conference on Computational Linguistics, pages 3146–3157
Santa Fe, New Mexico, USA, August 20-26, 2018.

The majority of existing QE solutions for all prediction levels have been designed and tested for Statistical MT (SMT). Popular features extracted from SMT translation models are clearly no longer applicable to neural MT (NMT), while MT system-independent features, such as target language model probabilities, are likely to be less effective. For the first time, we experiment with sentence and document-level QE methods on the output of both SMT and NMT, for a series of European languages. We show that the main challenge for QE of high-quality NMT lies in detecting errors in otherwise generally fluent text. We focus on the estimation of MT quality for news texts, a type of text where gisting is seen as a popular use of MT.

We start by discussing related work in Section 2. We present our light-weight hierarchical neural QE architecture in Section 3. We then introduce our experimental settings in Section 4. We provide the results of state of the art sentence-level methods in Section 4.1 and of the proposed document-level framework in Section 4.2.

2 Related work

QE targets the prediction of MT quality in the absence of reference translations. Given a set of training examples labelled for quality, their features extracted from source units and their corresponding MT units (black-box, system-independent), optionally complemented with features related to the translation process itself (glass-box, system-dependent), a QE model can be trained to predict a score for unseen MT units. Various types of units are possible: documents, paragraphs, sentences, words and phrases have been studied in previous work to different extents. Most work has focused on sentence or word-level prediction, which have clear application in dissemination scenarios, such as MT followed by post-editing. Document-level QE, which is applicable in assimilation (i.e. gisting) scenarios, has received much less attention.

Recently, neural methods have been successfully exploited to improve QE performance. The best-performing system at the WMT 2017 shared task on QE (Bojar et al., 2017) for the three levels of prediction (word, phrase and sentence), namely `POSTECH`, is purely neural and does not rely on feature engineering (Kim et al., 2017b). `POSTECH` is a modular architecture that revolves around an encoder-decoder Recurrent Neural Network (RNN) (so-called predictor), stacked with an bidirectional RNN (so-called estimator) that produces quality estimates. It predicts quality using the weights assigned by the predictor to the words we seek to evaluate, which are concatenated with the representations of their left and right one-word contexts, and then used to feed the estimator. To perform multi-level predictions, `POSTECH` relies on a multi-task learning approach which makes the quality estimates, for different levels of prediction, interdependent. The highest level of quality labels reported by the `POSTECH` system at WMT 2017 was sentence-level. Note that, to be effective, this architecture has to be pre-trained using a significant amount of parallel data, which leads to high training requirements in terms of time, processing power and dataset size.

Jhaveri et al. (2018) propose a series of neural models for sentence-level QE by simplifying and extending the `POSTECH` architecture (e.g. they skip the Predictor step, use convolutional encoders or an additional attention mechanism). We propose an alternative RNN-based simplification of `POSTECH`.

Another well performing system in the WMT shared QE task, Unbabel (Martins et al., 2017a; Martins et al., 2017b), also uses an encoder-decoder architecture with bidirectional RNN layers as part of its stacked architecture. It follows a hybrid approach where the input to this encoder-decoder is a pre-extracted feature set: pre-trained word and part-of-speech embeddings, word alignments and contexts. The system was designed for word and sentence QE.

State-of-the-art QE solutions specifically designed for document-level prediction employ traditional machine learning algorithms with non-linear kernels, such as Support Vector Machines (Cortes and Vapnik, 1995) and Gaussian Process (Rasmussen and Williams, 2005). Standard sets of document-level features are largely inspired by sentence-level features (Bojar et al., 2016a). Additionally, various discourse and neural-based features have been explored (Scarton et al., 2016).

Document-level QE is traditionally framed as averaging over sentence-level QE (Scarton et al., 2016). Sentence-level architectures consider each sentence separately; at the document level the entirety of

sentences in the document and the importance of each of these sentences should be taken into account. While the first problem can be addressed by, for instance, merging all sentences in a document and reusing a sentence-level QE system, the second problem requires considering every sentence separately yet as a part of the document, which requires a different QE architecture.

In this work we take advantage of the ability of neural networks to capture hierarchical structures, and propose a neural framework able to generalize over any sentence-level QE approach to produce document-level QE models. We test the framework using the state of the art neural sentence-level QE approach of Kim et al. (2017b), and a low-cost neural approach employing simple encoders, which we propose.

To our knowledge, the only attempt to shed some light on QE for NMT output is that by Rikters and Fishel (2017). They use attention mechanism distributions as an indicator the confidence of the neural decoder on its output at word-level. The hypothesis is that "good" translations can be characterized by strongly focused attention connections. However, this internal information has not been proved to map directly into translation quality: a very weak correlation with human judgements in a small-scale assessment was reported. Therefore, this is the first time that experiments are performed with fully fledged, MT system-independent QE models for NMT.

3 A neural-based architecture for QE

Our framework performs multi-level translation quality prediction, which has been shown to be successful in both traditional feature-engineered QE frameworks, such as QuEst++ (Specia et al., 2015), and neural QE architectures (Kim et al., 2017a; Martins et al., 2017a). In such architectures, the representations at a given level rely on representations from more fine-grained levels (i.e. sentences for document, and words for sentence).

This is motivated by the nature of the task at hand: a document that is composed of high quality sentences is likely to have high quality as well. However, simply aggregating sentence-level predictions is not a good strategy, as a document needs to be cohesive and coherent as a whole, i.e. sentences cannot be considered completely in isolation, and thus the need of a multi-level architecture that is trained jointly arises. Another important feature of document-level prediction is that certain parts of a document may be more important than others, such sentences containing keywords in a news article, versus sentences containing background information. Therefore one should also attempt to assess whether those sentences in particular are translated accurately. We do so by using different sentence-level weighting schemes for labelling documents, and by relying on an attention mechanism.

In what follows, we will first present the two sentence-level architectures we employ to then introduce our document-level framework.

3.1 Sentence-level architectures

The encoder-decoder approach (Sutskever et al., 2014; Bahdanau et al., 2015) provides a general architecture for sequence-to-sequence prediction problems. This approach has become very popular in many applications where inputs and outputs are sequential, such as MT. In this approach, an input sequence is encoded into an internal representation, and then an output sequence is generated left to right from this representation. Current best practices implement encoder-decoder approaches using RNNs, which handle inputs as a sequence (here a sequence of words), while taking previous words into account. We consider two different architectures, both based on the RNN encoder-decoder approach:

POSTECH We reimplement[1] the neural-based architecture for multi-level prediction by Kim et al. (2017a; Kim et al. (2017b), the best performing system at the WMT 2017 shared task on QE. This architecture is a two-stage end-to-end stacked neural QE model that combines (a) a *predictor* step, an encoder-decoder RNN model to predict words based on their context representations; and (b) an *estimator* step, a bidirectional RNN model to produce quality estimates for words, phrases and sentences based

[1]No code was originally available; our implementation is based on the NMT-Keras framework (Peris, 2017), and the Keras tool (Chollet and others, 2015). The code is publicly available online: `https://github.com/sheffieldnlp/deepQuest`.

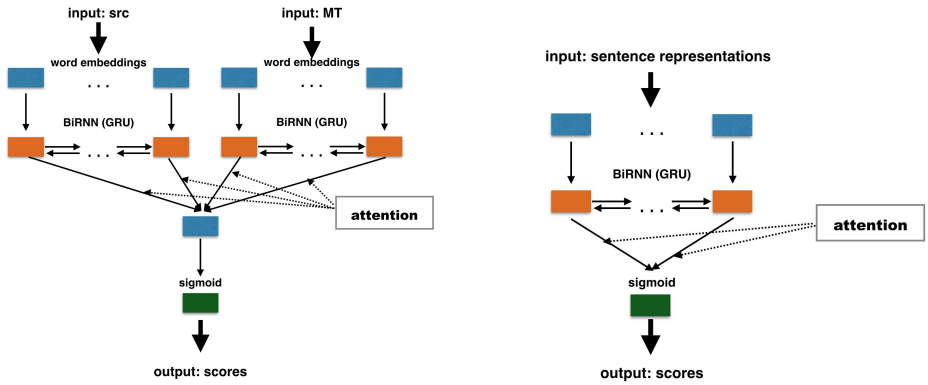

Figure 1: deepQuest framework. Left: the proposed sentence-level QE architecture: hidden states of source and MT encoders are concatenated and an attention mechanism over words is applied. Right: our document-level QE architecture: sentence representations are given to a bi-RNN and an attention mechanism over outputs of this RNN is applied to weight sentences according to their importance to the document.

on representations from the predictor. `POSTECH` requires extensive predictor pre-training to be effective, which means dependence on large parallel data and computational resources.

`BI-RNN` `BI-RNN` uses only two bi-directional RNNs (bi-RNN) as encoders to learn the representation of the (source, MT) sentence pair. A bi-RNN typically calculates a forward sequence of hidden states $(\overrightarrow{h}_1, ..., \overrightarrow{h}_J)$, and a backward sequence of hidden states $(\overleftarrow{h}_1, ..., \overleftarrow{h}_J)$. The hidden states $\overrightarrow{h}_j$ and $\overleftarrow{h}_j$ are concatenated to obtain the resulting representation h_j. In our approach, source and MT bi-RNNs are trained independently, as illustrated in Figure 1 (left side). The two representations are then combined via concatenation. However, sentence-level QE scores are not simple aggregations of word-level representations: they reflect some importance of words within a sentence. Thus, weights should be applied to those representations. Such weighting is provided by the attention mechanism. We apply the following attention function computing a normalized weight for each hidden state h_j:

$$\alpha_j = \frac{\exp(W_a h_j^\top)}{\sum_{k=1}^{J} \exp(W_a h_k^\top)}. \quad (1)$$

The resulting sentence vector is thus a weighted sum of word vectors: $v = \sum_{j=1}^{J} \alpha_j h_j$. A `sigmoid` output layer takes this vector as input and produces real-value quality scores.[2]

3.2 Document-level architecture

Our document-level framework uses a bi-RNN encoder. RNNs have been successfully used for document representation (Lin et al., 2015) and applied to a series of downstream tasks such as topic labeling, summarization, and question answering (Li et al., 2015; Yang et al., 2016).

The document-level quality predictor takes as input a set of sentence-level representations. The last hidden state of the decoder is the summary of an entire sequence. The sum, the maximum, or the average of hidden states for each sentence can then be provided to the output layer. Our assumption is that document-level QE scores are not a simple aggregations of sentence-level QE scores: they should reflect some notion of the importance of sentences within a document. To do so, we use an attention mechanism (Equation 1) to learn weights of different representations (different sentences). The weighted sum of the sentence representations is provided to the `sigmoid` output layer. This `sigmoid` output layer produces real-value predictions for a document, as illustrated in Figure 1 (right side).

[2]Note that Jhaveri et al. (2018) also propose an RNN-based QE architecture. However, following traditional NMT design, the attention mechanism is applied to the source encoder outputs, whereas we apply it to the outputs of both source and MT encoders.

4 Evaluation

In what follows, we first assess the performance of the sentence-level prediction approaches (Section 4.1), then move to the more coarse-grained level of predicting quality for documents (Section 4.2).

4.1 Sentence-level predictions

In this section we analyse the performance of our two sentence-level architectures against official baselines of the WMT 2017 QE shared task. We use the QE dataset in (Specia et al., 2017), which i) is a superset of the official dataset for the WMT 2017 QE task and for which the POSTECH architecture has been developed, allowing us to validate our reimplementation; ii) contains translations from neural MT systems. We also report results using the official evaluation metrics of the shared task: Pearson ρ correlation (primary) and Mean Average Error (MAE) (secondary).

Data The QE dataset contains 28,000 English-German (EN–DE) translations (IT domain) and 18,768 English-Latvian (EN–LV) translations (Life Science domain), produced with either a statistical MT (SMT), or an NMT system.

We randomly split the data for each language pair into training set (25K sentences for EN–DE, 16K for EN–LV), development set (1K sentences) and test (2K sentences) set.[3] In line with the WMT QE campaigns, data labelling was performed as described in (Bojar et al., 2017) using the TERCOM toolkit:[4] for sentence-level QE, with edit distance scores (HTER) used as labels.

To train POSTECH's predictor:[5] we used the Europarl corpus (Koehn, 2005) ($\approx$ 2M sentences; the version provided by Tiedemann (2012)) for EN–DE, and the parallel data of the WMT 2017 News translation task ($\approx$ 2M sentences) for EN–LV. Each experiment was run five times on the same split to estimate the stability of the model.

Baseline system: We reproduced the WMT 2017 baselines as described in (Bojar et al., 2017). For the extraction of the sentence-level features for EN–DE, we used the additional resources provided by the WMT 2017 QE shared task. For EN–LV, the corresponding resources were created using the data provided for the WMT 2017 News translation task, and the EMEA corpus (Tiedemann, 2009).

Implementation details: We implemented the sentence-level architectures using the Keras toolkit with Gated Recurrent Units (GRUs) (Cho et al., 2014) as RNNs, and the following hyperparameters: word embedding dimensionality = 300, vocabulary size = 30K, size of the hidden units of the encoder = 50. The model was trained to minimize the mean squared error loss using the Adadelta optimizer (Zeiler, 2012).

Results The results of our experiments are reported in Table 1. In general, different runs of the models do not lead to much variation in the performance. For EN–DE, a first observation is the major improvement in NMT quality compared to SMT (HTER = 0.09 vs. HTER = 0.24), which results in highly imbalanced NMT datasets (for EN–DE, $\approx$54% of all the sentences have 0 HTER vs. $\approx$13% for SMT). For EN–LV, the quality of NMT, limited by the amount of training data, is worse than SMT (HTER = 0.15 vs. HTER = 0.23).

These results show that the performance of baseline methods depends on the quality of translations rather than on the type of system that produced them. The baseline EN–DE methods achieve ρ scores that are 60% worse for NMT translations, as compared to SMT translation. For EN–LV, the behavior is the opposite: the performance is 45% better for NMT translations, as compared to SMT translations.

The performance of POSTECH is on average 40% higher for SMT than for NMT (e.g. for EN–LV, ρ=0.39 for SMT vs. ρ=0.24 for NMT). For EN–DE systems, this can be attributed to the data imbalance. For EN–LV systems, this could be because the neural QE system has difficulty to handle the many very

[3] As only part of the EN–DE SMT data was used for the WMT 2017 QE task, we could not use the task's official split.

[4] http://www.cs.umd.edu/~snover/tercom

[5] Hyperparameters size of hidden units of the word predictor = 500, word embedding dimensionality = 300, vocabulary size = 30K, QE vector size = 75.

long sentences produced by the EN–LV NMT ($\sigma^2 = 92$ of the distribution of the sentence length values for NMT vs. $\sigma^2 = 73$ for SMT).

For NMT the difference in variance of predicted HTER scores between language pairs is relatively high (as reflected in MAE differences between language pairs for neural methods, e.g., for POSTECH $\Delta = 0.084$), whereas for SMT this difference is lower (for POSTECH MAE $\Delta = 0.002$).

In general, without pre-training POSTECH does not perform better than the baseline methods (e.g. for EN–DE SMT, ρ=0.313 for the baseline vs. ρ=0.324 for POSTECH) and is systematically outperformed by BI-RNN (average $\Delta\rho$=0.06). This difference is statistically significant for both language pairs.[6] We believe that BI-RNN is able to better capture the fluency of NMT by encoding it directly as a sequence rather than assessing it word for word as POSTECH.

	EN–DE		**EN–LV**	
model	ρ	MAE	ρ	MAE
Baseline				
SMT	0.313 ±0.0	0.147 ±0.0	0.100 ±0.0	0.056 ±0.0
NMT	0.130 ±0.0	0.171 ±0.0	**0.318** ±0.0	0.070 ±0.0
POSTECH (no pre-training)				
SMT	0.324 ±0.015	0.146 ±0.002	0.294 ±0.015	0.136 ±0.002

BI-RNN				
SMT	0.363 ±0.010	0.142 ±0.002	0.357 ±0.004	0.133 ±0.004
NMT	0.311±0.004	0.090 ±0.003	0.231 ±0.012	0.183 ±0.004

Table 1: Performance on sentence-level predictions for the baseline with QuEst, the POSTECH architecture and our BI-RNN architecture for EN–DE and EN–LV (average and error margins over five runs). We highlight the best performing systems for a dataset.

4.2 Document-level predictions

As introduced above, our framework relies on representations at sentence level to produce its predictions at document level. Therefore, we experiment with sentence-level representations from either the POSTECH or our BI-RNN predictor.

The document-level labels we predict are variants of BLEU (Papineni et al., 2002): (i) document-level BLEU,[7] (ii) the weighted average of sentence-level BLEU for all sentences in the document, where the weights correspond to the reference lengths:

$$\text{wBLEU}_d = \frac{\sum_{i=1}^{D} \text{len}(R_i)\text{BLEU}_i}{\sum_{i=1}^{D} \text{len}(R_i)},$$

where BLEU_i is the BLEU score of sentence i, and D is the size of the document in sentences,[8] and (iii), a variant of WBLEU by weighting each sentence by its TFIDF score computed with regard to its aligned reference (TBLEU). The numerator in the WBLEU equation is therefore replaced by: $\sum_{i=1}^{D} \text{TFIDF}_i\text{BLEU}_i$. Here, for each news document, we learn a TFIDF model on its reference in the target language, and compute the TFIDF score for each translated sentence, based on that model.

[6] We performed Kolmogorov–Smirnov test for not normally distributed data.

[7] We compute BLEU scores with the NLP toolkit NLTK (Bird and Loper, 2004). For scoring documents, we used the corpus_bleu() function. For sentence-level scores we used the sentence_bleu() function with smoothing method 7.

[8] According to Chen and Cherry (2014), WBLEU achieves a better correlation with human judgement than the original IBM corpus-level BLEU.

Following Turchi et al. (2012), our intuition is that the document-level score should reflect the overall translation quality at sentence level, weighted by how important each individual sentence (important sentences have important words) is in that document.

Data: We gathered all submissions at the WMT News shared tasks for various years. This is a task where each participating system is required to translate a set of news documents.[9] This results in a large set of language pairs, as well as a wide range of different translation quality levels. We collected system submissions from WMT 2008 to 2017, for four language pairs: German-English (DE–EN, 14,640 documents for 2008-2017, excluding 2010),[10] and English–Spanish (EN–ES, 6,733 documents for 2008-2013, excluding 2010[10]), English–French (EN–FR, 11,537 documents for 2008-2014) and English-Russian (EN–RU, 6,996 documents for 2013-2017). For each language pair, we consider either the full set of system submissions, or a filtered version of it (FILT), composed by only both the best and the worst performing systems for each year. The filtering was done based on the overall BLEU score achieved by each system, as reported on `matrix.statmt.org`. Our intuition is that by considering only the extreme quality levels we would make our data, while smaller, easier to discriminate.[11] We note that for all language pairs, MT systems include a variety of approaches, from rules-based MT, to SMT, hybrid approaches, and – from 2016 – NMT approaches. The filtered variants include at least one NMT approach for the language pairs in 2016/2017 (i.e. DE–EN and EN–RU). To support the reproduction of our work, as well as the development of new models for document-level QE, we release this dataset.[12]

Taking the heterogeneity of the data into account (composed of outputs of different systems and runs), to evaluate our models we perform 5-fold cross validation. For each language pair we shuffle the data, and for each fold we split it per year into train, development and test sets, as follows: for the FILT dataset, 10% of the documents per year were randomly selected for the development set, an another 10% for the test set; for ALL, the train data in the quantity equal to the FILT train data was selected randomly (development and test data were fixed, since ALL contains FILT). We present the averaged results. and use Kolmogorov–Smirnov test for not normally distributed data to test significance. As an example, statistics on one of the splits are shown in Table 2. Note that to avoid computation precision issues, we multiply TBLEU scores by 10.

As `POSTECH` training is very expensive, for the contrastive experiments we use only DE–EN and EN–ES. For the experiments with `BI-RNN`, we use all language pairs.

Baseline system: We reproduced the WMT 2016 document-level baseline as described in (Bojar et al., 2016b). We extract 17 black-box features using `QuEst++` (Specia et al., 2015) and train a document-level QE system using the Support Vector Regression (SVR) algorithm available in `scikit-learn` (Pedregosa et al., 2011). The language resources were created using the News Commentary and Europarl corpora as provided by WMT campaigns for the corresponding languages ($\approx$ 2M lines per language pair). These corpora were also used to train `POSTECH` predictors.[13]

For `BI-RNN`, we followed the implementation details as described in Section 4.1. To optimize the usage of computational resources, in each experiment we fixed the size of a document to the upper quartile of the distribution of document length values (in sentences). Shorter documents were extended with dummy sentences to fit to this length, which is a common practice in the field (Hewlett et al., 2017).

Results Results of our experiments are reported in Tables 3 (baseline) and 4 (neural approaches). For both `POSTECH` and `BI-RNN`, we use only the last hidden states of the document decoder (`Last`) – a configuration that has been chosen empirically as the best performing among the configurations without attention, or the vector sum weighted by the attention mechanism (`Att`) as input to the output layer.

[9] We considered using the document-level QE dataset in (Graham et al., 2017), however, the small number of documents (62) and language pairs (only one) made this resource less appealing for this work.

[10] Individual submissions are not available but system combinations only

[11] In (FILT) we have also discarded submissions for years 2008 and 2009, since official system-level scores are not available.

Table 3: Baseline document-level score prediction results for DE–EN and EN-ES. We highlight the best performing systems for a dataset.

A first observation is that the performance of our neural approach varies significantly for different quality labels: the best performance is systematically observed for tBLEU, the worst – for BLEU (e.g. for DE–EN neural models, ρ=0.69 vs. ρ=0.39, on average respectively). This is not true for the baselines where the best performance is observed for other scores depending on the training data used. We attribute the high prediction performance for tBLEU to the fact that our architecture builds document-level representation from sentence-level representations, which in turn depend on word representations. The tBLEU reflects this hierarchy in the most consistent way as those document-level scores depend directly on semantic importance of words they contain. BLEU, on the other hand, depends on n-gram translation quality. MAE is in general the lowest for wBLEU with the lowest variance.

Table 4: Document-level score prediction results for neural approaches for DE–EN, EN–ES, EN–FR, and EN–RU. Last refers to the results after we take the last hidden state of the document-level encoder as input to the output layer; Att – with an attention mechanism. We highlight the best performing systems for a dataset.

The baseline yields poor performance (e.g., for BLEU ρ=0.07 on average across configurations), whereas BI-RNN systematically outperforms POSTECH for all three prediction tasks and across configurations (e.g., for DE–EN $\Delta\rho$=0.08). For DE–EN, this difference is statistically significant, while for EN–ES it is not. We believe this can be explained by lower stability of classifiers trained on the smaller EN–ES dataset.

The best performance improvement is observed for WBLEU, which we believe is because BI-RNN is less "focused" on word-level predictions (e.g., for DE–EN $\Delta\rho$=0.10). Additionally, BI-RNN is about 40 times faster to train than POSTECH.[14]

[14] BI-RNN takes around 20 minutes to train on a 12G GeForce TITAN X NVIDIA GPU with batch size = 10. Pre-training a POSTECH model in the same conditions with around 2M lines of parallel data takes around 12 hours plus the training of the

The contribution of the attention mechanism also depends on the type of quality label, but it is not statistically significant. It can be particularly beneficial for BLEU (for instance, for BI-RNN DE–EN across configurations, $\Delta\rho$=0.10 on average), but particularly harmful for WBLEU (for instance, for BI-RNN EN–RU, a decrease of ρ=0.12 is observed). This can be explained by the influence of variable reference lengths and hence the difficulty to find optimal weights.

The training data filtering procedure is not beneficial for the performance. This procedure is particularly harmful for DE–EN BLEU and WBLEU scores (for BI-RNN, average $\Delta\rho$=0.11), which is the most well represented language pair across WMT years. Thus, it may be the case that the random ALL selection contains more useful data.

Pre-training the predictor for POSTECH is essential for this architecture; for EN–ES BLEU Last, for example, a decrease of up to $\Delta\rho$=0.3 is observed without pre-training.

As for the difficulty of prediction for different language pairs: DE–EN and EN–RU BLEU prediction seems to be the most challenging (for BI-RNN, on average ρ=0.26 and ρ=0.40, respectively). This could be explained by the traditionally lower MT quality for those systems, involving significant word order differences for these language pairs.

5 Conclusions

We have proposed a new approach for neural-based document-level QE that is able to generalize any neural sentence-level architecture to the level of documents. This approach is part of our new framework for QE, named deepQuest, that reimplements the state of the art neural-based architecture to date for sentence-level quality prediction – the POSTECH approach – as well as our light-weight neural architecture relying on bi-directional RNNs. Our experiments have shown that latter outperforms POSTECH when used to predict document-level quality estimates for a range of quality scores and is 40 times faster to train. We also have reported a study of the performance of state of the art QE approaches on NMT output. Neural QE solutions are more efficient for imbalanced QE data, especially high-quality NMT. To our knowledge, this is the first time that results of QE on a large range of NMT data are reported.

In the future, we plan to reproduce our study for other document-level QE scores and text types. We also plan to adapt our light-weight neural architecture for other QE levels (e.g., phrase, paragraph levels). To support future work on these and other directions, we have made deepQuest open-source and freely available: https://github.com/sheffieldnlp/deepQuest.

Abstract

Knowing the state-of-the-art for a particular task is an essential component of any computational linguistics investigation. But can we be truly confident that the current state-of-the-art is indeed the best performing model? In this paper, we study the case of *frame semantic parsing*, a well-established task with multiple shared datasets. We show that in spite of all the care taken to provide a standard evaluation resource, small variations in data processing can have dramatic consequences for ranking parser performance. This leads us to propose an open-source standardized processing pipeline, which can be shared and reused for robust model comparison.

Title and Abstract in French

Effets papillon en analyse automatique de cadres sémantiques:
impact du traitement des données sur la hiérarchie des modèles

Connaître l'état-de-l'art pour une tâche donnée est un élément essentiel de toute entreprise de linguistique computationnelle. Peut-on néanmoins s'assurer que l'état-de-l'art connu est bel et bien le meilleur des modèles ? Dans ces travaux nous nous intéressons au cas de l'analyse automatique de cadres sémantiques, une tâche bien établie disposant de multiples jeux de données partagés. Nous montrons qu'en dépit du soin porté à la standardisation du processus d'évaluation, de faibles variations dans le prétraitement des données peuvent conduire à une remise en question du classement final des analyseurs. Cette constatation nous conduit à proposer une plateforme libre de traitement standardisée permettant d'obtenir des données de comparaisons fiables entre les performances des différents analyseurs.

1 Introduction

A typical contribution to Computational Linguistics research is a new *model* for a specific task, which improves performance on a known dataset. The proposed model, whilst being the object of focus in the associated publication, normally relies on some potentially extensive pre- and post-processing of data which may only be briefly reported. As shown in the seminal work by (Fokkens et al., 2013), small alterations to such processing can result in dramatic changes in model performance. In this paper, we pick up on this point and make a case for harmonizing evaluations by sharing not just datasets but entire experimental pipelines. We illustrate our point by focusing on recent frame semantic parsing literature.

Frame semantic parsing is the task of automatically extracting semantic structures in text following the theory of Frame Semantics (Fillmore, 1982) and the framework of FrameNet (Baker et al., 1998, hereafter FN). Formally defined in the SemEval 2007 shared task 19 (Baker et al., 2007), it consists of three separate subtasks: (1) *target identification*: the task of identifying all frame evoking words in a given sentence; (2) *frame identification*: the task of identifying all frames of pre-identified targets in a given sentence; and (3) *argument identification*: the task of identifying all frame-specific frame

Proceedings of the 27th International Conference on Computational Linguistics, pages 3158–3169
Santa Fe, New Mexico, USA, August 20-26, 2018.

element spans and labels for pre-identified targets in a given sentence. The following sentence provides an example of FN annotation for the predicate *splash*.v evoking the `Cause_fluidic_motion` frame, and its corresponding FLUID, SOURCE and GOAL arguments:

(1) $[\text{Wine}]_{\text{Fluid}}$ was **splashed** $[\text{from jug}]_{\text{Source}}$ $[\text{to cup}]_{\text{Goal}}$ and often drained in one loud gulp.

Thanks to the shared task, the FN community has produced valuable datasets to evaluate models against. Still, as we will show in this paper, the actual evaluation settings used by various research groups exhibit differences which can in some cases have dramatic consequences for the reported results. In particular, all available research on frame semantic parsing relies on some form of pre- and post-processing of FN XML data. Post-processing usually involves converting FN train, dev and test XML splits to standard CONLL-based formats while removing erroneous or problematic annotation. Preprocessing involves part-of-speech tagging *ad minima*, and often lemmatization and dependency parsing as well. We will see that those pre- and post-processing pipelines turn out to be rather inconsistent across published investigations (see §2.2), preventing fair comparison between models. In fact, we demonstrate that when using a cleaned up and standardized pipeline, the ranking of existing parsers can change quite substantially.

The deviations we observe across experimental setups cover various aspects of pre- and post-processing. First, inconsistencies in the post-processing pipeline lead parsers to be actually evaluated on slightly different test sets across studies. Moreover, those test sets contain duplicate sentences and annotations – leading parsers to be scored multiple times on the same data – as well as overlapping data between train and test sets – thereby artificially improving overall scores. Second, inconsistencies in the pre-processing pipeline prevent fair comparison across models by conflating the contribution of the pre-processing toolkit with that of the statistical model itself. We further note that all recent work on frame semantic parsing rely on the FN 1.5 dataset, while the FN 1.7 dataset, available since 2016, contains nearly 20% more gold annotated data, allowing for larger train and test sets and hence more robust baselines.

The goal of this paper is to highlight the impact of small deviations in experimental settings on model performance. Our contributions are fourfold: we (1) replicate past results of frame semantic parsing on a single robust pre- and post-processing pipeline; (2) quantify the impact of the pipeline on model performance; (3) analyze the robustness of past results when tested on a normalized FN 1.7 setup; and (4) provide robust baselines on both FN 1.5 and FN 1.7 experimental setups for future research.

We focus specifically on replicating frame identification results of the SIMPLEFRAMEID system of Hartmann et al. (2017), and argument identification results of the SEMAFOR system of Das et al. (2014), as modified by Kshirsagar et al. (2015), and the OPEN-SESAME system of Swayamdipta et al. (2017). We exclude the FRAMAT system of Roth and Lapata (2015) for brevity, as it uses a different evaluation script on argument identification given gold frames, and we ignore all other contributions (Hermann et al., 2014; Täckström et al., 2015; FitzGerald et al., 2015; Roth, 2016; Yang and Mitchell, 2017) which do not provide open source systems.[1]

Finally, rather than releasing a fixed preprocessed FrameNet dataset like Bauer et al. (2012), we propose an application for testing various frame semantic parsers in custom experimental setups. Our application allows converting FrameNet XML data to various standard NLP formats (such as, e.g., BIO or CoNLL-X) relying on a common architecture which handles data processing side effects observed throughout this work. Preprocessing pipelines can thereby be easily modified while guaranteeing the consistency and robustness of the experimental setups across parsers.

The structure of the paper is as follows: in Section 2, we introduce all past research on frame semantic parsing replicated throughout this work, the statistical models used, as well as their experimental and evaluation setups. In Section 3 we introduce our own experimental setup designed to overcome the limitations observed in past research. In Section 4, we provide both frame and argument identification scores for past models trained on our own experimental setup, on both FN 1.5 and 1.7 datasets. In Section 5 we discuss the impact of pre-processing on argument identification, and in Section 6 and Section 7 we provide new robust baselines on both FN 1.5 and 1.7 datasets and conclude.

[1] For (Roth, 2016), although decoding and models are open source, training software is not

2 Existing frame semantic parsing pipelines

2.1 Models

SIMPLEFRAMEID The *frame identification* model of SIMPLEFRAMEID (Hartmann et al., 2017) is based on distributed representations of predicates and their (syntactic) context. The overall model relies on a disambiguation classifier which learns weights for all frames in the lexicon, given a vector space model providing dense vector representations for the predicate and its context. The context of the predicate can include all words in the sentence (SENTBOW model), or be restricted to direct dependents of the predicate (DEPBOW model). The overall classifier can rely on two distinct classification methods: a two-layer neural network (NN) or a WSABIE-based method following the approach of Hermann et al. (2014), consisting in mapping input representations and frame representations to a common latent space using the WSABIE algorithm (Weston et al., 2011). In the standard decoding setup, the best scoring frame is selected among all possible frames of a given predicate, as specified in the lexicon. If the predicate is not found in the lexicon, the best scoring frame is selected among all frames, while if the predicate is unambiguous and has a single possible frame, the frame is assigned directly. Hartmann et al. (2017) provide three evaluation metrics for all their models: *total*, which provides an accuracy score for all predicates in the test set; *ambig* which provides accuracy scores for ambiguous predicates only (predicates with more than one possible frames in the lexicon); and *no-lex*, accuracy scores while treating each predicate as *unknown* and scoring all frames in the lexicon.

SEMAFOR The *argument identification* model of SEMAFOR is a system originally proposed by Das et al. (2014) and modified by Kshirsagar et al. (2015). The model derives the set of argument spans via a rule-based algorithms over the syntactic context of a predicate word, and labels roles using a conditional log-linear model over spans for each role of each evoked frames, trained using maximum conditional log-likelihood. The original model makes extensive use of handcrafted features, ranging from lexical items combinations to syntactic dependency paths. To the original features are added the *exemplar* and *hierarchy* features (henceforth EX and H) proposed by Kshirsagar et al. (2015). EX incorporates FN exemplar data – lexicographic examples annotating a single predicate – to the original 'fulltext' train set, while H incorporates information regarding specific frame relations (Inheritance and SubFrame). Decoding is done using beam search which produces a set of k-best hypotheses of sets of span-role pairs. The approach enforces multiple constraints including the fact that a frame element label may be assigned to at most one span and that spans of overt arguments must not overlap.

OPEN-SESAME OPEN-SESAME (Swayamdipta et al., 2017) is another *argument identification* system based on the SegRNN model of Kong et al. (2015), which relies on a combination of bidirectional RNNs and semi-Markov CRF – with a slight modification to favor recall over precision – to learn embedded representations of targets, lexical units, frames, frame elements and spans. In its basic form, the OPEN-SESAME parser is syntax-free, although it may also incorporate syntactic cues such as dependency parses or phrase structures. For brevity, and to ease the replication process, we focus in this work on the syntax-free and dependency-based models only. Note that, throughout this work, we report results with single models and not ensemble models, and that, due to differences in initialization, variations of F_1 scores can be observed over our reported results, of up to 1 point of F_1 score on FN 1.5 setups and .5 points of F_1 score on FN 1.7 setups.

2.2 Variations in existing experimental settings

SIMPLEFRAMEID and SEMAFOR rely on the original DAS sets (Das and Smith, 2011; Das et al., 2014). OPEN-SESAME extracts its test set relying on the exact same list of FN fulltext as Das and Smith (2011), but via a different pre-processing pipeline. We found both test splits to contain duplicate sentences and annotationsets,[2] as well as at least one overlapping sentence and corresponding annotationsets between train and test splits.[3] The DAS test split contains 4457 annotationsets when the OPEN-SESAME test

[2] In FN, an annotationset is defined as one set of labels for a predicate and its corresponding arguments in a given sentence.

[3] The sentence in question being *Even if Iran possesses these biological agents, it faces a significant challenge in their weaponization and delivery* .

split contains 4428 annotationsets. Corresponding parsers are therefore not evaluated on the exact same set of gold data. The difference in the number of annotationsets is partially explained by the fact that OPEN-SESAME relies on the BIO tagging scheme, which does not support overlapping frame elements, to generate its gold data. Of the 4457 annotationsets of the DAS split, at least 162 were actually duplicates. Of the 2420 sentences listed in both test sets, only 982 contained annotation, and 107 of them were duplicates, making for an actual test set of 875 unique annotated sentences.

In (Das et al., 2014; Kshirsagar et al., 2015; Hartmann et al., 2017), data are tokenized with SED, part-of-speech tagged with MXPOST (Ratnaparkhi, 1996), lemmatized with WORDNET (Miller, 1995) and dependency-parsed with the MST parser (McDonald et al., 2006). In (Swayamdipta et al., 2017), data retain the original FN tokenization, are lemmatized with NLTK (Bird et al., 2009) and part-of-speech-tagged and dependency-parsed with SYNTAXNET (Andor et al., 2016). To incorporate exemplars into the training set, Kshirsagar et al. (2015) apply an extra layer of filtering by excluding annotationsets containing no overt frame element labels from the training data. As detailed in §5.3, this has a non-negligible impact on argument identification and we treat this filtering layer as an independent feature.

All the above systems generate their *lexicons* by scanning the *entirety* of FN data. This includes the predicate-to-frame map of SIMPLEFRAMEID, the frame-to-frame-element map of SEMAFOR and OPEN-SESAME, and the frame-to-frame and frame-element-to-frame-element relation maps of SEMAFOR when used with the *hierarchy* feature. Such an approach leads systems to have partial access to information which is only included in the test set, such as the number of frames available for an unknown predicate,[4] the list of frame elements of a given unknown frame, and the relation between an unknown frame and a known frame.

2.3 Evaluation software

Throughout this work we rely on two distinct evaluation scripts, motivated by considerations over the design of the original perl evaluation script of the SemEval shared task 19 on frame structure extraction. Our first script, called SEMEVAL, is the original SemEval evaluation script as-is, and is used to score argument identification given predicted frames. Our second script, called ARGSONLY, is a modified version of the evaluation script originally provided by Kshirsagar et al. (2015), which we use to score argument identification given gold frames. Both scripts provide global precision, recall and F_1 scores microaveraged across a concatenation of the test set.

Modifications to the original SEMEVAL script are motivated by its computing scores for both frames and arguments jointly, which dilutes contributions to argument identification in gold frames settings by systematically granting extra credits for gold frames. Unlike the evaluation script of Kshirsagar et al. (2015) however, our ARGSONLY evaluation does not skip the evaluation of frame-only annotation sets with no arguments, as it would not penalize parsers for over-predicting arguments.

3 Building a new harmonized experimental setup

3.1 Datasets and post-processing

We generate our train, dev and test splits following the list of fulltext documents provided by Swayamdipta et al. (2017). For both FN 1.5 and FN 1.7 datasets, dev and test splits are generated from the same list of FN fulltexts. To guarantee no duplicates and no overlap within and across datasets, we apply a strong filter based on an annotationset hash generated from the concatenated annotationset sentence text hash and the annotationset target hash. The sentence text hash is the sentence text lower-cased on stripped of all its whitespaces while the target hash is a concatenation between the target predicate string and the target indexes. To guarantee near-perfect matching between SEMEVAL-formatted test XML data and the original gold FN XML data, we directly convert FN XML data without relying on intermediate formats (e.g. CONLL or BIO formats), and retain all annotationsets except those with inconsistent labels.[5]

[4] I.e. a predicate in the test set not seen during training.

[5] We define inconsistent labels as those with inconsistent start/end indexes, e.g. when only one of the two indexes is missing. Note that when such annotationsets are found, we filter out the entire annotationset and not just the erroneous label, as we consider the entire annotationset as an indivisible piece of information

Table 1 details the number of sentences and annotationsets in both FN 1.5 and 1.7 setups. The 50% increase in test gold data between FN 1.5 and 1.7 guarantees more robust baselines when testing on the 1.7 setup.

	TRAIN 1.5 FT	TRAIN 1.5 FT+EX	TEST 1.5	TRAIN 1.7 FT	TRAIN 1.7 FT+EX	TEST 1.7
#sent	2,654	150,426	875	3,362	168,792	1,247
#anno	16,706	170,889	4,148	19,550	192,554	6,446

Table 1: Number of sentences and annotationsets in train and test splits for both FN 1.5 and FN 1.7 setups, with training data generated from fulltexts only (FT) or fulltexts and exemplars (FT+EX)

3.2 Pre-processing

In all our experiments we retain the original FN tokenization, while lemmatizing data with NLP4J (Choi, 2016). For part-of-speech tagging, we experiment with MXPOST (Ratnaparkhi, 1996) and NLP4J, and for dependency parsing with the MST (McDonald et al., 2006) and BIST (Kiperwasser and Goldberg, 2016) parsers. The BIST parser is used in both its graph-based (BMST) and transition-based (BARCH) variants. Both MST and BIST parsers are trained on sections 02-21 of the Penn TreeBank (Marcus et al., 1993). We choose MXPOST and MST for the purpose of replicating previous studies, and NLP4J and BIST for performance. At the time when this research started, state-of-the-art results on frame semantic parsing were reported by Roth (2016) who recommended the use of both NLP4J and BIST for pre-processing.

3.3 Frame semantic parsers

We fork the branch of SEMAFOR used in (Kshirsagar et al., 2015), as well as the SIMPLEFRAMEID and OPEN-SESAME master branches. For each parser, we re-implement lexicon creation methods in order to include only data seen during training (see §3.1). That is, we reproduce the predicate-frame map of SIMPLEFRAMEID, the frame-to-frame-element map of SEMAFOR and OPEN-SESAME, and the hierarchy feature-related relation maps of SEMAFOR. We keep all parsers and hyperparameters as detailed in (Hartmann et al., 2017), (Kshirsagar et al., 2015) and (Swayamdipta et al., 2017), and set the regularization parameter λ for SEMAFOR to $\lambda = 10^{-5}$.

3.4 Pipeline release

To ease replication and future work on frame semantic parsing, we release a single Python application called PYFN, which provides a set of Python models to process FN annotation. We thereby enforce data consistency across experiments, as data conversion[6] is processed via a single set of models. We create a larger standalone bundle including all forked parsers used as well as all datasets, resources and scripts necessary to replicate our experiments, and release it open source at `https://gitlab.com/akb89/pyfn`. Each experiment introduced in this work is labeled with a unique #id, to which corresponds a README file listing all necessary instructions for replicating the experiment, found under the *experiments* directory of the PYFN repository.

4 Replication of previous studies

The purpose of this section is to measure the contribution of each model introduced in §2.1 on our robust experimental setup (§3.1). Given that we use slightly different test sets and lexicons from the original studies, we focus on comparing the order of magnitude of each contribution and the resulting ranking of models, as well as analyzing the robustness of each contribution when tested on the FN 1.7 dataset.

4.1 Frame identification: the SIMPLEFRAMEID system

On frame identification, Tables 3 and 4 confirm one of the main results of Hartmann et al. (2017) presented in Table 2, namely, that the NN model outperforms the WSABIE model, and this in both FN 1.5

[6]E.g. to and from FN XML format, SEMEVAL XML format, CONLL-09 format, CONLL-X format, BIO tagging format, etc.

and FN 1.7 setups. Table 3 also confirms the hierarchy between models on the FN 1.5 setup, albeit not as clearly as originally reported, with differences between NN and WSABIE models closer to 2 points of accuracy rather than 3. However, Table 4 shows that the hierarchy between the NN + SENTBOW and NN + DEPBOW models are not robust across datasets, as the NN + DEPBOW model performs better than the NN + SENTBOW model on the FN 1.7 setup, by a margin of .6 accuracy point overall.[7] We conclude that the superiority of the NN + SENTBOW model cannot be generically ascertained, in line with original experiments reported by Hartmann et al. (2017).

Hartmann et al. (2017) FRAMENET 1.5 SETUP					
system	pos	dep	total	ambig	no-lex
WSB + SENTBOW	MXPOST	MST	84.5	67.6	72.0
WSB + DEPBOW	MXPOST	MST	85.7	69.9	71.2
NN + SENTBOW	MXPOST	MST	**87.6**	**73.8**	**77.5**
NN + DEPBOW	MXPOST	MST	87.5	73.6	76.5

Table 2: SIMPLEFRAMEID frame identification accuracy scores on DAS splits

(OUR) FRAMENET 1.5 SETUP

#67	**NN + DEPBOW**	**83.0**	**71.7**	76.1

Table 4: SIMPLEFRAMEID frame identification accuracy scores on our **FN 1.7** splits

4.2 Argument identification: OPEN-SESAME and SEMAFOR

On argument identification, we first try and replicate past results relying on our FN 1.5 and FN 1.7 splits, as well as a common pre-processing pipeline combining MXPOST and MST, in order to match as closely as possible the pipeline most widely used in past studies (see Table 5). We report results for the standard version of SEMAFOR and for all its adaptations introduced in (Kshirsagar et al., 2015), which include the hierarchy feature (H), the exemplar feature (EX) and the filtering feature (F).

Argument identification on FN 1.5				Gold Frames			Predicted Frames		
	POS	DEP		P	R	F_1	P	R	F_1
SEMAFOR	MXPOST	MST	(Das et al., 2014)	65.6	53.8	59.1	-	-	66.8
SEMAFOR H	MXPOST	MST	(Kshirsagar et al., 2015)	67.2	54.8	60.4	-	-	-
SEMAFOR EX + F	MXPOST	MST	(Kshirsagar et al., 2015)	66.0	58.2	61.9	-	-	-
SEMAFOR H + EX + F	MXPOST	MST	(Kshirsagar et al., 2015)	66.0	60.4	63.1	-	-	67.9
OPEN-SESAME	SYNTAXNET	-	(Swayamdipta et al., 2017)	64.7	**61.2**	62.9	68.0	**68.1**	68.0
OPEN-SESAME	SYNTAXNET	SYNTAXNET	(Swayamdipta et al., 2017)	**69.4**	60.5	**64.6**	**71.0**	67.8	**69.4**

Table 5: Argument identification scores given gold and predicted frames on DAS splits, as originally reported in (Kshirsagar et al., 2015; Swayamdipta et al., 2017). Frames are predicted with the proprietary system of Hermann et al. (2014)

[7] Note that decrease in absolute score was expected given that all models use a reduced lexicon compared to (Hartmann et al., 2017), although the unpredictability of performance on duplicates in the DAS test set could have compensated either way.

Table 6 shows that, contrary to what was previously reported, the OPEN-SESAME parser does not outperform the best version of SEMAFOR on the FN 1.5 splits. Although the dependency-based version of OPEN-SESAME does achieve comparable results than SEMAFOR, the syntax-free version is outperformed by a margin of .9 points of F_1 score. The contribution of each H, EX and F feature is confirmed across datasets, with similar order of magnitudes. Ranking of models changes however across datasets, and results on the FN 1.7 splits (Table 7) provide a ranking of models closer to the one reported in Table 5.

XP	FRAMENET 1.5 SETUP			P	R	F_1
#42	SEMAFOR	MXPOST	MST	59.1	54.3	56.6
#86	SEMAFOR H	MXPOST	MST	**60.3**	54.9	57.5
#75	SEMAFOR EX + F	MXPOST	MST	59.9	58.9	59.4
#89	**SEMAFOR H + EX + F**	MXPOST	MST	60.1	**60.6**	**60.4**
#43	OPEN-SESAME	MXPOST	-	59.7	59.4	59.5
#44	OPEN-SESAME	MXPOST	MST	59.8	59.8	59.8

Table 6: Argument identification scores given gold frames on our **FN 1.5** splits while pre-processing with MXPOST and MST

XP	FRAMENET 1.7 SETUP			P	R	F_1
#54	SEMAFOR	MXPOST	MST	61.2	53.5	57.1
#61	SEMAFOR H	MXPOST	MST	62.5	53.7	57.8
#97	SEMAFOR EX + F	MXPOST	MST	**64.8**	54.9	59.4
#63	SEMAFOR H + EX + F	MXPOST	MST	63.6	57.4	60.4
#53	OPEN-SESAME	MXPOST	-	62.9	58.4	60.6
#80	OPEN-SESAME	MXPOST	MST	63.2	**58.9**	**61.0**

Table 7: Argument identification scores given gold frames on our **FN 1.7** splits while pre-processing with MXPOST and MST

So while frame identification results proved rather consistent across setups in §4.1, argument identification results proved more erratic, with a clear mismatch of model hierarchy on the FN 1.5 setup, contradicting previous studies.

5 Impact of the preprocessing pipeline

In this section we report on the impact of different preprocessing pipelines on argument identification scores for both the SEMAFOR and OPEN-SESAME systems. Note that in §5.1 and §5.2, we compare OPEN-SESAME to the standard SEMAFOR model, without the H, EX or F features. However, similar trends can be observed for the feature-expanded versions of SEMAFOR (see §5.3).

5.1 Part-of-speech tagging

Table 8 shows a systematic improvement of F_1 score on the FN 1.5 splits when using NLP4J over MXPOST for part-of-speech tagging (compare with Table 6: #69 vs #42, #78 vs #43, and #79 vs #44). Results presented in Table 9 (compare with Table 7) tend to show that increase in performances with NLP4J is not robust across datasets (see notably #56 vs #54). However, further experiments, presented in §5.2 and §5.3 show that performance on argument identification is highly dependent on the *combination* of the part-of-speech tagger *and* the dependency parser used. In our case, the combination of NLP4J with the BIST dependency parser actually outperforms any MXPOST-based pre-processing pipeline.

XP	FRAMENET 1.5 SETUP			P	R	F_1
#69	SEMAFOR	NLP4J	MST	60.2	55.4	57.7

#55	OPEN-SESAME	NLP4J	MST	64.4	59.6	61.9

Table 9: Argument identification scores given gold frames on our **FN 1.7** splits while pre-processing with NLP4J and MST

5.2 Dependency-parsing

Table 10 and Table 11, show a near-systematic improvement of F_1 score for both SEMAFOR and OPEN-SESAME systems when using the BIST dependency parser over MST. On FN 1.5 , the contribution of the dependency parser itself to overall performance proves non-negligible, with an observed improvement ranging from .6 points of F_1 score for OPEN-SESAME between MST and BARCH (#79 and #83), to 4

points of F_1 score for SEMAFOR between MST and BARCH (#69 and #81). On certain FN 1.5 setups, the combination of pos tagger and dependency parser may even account, in order of magnitude, for more than half of the previously reported contribution of the OPEN-SESAME model over the SEMAFOR model (consider, e.g., #82 in Table 10 and #44 in Table 6 compared to the 1.5 F_1 score improvement reported in Table 5 between the best SEMAFOR model and the dependency-based OPEN-SESAME model).

XP	FRAMENET 1.5 SETUP			P	R	F_1

Table 11: Argument identification scores given gold frames on our **FN 1.7** splits while pre-processing with NLP4J and MST, BMST or BARCH

5.3 Data filtering

As previously introduced in §2.2, Kshirsagar et al. (2015) apply a filtering layer on training data by removing all annotationsets with no overt role labels from the exemplar data. Such a filter may remove valid annotationsets where all arguments of the predicate are found to be *null instantiations* (Ruppenhofer et al., 2016) – which may correspond, e.g., to intransitive predicates, lexically licensed zero anaphora or imperative and passive constructions – but can also remove incompletely annotated annotationsets, where predicates have been disambiguated (frames have been assigned to specific targets), but frame element labels have yet to be specified. Such cases are much more frequent in exemplar than in fulltext data, justifying *a priori* the filtering layer of Kshirsagar et al. (2015) to prevent negatively biasing SEMAFOR.

Table 12 and Table 13 show that the filter feature has a systematic positive effect on argument identification performance, and that this result is robust across datasets and across pre-processing pipelines. Note that, in a configuration where EX and H features are combined, the addition of the F feature leads to a .5 F_1 (compare #89 and #87) to 1.4 F_1 (compare #63 and #62) increase in performance depending on the setup. This result suggests that the filtering layer applied by Kshirsagar et al. (2015) should be considered as a standalone feature, which contribution should be clearly separated from that of the exemplar feature, in order to better quantify the contribution of the exemplar feature itself.

XP	FRAMENET 1.5 SETUP			P	R	F_1

Overall, we showed that divergence in the pre-processing pipeline can actually account for a significant part of the difference in performance previously observed across models, enforcing the need for standard pre-processing pipelines against which models can be fairly compared.

6 New baselines for FN 1.5 and FN 1.7

Building upon results of the previous sections, we introduce new baselines for both frame and argument identification on our FN 1.5 and FN 1.7 splits, relying on an updated preprocessing pipeline combining NLP4J for lemmatization and part-of-speech tagging, and the BMST variant of the BIST parser for dependency parsing. Although not necessarily the best pipeline observed in all setups, the NLP4J + BMST combination proved to be the best compromise between performance and speed, an important factor to take into account for facilitating future replication.

Table 14 and Table 15 confirm, in addition to Table 6 and Table 7, that the ranking of models reported in (Swayamdipta et al., 2017) is not robust across datasets and experimental setups. In the most robust setup (FN 1.7 with NLP4J and BMST reported in Table 15) SEMAFOR still outperforms both syntax-free and dependency-based versions of OPEN-SESAME, by a margin of at least 1.5 points of F_1 score.

Surprisingly however, the ranking of models is significantly modified when testing models with predicted frames output by SIMPLEFRAMEID, and a 10 points drop in recall is observed between the feature-expanded and the standard version of SEMAFOR (Tables 16 and 17). Those results suggest that the feature-expanded version of SEMAFOR acquires, most likely via the exemplar data, representations that deviate too much from that of those found in the fulltext test set, making it unable to compensate for the wrongly predicted frames of SIMPLEFRAMEID. Such considerations stress once again the possible domain-specific nature of both fulltext and exemplar data (Das et al., 2014), considerations which are reinforced by our results on frame identification trained on exemplar (see Table 18 and Table 19) which show a systematic decrease in performance on ambiguous predicates, suggesting that ambiguous predicates observed in the exemplar training data do not beneficially contribute to predictions on ambiguous predicates in the fulltext test set.

7 Conclusion

In this paper, we have discussed the impact of pre- and post-processing pipelines on frame semantic parsing performance. We have shown that the ranking of existing state-of-the-art systems can be severely impacted by arguably 'small' factors outside of the main models, to the point that respective model performance cannot be fully ascertained.

Our replication study drew the following conclusions. We found that on the whole, previous frame identification results by (Hartmann et al., 2017) could be replicated. Results on argument identification, however, gave a much patchier picture. Replication on a robust experimental setup showed a change in model ranking between OPEN-SESAME and SEMAFOR. Further experiments on pre-processing demonstrated that the *combination* of a particular parts-of-speech tagger and dependency parser (NLP4J and BIST) gives best performance on the task. The contribution of the dependency parser itself may be more than previously reported: we found that half of the advantage of OPEN-SESAME over SEMAFOR may be due to this pre-processing choice, closing the gap between the two models. We also highlighted that filtering the training data has a robust and very significant effect on performance.

Building upon these results, we ran two robust baselines on both FN1.5 and FN1.7. These experiments result in a different model ranking from what has previously been reported in the literature. However, we also found that the feature-expanded version of SEMAFOR suffers a huge drop in recall when given predicted rather than gold frames. Here again, it seems vital to be able to distinguish the contribution of different processing stages on the actual model.

On the back of the replication results presented here, we feel there is a need for a standardized experimental pipeline that would allow researchers to fully test the contribution of different pre- and post-processing factors independently from their model. Following on this recommendation, we release an open source toolkit[8] including all necessary scripts and datasets to replicate our experiments in a robust setting. We hope to thus foster more fine-grained analyses of past and future results in frame semantic parsing.

Abstract

We present a variation of the incremental and memory-limited algorithm in (Sadeghi et al., 2017) for Bayesian cross-situational word learning and evaluate the model in terms of its functional performance and its sensitivity to input order. We show that the functional performance of our sub-optimal model on corpus data is close to that of its optimal counterpart (Frank et al., 2009), while only the sub-optimal model is capable of predicting the input order effects reported in experimental studies.

1 Introduction

It has been suggested that early word learning is guided by observing the referent of words across situations (*cross-situational word learning*). Surely the co-occurrence statistics of word-object mappings is noisy (e.g., when the referent of a word is absent in the scene) and only provides ambiguous information (due to referential ambiguity) about word-object mappings, but it is the only source of information used by a true novice who does not have access to social and linguistic cues (Baldwin, 1993; Arunachalam and Waxman, 2010) to narrow down the hypothesis space of words' meanings. In fact, development of some initial meaning interpretations is the prerequisite for the development of useful social and syntactic knowledge (cues) for bootstrapping the process of word learning.

Recent experimental findings (Medina et al., 2011; Trueswell et al., 2013; Zhang and Yu, 2017) indicate that word learning is sensitive to the presentation order of learning trials. More specifically, their results suggest that early wrong interpretations of words' meanings can inhibit the acquisition of correct words' meanings and that performance is best when highly informative learning trials (e.g., with lower referential ambiguity) precede the low informative learning trials, so that the possibility of starting with wrong meaning interpretations is minimized. These results are incompatible with the prediction of the existing well-known word learning models which employ global learning and are equipped with perfect memory of past observations (Yu and Ballard, 2007; Kachergis et al., 2012; Xu and Tenenbaum, 2007; Frank et al., 2009; Alishahi and Fazly, 2010). These models are insensitive to input order due to two major reasons: (1) being purely driven by co-occurrence regularities and assuming full access to co-occurrence statistics which stays the same regardless of input order or (2) processing the data in batch. Word learning is one of a wide range of cognitive tasks which exhibit sensitivity to the presentation style of input. Inductive category learning (Carvalho and Goldstone, 2015), category generalization (Spencer et al., 2011), property projection (Lawson, 2017), etc. all demonstrate important differences under sequential vs. simultaneous presentation of input. Therefore, the root causes of the effects of presentation order on word learning results should be understood as it may generalize to other cognitive tasks and can make up an important aspect of word learning models.

The recent findings regarding the effect of presentation style and order provide evidence for local approaches to learning, while they fail to rule out the possibility of global learning. Exploring the intermix of local and global approaches to learning is important on three levels: (1) replicating human performance, (2) departing from computationally expensive ideal learners that become inefficient as the size of

Proceedings of the 27th International Conference on Computational Linguistics, pages 3170–3180
Santa Fe, New Mexico, USA, August 20-26, 2018.

input data grows, and (3) giving accounts for the real-world constraints faced by word learners (e.g., It is cognitively implausible to assume that infants can remember the details of all past observations). We use a variation of the incremental and memory-limited learning algorithm proposed in (Sadeghi et al., 2017) and provide the first corpus evaluation of this sub-optimal model in terms of its functional performance and the patterns of sensitivity to input order it exhibits which match those reported in the experimental studies (Medina et al., 2011).

2 Model Overview

Similar to previous work (Yu and Ballard, 2007; Alishahi and Fazly, 2010; Frank et al., 2009), we assume that the learner is capable of object and action categorization prior to word learning and the goal is to learn the basic level object category names. The *input* to the model (*observations*) are word learning *situations* (*trials*) each of which consists of an un-ordered set of words as utterance paired with a list of objects as the scene. The notion of *memory* refers to the number of observations (trials) that can be remembered at a time and the current model assumes memory=1. In each situation, the proposed incremental model (1) utilizes a Bayesian approach to infer the correct word-object mappings and (2) integrates the newly inferred word-object mappings (*mini-lexicon*) in the previously learned many-to-many mapping between words and objects (*lexicon*), based on their association strength in the presence of alternative mappings. The model's memory is limited to the word-object mappings stored in its full lexicon and the details of the current situation. The Bayesian approach is constrained on two distinct levels: (1) hypothesis generation (mini-lexicon generation) and (2) hypothesis evaluation (inferring the best mini-lexicon). Both hypothesis generation and hypothesis evaluation are limited to the knowledge stored in the lexicon and the details of the current situation. Therefore in our model, Bayesian approach neither performs global optimization, nor has access to all possible hypotheses (all possibilities if the model had full access to all observations). Instead, the Bayesian approach is a local approach as both hypothesis generation and hypothesis evaluation are limited to the knowledge stored in the lexicon and the details of the current situation.

3 Speaker's Model of Utterance Generation

The learner assumes that in each situation, the speaker uses the generative process illustrated in Fig. 1 to produce an utterance (W_s) corresponding to the current scene (O_s) and using a context appropriate portion (L) of the full lexicon. In each situation, the model has to infer which words are *referential* and to which object they refer to, where a *referential* word is a noun with a concrete object referent in the scene. *Referential intentions* of the speaker (I_s), which refer to the objects that are present in the scene and the speaker is talking about them, determine the space of possible referents for each referential word in the utterance (W_s).

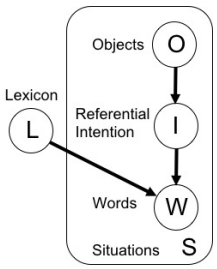

Figure 1: The graphical model describing the probabilistic dependencies between model random variables: utterance (W_s), intention (I_s), lexicon (L), and the objects present in the scene (O_s), where s indexes the situation. The plate indicates multiple copies of the model for different situations (utterance-scene pairs).

In each situation, the speaker uniformly samples a subset from the power-set of all the objects (O_s) present in the scene as the referential intention(s) of the speaker (I_s). For each object in I_s, one word

mapping is drawn from the lexicon and added to the utterance. The non-referential words of the utterance are generated randomly with probability $P_{NR} = 1$. In each situation the learner tries to reverse the generative process described in Fig. 1 to infer a context-appropriate portion of the full lexicon (*mini-lexicon*) used by the speaker, where *context* refers to the objects in the current situation. The inferred mini-lexicon then will be integrated in the full lexicon available to the learner (details in Section 4).

Inferring the best mini-lexicon in each situation, requires finding the MAP (maximum a posteriori) mini-lexicon by marginalizing over all possible referential intentions, since I_s is unobserved. The model finds the MAP mini-lexicon ($argmax_L P(L|C)$) according to the Bayes equation and the probability distribution that it defines over unobserved mini-lexica (L) and the corpus of situations (C). The current model only remembers one situation at a time (memory=1) due to which C includes one observed situation plus the context-appropriate situations extracted from the lexicon (see 4.2 for details).

$$P(L|C) \propto P(C|L)P(L) \tag{1}$$

We use $P(L) \propto e^{-\alpha \cdot |L|}$ serving as a soft mutual exclusivity constraint to produce a preference for one-to-one mappings in the mini-lexicon inferred in each situation. Marginalizing over all possible intentions in each situation we can rewrite the likelihood term $P(C|L)$ as:

$$P(C|L) = \prod_{s \in C} \sum_{I_s \subseteq O_s} P(W_s|I_s, L)P(I_s|O_s) \tag{2}$$

Assuming that $P(I_s|O_s) \propto 1$ and that the words of the utterance are generated independently, we can rewrite the term $P(W_s|I_s, L)$ as:

$$P(W_s|I_s, L) = \prod_{w \in W_s} [\gamma \cdot \sum_{o \in I_s} \frac{1}{|I_s|} P_R(w|o, L) + (1 - \gamma) P_{NR}(w|L)] \tag{3}$$

The words of utterance can be generated in two different ways: (1) referentially (with a concrete object referent in the scene) with probability γ and (2) non-referentially with probability $1 - \gamma$. The probability of non-referential use (P_{NR}) of a referential word (words in the model lexicon) is set to $\kappa < 1$ (to penalize the non-referential use of referential words), and is set to 1 for non-referential words. The probability of referential use of a referential word in reference to a particular object (P_R) is the probability of the word being chosen uniformly from the set of all words linked to that object in the lexicon.

4 Incremental Learning Algorithm

Our learning algorithm is a variation of the incremental and memory-limited algorithm proposed in (Sadeghi et al., 2017) which accounts for the following real-world constraints: (1) seeing each situation only once with no iteration over data, (2) using only the acquired knowledge and the current observation for hypothesis generation and evaluation. These constraints exclude the use of many proposed incremental algorithms in the literature (Liang et al., 2009; Pearl et al., 2010; Börschinger and Johnson, 2011; Börschinger and Johnson, 2012). In this section we first give a high-level overview of the incremental learning algorithm, while highlighting the differences between our version and the original version proposed in (Sadeghi et al., 2017). We refer the reader to (Sadeghi et al., 2017) for the details shared between the two algorithms. Furthermore, we refer curious readers to (Sadeghi and Scheutz, 2017; Sadeghi and Scheutz, 2018) which demonstrate the application of similar learning algorithms to the augmented versions of the graphical model presented here.

Our algorithm is composed of two major components: (1) inferring the MAP mini-lexicon in each situation, and (2) integrating the new mini-lexicon in the previous lexicon. Inferring the MAP mini-lexicon, subsequently has two components: (1) hypothesis generation (generating mini-lexicon proposals) and (2) hypothesis evaluation (evaluating the mini-lexicon proposals using Eq. 1).

Our algorithm departs from its batch counterpart (Frank et al., 2009) in the notion of C and L. L in (Frank et al., 2009) refers to the entire dictionary used by the speaker while in our model L (mini-lexicon)

refers to a part of the dictionary used by the speaker to produce the current utterance in correspondence to the current scene. In each situation, we try to infer a portion of the entire dictionary used by the speaker and we refer to the aggregation of all these mini-lexica as the lexicon. Similarly, C in (Frank et al., 2009) refers to all the observed situations (<*utterance*,*scene*> pairs), assuming full access to data, but in our model C refers to the current situation and a number of relevant situations extracted from the lexicon.

Our algorithm departs from the algorithm in (Sadeghi et al., 2017) in the definition of *context* and subsequently the *context-appropriate mappings* and the *context-appropriate situations* used for hypothesis generation and hypothesis evaluation accordingly in each situation. *Context* in our model refers to the list of objects present in the scene while *context* in (Sadeghi et al., 2017) refers to the objects and words present in the scene and utterance. Given *trial*=<*utterance*,*scene*>, we define *context*=*trial.objects*=$\{o_j | o_j \in$ *scene*$\}$, *trial.words*=$\{w_i | w_i \in$ *utterance*$\}$, and *trial.mappings*=$\{< w_i, o_j > | (o_j \in$ *scene*$) \wedge (w_i \in$ *utterance*$)\}$. Then the context appropriate information are defined as: *context-appropriate-mappings*=*trial.mappings* $\cup \{< w_i, o_j > | (< w_i, o_j > \in$ *lexicon*$) \wedge (o_j \in$ *context*$)\}$, and C=*context-appropriate-situations*=$\{<$ *utterance*=w_i,*scene*=$o_j > | (< w_i, o_j > \in$ *lexicon*$) \wedge (o_j \in$ *context*$)\} \cup$ *trial*.

We focus on objects as the context to extract appropriate information from the lexicon, since the goal of the model is to learn the label of objects while the mappings stored in the lexicon are noisy and can include object mappings for non-referential words. Therefore, we can benefit from filtering out the potential noise (co-occurrence of the non-referential words and objects) and retrieving only the stored mappings of the objects as a proxy for true object labels during hypothesis generation and hypothesis evaluation.

4.1 Generating Mini-Lexicon Proposals

Generating mini-lexicon proposals in each situation, is guided by semi-stochastic search techniques on the context-appropriate mappings based on their association strength (Point-wise mutual information accumulated incrementally and globally) analogous to (Sadeghi et al., 2017). Upon receiving a new input situation, first, we initialize 40 mini-lexica and take the one with the highest un-normalized posterior probability as the best initialized mini-lexicon (*init-lex*). We then explore the neighborhood around *init-lex* by mutating it *nStep* times (we used *nStep*=3). Mutation can be thought of as generating a tree of height=*nStep*+1, with branch factor of 3 (performing 3 operations on mappings of the lexicon at each node: add, remove, swap), the *init-lex* at the root, and its mutated versions on the leaves. We then compare the *init-lex* and its mutated versions against each other and report the one with the highest un-normalized posterior probability as the inferred mini-lexicon.

4.2 Evaluating Mini-Lexicon Proposals

The mini-lexica generated in the previous section are evaluated based on their relative posterior probability computed according to Eq. 1. C includes the context-appropriate situations and is used as evidence for Bayesian inference when evaluating the mini-lexicon proposals. Note that the model does not remember the details of past observations but is able to remember what it learned from them (word-object mappings stored in the lexicon). Hypothesis evaluation in our model departs from hypothesis evaluation in (Sadeghi et al., 2017) by virtue of using a different notion of context and context-appropriate situations used as evidence for Bayesian inference.

4.3 Integrating the MAP Mini-Lexicon in the Lexicon

Integration of the MAP mini-lexicon modifies (adds, deletes or keeps) the word mappings stored in the lexicon, for each item in the context (objects in the current scene). Our algorithm departs from the original version in how it handles conflict resolution when integrating the newly inferred mini-lexicon in the previous lexicon. In (Sadeghi et al., 2017), during conflict resolution, alternative mappings compete with each other and only mappings with the highest co-occurrence statistics are allowed in the output lexicon. This strict mutual exclusivity constraint not only inhibits learning of alternative word-object mappings (e.g., “cat”,“kitten”, and “kittycat” all refer to the same concept “CAT”), but also destabilizes the learning results. Our model on the other hand, modulates this strict mutual exclusivity constraint by

allowing the addition of alternative mappings for each object, if their co-occurrence statistics fall within a certain range of the co-occurrence statistics of the best existing mapping for that object. We introduce two parameters: (1) *keep-fraction* and (2) *add-fraction* for the inclusion of alternative mappings in the output lexicon, correspondingly from the previous lexicon and the MAP mini-lexicon. For each object in current context, we allow mappings from the previous lexicon and from the MAP mini-lexicon in the output lexicon if their association strength are correspondingly not less than *keep-fraction* and *add-fraction* of the word mapping with the highest association strength available in memory, for that object. Using small values for *keep-fraction* and *add-fraction* would enforce softer mutual exclusivity constraints and using large values would enforce harder mutual exclusivity constraints.

5 Evaluation Data

5.1 Input Properties

The input properties we study include: (1) the information inherent in learning trials and (2) the serial order of their presentation. We categorize the trials into two categories: *referential* and *non-referential* trials. A trial is *non-referential* if no word in its utterance has a concrete object referent in the scene. Otherwise, the trial is regarded as a *referential trial*. *non-referential* trials are misleading trials as the word-object co-occurrence statistics inherent in them do not guide the model towards learning the correct word-object mappings. Note that *non-referential* trials are generally misleading for any learner which uses object-word co-occurrence statistics to guide word learning. We use *misleading* and *non-referential* interchangeably to refer to the same kind of trials. The referential trials in turn, contain graded levels of useful co-occurrence statistics based on their overall *referential ambiguity*. We use the product of the number of objects in the scene and the number of words in the utterance as a simple measure of trial *ambiguity*.

5.2 Corpus Properties

Table. 1 and Table. 2 report the properties of the two annotated video files used for our corpus evaluations. Note that di06 and me03 differ from each other in the ratio of referential to non-referential trials (1:2.07 for di06 and 1:4.64 for me03) meaning that overall the data in di06 is more informative than the data in me03 for labeling objects. D-di-me and D-me-di differ from each other in the presentation order of the more informative video and D-diRef-meRef differs from D-di-me in that it contains no non-referential (misleading) trials. Our evaluation data is available at `https://tinyurl.com/y9omp52c`.

Table 1: Properties of the annotated child-directed video files used for corpus evaluations. di06 and me03 are taken from the Rollins section of CHILDES (MacWhinney, 1991). We used the annotations and gold lexicon used in (Frank et al., 2009).

Video	Referential trials	Non-referential trials	Average ambiguity	Average ambiguity (referential trials)
me03	56	260	7.3	10.73
di06	100	207	9.35	12.02

Table 2: Different datasets made up of the trials in me03 and di06 for testing the incremental model.

Data	Video files
D-di-me	trials in di06 followed by trials in me03
D-me-di	trials in me03 followed by trials in di06
D-diRef-meRef	referential trials in di06 followed by referential trials in me03

5.3 Target Effects of Input Properties

Recent experimental studies (Medina et al., 2011; Trueswell et al., 2013; Zhang and Yu, 2017) report a huge effect of input order in word learning results, where performance is reported to be sensitive to the

presentation order and informativity of learning trials. It has been demonstrated that highly informative trials (referential trials with low ambiguity) facilitate the acquisition of correct meaning interpretations while low informative trials (highly ambiguous referential trials or non-referential trials) facilitate the acquisition of incorrect meaning interpretations. Additionally, it has been reported that early correct interpretations of words' meanings can facilitate the acquisition of correct words' meaning in later encounters while early wrong interpretations of words' meanings can inhibit the acquisition of correct words' meanings in later encounters.

Taking these results together, we expect the model performance: (1) to be sensitive to the presentation order of learning trials, (2) to be best when there is no misleading learning trials in the input data, and (3) to be best when highly informative learning trials precede the low informative learning trials, so that the possibility of starting with wrong meaning interpretations is minimized. We assume that referential trials are more informative than non-referential (misleading) trials and that referential trials with low ambiguity are more informative than referential trials with high ambiguity.

6 Evaluations

In the following sections, for each model, we use precision, recall and fscore of its output lexicon (w.r.t the gold standard lexicon) to measure its functional performance at the end of the simulation and we use *mean word acquisition score* (Alishahi and Fazly, 2010) to evaluate its incremental performance during the simulation.

$$\textbf{mean word acquisition score} = \frac{\sum_{<w,o>\in goldLexicon} P(w|o, lexicon)}{size(goldLexicon)} \quad (4)$$

6.1 Functional Performance

Table. 3 contrasts the functional performance of the our proposed incremental model with that of its batch (optimal) counterpart (Frank et al., 2009) as well as a number of baseline incremental models (please refer to (Frank et al., 2009) for more details about the comparison models). The results reported for the comparison models are taken from (Frank et al., 2009). Analogous to (Frank et al., 2009), we report the precision, recall and fscore of the best lexicon found by the incremental model, where the lexicon with the highest fscore value is considered the best. We performed a grid search in the space of parameters to find the best lexicon for each model and data pair (top three scores are highlighted in each category).

The proposed incremental model is tested on three different datasets (see Table. 2) to evaluate the effect of input properties on model performance. We did not do the same for other models as they are not sensitive to input order.

Table 3: Precision, recall, and f-score of the best lexicon found by each model when run on two annotated video files (di06 and me03) from the Rollins section of (MacWhinney, 1991). The incremental model is the only model which is sensitive to input order and is tested on a number of datasets presented in Table. 2.

Model(data)	Precision	Recall	F-Score
batch model (Frank et al., 2009)	**0.67**	0.47	**0.55**
Incremental model(D-di-me)	**0.259**	**0.617**	**0.365**
Incremental model(D-me-di)	0.204	**0.558**	0.299
Incremental model(D-diRef-meRef)	**0.415**	**0.647**	**0.505**
Association frequency	0.06	0.26	0.1
$P(object\|word)$	0.07	0.21	0.1
$P(word\|object)$	0.07	0.32	0.11
Point-wise MI	0.06	0.47	0.11
Translation Model $P(object\|word)$	0.07	0.32	0.12
Translation Model $P(word\|object)$	0.15	0.38	0.22

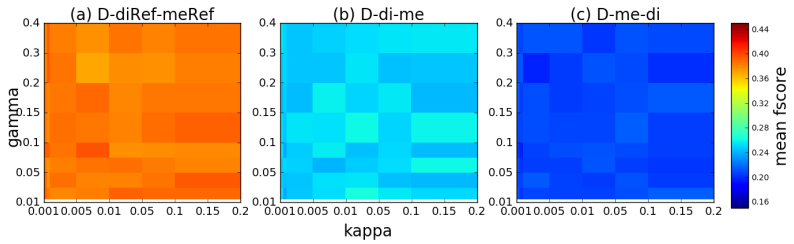

Figure 2: The mean fscore of the lexica found by running the model on (a) D-diRef-meRef, (b) D-di-me, and (c) D-me-di. D-di-me and D-me-di have 623 trials each, while D-diRef-meRef has only 156 trials. In each heatmap, the results are averaged over 50 runs for each set of parameter values using $\alpha = 3$, *keep-fraction* $= 0.5$, *add-fraction* $= 0.5$, and varying κ and γ.

Unsurprisingly, the batch model which has access to all datapoints has the highest precision and fscore on the dataset. Our incremental model has the second best fscore and the highest recall among all models as well as the best fscore among the incremental models. We used *keep-fraction* $=$ *add-fraction* $= 0.5$ (a soft mutual exclusivity constraint) which facilitates the addition of more mappings to the lexicon. This tends to improve the recall and hurt the precision of the model on small datasets such as the ones used here.

Note that the incremental model exhibits its best performance when misleading trials are removed from the corpus data (on D-diRef-meRef) which is inline with our second expectation discussed in Section 5.3 suggesting that misleading trials inhibit the process of learning the correct mappings by facilitating the acquisition of wrong meaning interpretations which in turn can interfere with the acquisition of correct meaning interpretations in later encounters.

As can be seen in Table. 1, the ratio of referential to non-referential trials in di06 is higher than that of me03. Therefore, based on what was discussed in Section 5.3, we expect the incremental model to exhibit better performance when: (1) di06 is presented first compared to when me03 is presented first, and (2) when non-referential trials are removed. Both (1) and (2) help minimize the possibility of early acquisition of wrong meaning interpretations. Our result is compatible with this expectation as the incremental model achieves better results on D-di-me dataset compared to D-me-di (reversed presentation order of video files), and better results on D-diRef-meRef compared to D-di-me (due to removal of misleading trials). Fig. 2 demonstrates that this outperformance pattern is robust against the choice of model parameters and is not an artifact of evaluating the best fscore values.

As can be seen in Fig. 2, regardless of parameter values, mean fscore values on D-diRef-meRef are better than mean fscore values on D-di-me which are in turn better than mean fscore values on D-me-di. Similar outperformance patterns were observed on the heatmaps of mean precision and mean recall scores. Furthermore, additional heatmaps generated using different α values provided further evidence for the robustness of the observed model outperformance on certain datasets regardless of the choice of model parameters and regardless of whether mean or max scores are used for comparison.

6.2 The Presentation Order of Ambiguous Trials

In this section, we seek to examine the effect of the presentation order of ambiguous trials. In order to filter out the effect of misleading trials, we use D-diRef-meRef with no misleading trials (see Table. 2) as the default ordered dataset. We reorded the trials in this dataset and created two new datasets: (1) with ascending trial ambiguity and (2) with descending trial ambiguity.

Fig. 3 demonstrates both the ideal rate of word acquisition (using a perfect model which only learns the correct mappings at the end of each trial) and the word acquisition rate achieved by the incremental model, on each dataset. As can be seen, high referential ambiguity (early trials of the data with descending order of ambiguity as well as the last trials of the data with ascending order of ambiguity) slows the rate of word acquisition as reflected on the slope of the green and red solid lines.

According to recent findings discussed in Section 5.3, performance is best when trials with low ref-

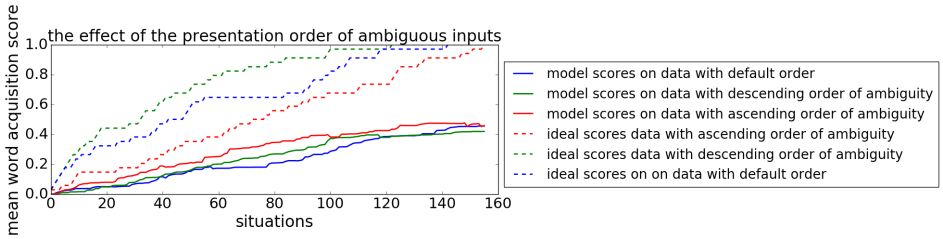

Figure 3: The mean word acquisition score over time as the incremental model (solid lines) is presented with three different datasets: (1) D-diRef-meRef (data with default order), (2) reordered D-diRef-meRef in ascending order of trial ambiguity, and (3) reordered D-diRef-meRef in decreasing order of trial ambiguity. The results are averaged over 50 runs, using the following parameter values: $\kappa = 0.005$, $\gamma = 0.3$, $\alpha = 5$, *keep-fraction* $= 0.5$ and *add-fraction* $= 0.5$. The dashed lines demonstrate the presentation rate of words in the gold standard lexicon in each dataset. The dashed lines also demonstrate the ideal mean word acquisition scores over time, if the model were to learn only the correct mappings at the end of each trial.

erential ambiguity precede the trials with high referential ambiguity. The results from our incremental model is in line with this expectation as the model achieves its best performance on the data with ascending order of ambiguity. Furthermore, the gap between the model performance and the ideal performance is the least when the data is presented in an increasing order of ambiguity. Finally, our results indicate that although input order affects the rate of acquisition, but (1) as more data becomes available, the extra cross-situational information inherent in data can make up for early input order effects resulting in similar word acquisition scores at the end of these experiments, and (2) that it is possible to replicate the input order effects using memory-limited continuous word learning mechanisms that accumulate information across all input trials.

6.3 The Presentation Order of Misleading Trials

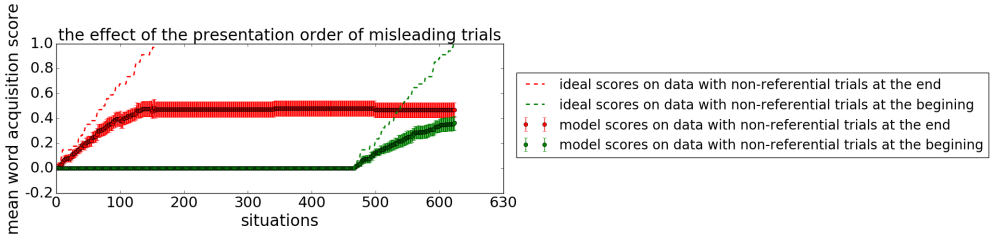

Figure 4: The mean word acquisition score over time as the incremental model (solid lines) is presented with two different datasets: (1) non-referential trials of di06 and me03 added at the end of D-diRef-meRef, (2) non-referential trials of di06 and me03 added at the beginning of D-diRef-meRef. The results are averaged over 50 runs, using the following parameter values: $\kappa = 0.005$, $\gamma = 0.3$, $\alpha = 5$, *keep-fraction* $= 0.5$ and *add-fraction* $= 0.5$. The dashed lines demonstrate the presentation rate of words in the gold standard lexicon in each dataset. The dashed lines also demonstrate the ideal mean word acquisition scores over time, if the model were to learn only the correct mappings at the end of each trial.

in Section 6.1, we demonstrated the inhibitory effect of misleading trials and their early presentation in the input data (as in D-me-di) on final word learning results (fscore, precision and recall). In order to establish what happens during the presentation of misleading trials and how the model is affected by these trials incrementally, we perform two more follow-up experiments using D-diRef-meRef dataset in increasing order of trial ambiguity: (1) putting back the non-referential trials of di06 and me03 at the beginning of D-diRef-meRef, (2) putting back the non-referential trials of di06 and me03 at the end of

D-diRef-meRef. These two follow-up experiments can be used to verify (1) if re-ordering the misleading trials can modulate their negative effect, and (2) how long lasting the effect of misleading trials is on word learning results.

Fig. 4 suggests that presenting the misleading trials after the referential trials seem to have no significant effect on previously learned correct mappings as no significant performance drop is observed on the red line. On the other hand, presenting the misleading trials before the referential trials, significantly affects the model performance as the solid green line remains significantly below the solid red line.

7 Discussion and Conclusion

We presented a variation of the incremental and memory limited word learning model in (Sadeghi et al., 2017) and provided the first corpus evaluations of this type of sub-optimal model. Our corpus evaluations demonstrated superior model performance compared to baseline incremental models. In addition to that the performance of the incremental model was close to the performance of the its batch counterpart (Frank et al., 2009), specially when misleading trials were removed from the corpus but only the incremental model was capable of accounting for input order effects.

We examined the replication of significant input order effects reported in (Medina et al., 2011; Trueswell et al., 2013; Zhang and Yu, 2017) in our model (1) incrementally, (2) on multiple datasets with different size and presentation order of ambiguous and misleading data, and (3) using different parameter values (Fig.2). The predictions of our model regarding the input order effects were in line with the recent empirical findings in (Medina et al., 2011; Trueswell et al., 2013; Zhang and Yu, 2017) as the model exhibited sensitivity to the information content of input trials as well as their presentation order. More specifically the model performance was best when highly informative (with low referential ambiguity) trials preceded the low informative (with high referential ambiguity) trials and when misleading trials were removed. Our simulations with different parameters showed that these outperformance patterns were robust against the choice of model parameters. Furthermore, our simulation results suggest that exposure to more data can neutralize early input order effects and that *memory-limited* continuous word learning mechanisms can replicate the input order effects.

The presented model is more cognitively plausible than its batch counterpart in that it is incremental and memory-limited. In addition to that, it relies on sub-optimal learning approaches (local optimization) as it utilizes a limited memory of past observations for incremental hypothesis generation and hypothesis evaluation performed by Bayesian inference. Applying the Bayesian inference locally and with limited data as evidence, allows the model to avoid becoming inefficient as the size of input data grows.

This work is the first corpus evaluation of a sub-optimal word learner which not only produces comparable functional performance to that of its optimal counterpart (Frank et al., 2009), but also successfully replicates the input order effects reported in experimental studies. Overall, the presented sub-optimal word learner is the first step towards exploring (1) local approaches to learning, (2) which depart from computationally expensive ideal learners, (3) without a huge loss in functional performance, (4) while replicating human performance, and (5) accounting for real-world constraints faced by learners (e.g., an infant or a robot). Furthermore, this work serves as an examination of the loss and gain of departing from optimal learners by performing direct comparisons between a sub-optimal model and its optimal counterpart. Taking (Frank et al., 2009) as a particular optimal model and the proposed model here as its sub-optimal version, we presented the loss (in functional performance) and gain (predicting input order effects) of departing from an optimal model (Frank et al., 2009).

In future work we plan to modulate model's memory of past observations (the number of observations that can be remembered with full details) to establish the effect of memory on replication of input order effects. Furthermore, we plan to compare our model with other sub-optimal models (Stevens et al., 2017) to gain a better understanding of the computational requirements for modeling the input order effects reported in experimental word learning literature.

Sentence Weighting for Neural Machine Translation Domain Adaptation

Shiqi Zhang **Deyi Xiong***
School of Computer Science and Technology, Soochow University, Suzhou, China
zzssq77@163.com, dyxiong@suda.edu.cn

Abstract

In this paper, we propose a new sentence weighting method for the domain adaptation of neural machine translation. We introduce a domain similarity metric to evaluate the relevance between a sentence and an available entire domain dataset. The similarity of each sentence to the target domain is calculated with various methods. The computed similarity is then integrated into the training objective to weight sentences. The adaptation results on both IWSLT Chinese-English TED task and a task with only synthetic training parallel data show that our sentence weighting method is able to achieve an significant improvement over strong baselines.

1 Introduction

Neural machine translation (NMT) has achieved more satisfactory performance than statistical machine translation (SMT) on many language pairs with various advantages over SMT, such as no pipeline-style training, more fluent translations and so on. However, it is still confronted with a big challenge in domain adaptation as the translation quality of NMT is heavily dependent on the quantity of training data and the relevance between the training data and the in-domain testing data. The training corpus usually varies across domains, where out-of-domain instances that are relevant to the target domain are beneficial for training while those which are irrelevant to the in-domain may deteriorate translation quality. The widely-used domain adaptation method in NMT is to fine-tune an existing out-of-domain model with the in-domain data (Luong and Manning, 2015). However, the fine-tuning method is of no consideration for the harm caused by irrelevant out-of-domain data. It also tends to overfit rapidly due to the small size of the in-domain data.

In this paper, we propose a sentence weighting method that evaluates the weights of sentences with respect to the relevance of sentences to the target domain. We train NMT models by assigning each sentence with a corresponding weight computed according to a domain similarity metric. Domain similarity has been successfully used in some tasks such as parsing, knowledge adaptation, etc.(Plank and Van Noord, 2011; Ruder et al., 2017). We employ domain similarity to measure relevance between the sentences of out-of-domain and in-domain data. In this way, we take into consideration both the goodness and the badness brought by out-of-domain data, in a weighting fashion. Additionally, different from current sentence weighting methods used for NMT that score sentences by making use of other toolkits like the SRI Language Modeling Toolkit (Stolcke, 2002), or an RNN classifier (Chen et al., 2017), our method exploits the information from the NMT system itself. This means that we do not need to train extra toolkits. We also examine the effectiveness of the proposed sentence weighting method on NMT trained with only synthetic parallel data, which is beneficial for the low-resource domain translation. Our method can also be used in back translation and in conjunction with other training methods.

Experiments show clear gains on the IWSLT Chinese-English task. Comparing to the previous sentence weighting method (Wang et al., 2017b), we achieve the highest improvement of 1.71 BLEU among four test sets, and obtain an average gain of 1.42 BLEU over Wang et al. (2017b)'s method. The experiments on NMT trained with only synthetic parallel data further confirm the effectiveness of our sentence weighting method on domain adaptation.

The paper is organized as follows. Section 2 overviews related work. In section 3, we give a background introduction of NMT. We present our sentence weighting method in Section 4. In section 5, we introduce the experimental setting and the NMT model configurations. In section 6 we show and discuss the results of our two groups of experiments, followed by our conclusion and future works in section 7.

2 Related Work

A lot of investigations have already been conducted for domain adaptation in SMT while few in neural machine translation. These methods can be roughly categorized into two classes: the model-level and data-level method.

At the model level, combining multiple translation models in a weighted manner is used for SMT domain adaptation. For NMT, fine tuning, model stacking and muti-model ensemble have been explored (Sajjad et al., 2017). Luong and Manning (2015) propose a fine-tuning method, which continues to train the already trained out-of-domain system on the in-domain data. Model stacking is to build an NMT model in an online fashion, training the model from the most distant domain at the beginning, fine-tuning it on the closer domain and finalizing it by fine-tuning it on the in-domain data. Muti-model ensemble combines multiple models during decoding using a balanced or weighted averaging method.

At the data level, traditional domain adaptation approach can be done by data selection, data weighting or data joining. Data selection approaches select data similar to the in-domain data according to some criteria. Normally, the out-of-domain data can be scored by a model trained on the in-domain data and out-of-domain data. For example, a language model can be used for scoring sentences (Axelrod et al., 2011). Data weighting methods weight each item which can be a corpus, a sentence or a phrase, and then train SMT models on weighted items.

Although some existing SMT domain adaptation techniques can be directly applied to NMT, it is challenging for applying data weighting to NMT. For NMT, the data selection approach can also be used. Wang et al. (2017a) employ the data selection method for domain adaptation, which uses sentence embeddings to measure the similarity of a sentence pair to the in-domain data. A recent method to apply sentence weights to NMT is cost weighting (Wang et al., 2017b; Chen et al., 2017). The NMT objective function is updated by sentence weighting when computing the cost of each mini-batch during NMT training. Wang et al. (2017b) exploit an in-domain language model (Axelrod et al., 2011) to score sentences. Chen et al. (2017) use a classifier to assign weights for individual sentences pairs.

Domain control uses word-level domain features in the word embedding layer, aiming to allow a model to be built from a diverse set of training data to produce in-domain translations (Kobus et al., 2017).

3 NMT

In this paper, we use the vanilla attention-based NMT (Bahdanau et al., 2014), which we will briefly summarize here.It is built on a recurrent neural networks (RNN) in an encoder-decoder framework (Sutskever et al., 2014; Pascanu et al., 2013).

Given a source sentence $x = (x_1, x_2, ..., x_m)$ and its corresponding target sentence $y = (y_1, y_2, ..., y_n)$, NMT employs the encoder-decoder framework to jointly train to maximize the conditional probability $p(y|x)$. To solve the problem that a basic encoder-decoder framework deteriorates rapidly as the length of input sentence increases, the attention mechanism (Bahdanau et al., 2014; Luong et al., 2015) is proposed.

The encoder employes a bi-directional RNN to encode the source sentence x into a sequence of hidden states h. h is the concatenation of the forward hidden state $\overrightarrow{h_i}$ and backward hidden state $\overleftarrow{h_i}$. Each hidden state h_i is computed from the previous hidden state h_{i-1} and the current source word x_i as follows.

$$\overrightarrow{h_i} = f(\overrightarrow{h}_{i-1}, x_i)$$

The decoder reads the hidden states and predicts the target translation by maximizing the conditional log-probability of the correct translation y. Each word y_i is predicted based on a recurrent hidden state s_i and a context vector c_i that aims at capturing relevant source-side information. c_i is computed as a weighted sum of the annotation h_i,

$$c_j = \sum_{j=1}^{m} \alpha_{ji} h_i$$

The weight α_{ji} of each annotation h_i is a normolized output from a softmax operation with a two layer feed-forward neural network ϕ. The weight α_{ji} of each annotation h_i indicates the probability of the target y_j being aligned to the source x_i.

$$\alpha_{ji} = \frac{exp(\phi(s_{j-1}, h_i))}{\sum_{k=1}^{n} exp(\phi(s_{j-1}, h_k))}$$

The probability of the target sentence y given a source sentence x is modeled as

$$P(y|x) = \prod_{j=1}^{m} P(y_j|s_j, y_{j-1}, c_j)$$

with s_j being the decoder state, c_j being the context, y_{j-1} being the last generated word.

Given a parallel corpus D, the parameters θ are trained to maximize the conditional probabilities of all sentences:

$$J = \sum_{(x,y)\in D} log(y|x)$$

4 Sentence Weighting for NMT

We evaluate domain adaptation methods on two different kinds of scenarios. One is for the usual domain adaptation that adapts a model trained on a rich-resource out-of-domain corpus to the in-domain with limited data. The other is for low-resource domain translation task, where only synthetic parallel data are available. For the latter, all the data are from the same domain while there are some differences between the true data and pseudo data. There also must be some mismatch between pseudo data and test data. For this kind of translation task, we can consider the development set as in-domain data, and the whole training data as out-of-domain data, though actually all data are from the same domain.

4.1 Sentence Weighting for Standard Domain Adaptation

We evaluate the out-of-domain sentences according to their domain similarity to the in-domain data. We consider the distribution of sentences in one domain corpus as the representation of the domain. Our hypothesis is that the average of all sentence embeddings (Wang et al., 2017a) in the domain space represents the core of the domain. In this way, we define the similarity measure between a sentence and a domain into that of the sentence to the core of the domain. The sentence embedding (Wang et al., 2017a) s_i is the representation of the initial hidden state for the decoder (Bahdanau et al., 2014). We can measure the Euclidean distance between the sentences and the domain with a method used by Wang et al. (2017a). In addition, we propose a new sentence weighting method using Jensen-Shannon (JS) Divergence (Lin, 1991) to measure the domain similarity.

We use softmax function to transform sentence embeddings into a probability distribution. Given a domain corpus of size N where each sentence embedding s_i is the initial hidden state for the decoder which is transformed from the embedded source sentence vector (Wang et al., 2017a), the probability of a sentence is computed as follows.

$$\sigma_{s_i} = \frac{exp(s_i)}{\sum_{k=1}^{k=N} exp(s_k)}$$

We therefore choose the Jensen-Shannon (JS) Divergence as the similarity function to measure the similarity between a sentence and a domain based on the distribution..

The Jensen-Shannon Divergence is a probabilistically-motivated function. It is symmetric and computes the Kullback–Leibler (KL) divergence between q and r, and their average. We use the JS divergence defined in (Lee, 2001):

$$JS(q,r) = \frac{1}{2}\left[D(q||avg(q,r)) + D(r||avg(q,r))\right]$$

where $D(q||r)$ is the KL divergence, which is a classical measure of "distance" between two probability distributions, and is defined as:

$$D(q||r) = \sum_y q(y) log \frac{q(y)}{r(y)}$$

We use JS Divergence to rank the out-of-domain sentences as follows:

$$-(JS_I(\sigma_{s_i}) - JS_O(\sigma_{s_i}))$$

where $JS_I(\sigma_{s_i})$ is the JS divergence between sentence representation σ_{s_i} and the in-domain representation. $JS_O(\sigma_{s_i})$ is the JS divergence to the out-of-domain data.

In practice, we use bilingual JS Divergence to compute the similarity metric, partially inspired by (Axelrod et al., 2011; Wang et al., 2017a; Wang et al., 2017b). Bilingual JS Divergence indicates that we takes into account both similarities on the source and target side of the corpus, which is calculated as follows.

$$\begin{aligned}\alpha_i = JS_{Osrc}(\sigma_{s_i}) - JS_{Isrc}(\sigma_{s_i}) \\ + JS_{Otrg}(\sigma_{s_i}) - JS_{Itrg}(\sigma_{s_i})\end{aligned}$$

$w(s_i)$ is a normalized output from a Min-Max Normalization (Priddy and Keller, 2005) over α_i. $w(s_i)$ estimates the weight of sentence s_i, in range of [0,1].

$$w(s_i) = \frac{\alpha_i - min(\{\alpha_i\}_{i=1}^N)}{max(\{\alpha_i\}_{i=1}^N) - min(\{\alpha_i\}_{i=1}^N)}$$

To train NMT with the weighted sentences, we update the objective function as follows:

$$J^* = \sum_{(x,y)\in D} w(s) log(y|x)$$

4.2 Sentence Weighting for NMT Trained with Only Synthetic Parallel Data

In domain adaptation, we measure the similarity between sentences in out-of-domain and the in-domain. We also test our sentence weighting method on synthetic parallel data. The existing pseudo parallel corpora is constructed with true and synthetic sentence pairs. The pseudo

IWSLT ZH-EN	#sentences

TED tst 2014	1.3k

Table 1: Statistcs of the data used for the IWSLT task

parallel corpora can be source-originated, target-originated or mixture of them. In the low-resource domain translation task , we evaluate the similarity between sentences in training data and the development set. We use the bilingual JS Divergence method as follows:

$$\alpha_i = -JS_{Isrc}(\sigma_{s_i}) - JS_{Itrg}(\sigma_{s_i})$$

We regard all training data in the low-resource domain as out-of-domain data. To improve the translation performance, we apply a different cost weighting method by adding 1 to the normalized probability (Chen et al., 2017). This is to give the original training data a bonus to some degree. We use the following objective function instead:

$$J^* = \sum_{(x,y)\in D} (1 + w(s))log(y|x)$$

5 Experiments

The proposed methods were evaluated on two scenarios: standard domain adaptation and translation with synthetic parallel data which can be cast as a domain adaptation task. We will detail the experiment settings and results in this section.

5.1 Domain Adaptation

5.1.1 Data

For the Chinese-to-English translation domain adaptation task,we used an LDC news corpus as the out-of-domain data for the IWSLT 2017 (mainly contains TED talks) target domain corpus. The LDC bilingual corpus contains 1.25M sentence pairs extracted from LDC corpora, with 27.9M Chinese words and 34.5M English words. The IWSLT 2017 in-domain corpus contains 210k and 0.9k sentence pairs, for training and development set, respectively. We chose the TED TST2010, TED TST2011, TED TST2012, TED TST2014 datasets as our test sets. Statistics on the data of this task are shown in Table 1.

5.1.2 Setting

We used the case-insensitive 4-gram NIST BLEU score as our evaluation metric (Papineni et al., 2002) and the script 'mteval-v11b.pl' to compute BLEU scores. For the efficient training of the neural networks, we limited the source (Chinese) and target (English) vocabularies to the most frequent 30k words, covering approximately 97.7% and 99.3% words of the two corpora respectively. All the out-of-vocabulary words were replaced with a special token UNK. The dimension of word embedding was 620 and the size of the hidden layer was 1000. All other settings were the same as in (Bahdanau et al., 2014). The maximum length of sentences that we used to train the NMT model in our experiments was set to 50, for both the Chinese and English sides. Additionally, during decoding, we used the beam-search algorithm and set the beam size to 10. The model parameters were selected according to the maximum BLEU points on the development set.

Methods	tst2010	tst2011	tst2012	tst2014	Avg
In+Out	17.26	18.73	17.43	16.1	17.38
Wang et al. (2017b)	17.1	19.35	17.26	16.69	17.6
JS	17.57	19.74	17.84	17.78	18.23(+0.63)
ED	18.81	20.45	18.81	18.02	19.02(+1.42)

Table 2: IWSLT Chinese-English results

5.1.3 Results

Experiment results are shown in Table 2. "In+Out" indicates that the NMT training corpus is the mixture of in-domain and out-of-domain data. We also compared Wang et al. (2017b)'s sentence weighting method (hereafter WM), which uses a language model to score sentences. "JS" and "ED" indicate the methods that we proposed in Section 4.1 with similarity measured by Jensen-Shannon Divergence and Euclidean distance functions, respectively.

Our "JS" method achieves improvements over NMT (In+Out) by 0.31 - 1.68 BLEU. It also outperforms Wang et al. (2017b)' s sentence weighting method by 0.39 - 1.09 BLEU, and achieves an average gain of 0.63 BLEU over WM. Our "ED" method is much better than NMT (In+Out) by 1.38 - 1.92 BLEU, outperforming Wang et al. (2017b)' s sentence weighting method by 1.1 - 1.71 BLEU, and achieves an average gain of 1.42 BLEU over WM.

5.2 NMT with Only Synthetic Parallel Data

5.2.1 Data and Setting

We crawled Chinese and English monolingual sentences from E-commerce websites, including JD.com, Suning.com, Ebay and Amazon.com. We translated the crawled Chinese sentences into English and English sentences into Chinese using Google Translate API. This process provided us with a pseudo parallel corpus where either the source or the target side is correct. The final corpus contains 720k sentence pairs after filtering. We used this crawled and machine-translated corpus as our bilingual training data for E-commerce experiments. we also used BPE to process the training data.

The test and development set are from Alibaba. The development set contains 500 sentences and the test set contains 1,500 sentences. All model parameters are the same as indicated in Section 5.1.2, except for using Adadelta optimizer.

5.2.2 Results

The baseline is a system trained with the entire pseudo parallel corpus. We also apply Wang et al. (2017b)' s method in our experiment. The "JS" method obtains 0.7 BLEU points over the baseline, and outperforms WM by 0.44 BLEU points. The "ED" method is also better than WM.

In addition, we introduce a weighting and stacking training method that is inspired by model stacking method as described in Section 2. We trained several models in an online fashion, in the order of the similarity between the training corpus and the development set. We employed our sentence weighting approach described in Section 4 to calculate weights for sentences, and order training sentences by their weights. We start training the model on the entire training data. Similar to the model stacking method, we continue to train the model with half data of the ordered training corpora in the next epoch. Then we continue the training process with the quarter data in the same way. This weighting and stacking method outperforms the baseline by 1.15 BLEU points on the test set.

Methods	dev	tst
Baseline	15.46	13.35
Wang et al. (2017b)	16.04	13.61
JS	15.17	14.05
ED	15.34	13.73
Weighting and Stacking	15.36	14.50

SRC	各位女同胞们，大家好！你们还好吗?
REF	Hello, TEDWomen, what's up.
In+Out	ladies and gentlemen , hello ! are you okay ?
Wang	ladies and gentlemen , everybody ! are you good ?
JS	you guys , everyone ! are you okay ?
SRC	如果有什么类似受压迫奥运会，我肯定能拿金牌。
REF	if there was an Oppression Olympics, I would win the gold medal.
In+Out	if anything like the <UNK> Olympics, I will have a gold medal.
Wang	if there's something like the <UNK> Olympics, I certainly have a gold medal.
JS	if there were any similar olympic games, I would certainly take the gold medal.
ED	if there was something like the <UNK> Olympics, I would have a gold medal.

Table 4: Examples from the test set. Header "SRC" denotes source sentences. Header "REF" denotes reference translations. "In+out" represents the translations generated by "in+out" method, "Wang" by the sentence weighting method proposed by Wang et al. (2017b).

6 Analysis

6.1 Analysis on Sentence Representations

Evidence of the efficacy of the proposed similarity measure method can be visualized in Figure 1. In this figure, each symbol indicates one sentence which is represented by the normalized sentence embedding output σ_{s_i} from a softmax operation. We sample the out-of-domain (the LDC corpus) source sentences into 3 groups. Each group contains 20 sentences whose weights are around 0, 0.5 and 0.9 respectively. We also randomly select 20 sentences from the in-domain data.

From this figure we can see that the in-domain sentences are around the center of the in-domain, so do the out-of domain sentences. The visualization confirms our hypothesis in that the average of sentence embeddings represents the core of the domain (Section 4.1). What's more, we can find that the weight generated by our domain similarity method is reasonable. Sentences assigned similar weights are grouped together and far apart from those with different weights. In addition, the more similar the representation of a sentence to the core of in-domain, the higher the weight assigned to it.

6.2 Analysis on Translation Examples

We show two translation examples in Table 4 to provide a deep look into how the proposed method help adapt the model to the in-domain data. In the first example in Table 4 , the reference sentence has an informally utterance, where the greeting "what's up" indicates that it is in an informal atmosphere. As depicted in the Table 4, the greeting "ladies and gentlemen" translated by "In+Out" and "Wang et al. (2017b)" is used on formal occasions. "you guys" in "JS" method is uesd in an informal occasion. The "JS" method is able to adapt the more official LDC style to the spoken language domain.

The source and reference sentences in the second example in Table 4 are expressions in sub-

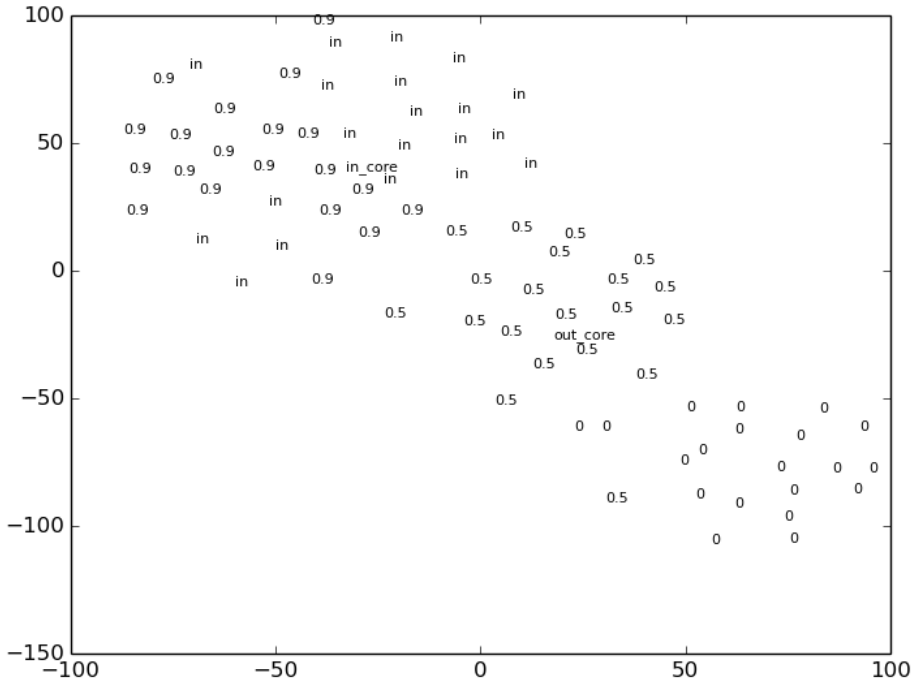

Figure 1: Visualization of sentence representations of both in-domain and out-of-domain examples by t-SNE. The symbols of "in", 0, 0.5, 0.9 in the figure represent the in-domain sentences, out-of-domain sentences with weights 0, 0.5 and 0.9, respectively. The symbol "in_core" denotes the in-domain center and "out_core" indicates the out-of-domain center.

junctive mood, which describes things that impossibly happen in real life. The translations of both "ED" and "JS" use the subjunctive mood and express the coincident meaning with the reference sentences. On the other hand, both "in+out" and "Wang et al. (2017b)" methods don't learn the right moods. As our LDC training data are in the news domain, sentences in this corpus seldom use the subjunctive mood. In the spoken language domain, the utterance is more free. Both the "ED" and "JS" methods have successfully adapted the model to the spoken language domain.

6.3 Analysis on the Terminology Adaptation

In domain adaptation, one of our goal is to extend generic NMT models to cover terminologies and styles in the target domain(Kobus et al., 2017). We analyse the distribution of terminologies on the IWSLT Chinese-English experiment. We calculate the proportion of in-domain and out-of-domain terminologies with respect to all words in the test set. We obtain terminology vocabularies according to differences of two sequences of words in both domains. The more in-domain terminologies and the fewer out-of-domain terminologies contained in the translations of the in-domain test sets, the better the domain adaptation is. The results are displayed in Table 5. The "ED" method with the best performance in terms of BLEU has successfully decreased the ratio of out-of-domain terminologies from 0.37% to 0.15% and increased the ratio of in-domain terminologies from 44.28% to 45.37%, indicating its ability to terminology adaptation.

7 Conclusions and Future Work

In this paper, we have proposed a sentence weighting method for neural machine translation on two different scenarios. We calculate the similarity of an out-of-domain sentence to the in-

Methods	ratio of O-D terminology(%)	ratio of I-D terminology(%)
In+Out	0.37	44.28
Wang et al. (2017b)	0.28	42.97
JS	0.20	43.80
ED	0.15	45.37

Table 5: The proportion of domain terminologies in the test sets of each method. "O-D" in header denotes out-of-domain. "I-D" represents in-domain.

domain with a variety of methods, including JS divergence and ED. The computed similarity scores are further incorporated into the training objective to weight sentences. The proposed method has obtained an achievement on both domain adaptation and NMT models trained with only synthetic parallel data where there is some mismatch between the training and test data. In the future, we would like to explore more accurate measures of domain similarity. We are also interested in the study of other weighting methods for NMT domain adaptation.

Acknowledgements

The present research was supported by the National Natural Science Foundation of China (Grant No. 61622209).We would like to thank three anonymous reviewers for their insightful comments and Alibaba for providing the test and development sets for our E-commerce experiments.

Quantifying training challenges of dependency parsers

Lauriane Aufrant[1,2], **Guillaume Wisniewski**[1] and **François Yvon**[1]

Abstract

Not all dependencies are equal when training a dependency parser: some are straightforward enough to be learned with only a sample of data, others embed more complexity. This work introduces a series of metrics to quantify those differences, and thereby to expose the shortcomings of various parsing algorithms and strategies. Apart from a more thorough comparison of parsing systems, these new tools also prove useful for characterizing the information conveyed by cross-lingual parsers, in a quantitative but still interpretable way.

1 Introduction

10 annotated sentences suffice to train a dependency parser that can correctly predict around 70% of the dependencies in French and Italian, but also in Japanese, Greek, Urdu and other languages. This surprising fact raises questions on how to interpret such numbers: what do those 70% dependencies look like? Are they evenly distributed or do they correspond to specific dependency structures?

This work is based on the intuition that in any treebank, some dependencies are intuitively easy to learn (typically nearly deterministic attachments like the dependencies between a noun and its determiner), while others seem much harder to predict, corresponding to complex semantic attachments or long lists of exceptions in the underlying grammar of the language. We thus propose one way to investigate that distinction, by evaluating the amount of training material needed to learn each kind of dependencies: with that viewpoint, a dependency structure is qualified as 'easy to learn' when it can be learned from only a few examples and as 'difficult to learn' otherwise. In this paper, we formalize this idea and propose empirical ways to measure the difficulty to learn certain dependencies.

Our metric proposal can be useful as an analysis tool for comparing existing parsers, which we illustrate both in monolingual and cross-lingual settings, but also to gain some insight on the information reliably conveyed by parsers trained on a few sentences. Ulinski et al. (2016) have indeed shown that such parsers can be successfully leveraged to speed up the manual annotation process. This observation confirms that they provide *some* useful content to the annotators, which our formalism can help characterizing beforehand.

The rest of this paper is organized as follows. Section 2 presents the dependency parsing task and the parsers used in this study. Our method for estimating difficulty is introduced in Section 3. We then apply these newly designed tools to conduct two analyses: a detailed comparison of several state-of-the-art parsers (Section 4), as well as a fine-grained evaluation of cross-lingual transfer (Section 5).

2 Dependency parsing

The purpose of the dependency parsing task is to predict, for each token in a sentence (the child), the token it depends on (its head), and thereby to build a tree structure over the sentence. There are several approaches to build such parsers, mostly corresponding to two categories: transition-based parsers

Proceedings of the 27th International Conference on Computational Linguistics, pages 3191–3202
Santa Fe, New Mexico, USA, August 20-26, 2018.

(which score and apply locally a sequence of transitions affecting the parser's inner state) and graph-based parsers (which compute attachment scores for all pairs of tokens and then optimize the sentence score globally).

In this work, we consider three dependency parsers, based on diverse parsing algorithms and classifiers, to assess the generality of our findings: UDPIPE (transition-based parser, with a feedforward neural classifier, i.e. embedding-based), BEAM (transition-based parser, with an averaged perceptron classifier, i.e. feature-based), and MSTPARSER (graph-based parser). We use version 0.5.1 of MSTPARSER (McDonald et al., 2005) with default parameters. For UDPIPE, we use version 1.1 (Straka and Straková, 2017) with the same hyperparameters as Straka (2017), but without the word embeddings pre-trained on massive monolingual data (to ensure comparability). For BEAM, we rely on our own open source[1] implementation, PANPARSER (Aufrant and Wisniewski, 2016), using the ArcEager version (Nivre, 2004) with a dynamic oracle (Goldberg and Nivre, 2012) adapted for beam search (Aufrant et al., 2017) and the feature sets of Zhang and Nivre (2011) (coarse PoS, no labels).

3 Measuring difficulty

The purpose of this work is to investigate dependencies for the learning of which large training datasets are unnecessary, and which can therefore be qualified as 'easy to learn'. In this section, we formalize this intuition and introduce several empirical measures to quantify it. We then exploit the results of large-scale evaluations to design a new metric, COMPLEXITY, which estimates the challenges faced when learning a given 'type' of dependencies: by departing from individual dependencies, we aim at discovering higher-level properties related to language-independent syntactic phenomena (like the simplicity of annotating determiners, independently of the language and the parsing system).[2]

As our focus is on how parsers exploit the first examples of a training set, even just 10 sentences, we consider in this work only treebanks under 500 sentences.[3]

For all experiments, we use the Universal Dependencies 2.0 dataset (Nivre et al., 2017b; Nivre et al., 2017a), containing 73 treebanks covering a wide array of language families. We first downsize each treebank, when possible, to the 500 first training sentences,[4] and resample smaller trainsets of increasing sizes.[5] Since training is significantly unstable at that scale, all reported scores are averaged over five random samplings, thereby amounting to 5,880 parsers trained on 56 languages. UAS evaluation is performed using gold PoS tags,[6] excluding punctuation.

3.1 Class-level learning rate

Dependency *classes* refer, in the following, to any criterion describing a subset of dependencies (and by extension, a subset of child tokens) in a treebank. The definition of a class can, for instance, be based on child-head distance, in-tree depth, edge direction, dependency label, empirical values like frequency, PoS tags, etc. Even though our method applies to any such criterion, we focus in this section on classes defined by the child PoS and its attachment direction. Indeed, it fits particularly well our intuition regarding many parsing difficulties: due to its frequency and determinism, the $\overset{\curvearrowleft}{\text{ADJ}}$ class (that is, all adjectives whose head is on the right) appears for instance simple in the English UD as it mostly corresponds to the bigram 'ADJ NOUN' and, sometimes, to predicative adjectives. On the contrary, the

[1] Source code available at `https://perso.limsi.fr/aufrant`.

[2] Such properties can still depend on the annotation scheme though, as repeatedly pointed out in the literature (Schwartz et al., 2012; Wisniewski and Lacroix, 2017; Wisniewski et al., 2018).

[3] This size has been chosen to cover both the scale of 10 sentences and that of existing treebanks, around 300 sentences: there have been publications with 300 Irish sentences (Lynn et al., 2012) or 371 in Slavomír Čéplö's Maltese treebank (Tiedemann and van der Plas, 2016).

[4] We similarly downsize the validation sets, used only for early stopping, to their first 10 sentences. We do not alter the test sets. We only experiment on the 56 treebanks that are large enough to apply these sampling procedures. `ar_nyuad`, whose complete data is under license, is also excluded.

[5] Resulting trainsets contain 5, 10, 20, 50, 100, 200 and 500 sentences.

[6] While less representative of real-world processing capacities (Tiedemann, 2015), we believe this choice to be crucial in such studies focusing on syntactic properties, whose measurement would otherwise be biased by properties of the taggers and language-dependent vocabulary issues.

attachment decisions on $\overset{\curvearrowright}{\text{ADJ}}$ tokens seem more complex, first of all because the PoS of the head is uncertain (sometimes a VERB, a NOUN, another ADJ, etc.). What remains to ascertain is whether this simple/complex distinction can relate to measurable properties.

Our first experiment aims at studying the rate at which the different dependency classes are learned. In this experiment, we are not interested in the absolute scores over each class, but rather in how fast the *available* information (regarding a given class) can be extracted from a treebank: has everything been already learned in the 10 first sentences? Would 100 more sentences be really informative? Consequently, all measures are performed in terms of UAS normalized by its maximum, in order to set aside the differences due only to the inherent accuracy of a class. In other terms, for class C (e.g. $\overset{\curvearrowright}{\text{DET}}$) and treebank size s (e.g. 50 sentences), we measure $\text{UAS}_s[C]$, the number of tokens in class C whose head has been correctly predicted based on a treebank of size s, and then compute $\frac{\text{UAS}_s[C]}{\text{UAS}_{500}[C]}$. These values are computed separately for each language, and then averaged over all languages[7] to expose language-independent trends, i.e. searching for properties of e.g. determiners as a universal category, while ignoring their idiosyncratic uses in individual languages (e.g. their scarcity in Latin, the annotation scheme for French multi-word expressions containing determiners, etc.).

Figure 1 presents the resulting learning curves for the UAS broken down by class, as well as for the overall score in each language (using BEAM parsers). For legibility (notably around 10 sentences), but also to consider equally the learning speed at all size scales, it is displayed with a logarithmic scale. In this view, the slope of the curve can be interpreted as the marginal utility of doubling the treebank size.

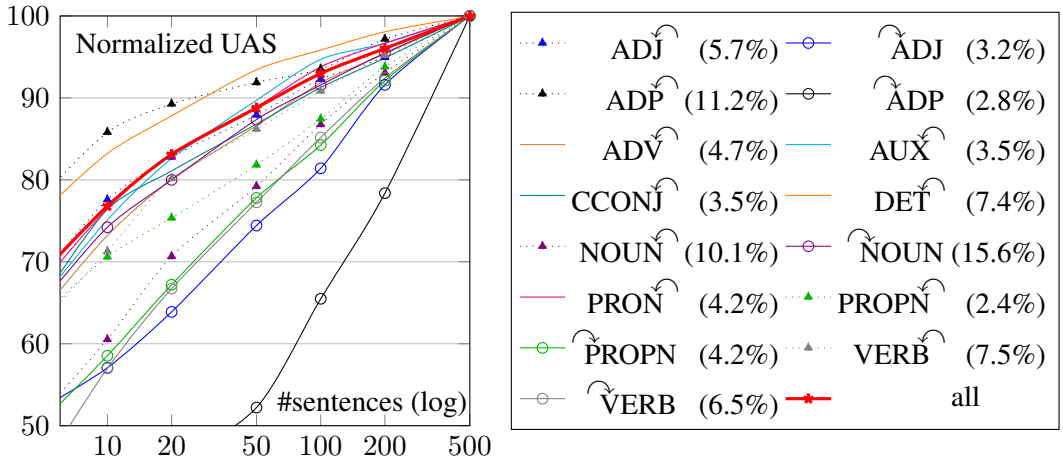

Figure 1: Learning curves of UAS by PoS/direction class. $\overset{\curvearrowright}{\text{P}}$ (resp. $\overset{\curvearrowleft}{\text{P}}$) means all dependencies whose child PoS is P and reference head is on the left (resp. right, including roots). Percentages indicate the size of each class; the rarest ones are not represented.

Unsurprisingly, all fine-grained curves and the overall one are roughly linear: even though they rise quickly to high accuracies, subsequent examples tend to contribute less and less to accuracy, so that the dataset must be doubled each time to achieve substantial UAS improvements. This supports the idea that, overall but also *for each class*, most knowledge is extracted from the first few examples, and additional data is poorly informative.

What is more intriguing in Figure 1 is that the relative curves can clearly be partitioned into two groups,[8] quickly-converging curves and slower-increasing ones, separated by a significant margin. This observation is consistent with our intuition whereby there are two kinds of dependency classes, the simple and the complex ones: as expected, $\overset{\curvearrowright}{\text{DET}}$ and $\overset{\curvearrowleft}{\text{AUX}}$ for instance belong to the former, i.e. the classes for which most of the available information can already be found in the first examples.

[7] To ensure reliable scores, we exclude the treebanks whose test set contains less than 30 occurrences of the considered class.

[8] Because Figure 1 has 3 outliers, it contains in fact 4 groups, but such detailed distinctions are out of the present scope, and the two retained groups are the curves which start at 70% of their final value, and those which start around 50%.

One explanation to these differences in learning rate could be the frequency of classes: those which occur more often are more likely to appear a lot in the first examples, which makes them mechanically easier to learn. However, the ranking of the curves does not seem fully consistent with the size of the corresponding classes: DET has a steeper curve than ADJ, which is itself steeper than NOUN, although ADJ is the least frequent of all three.

Evidence rather suggests that this ranking relates to linguistic properties (like word order entropy), complemented by phenomena of the 'rule versus exception' kind: among competing classes (with different directions for the same PoS, e.g. ADJ versus ADJ), there is systematically one simple and one complex class, in general according to their frequency – but not always, as shown by PROPN. A thorough investigation to explain learning speed differences is however out of the scope of this work, which focuses on measuring them.

3.2 Complexity measures

Although the aforementioned experiment has already revealed interesting trends, a systematic evaluation of complexity requires to go beyond visual reading of curve shapes. But their slope is not properly defined, considering that for several classes, learning speed can show significant variations between 5 and 500 sentences. We consequently aggregate the curve shape into a single metric by computing the area under the curve; yet we calibrate it on the average curve to enable cross-treebank comparison.[9] Formally, we define the COMPLEXITY of a class as the signed area[10] between the learning curve of the (normalized) overall score and that of the class. The logarithmic scale is kept to ensure that the slope at the smallest scale significantly contributes to the metric.[11] A negative COMPLEXITY (curve above average) means that training on this class is simple (most knowledge is embedded in the first few examples), a positive value denotes a complex class (compared to the typical complexity of the treebank). From now on, the terms *simple* and *complex* are respectively used to denote classes with negative and positive COMPLEXITY.

Table 1: Comparison of the COMPLEXITY and UAS rankings for all 3 systems. For each system, the classes with the largest difference between both rankings are highlighted in blue. N, PN and V stand for NOUN, PROPN and VERB.

Beyond a sign-based grouping criterion, these quantitative measures also provide an interesting diffi-

[9] This aggregation step is inspired by Zubek and Plewczynski (2016)'s work on data complexity, which is close in spirit to ours (with the same intuition that a dataset is simple if most information can be found in the first few examples) but explores a different setting: in their work, they measure the similarity of subsets of increasing sizes to the dataset itself (without involving a prediction step) and aggregate these values to estimate the complexity of that dataset.

[10] This can be computed easily using any numerical integration method. In the following experiments, we use Simpson's rule.

[11] In these experiments the area is computed between 5 and 500 training sentences, but another low-resource range could be chosen, provided that it is the same for all treebanks.

culty ranking. Table 1 compares the rankings based on UAS (using 500 training sentences) and COMPLEXITY. Overall, the results remain consistent with intuition: the simplest classes are closed PoS classes with very deterministic attachments (DET$^{\curvearrowleft}$, ADP$^{\curvearrowleft}$), the most complex ones are rare ($^{\curvearrowright}$ADP) or semantics-driven attachments ($^{\curvearrowright}$VERB), while classes of average difficulty are mostly NOUNs and other open classes. But differences between both metrics still appear clearly, thereby confirming that they capture different properties. For instance, high accuracies are achieved on SCONJ$^{\curvearrowleft}$, but getting there is cumbersome as it requires many training examples. Conversely, UDPIPE does not learn much about the $^{\curvearrowright}$AUX class (whose UAS is particularly low), but it does so almost immediately (as shown by its low complexity).

Finally, we perform similar computations on each treebank separately:[12] they reveal that, even though some classes have emerged as consistently simple across languages, this property can still depend on the language (sometimes even on the corpus). For instance, ADJ$^{\curvearrowleft}$ is simple and $^{\curvearrowright}$ADJ is complex in the English treebank, but in French it is the opposite, which is consistent with the respective frequencies of those classes (and thus with the initial intuition). Similarly, $^{\curvearrowright}$ADP is complex for all but 6 treebanks (from which the competing class ADP$^{\curvearrowleft}$ is virtually absent), and DET$^{\curvearrowleft}$, whose attachments are highly deterministic, is a simple class for all but 7 treebanks (mostly Old Church Slavonic, Arabic, Latin-PROIEL, but also Basque, Estonian, Korean and Polish to a lesser extent).

4 Application 1: fine-grained comparison of parsers

The metrics we have proposed can now be used for large-scale computation of fine-grained evaluations, and therefore detailed comparison of parsers. This newly defined notion of complexity opens indeed new evaluation perspectives, as a complement to the more explicit properties (length, PoS tags, projectivity, etc.) used in prior work on comparative error analysis (McDonald and Nivre, 2007).

Complexity variations Coming back to Table 1, comparing the rankings between all 3 systems also emphasizes on their respective shortcomings. UDPIPE notably seems to have troubles with determiners: not only does it achieve a lower score on DET$^{\curvearrowleft}$ dependencies, but it is also much slower learning those, compared to the other systems; UDPIPE consequently appears to under-exploit the determinism of that class.[13] It is conversely particularly efficient on CCONJs. As for MSTPARSER, it handles VERB$^{\curvearrowleft}$ significantly faster than BEAM and UDPIPE, presumably because it does not rely on mostly local features, as transition-based parsers do. Regarding the BEAM system, its main particularity is its efficient handling of AUX$^{\curvearrowleft}$ attachments, even though their UAS is around the same. Overall, according to Figure 2, COMPLEXITY correlates well with UAS_{500}, at least for BEAM and MSTPARSER (Spearman's ρ = -.886 and -.882); but it is hardly the case for UDPIPE (ρ = -.576), which points out at least a difference, and maybe an issue, which remains to ascertain. All those remarks provide a valuable feedback on the inner workings of each parsing system, and thereby new insights on possible issues. The COMPLEXITY metric thus provides a promising way to analyze and improve parsing algorithms in general.

Composite scores A more systematic way to study fine-grained differences between parsers is to investigate composite scores. However, for large inventories of classes, class-level analysis can be tedious and hide the main trends. For this reason, we advocate aggregating that information into 2 scores only, as a trade-off between simplicity and detailed analysis. Contrasting differences among parsers along two categories, simple and complex dependencies in the present case, is indeed already much more informative than relying on a single metric.

Table 2 reports the average UAS of the 3 parsers, when computed separately on simple and complex classes (that is, depending on the sign of COMPLEXITY), and for various data sizes. It appears that all

[12] In other words, we compute the area under a specific learning curve, instead of the area under the average of all learning curves.

[13] As UDPIPE is the only neural parser in our experiments, this differential treatment of deterministic classes may be related to the choice of classifier; concluding on such properties is out of the scope of this paper, though.

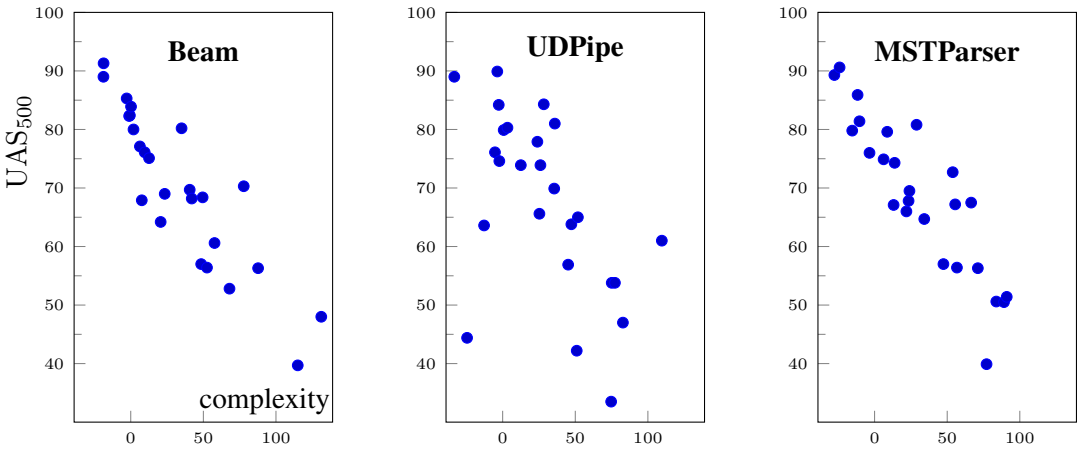

Figure 2: UAS of all 3 systems, with 500 training sentences, for classes of increasing complexity.

systems present a significant score difference (up to 30 points) between both categories, in favor of the simple one, in particular for tiny data (i.e. 10 sentences).

It is important to note that this result was not expected: it is true that UAS measures are involved when computing COMPLEXITY, but all these scores are first normalized. Therefore, the simple classes are not *by design* those with high accuracies on tiny data, despite what the results suggest.[14] In this regard, the score difference between both groups is an actual finding. Besides, the score gap is mostly maintained for full datasets, which means that the classes that have been singled out using tiny data have truly different properties (or at least are handled differently by the systems), whatever the data size.

	UAS_{10}			UAS_{500}			$UAS_{\text{full UD}}$		
	simple	overall	complex	simple	overall	complex	simple	overall	complex
UDPIPE	52.8	42.5	28.4	81.8	74.7	65.2	87.6	83.2	**77.3**
MSTPARSER	64.4	52.8	36.9	82.7	75.1	64.9	**88.2**	**83.4**	77.1
BEAM	**71.1**	**59.0**	**42.7**	**82.9**	**76.1**	**67.1**	87.3	82.6	76.4

Table 2: UAS of the 3 studied systems, broken down by simple and complex PoS/direction classes, and for various data sizes. The partitions and corresponding scores are computed separately for each language, before averaging. All partitions are computed using BEAM, so that the absolute scores remain comparable (best system in bold). 'Full UD' trainsets contain between 598 and 68,495 sentences.

When comparing each system's results, the dynamics between them become clear: while BEAM prevails across the categories around 10 sentences, MSTPARSER catches up first on simple dependencies (for 500 sentences), then also on the complex ones (for full UD). As for UDPIPE, it performs poorly with 10 training sentences, but then gradually reveals its worth for parsing specifically complex classes (which is consistent with its difficulties with determiners: this system is not so relevant for deterministic dependencies, its value is elsewhere).

5 Application 2: fine-grained evaluation of cross-lingual parsers

Apart from comparing systems, our proposal can also be used to compute reference values when evaluating other kinds of parsers, typically cross-lingual parsers. Cross-lingual transfer is an approach to process low-resourced languages, whereby resources available in other languages (the sources) are leveraged to

[14]There remains however an indirect impact of absolute scores on COMPLEXITY: the classes that reach already high scores (over 80 UAS) with only 10 sentences are doomed to be simple classes, because being complex would imply achieving more than 100 UAS with 500 sentences. So, there is indeed a score bias towards simple classes. But such classes with early high scores represent a minority of the dependencies (19% on average), and there are many other kinds of simple classes (for a total of 57% of dependencies), including poorly accurate ones.

build new systems in the language of interest (the target). The main methods involve typically projecting information through word-aligned parallel data (Yarowsky and Ngai, 2001), or training source models on delexicalized data (that is, using PoS information only) and directly applying them on the target side (Zeman and Resnik, 2008). The link with our work above is twofold: cross-lingual parsers also focus on low ranges of training sizes, and at the same time many of them yield UAS around the range covered by our 5 to 500-sentence long treebanks. We therefore propose to exploit our upper results in this new frame, with the goal of quantifying and characterizing the amount of knowledge that has been effectively transferred: what kind of information is learned by cross-lingual parsers – only simple classes or complex knowledge about non-trivial classes?

Multi-source weighted delexicalized transfer Our analysis first focuses on Rosa and Zabokrtsky (2015)'s state-of-the-art method for cross-lingual parsing: it consists in delexicalized transfer, where the hypotheses stemming from multiple sources are weighted and combined based on the KL_{cpos^3} metric (the Kullback-Leibler divergence of PoS trigram distributions between the source and the target). It is meant to favour the languages that are syntactically close to the target, while still benefiting from the diverse information conveyed by a large set of sources.

We reimplement the method of Rosa and Zabokrtsky (2015) on top of the BEAM system: we include as sources the delexicalized BEAM models based on all 56 (full) treebanks except those covering the same language. All scores are again averaged over 5 different trainings. To be fair regarding the available target resources, the KL_{cpos^3} metric is computed using the whole source treebank but only 10 target sentences. In the following, this strategy is referred to as KL-BEAM.

Composite scores Similarly to what has been done for monolingual parsers, we can express the performance of KL-BEAM in terms of simple-only UAS and complex-only UAS (using the partition computed monolingually with BEAM for instance). Those values alone are, however, hard to interpret, and notably to relate to the actual amount of knowledge transferred via KL-BEAM.

We therefore propose to position those scores along the learning curves of the monolingual parser, following Aufrant et al. (2016): if the cross-lingual parser achieves the same score as a parser trained on n sentences, we consider that the amount of transferred knowledge is the amount of knowledge contained in n sentences. Figure 3 consequently pictures the learning curves of each system on simple and complex classes (using the PoS/direction criterion), as well as the split UAS for KL-BEAM on the same categories.

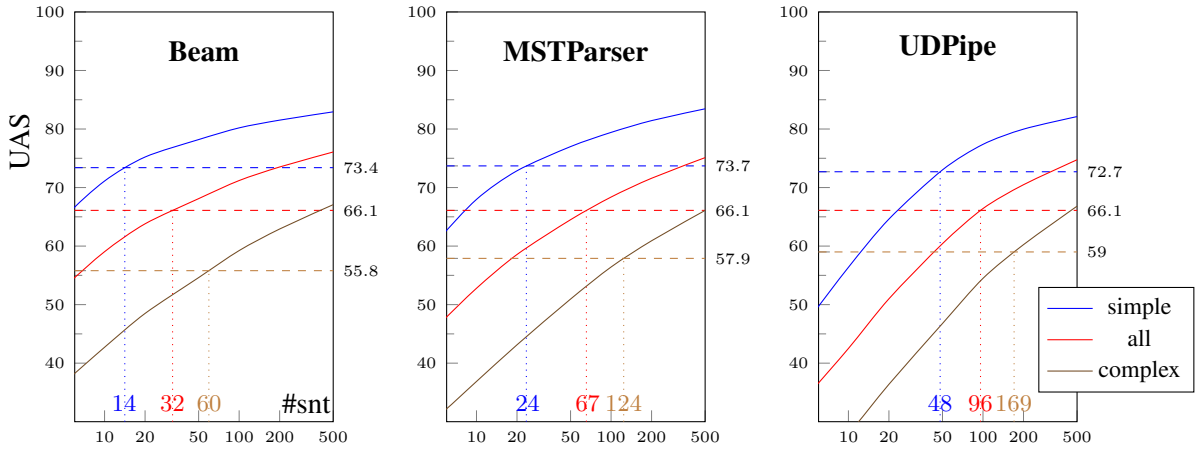

Figure 3: Overall and simple/complex UAS of all 3 parsers with increasing training sizes. The partitions and corresponding scores are computed separately for each language and system, before averaging. Dashed lines correspond to the overall, simple and complex UAS for KL-BEAM, using the partition computed for each system. Dotted lines represent the corresponding numbers of annotated training sentences.

Overall, KL-BEAM achieves 66.1 UAS on average, which corresponds to what could have been achieved by BEAM with 32 sentences. In other words, if more than 32 target sentences are available,

on average one should prefer monolingual parsing (at least when using BEAM) over KL-BEAM transfer:[15] the amount of knowledge transferred across languages seems very limited.

However, when considering the simple/complex scores, it appears that their difference is less pronounced for the cross-lingual parser than the monolingual ones, which results in distinct data-size equivalents. Delexicalized transfer thus appears much more useful for complex classes (score equivalent to 60 sentences) than for simple classes, for which few information was transferred (score equivalent to 14 sentences). This means that KL-BEAM is qualitatively better than a BEAM trained on 32 sentences: it is able to convey non-trivial information, which otherwise would have only been accessible by collecting more data.

As UDPIPE and MSTPARSER are less efficient on very small treebanks, the data-size equivalents are much higher, but the simple/complex difference remains similar in proportions. We additionally perform similar experiments with other class criteria and obtain similar results, although the simple/complex gap marginally fluctuates: for BEAM, we measure 20 versus 43 sentences (74.6 and 58.9 UAS) when considering only the PoS, 15 versus 60 sentences (74.6 and 56.4 UAS) when considering the relation label only, and 13 versus 67 sentences (74.8 and 53.6 UAS) when using the PoS, label and direction at the same time.

Other non-conventional parsers The observations made in this section shed a new light on the performance of state-of-the-art parsers trained using non-conventional data. The accuracies achieved with very small datasets are indeed comparable to other scores reported in the recent literature.

In the original experiments conducted with multi-source weighted delexicalized transfer (not based on BEAM), Rosa and Zabokrtsky (2015) achieve an UAS of 52.5 on HamleDT 2.0; in another line of cross-lingual parsing, the projection technique of Tiedemann and Agić (2016) yields 75.43 UAS on UDT 1.0 (COMBG model). Although neither work is conducted on UD 2.0, and thus the comparison is inexact, our metrics can still provide a rough estimation of each method's success: using UD 2.0, these scores would have been achieved by training on, respectively, 5 and 444[16] sentences. Empirical evidence hence raises serious doubts on the actual effectiveness of the main transfer techniques: cross-lingual parsers embed a limited amount of knowledge, and do not save much annotation effort. This is less true for methods based on projection, but these already require large data and significant human efforts to find, clean and sentence-align parallel data – a work which may turn out to be more demanding than annotating a small treebank.

Unsupervised parsing is another field in which parsers are trained in a non-conventional way, and would thus benefit from a comparison with monolingual supervision. For instance, Mareček and Straka (2013) achieve 48.7 UAS on average over the CoNLL 2006-2007 treebanks, while the average UAS of the rule-based approach of Martínez Alonso et al. (2017) is 57.5 on UD 1.2. These UAS correspond to 4 and 9 annotated sentences, which, again despite the dataset mismatch, still highlights how much work remains to be done in that field.

Size-based evaluation can consequently provide interesting reference points for parsers stemming from many fields: cross-lingual transfer and unsupervised models, but also many others like domain adaptation for instance.

Information conveyed by one source As a final experiment, we propose to evaluate the contribution of a given source to multi-source transfer, in terms of the amount of conveyed information.

[15] Because it is an average, this boundary should not be interpreted in a strict sense but as a trend: it is not applicable to each individual language in the considered set. The ability to transfer syntactic information depends indeed a lot on the linguistic setting (standard deviation of 15.3 UAS for KL-BEAM), so that the averages presented here do not replace any prior knowledge on transfer results for a given known language. However, when tackling a *new* language, they can provide a rough estimate to choose between the monolingual and cross-lingual approaches.

[16] While this amount can appear already substantial, it also denotes the fact that Tiedemann and Agić (2016)'s evaluation is based on a set of languages with marked relatedness, and thus good transfer properties. When averaging our measures only over that set of languages (but still not the same treebanks), the data-size equivalent drops to 92 sentences. Similarly, Lacroix et al. (2016)'s projection approach achieves 79.62 UAS, which is higher than with 500 sentences when considering all UD 2.0 treebanks, but corresponds to 295 sentences when retaining the same set of languages. Overall, the magnitude remains around a few hundred sentences for projection methods.

We build a cross-lingual parser for Romanian, using KL-BEAM as before but with a much smaller source set: French, Italian, Spanish and Bulgarian. The choice of the first three is motivated by their language family (Romance, like Romanian), and Bulgarian by geographic proximity (and hence various influences across history). This parser is then compared (overall and also along simple/complex classes) with those obtained when removing either one of the sources, in order to characterize precisely their contribution.

Table 3 reports the overall and simple/complex UAS measures, as well as data-size equivalents based on the Romanian BEAM. Comparing the full source set with the reduced ones, the respective benefits of each source appear clearly: Italian and French convey mostly complex information (respectively +0.3/+1.8 and +0.2/+1.2 on simple/complex scores), while Bulgarian improves mostly on simple classes (+1.5/+0.2 on simple/complex scores) and Spanish contributes equally in both cases (+1.5/+1.2).

Sources	UAS (ro)			#sentences (ro)		
	simple	overall	complex	simple	overall	complex
fr + it + es + bg	81.4	74.4	60.3	167	213	231
✗ it es bg	81.2	73.8	59.1	149	165	179
fr ✗ es bg	81.1	73.6	58.5	142	155	162
fr it ✗ bg	79.9	73.0	59.1	77	131	179
fr it es ✗	79.9	73.3	60.1	77	142	219

Table 3: Cross-lingual UAS and equivalent monolingual supervision in Romanian, for a KL-BEAM parser trained with various sets of sources. The simple/complex partition is that of BEAM in Romanian.

Regarding Spanish and Bulgarian, it is interesting to note that combining both sources more than doubles the amount of knowledge on simple classes (from 77 to 167). This suggests that multi-source combination itself enables valuable interactions between languages, thereby granting access to knowledge that would have been hard to obtain otherwise.

The results for Bulgarian are worth a closer look: the kind of information it conveys corresponds to syntactic structures that are easy to learn in Romanian (possibly deterministic), and yet not provided by other (Romance) sources. The Bulgarian influence on Romanian – in other words the structures that are out of the scope of Romance syntax – consequently seems to materialize as straightforward dependencies on unambiguous patterns.

On a final note, looking at composite scores instead of UAS only safeguards against overrating a given language: for instance, even though Spanish seems more valuable as a source than Italian (73.6 vs 73.0), it is only so because of the (numerous) simple dependencies, and it actually underperforms Italian on complex dependencies, where the true challenge is though.

6 Conclusion

In this work, we have introduced a new metric, called COMPLEXITY, to evaluate the difficulty to learn a given class of dependencies, in terms of data requirements: inspired by an in-depth analysis of fine-grained learning curves, we have aggregated their information into a single value. A series of systematic computations using that metric has unveiled interesting properties of the 3 considered parsing algorithms; it has notably revealed the kind of dependencies for which the parsers make an abnormally high amount of efforts during training, and hinted at some syntactic properties that they under-exploit.

Computing composite scores by separating simple and complex dependencies has been further enlightening for analyzing the aforementioned parsers, but above all it has enabled an extensive assessment of the benefits of parsers trained in a non-conventional way, typically cross-lingual parsers. While the typical UAS achieved by delexicalized transfer remain low and can easily be obtained with just a sample of target-side supervision, the information conveyed by cross-lingual parsers has in fact appeared of better quality: their actual added value is on complex dependencies. As a final case study, we have

leveraged the notion of complexity to characterize the contribution of a given source to a multi-source transfer procedure.

Regarding the notion of complexity, additional experiments with other class criteria can be found in the PhD thesis of the first author (Aufrant, 2016), as well as some insights on what makes a class complex, and proposals on how to leverage the COMPLEXITY information to improve cross-lingual transfer.

A natural continuation of this work would be to reproduce these measures with other cross-lingual transfer algorithms, and also with other kinds of non-conventional parsers, like unsupervised or out-of-domain parsers. Since the proposed procedure for estimating COMPLEXITY is in fact not specific to dependency parsing (only the class criterion is), it may also be interesting to apply it to other sequence labeling tasks, for instance PoS tagging.

Abstract

This paper presents a sequence to sequence (seq2seq) dependency parser by directly predicting the relative position of head for each given word, which therefore results in a truly end-to-end seq2seq dependency parser for the first time. Enjoying the advantage of seq2seq modeling, we enrich a series of embedding enhancement, including firstly introduced subword and node2vec augmentation. Meanwhile, we propose a beam search decoder with tree constraint and sub-root decomposition over the sequence to furthermore enhance our seq2seq parser. Our parser is evaluated on benchmark treebanks, being on par with the state-of-the-art parsers by achieving 94.11% UAS on PTB and 88.78% UAS on CTB, respectively.

1 Introduction

Dependency parsing for syntactic structure can be unstrictly put into two categories in terms of searching strategies over parsing trees, graph-based and transition-based. The previous work (Eisner, 1996; Mcdonald et al., 2005) searched the entire tree space but limited to local features with higher computational costs, while (Nivre, 2003) could adopt rich features but subjected to limited searching space. Besides, ensemble or hybrid methods on both the basic models have been well studied (Nivre and Mcdonald, 2008; Zhang and Clark, 2008). Most traditional dependency parsers rely heavily on feature engineering, especially for graph-based parser, which suffers from poor efficiency and generalization ability. Recent tendency for dependency parsing is adopting neural networks due to their significant success in a wide range of applications. Specially, leveraging sequence-to-sequence (seq2seq) model for dependency parsing started to appear (Wiseman and Rush, 2016; Zhang et al., 2017b).

The recently proposed seq2seq parsers focus on predicting a transition sequence to build a dependency tree, which makes them actually fall back into the transition-based model constrained by the adopted transition parsing algorithm. In this paper, we propose a seq2seq parser with a novel parsing structure encoding independent of transition parsing operation sequence. The proposed parser first directly generates the head position for each word in an input sentence using a seq2seq model, and then employs a BiLSTM-CRF model (Huang et al., 2015) to predict the relation label for each determined dependency arc. Since the greatest challenge of the applying seq2seq model in dependency parsing is to guarantee the tree structure of the outputs, a beam search with tree constraint method is proposed to enforce a well-formed dependency tree in the decoder side. Besides, dependency parsing has to well handle long-distance parsing with corresponding to too long sequence learning bias in seq2seq models, we accordingly introduce a sub-root based sequence decomposition to effectively alleviate this issue.

Our proposed parser is evaluated on benchmark treebanks on both English and Chinese, which demonstrates that our model achieves the state-of-the-art scores among seq2seq parsing, and yields competitive performance with traditional transition- and graph-based parsers. In summary, this paper provides the following contributions:

Santa Fe, New Mexico, USA, August 20-26, 2018.

• We propose a seq2seq model which does not rely on any transition sequence by directly predicting the head position for each word in the sentence, unlike all previous work that first predicted a transition sequence and then built dependency tree using a known transition parsing algorithm.

• We especially design a beam search algorithm in the decoder side, which always guarantees the output to be a well-formed dependency tree.

• To deal with the long-distance dependency, we introduce sub-root decomposition and it also alleviates the problem caused by too long seq2seq learning in the meantime.

2 Related Work

Early researches (Ma and Zhao, 2012; Martins et al., 2013) achieved comparable results with high-order feature. With the impressive success of deep neural networks in a wide range of NLP tasks (Cai and Zhao, 2017; Qin et al., 2017; He et al., 2018; Cai et al., 2018; Zhang et al., 2018; Bai and Zhao, 2018; Huang et al., 2018), neural models have been successfully applied to various dependency parsers (Li et al., 2018; Wang et al., 2017; Zhang et al., 2016). Dyer et al. (2015) introduced the stack LSTM to promote the transition-based parsing. Kiperwasser and Goldberg (2016) incorporated the bidirectional Long Short-Term Memory (BiLSTM) into both graph- and transition-based parsers. Andor et al. (2016) proposed globally normalized networks and achieved the best results of transition-based parsing, while the state-of-the-art result was reported in Dozat and Manning (2016), which proposed a deep biaffine model for graph-based parser.

Though previous neural parsers have achieved such inspiring progresses, the majority of them heavily rely on the primitive parsing framework. Usually, those neural parsers build a network for feature extracting and use the neural features in place of handcrafted ones to predict some discrete actions in a traditional parsing algorithm. Until recently, few work (Wiseman and Rush, 2016; Zhang et al., 2017b) considered the seq2seq model, resulting in an end-to-end parser. However, those seq2seq parsers focus on predicting the transition sequences and thus actually need some kinds of complicated post-processing to build well-formed dependency trees, which make them fall back to a transition-based parser with a seq2seq transition predictor.

In this work, we attempt to build a true seq2seq parser without transition parsing algorithm for post-processing. The proposed parser is different from previous proposed seq2seq parser in the way that it directly predicts the head position instead of the transition. Though both our parser and Zhang et al. (2017a) make direct head prediction during parsing, our parser essentially differs from their parser in two aspects. Firstly, their parser runs standard graph-based maximum spanning tree (MST) algorithm to guarantee the tree structure, and thus called head selection in their parser serves for the purpose of speeding up the graph-based parsing, while ours introduces a beam search with tree constraint only in the decoder side to enforce a well-formed tree and thus gets rid of relying on specific parsing algorithm. Secondly, each time the head selection parser selects a head, it relies on referring to each pair of words in the sentence. While our parser performs a fully generative decoding in one pass by using an attention layer to keep around the context of each word.

Another line of studies related to this work focus on beam search, which have attracted much interest and have been adopted to improve the performance of greedy parsers. Beam search commonly adopts approximate strategy for computational tractability, which aims at including more sophisticated features within reasonable cost. Zhang and Clark (2008) proposed a beam search based parser applied to integrate graph-based and transition-based parsers. Most transition-based neural models (Weiss et al., 2015; Zhou et al., 2015; Andor et al., 2016) incorporated the structured perceptron with beam search decoding, resulting in substantial improvement of accuracy. Additionally, beam search has been also incorporated in the seq2seq framework (Wiseman and Rush, 2016).

Following the previous works, we also adopt a beam search in our decoder. However, since our parser aims at predicting a structure instead of sequence, we especially design a beam search algorithm with several searching constraints, which enforces the tree structure of the outputs.

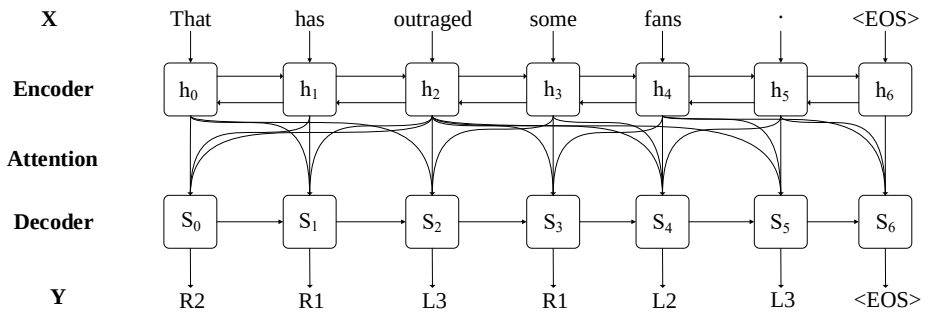

Figure 1: The framework of the proposed seq2seq model.

3 Seq2seq Parser

In this study, our parser is built upon a seq2seq model (Sutskever et al., 2014), which encodes the input sentence forward and backward, and predicts the head position for each word in the sentence. Our model contains three main components: (1) an encoder that processes the input sentence and maps it into some hidden states that lie in a low dimensional vector space $\mathbb{R}^h$, (2) a decoder that incorporates the hidden states and the previous prediction to generate head position of the current word, and (3) an attention layer that encodes the context for each focused word. Figure 1 illustrates our model.

Recurrent neural networks (RNNs) (Elman, 1990) is commonly used to build block for seq2seq model. Specifically, our model employs the Long Short-Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) variant of RNN, which uses numbers of gates to address the problem of vanishing or exploding gradient when trained with back-propagation through time. A standard LSTM unit consists of an input gate i_t, a forget gate f_t, an output gate o_t, a memory cell c_t and a hidden state h_t, where the subscript t denotes the time step.

3.1 Encoder

The encoder of our parser is a BiLSTM, which processes an input sequence in both directions by incorporating a stack of two distinct LSTMs.

Given an input sentence $X = \{w_1, \cdots, w_L\}$, the i-th element w_i is encoded by first feeding its embedding representation e_i in to two distinguish LSTMs: the forward LSTM and the backward LSTM, to obtain two hidden state vectors: h_i^f and h_i^b respectively, and then concatenating the two vectors as $h_i = [h_i^f; h_i^b]$.

3.1.1 Source Representation

Given a vocabulary W, each individual word $w_i \in W$ is mapped into a real-valued vector (word embedding) $w \in \mathbb{R}^m$ where m is the dimension. We employ the GloVe (Pennington et al., 2014) and Node2Vec (Grover and Leskovec, 2016) to generate the pre-trained word embedding, obtaining two distinct embedding for each word.

It is worth noting that Node2Vec is an embedding method that is capable of encoding the topological information of inside structure. To further incorporate the structural information of dependency tree, we perform a Node2Vec pre-training on the training set.

Besides, our model adopts subword which is obtained though BPE segmentation (Sennrich et al., 2015) broadly used in neural machine translation (NMT), and character augment embedding with AllenNLP toolkit according to (Gardner et al., 2017). A subword dictionary is built by running BPE on the Wikipedia, which segments each word into several subwords. Each subword in the dictionary is mapped into a real-valued vector (subword embedding). In our experiments, the subword embedding is randomly initialized and then trained jointly with other components of the network. To get the representation of the original word, we use an additional neural network component (Peters et al., 2018) to distill the character and subword embedding for representation. Our model also employs the part-of-speech (POS) tag embedding following previous works (Kiperwasser and Goldberg, 2016; Dozat and Manning, 2016). The

POS embedding is randomly initialized and jointly trained with other model parameters too.

The adopted word representation of our model is the concatenation of all above-mentioned embeddings: $e = [e^g; e^n; e^s; e^c; e^p]$, where e^g is the GloVe embedding, e^n is the Node2Vec embedding, e^s is the subword embedding, e^c is the character embedding and e^p is the POS tag embedding.

3.2 Decoder

In our model, an LSTM decoder predicts the head position for each word in the input sentence. Given a word w_i, the probability of each word in the vocabulary to be its head is given by:

$$p(\hat{y}_i|\hat{y}_1, \cdots, \hat{y}_{i-1}) = LSTM^{\mathcal{D}}(\hat{y}_{i-1}, h_i), \tag{1}$$

where $\hat{y}_{i-1}$ is the last output of the LSTM decoder, h_i is the hidden state of current word. The joint probability of the final output is then a product of conditional probability of each predicted head:

$$P(\hat{y}) = \prod_{i=0}^{M} p(\hat{y}_i|\{\hat{y}_1, \hat{y}_2, \cdots, \hat{y}_{i-1}\})$$

3.2.1 Target representation

In NMT context, the decoder output is sampled from the entire vocabulary using the probability computed by Eq.(1). However, in dependency parsing situation, the candidate set of the head words is subject to the words in the sentence. Thus, the predicted head would likely fall outside the input sentence when decoding with a full vocabulary upon corpus. To keep the generation of head within bounds, our model predicts the relative position instead of word form when assigning a head for each word. In the training process, we convert each head into a position representation, encoding relative distance between word and its head. When working, the parser picks a head for each word by predicting the relative position of the head. Our experiments show that the conversion is effective in bounding the output of our seq2seq parser.

Given a word w_i and its head word w_j, the relative position representation of w_j is obtained by:

$$R_{i,j} = \begin{cases} L_{j-i} & if \quad i < j, \\ R_{i-j} & if \quad i > j. \end{cases}$$

Figure 2 illustrates our relative position tag encoding for the output dependency structures.

3.3 Attention Mechanism

As usual, we employ an attention layer (Luong et al., 2015) to encode the context for each word. The context vector c_j at the j-step of the decoding process is calculated as the weighted sum of the hidden states of the input sequence:

$$c_j = \sum_{i=1}^{N} \alpha_j(i) h_i.$$

The attention weight $\alpha_j(i)$ between the i-th encoder hidden state h_i and the j-th decoder hidden state h_j is computed by a softmax function:

$$\alpha_j(i) = \frac{v^{\mathsf{T}} \tanh(W^{(a)}[h_i; h_j])}{\sum_{k=1}^{N} v^{\mathsf{T}} \tanh(W^{(a)}[h_k; h_j])},$$

where $[h_i; h_j]$ and $[h_k; h_j]$ denote the vector concatenation of the rows, $W^{(a)}$ and v are learnable parameters.

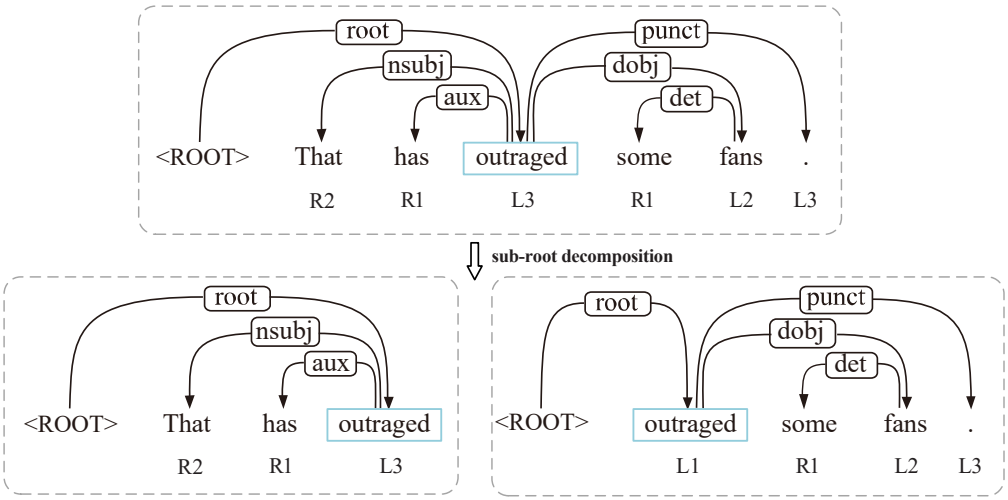

Figure 2: Illustration of target representation and sub-root segmentation for sentence ***That has outraged some fans .*** from PTB. The sequences below the word are the relative position tags which demonstrate the corresponding distance and direction (R: right, L: left) between the node and its syntactic head. The word **outraged** is defined as **sub-root**.

4 Sub-root Decomposition

It is well known that correctly recovering the long-distance dependency is the greatest challenge in dependency parsing. Even incorporating the BiLSTM encoder and the attention layer, the primitive seq2seq parser still performs poorly when encountering long sequences, as the long-distance dependencies heavily prevent the parser from building a correct tree.

To address the long-distance dependency problem and alleviate error propagation, we propose sub-root decomposition over the input parse tree. Such decomposition will cause the original dependency tree accordingly segmented into two or more subtrees, and the original input sentence segmented into shorter pieces. We define the notation **sub-root** as the direct syntactic children of the **ROOT** node. When working on 'nearly' projective dependency parsing, such decomposition would not break dependency arc in most situations.

Formally, given an input sentence sentence with length L: $X = \{w_1, w_2, \cdots, w_L\}$, for the i-th word w_i, we represent its head as $w_i.head$. Besides, we define a decomposition threshold β to determine whether an input sentence should be segmented into shorter ones. Only if the sentence length L is larger than the threshold β, we perform a decomposition on the sentence.

To perform the sub-root decomposition, we should first recognize the sub-root for a given sentence. We regard the sub-root recognition as a sequence tagging task, and employ a BiLSTM-CRF model which consists of 4-layer Bi-LSTM and a CRF layer to tag the sub-roots of a sentence. The output of this model is a binary indicator that distinguishes the sub-root nodes from others:

$$I(w_i) = \begin{cases} 0 & if \quad w_i.head \neq ROOT, \\ 1 & if \quad w_i.head = ROOT. \end{cases}$$

After recognizing the sub-root nodes, we decompose a sentence into several parts that come from collecting all nodes rooted by every sub-root, and perform the parsing on the sub-sentence. For example, given a sentence $X = \{w_1, w_2, \cdots, w_L\}$ with w_k as its sub-root, the sentence is decomposed into two sub-sentences: $X_1 = \{w_1, w_2, \cdots, w_k\}$ and $X_2 = \{w_k, w_{k+1}, \cdots, w_L\}$. Then we use the sentences X_1 and X_2 which are both rooted at w_k for training and parsing. It is worth noting that we use the gold sub-root to decompose a sentence in training, and predict the sub-roots for sentences in testing. Besides, the merge operation is necessary after decoding. The merge operation simply concatenates the sub-sentence together and set the head of sub-root node as ROOT.

4.1 Beam Search with Tree Constraint

Beam search is a popular approach to enlarge searching space in transition-based dependency parsing. The typical beam search algorithm keeps a fixed number (say K) of candidate states in the beam according to their scores (or probabilities). Each time a searching is performed, the algorithm explores all the possible next states for each states in the beam, and keeps the top-K states in beam again.

In inference stage, the beam B of time step ts is updated based on K states (hypotheses) of the last beam:

$$B_{ts} = topK[Y^k_{ts-1}, y^{k,n}_{ts}],$$

where $1 \leq k \leq K$ and $1 \leq n \leq N_k$. N_k is the number of branches of the k-th hypotheses in the last step. Y^k_{ts-1} represents the historical output and y_{ts} indicates the candidate target in the ts-th step. For each new exploring state, its score is computed by,

$$S(Y^k_{ts-1}, y^{k,n}_{ts}|x) = S(Y^k_{ts-1}|x) \ + \log p(y^{k,n}_{ts}|x, Y^k_{ts-1}).$$

Since our model directly predicts the head position for each word, its output might sometime violate the constraints of dependency tree structure. To enforce the model output to be a well-formed dependency tree, we introduce several constraints into the primitive beam search algorithm, resulting in the beam search with tree constraint.

The constraints that ensure a projective dependency tree are listed as follows:

• *Single headed*: A node should be assigned one and only one head. For our seq2seq parser, this also implies that the output sequence length should be exactly same as the input sequence length.

• *Acyclic*: In the decoding process, a newly generated head should not introduce a cycle in the dependency path.

• *Projective*: For the projective dependency parsing, the newly generated head should not cross the arc built by previous prediction (99.9% of PTB-SD, 100% of CTB on the training dataset are projective).

To enforce the above constraints, we introduce a weighted function $f_c(\cdot)$ that computes an additional weight for each candidate state to indicate whether the constraints are satisfied.

$$S(Y^k_{ts-1}, y^{k,n}_t|x) = S(Y^k_{ts-1}|x) \ + \log(p(y^{k,n}_t|x, Y^k_{ts-1}) \cdot f_c(y^{k,n}_{ts}|Y^k_{ts-1})),$$

$$f_c(y_{ts}^{k,n}|\cdot) = \begin{cases} 0, & ts > L, y_{ts} \neq \textbf{EOS}, \\ \alpha_c, & cycle(y_{ts-\delta}, \cdots, y_{ts}), \\ \alpha_p, & nproj(y_{ts-\delta}, \cdots, y_{ts}), \\ 1, & others. \end{cases}$$

where **EOS** is an additional symbol indicating the end of the predicted sequence, L is the length of the input sequence, $cycle(\cdot)$ is the cycle detected function which returns *True* if there exists a cycle on the input path, $nproj(\cdot)$ is an indicator of whether the resulting tree is projective. Note that for the sake of efficiency, we detect the violations of the *Acyclic* and *Projective* constraints by looking back a fixed number δ of historical predictions instead of enforcing them on the whole sequence. Thus, both $cycle(\cdot)$ and $nproj(\cdot)$ take a subsequence $y_{ts-\delta}, \cdots, y_{ts}$ instead of the whole sentence as input. By loosing the global constraints to local ones, the incorrect historical decisions that fall outside a window with size δ can never disturb a current prediction. In our experiments, δ is set to 8, both α_c and α_p are set to 0.8. Algorithm 1 shows the detail of the proposed beam search decoding with tree constraint.

5 Experiments

The proposed seq2seq parser is evaluated on the Penn Treebank (PTB) and the Chinese Treebank (CTB 5.1) with the unlabled attachment score (UAS) and the labeled attachment score (LAS) metrics (excluding punctuation). Follow the usual way processing the PTB and CTB:

For PTB, applying Stanford basic dependencies (SD) representation (De Marneffe et al., 2006), using sections 2-21 for training, section 22 for development and section 23 for testing as same as the standard splitting and tagging POS tag with the Stanford tagger (Toutanova et al., 2003).

For CTB, adopting Penn2Malt tool for conversion, splitting the dataset by sections 001-815, 1001-1136 for training, sections 886-931, 1148-1151 for development, and sections 816-885, 1137-1147 for testing as (Zhang and Clark, 2008) and using the golden segmentation and POS tags as (Chen and Manning, 2014).

5.1 Setup

In the experiments, our seq2seq parser implemented based on the OpenNMT-py project (Klein et al., 2017), in which employs a 4-layer Bi-LSTM as encoder and a 2-layer LSTM as decoder. The parameters are randomly initialized and optimized using the Adam algorithm with mini-batch size of 64. The initial learning rate is set to 0.001 (with $\beta_1 = 0.9, \beta_2 = 0.999$), and decays by 0.5 every epoch after running 20 epochs. In training phase, we adopt a dropout rate of 0.3. The size of the vocabulary in the target side is limited to 100 by setting the maximum relative position to 50, namely, the target side vocabulary is:

$$\mathcal{V}_t = \{L1, L2, \cdots, L50, R1, R2, \cdots, R50\}$$

In our experiments, the beam size is set to 5.

The representation of each input token is the concatenation of GloVe embedding, node2vec embedding and subword embedding. The GloVe embedding is pre-trained on Wikipedia 2014 and Gigaword 5 with 100 dimension (6B tokens). The node2vec embedding is pre-trained on the training set and the dimension is 128. It is trained with random walks in the syntactic graph (in order to make all the dependency tree form the graph, we add a dummy **ROOT** node). The walk length of node2vec is set to 30, per node visit(walk) times is 200 and the skip-gram window size is 10. To obtain subword segmentation for each word, we train the BPE model on the English and Chinese Wikipedia dataset respectively with number of merge operations set to 10K.

The sub-root tagging model consists of a 4-layer Bi-LSTM and a 1-layer CRF, taking the word and POS tag as inputs. Besides, after getting a dependency tree of the input sentence, we employ another BiLSTM-CRF model to predict the dependency relation of each arc. The predictor takes the word embedding, POS embeddings of head and dependent respectively as input, and performs a multiple labels tagging.

The code is available at `https://github.com/bcmi220/seq2seq_parser`.

5.2 Results

Table 1 shows comparison of our seq2seq parser with previously published parsers on PTB-SD and CTB. Unlike the transition-based parsers listed in ***Transition-NN*** block and the graph-based listed in the ***Graph-NN*** block, our model pursues a more simple way without any kind of transition- or graph-based algorithm. Our model outperforms most parsers that use either transition- or graph-based algorithm. Our model is competitive to the transition-based model of Andor et al. (2016) and slightly lower than the one of Zhu et al. (2015) which introduced a recursive convolutional neural network to encode the dependency tree and re-ranked the k-best trees. It is worth noting that Dozat and Manning (2016) used deep biaffine attention in the graph model (Kiperwasser and Goldberg, 2016), achieving the best results among traditional graph and transition parsing.

The parsers (Wiseman and Rush, 2016; Zhang et al., 2017b) are also seq2seq models, but they used transition sequence as target sequence encoding. The comparison shows our parser achieves state-of-the-art performance among seq2seq models. Kuncoro et al. (2016) also reported parsing result of 95.8% UAS on PTB. Since its result is converted from phrase-structure parsing and beyonds our focus, we excluded it from the table.

System	Method	PTB-YM LAS	PTB-YM (%) UAS	PTB-LTH LAS	PTB-LTH (%) UAS	PTB-SD LAS	PTB-SD (%) UAS	CTB LAS	CTB (%) UAS

5.3 Analysis

5.3.1 Sub-root Decomposition

This subsection gives an analysis on the effectiveness of the proposed sub-root decomposition algorithm. Figure 3 shows sentence length distribution on PTB and our sub-root tagging $F1$ score. For the sub-root tagging model, we get 96.73% and 96.01% $F1$ scores on development and test datasets, respectively.

To determine an optimal decomposition length threshold, we conduct experiments on PTB and the results are shown in Figure 4, which indicates that the threshold 40 performs best, though sub-root tagging model got the similar performance below the length 40. Meanwhile, all thresholds larger than 40 are superior to the case without decomposition, especially for the sentences longer than 40. We are surprised that all the other threshold settings are not better than the original case without any decomposition, which can be attributed to the dissatisfactory sub-root tagging $F1$ score.

Our experiments reveal that the sub-root decomposition method does work in improving the performance of our seq2seq parser, for its help on alleviating the long-distance dependencies and error propagation in the course of decoding.

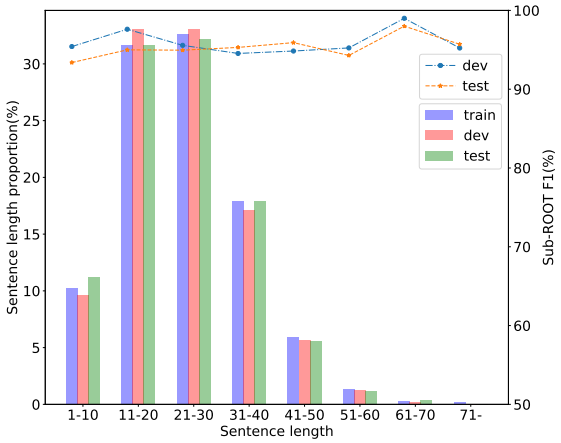

Figure 3: Sentence length distribution in PTB and the corresponding sub-root tagging accuracy.

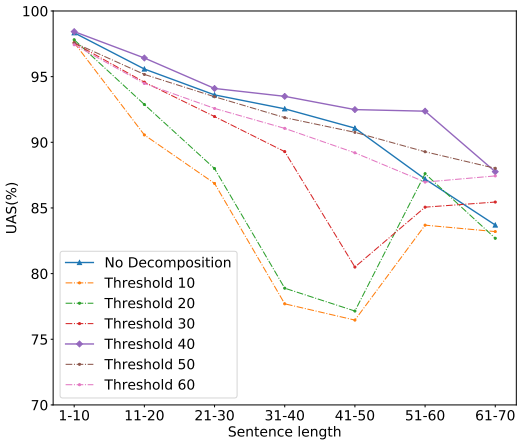

Figure 4: The UAS on PTB test dataset under different decomposition threshold.

5.3.2 Target Sequence

To make a direct comparison on the target encoding between our relative position sequence and previous transition sequence, we build a basic seq2seq model with the same source embedding, but without sub-root decomposition. The results are shown in Table 2, which indicates our relative position sequence is a better solution.

Since we limit the length of target sequence equal to the input sequence, the relative position sequence can also be predicted by sequence tagging model. We further compare the conventional sequence tagging model (Bi-LSTM+CRF with the same parameter settings as sub-root tagger) and the basic seq2seq model. The results demostrate that the seq2seq is necessarily better than the sequence tagging model for our concerned task.

Target encoding	**Model**	**Dev** (%) LAS	UAS	**Test** (%) LAS	UAS
Transition	seq2seq	83.56	87.34	82.77	87.49
Relative position	sequence tagging	83.81	87.58	81.37	87.60
Relative position	seq2seq	84.99	89.16	85.03	89.32

Table 2: Transition vs. relative position sequences in basic seq2seq model and sequence tagging vs. seq2seq model with relative position sequence (**without decomposition**).

5.3.3 Ablation Study

	Dev (%) LAS	UAS	**Test** (%) LAS	UAS
This work	91.86	93.84	92.08	94.11
-subword emb	91.35	93.76	91.77	93.95
-node2vec emb	91.60	93.71	91.85	94.01
-tree constraint	91.12	93.21	90.75	93.60

Table 3: Contribution of different components in our model.

In order to explore the contribution of the beam search with tree contraint and embeddings employed, we conduct a group of ablation experiments on PTB-SD dataset. The settings keep the same as before mentioned. Table 3 shows that the beam search with tree constraints substantially enhances the performance of our seq2seq parser. Meanwhile, both subword embedding and node2vec embedding contribute

to improving the parsing results.

6 Conclusion

In this paper, we propose a seq2seq parser with representation enhancement that directly predicts head positions without relying on transition sequence. To mitigate the long-distance dependency problem, we introduce the sub-root decomposition to shorten the sequence. To enforce a well-formed tree structure and alleviate error propagation, we employ beam search with constraints. Experiments on English and Chinese Penn Treebank verify the effectiveness of the proposed model. To the best of our knowledge, this is the first reported seq2seq parser with direct head prediction achieving promising performance.

Abstract

Hierarchical Multiscale LSTM (Chung et al., 2016a) is a state-of-the-art language model that learns interpretable structure from character-level input. Such models can provide fertile ground for (cognitive) computational linguistics studies. However, the high complexity of the architecture, training procedure and implementations might hinder its applicability. We provide a detailed reproduction and ablation study of the architecture, shedding light on some of the potential caveats of re-purposing complex deep-learning architectures. We further show that simplifying certain aspects of the architecture can in fact improve its performance. We also investigate the linguistic units (segments) learned by various levels of the model, and argue that their quality does not correlate with the overall performance of the model on language modeling.

1 Introduction

Verifying and reproducing claims published in scientific articles is an essential part of building a solid foundation for future research. As such, reproduction has a long history in many scientific fields (Willett et al., 1985; Venables et al., 1993; Waltemath et al., 2011). Recent large-scale studies, however, raise concerns about the reproducibility in a variety of areas and the potential effect of this crisis (Baker, 2016). A reproduction study by the Open Science Collaboration (2015) estimates that only 40% of research in psychology is reproducible, while Begley and Ellis (2012) end up confirming only 11% of preclinical cancer studies. The latter work makes an important link between the low reproducibility rates and the notoriously low impact of preclinical cancer research on clinical practice (Hutchinson and Kirk, 2011).

Our work is motivated by a similar concern, specifically the applicability of complex deep learning architectures for computational (cognitive) linguistics research. State of the art systems often employ complex architectures which integrate various design features and use many optimization techniques. Because the focus is on boosting the final performance on a given task, often little effort is put into understanding where the power of the system comes from. This makes these models much harder to adapt for new tasks or domains. In our view, it is essential not only to be able to reproduce reported results, but also to understand the contribution of various design features through systematic ablation experiments.

The higher performance brought by modern neural network architectures often comes at the cost of our understanding of the representations and structural information the system learns. However, for models to be generalizable to new domains, it is important to move towards analyzing such structural representations, and investigating their impact on the final performance of the model.

In the current study, we examine the reproducibility of a language model with the ability to learn explicit linguistic structure: the Hierarchical Multiscale Recurrent Neural Network (HMLSTM) model. This architecture was introduced by Chung et al. (2016a) and set a new

Proceedings of the 27th International Conference on Computational Linguistics, pages 3215–3227
Santa Fe, New Mexico, USA, August 20-26, 2018.

state of the art on language-modeling benchmarks Text8, Hutter Prize and character-level Penn Treebank. Additionally, the paper features examples where the lowest layer of the model recovers word-level segmentation and in some cases performs interpretable morphological analysis. With this reproduction study our motivation is to provide insight into the dynamics of the model, which can facilitate re-using and further developing its architecture and repurposing it for tasks other than language modeling. Crucially, we investigate whether the performance of the model depends on the acquisition of high-quality linguistic structure.

1.1 The importance of reproducibility

There is no established tradition of reproduction studies in computational linguistics; however, scattered attempts at reproducing a number of studies have highlighted the importance of investigating the dataset, the model architecture and the evaluation scheme used in experimental designs. For example, Mieskes (2017) quantifies the availability of non-benchmark datasets underlying the experiments. Horsmann and Zesch (2017) re-run coarse-grained multilingual part-of-speech tagging experiments by Plank et al. (2016) and confirm the superior performance of LSTM-based architectures on fine-grained tagsets. Marrese-Taylor and Matsuo (2017) fail to reproduce the results of three articles in the domain of aspect-based opinion mining, with the conclusion that repeating experiments without the availability of source code is hindered due to lack of details on pre-processing, model architecture specification and exact parameter settings. Morey et al. (2017) replicate the results of 9 discourse parsers trained on the RST Discourse Treebank (RST-DT) (Carlson et al., 2003) and show that most of the recent gains in the domain are due to non-trivial differences in evaluation methodology.

We propose one further step in this direction: in addition to reproducing reported results, it is important to investigate the role the components of complex models play and examine their impact on the behavior of the model. The HMLSTM model that we choose as our case study has many desirable properties. However, it is fairly complex and allows for a considerable degree of freedom for implementation. We experimentally explore the function of architectural details of the HMLSTM model, as well as experiment with varying the specifics of the training procedure. We aim to shed light on the potential bottlenecks involved in re-purposing a complex deep learning sequence modeling architecture for computational linguistics studies.

1.2 The importance of interpretability

Language data, both in the form of speech and text, exhibits hierarchical structure: characters or phonemes form morphemes and words, which form phrases, which in turn form whole sentences. At each level, the units are composed to build up the meaning of the sentence at the highest level. Modern RNN architectures have been very successful in solving character-level NLP tasks (Chung et al., 2016b; Golub and He, 2016; Mikolov et al., 2012). However, they do not make the learned linguistic structure explicit: rather it can be presumed to be cryptically encoded in the states of the hidden layers. The higher performance brought by modern neural network architectures often comes at the cost of our understanding of the representations and structural information such systems learn. However, for a model to be generalizable to new domains, it is important to move towards analyzing such structural representations, and investigating their impact on the final performance of the model.

Understanding the structural information encoded in black-box neural network architectures has been a desired target since Elman (1990) and several studies have used indirect post-analysis techniques and auxiliary tasks to probe the acquired structure. For example, recent studies have assessed the ability of Long Short-Term Memory (LSTM) language models to encode subject-verb agreement (Linzen et al., 2016), analyzed the translation quality of character-level sequence-to-sequence models in terms of several morpho-syntactic grammaticality tests (Sennrich, 2016), Li et al. (2016) introduce a representation erasure technique to measure the amount of contribution of input words and specific phrases to the decision of RNN-based sentiment classifiers, Kádár et al. (2017) examine the linguistic representations of Gated Recurrent Unit-based architectures

for image-sentence ranking, and Chrupała et al. (2017) and Alishahi et al. (2017) analyze the linguistic structure learned by Recurrent Highway Network models of visually grounded speech understanding.

As an alternative approach, a number of *white-box* architectures have been proposed which learn explicit representations of linguistic structure. For example, Dyer et al. (2016) examine Recurrent Neural Network grammars and analyze its learned syntax (Kuncoro et al., 2016). They conclude that their architecture learns a similar notion of headedness as established head-rule sets and the model learns structure similar to traditional nonterminal categories. Williams et al. (2017) explore the learned grammars of two state-of-the-art natural language inference models: SPINN (Bowman et al., 2016) and Gumbel Tree-LSTM (Choi et al., 2017). They find that both SPINN and Gumbel Tree-LSTM have close to or worse than chance-level parsing performance on standard benchmarks. Furthermore, they note that in the case of the SPINN architecture the learned structure depends on the tuning of the model and that their findings are different from the SPINN implementation of Yogatama et al. (2016). They further note that consistency of the parses produced by Gumbel Tree-LSTM across multiple runs is not far off chance level.

The Hierarchical Multi-scale LSTM architecture (Chung et al., 2016a) is in the latter class of white-box models. It is designed specifically to allow for learning explicit structure in data: at each layer, it predicts a binary boundary variable at each time-step. These boundaries correspond to an explicit, interpretable segmentation of the input utterance at multiple levels, which can be thought of as different levels of granularity in linguistic structure. At the same time, it reportedly has state-of-the-art performance on several language modeling benchmarks. As such, we believe the model has the potential to impact future computational cognitive linguistics studies. However, it is not clear whether the high performance of this model demands the acquisition of high-quality linguistic structure from input text. Furthermore, due to the complex architectural design, implementation details might play a large role in the conclusion that can be drawn from the learned structure as in Williams et al. (2017). We examine the segmentation of the input characters by different versions of this model to see whether their quality impacts the overall performance.

2 Hierarchical Multiscale LSTM

Let us introduce the notations used throughout this section with the standard LSTM equations:

$$\begin{bmatrix} \mathbf{i}_t \\ \mathbf{f}_t \\ \mathbf{u}_t \\ \mathbf{o}_t \end{bmatrix} = W\mathbf{x}_t + U\mathbf{h}_{t-1} + \mathbf{b} \qquad \text{(gates and candidate)}$$

$$\mathbf{c}_t = \mathbf{c}_{t-1} \odot \sigma(\mathbf{f}_t) + \tanh(\mathbf{u}_t) \odot \sigma(\mathbf{i}_t) \qquad \text{(cell state)}$$

$$\mathbf{h}_t = \sigma(\mathbf{o}_t) \odot \tanh(\mathbf{c}_t) \qquad \text{(hidden state)}$$

The input to an LSTM are the current input $\mathbf{x}_t$, previous state $\mathbf{h}_{t-1}$ and previous cell state $\mathbf{c}_{t-1}$. Variables $\mathbf{x}_t$ and $\mathbf{h}_{t-1}$ are used to compute the input gate $\mathbf{i}_t$, forget gate $\mathbf{f}_t$, candidate activation $\mathbf{u}_t$ and output gate $\mathbf{o}_t$. In the second equation $\mathbf{f}_t$ and $\mathbf{i}_t$ are used to trade off the candidate activation $\mathbf{u}_t$ and the previous cell-state $\mathbf{c}_{t-1}$ using the element-wise multiplication $\odot$. This results in the current cell state $\mathbf{c}_t$. Finally, the output gate soft-selects the components of $\tanh(\mathbf{c}_t)$ to write to the hidden state $\mathbf{h}_t$. The function σ refers to the sigmoid function.

HMLSTM – To make the explanation of the HMLSTM architecture more straight-forward, let us first consider the bottom- and top-layer as they are special cases of any ℓ-th layer. In addition, we provide vectorized version equations of the HMLSTM architecture which allow for batch sizes larger than 1 (see Appendix A).

Bottom Layer – The bottom layer of the HMLSTM takes as input: 1) *bottom-up connection*: input at the current time-step $\mathbf{x}_t$; 2) *recurrent connection*: hidden and cell states $< \mathbf{h^1}_{t-1}, \mathbf{c^1}_{t-1} >$ and previous boundary variable z^1_{t-1} from $\ell = 1$; and 3) *top-down connection*: hidden state $\mathbf{h^2}_{t-1}$ from $\ell = 2$. It outputs the state tuple $< \mathbf{h}^1_t, \mathbf{c}^1_t >$ and boundary variable z^1_t.

$$\begin{bmatrix} \mathbf{i}_t \\ \mathbf{f}_t \\ \mathbf{u}_t \\ \mathbf{o}_t \\ z_t \end{bmatrix} = W\mathbf{x}_t + U\mathbf{h}^1_{t-1} + z_{t-1}V\mathbf{h}^2_{t-1} + \mathbf{b} \tag{1}$$

The activation function on z_t is the hard-sigmoid followed by the rounding operation to discretize it to $\{0, 1\}$: $z_t := \text{round}(\text{hard\_sigmoid}(z_t))$. The top-down connection is turned on and off by z_{t-1}. When the layer detects a boundary in the previous step (i.e. $z_{t-1} = 1$), takes context from the higher layer through the top-down connection. After computing the activations the layer either runs a regular LSTM UPDATE or does a FLUSH of its input:

$$\mathbf{c}_t = \begin{cases} \mathbf{c}_{t-1} \odot \sigma(\mathbf{f}_t) + \tanh(\mathbf{u}_t) \odot \sigma(\mathbf{i}_t) & \text{if } z_{t-1} = 0 \text{ (UPDATE)} \\ \tanh(\mathbf{u}_t) \odot \sigma(\mathbf{i}_t) & \text{if } z_{t-1} = 1 \text{ (FLUSH)} \end{cases} \tag{2}$$

The final hidden state is given by the regular LSTM update $\mathbf{h}_t = \sigma(\mathbf{o}_t) \odot \tanh(\mathbf{c}_t)$.

Top Layer – The top layer has both bottom-up $\mathbf{h}^{\ell-1}_t, z^{\ell-1}_t$ and recurrent connections $< \mathbf{h^\ell}_{t-1}, \mathbf{c^\ell}_{t-1} >$, but no top-down connection. At each step, it outputs the state tuple $< \mathbf{h}^\ell_t, \mathbf{c}^\ell_t >$:

$$\begin{bmatrix} \mathbf{i}_t \\ \mathbf{f}_t \\ \mathbf{u}_t \\ \mathbf{o}_t \end{bmatrix} = z^{\ell-1}_t W\mathbf{h}^{\ell-1}_t + U\mathbf{h}^\ell_{t-1} + b \tag{3}$$

The bottom-up input $\mathbf{h}^{\ell-1}_t$ is gated by $z^{\ell-1}_t$. When $z_t = 1$ the higher layer takes one step and performs UPDATE; otherwise it ignores the current time-step and performs COPY:

$$\mathbf{c}_t = \begin{cases} \mathbf{c}_{t-1} \odot \sigma(\mathbf{f}_t) + \tanh(\mathbf{u}_t) \odot \sigma(\mathbf{i}_t) & \text{if } z_t = 1 \text{ (UPDATE)} \\ \mathbf{c}_{t-1} & \text{if } z_t = 0 \text{ (COPY)} \end{cases} \tag{4}$$

Middle layers – The general HMLSTM layer runs all operations: UPDATE, COPY and FLUSH. It takes as input 1) *bottom-up connection*: lower layer state $\mathbf{h}^{\ell-1}_t$ and boundary variable $z^{\ell-1}_t$; 2) *recurrent connection*: hidden and cell states $< \mathbf{h^\ell}_{t-1}, \mathbf{c^\ell}_{t-1} >$ and boundary variable z^ℓ_{t-1}; and 3) *top-down connection*: hidden state $\mathbf{h}^{\ell+1}_{t-1}$. It outputs the tuple $< \mathbf{h}^\ell_t, \mathbf{c}^\ell_t >$ and boundary variable z^ℓ_t:

$$\begin{bmatrix} \mathbf{i}_t \\ \mathbf{f}_t \\ \mathbf{u}_t \\ \mathbf{o}_t \\ z_t \end{bmatrix} = z^{\ell-1}_t W\mathbf{h}^{\ell-1}_t + U\mathbf{h}^\ell_{t-1} + z^\ell_{t-1}V\mathbf{h}^{\ell+1}_{t-1} + b \tag{5}$$

The bottom-up connection is masked by $z^{\ell-1}_t$ as in the top-layer, while the top-down connection is masked by z^ℓ_{t-1} as in the bottom-layer. The variables $z^{\ell-1}_t$, z^ℓ_{t-1} determine which of the three operations the cell runs. FLUSH is executed if the layer detects a boundary in the previous step (i.e. $z^\ell_{t-1} = 1$). If this is not the case and the lower layer does not detect a boundary, the layer runs COPY. However, if the lower layer does detect a boundary $z^{\ell-1}_t$, it runs UPDATE:

$$\mathbf{c}_t = \begin{cases} \tanh(\mathbf{u}_t) \odot \sigma(\mathbf{i}_t) & \text{if } z_{t-1}^{l} = 1 \text{ (FLUSH)} \\ \mathbf{c}_{t-1} & \text{if } z_{t-1}^{\ell} = 0 \text{ and } z_{t}^{\ell-1} = 0 \text{ (COPY)} \\ \mathbf{c}_{t-1} \odot \sigma(\mathbf{f}_t) + \tanh(\mathbf{u}_t) \odot \sigma(\mathbf{i}_t) & \text{if } z_{t-1}^{\ell} = 0 \text{ and } z_{t}^{\ell-1} = 1 \text{ (UPDATE)} \end{cases} \tag{6}$$

Output gate – The output embedding $\mathbf{h}_t^e$ of the HMLSTM is computed by the following gating mechanism:

$$g_t^\ell = \sigma(\mathbf{w}_\ell^T [\mathbf{h}_1; \mathbf{h}_2; \mathbf{h}_3]) \tag{7}$$

$$\mathbf{h}_t^e = \text{ReLU}(g_t^\ell W_\ell^e \mathbf{h}_t^\ell) \tag{8}$$

It takes states from the three layers and computes a gating value for each g_t^1, g_t^2 and g_t^3 using the parameter vector $\mathbf{w}^\ell$. These scalars are used to weight the $W_l^e \mathbf{h}_t^l$ for each layer where W_ℓ^e is a learned parameter. It is important to add some mechanism to combine the activations of the three layers for language modeling as all three layers tick on a different time-scale, but the network has to generate an output at each time-step. This combined embedding $\mathbf{h}_t^e$ is then used in the final softmax layer to predict the probability distribution over the next character.

3 Experiments

3.1 Experimental setup

Upon our request, the authors of the original paper shared a code base with us implementing the HMLSTM architecture and functionality to run the experiments on Penn Treebank (henceforth PTB). The code was implemented in Tensorflow version 1.1 (Abadi et al., 2016), which we ported with minimal modifications to version 1.6 to be able to run it on our system. In the default settings, the code contains ℓ^2-norm weights penalty term with a coefficient of 0.0005, which we also kept fixed across experiments. Furthermore, the given source code has a special initialization strategy used for the weights matrices: until the last column vector it is initialized with orthogonal initialization with standard normal distribution. The last column vector (corresponding to the logit of z) is initialized with Glorot uniform initialization with $\sigma = \sqrt{\frac{6.0}{\text{fanin+fanout}}}$. Due to no initialization details in the original paper we used the initialization defaults provided in the code base for all PTB and Text8 experiments. Lastly, the authors did not refer to publicly available pre-processed versions of the datasets and we used our versions following the details of the paper. We made the following changes to the original code:

Baseline – The authors report LSTM baselines for both PTB and Text8 data sets. The exact configuration of the baseline is not discussed in the paper, however, the authors do share that they implement both layer-normalization and the output module. We train a three-layer stacked LSTM with the same hyperparamters as the HMLSTM.

Layer normalization – The original paper reports results using layer normalization (Ba et al., 2016), which was not implemented in the code base. There are multiple options where to apply it in the case of a LSTM cell. For the HMLSTM cell we implemented it based on equations 20-22 in the paper introducing the technique (Ba et al., 2016). Furthermore, we applied layer-norm to the input and output embedding layers since the performance of the model was found to be unstable otherwise.

Learning-rate schedule and early-stopping – The code base did not include an implementation of the learning-rate schedule that was reported to be used in the original experiments. The learning-rate schedule reported in the paper divides the learning rate by 50 when no improvement is observed in the validation loss. In our code we monitor the validation loss at each epoch. The original code base ran the models for 500 epochs with no early-stopping

and no learning-rate schedule, however, we use early stopping with patience of 4 as very small improvements are observed after reducing the learning rate four times by 50.

Evaluation – We report the bits-per-character (bpc) of the trained models by computing the entropy (in base 2) of the entire test set and dividing it by the number of characters. The code did not implement the evaluation procedure and we have not found the exact details in the paper. Our implementation follows Mikolov et al. (2012): we use batch size of 1 and carry the states of the recurrent model over to the following batch of 100 characters until the whole test sequence is processed.

The experimental results reported in Section 4 are all using this revised implementation, manipulating various ablation factors as described in Section 3.2. Following Chung et al. (2016a), we report results on the following two datasets.

Character-level Penn Treebank – The smaller-scale experiments apply variations of the model on the Penn Treebank dataset (Marcus et al., 1993) using the splits and preprocessing from Mikolov et al. (2012). All models are trained with sequence lengths of 100 and batch size of 64. Before each epoch the dataset is randomly cropped to be divisible by 100. The parameters are optimized with Adam (Kingma and Ba, 2014) with initial learning rate of 0.002, which is divided by 50 if no improvement on the validation data is observed after a full epoch. The norm of the gradient is clipped at 1.0. For all models we use 512 units for all layers and 128 dimension character embeddings as reported in the paper.

Text8 – The Text8 dataset (Mahoney, 2011) is extracted from Wikipedia and is a sequence of 100 million alphabetical characters and spaces. The splits used by Chung et al. (2016a) correspond to the (by now standard) splits introduced in Mikolov et al. (2012): first 90M characters for training, the next 5M for validation and the final 5M characters for testing. On this dataset models are trained on sequence length of 100 and batch size of 128. The initial learning rate of Adam was set to 0.001 and we applied the learning-rate schedule and early-stopping strategy described before. The norm of the gradient is clipped at 1.0. We use 1024 units for the HMLSTM layers and 2048 output embedding units.

Like in the original paper, models are trained to minimze the log-likelihood of the training set and the non-differentiability gap caused by the rounding operation when discretizing the boundary variables is solved by using the straight-through estimator (Bengio et al., 2013).

3.2 Ablation factors

In order to analyze the behavior of the model and the impact of its various architectural design features as well as evaluation settings, we manipulate the following factors in our experiments.

Layer normalization (LN). As mentioned in the previous section, there was a mismatch between the description of the HMLSTM model in Chung et al. (2016a) and the code base provided to us in terms of layer normalization. Therefore we report our experimental results both with and without layer normalization.

Learning-rate schedule (Schedule). Similarly, the paper and the code base do not match in applying learning-rate schedule, therefore we report results with and without scheduling.

Sensitivity to slope (α). Hard-sigmoid (Gulcehre et al., 2016) is a piecewise linear approximation of the sigmoid function, defined as the first-order Taylor expansion of the sigmoid around $x \approx 0$ and clipped between the limits of the original function (0 and 1): $\max(0, \min(1, 0.25x + 0.5))$; where 0.25 is the slope α. The authors describe the slope annealing trick for the PTB experiments and state that they start from slope 0.5 and slowly increase it at maximum until 2.5. We have not found details regarding the α values in other experiments, but used the default $\alpha = 0.5$ in the code-base. We test whether the

hard-sigmoid slope $\alpha = 0.25$ reaches the same performance as the specific choice of $\alpha = 0.5$. Furthermore, we gauge sensitivity to α using values 0.125 and 1.0.

COPY operation on the last layer (CopyLast). The code base by default, only applies the COPY operation at the last layer on the cell state $\mathbf{c}_t^l$, but not on the hidden state $\mathbf{h}_t^l$. In the latter case if the layer runs COPY it takes the previous cell state and applies the new output gate on it along with the tanh function $\mathbf{o}_t \odot \tanh(\mathbf{c}_{t-1})$. This is different from the original formulation of the HMLSTM. The main experiments were run with this default, but we also report the impact of changing this parameter.

Top-down connection (NoTopDown). When the HMLSTM cell runs the FLUSH operation, it computes the new cell-state by $\mathbf{i}_t \odot \mathbf{u}_t$ and the previous cell-state is dropped from the computation. However, both $\mathbf{i}_t$ and $\mathbf{u}_t$ depend on the previous state $\mathbf{h}_{t-1}$. As such, information from the past steps still "leaks" even at FLUSH and each layer can potentially retain enough information for future computations without the use of top-down connections. In our experiments we run the HMLSTM model with and without top-down input to evaluate the impact of this simplification.

Simpler output layer (SimplerOut). The hidden state of the last layer of the HMLSTM is not updated at every time-step and as such it computes a gated embedding combining the representation of all three layers to be able to provide a prediction for every time-step. Here we implement a simplification to the output layer by replacing it with a single affine transformation, embedding the concatenated hidden states: $\mathbf{h}_t^e = \text{ReLU}(W^e[\mathbf{h}_1; \mathbf{h}_2; \mathbf{h}_3])$.

Alternative architecture (HMRNN). One of the motivations for the HMLSTM architecture in the original paper (Chung et al., 2016a) is that the hierarchical multiscale structure might help with the vanishing gradient problem as gradients are back-propagated through fewer time-steps. Here we introduce an alternative architecture that we call HMRNN, which replaces the LSTM updates with simple Elman RNN recurrence. It is a much simpler model and it helps in understanding if the hierarchical multiscale structure itself is enough to alleviate the vanishing gradient problem, or if the LSTM-style updates are essential for the good performance.

$$\mathbf{h}_t = \begin{cases} \tanh(W\mathbf{h}_t^{l-1} + V\mathbf{h}_{t-1}^{l+1}) & \text{if } z_{t-1}^l = 1 \text{ (FLUSH)} \\ \mathbf{h}_{t-1} & \text{if } z_{t-1}^l = 0 \text{ and } z_t^{l-1} = 0 \text{ (COPY)} \\ \tanh(W\mathbf{h}_t^{l-1} + U\mathbf{h}_{t-1}^l) & \text{if } z_{t-1}^l = 0 \text{ and } z_t^{l-1} = 1 \text{ (UPDATE)} \end{cases} \tag{9}$$

The HMRNN architecture implements a simple formulation of the hierarchical multiscale intuition. In case of the FLUSH operation, it only takes as input the hidden state of the lower layer and the hidden state of the higher layer at the previous step. In case of COPY it just uses the previous hidden state. Finally, when running UPDATE it applies the simple Elman network update. See Appendix B for a vectorized implementation.

4 Experimental Results

4.1 Reproducing language modeling results

We attempt to replicate the language modeling experiments of Chung et al. (2016a) on the character level Penn Treebank and Text8 datasets. Table 1 shows the language modeling results reported by Chung et al. (2016a) on both datasets. It also reports results of our reproduction of the original experiments as described in the paper. This means using the HMLSTM architecture with layer normalization on all layers, and with learning-rate scheduling. Since the use of the COPY operation on the last layer is ambiguous and not consistent between the original paper and the code base, we report results both with COPY on and off.

	PTB	Text8
HMLSTM reported by (Chung et al., 2016a)	1.25	1.29
3-layer LSTM reported by (Chung et al., 2016a)	1.29	1.39
3-layer LSTM + Schedule + LN	1.32	1.37
HMLSTM + Schedule + LN	1.27	1.36
HMLSTM + Schedule + LN + CopyLast	1.29	1.36

Table 1: Reproducing language modeling results (in bpc) on PTB and Text8 datasets.

Our most faithful reproduction of the original experiments, which uses the HMLSTM architecture with learning-rate schedule, layer normalization and COPY on the last layer, results in 1.29 bpc on the PTB dataset. Dropping the COPY option improves the results to 1.27 bpc, which is still below the results reported in Chung et al. (2016a) on the same dataset (1.25). Our 3-layer LSTM baseline on PTB also under performs the baseline reported by Chung et al. (2016a)(1.32 compared to 1.29 bpc).

On the Text8 dataset, our results (1.36) are much further from the published ones (1.29), with the HMLSTM performing very close to the 3-layer LSTM baseline (1.37). We did not pursue further experiments on this dataset. The discrepancy could be due to the fact that the script that the authors shared with us was optimized for PTB, and some of the settings might need to be changed for Text8. However, since we have not found such differences reported in the paper, we used the same setting for both datasets. Interestingly, contrary to the HMLSTM results, our implementation of the 3-layer LSTM basline improves the reported baseline performance from 1.39 to 1.37 bpc.

4.2 Ablation results

		BPC	Iter.	z^1	z^2	z-ratio
1	HMLSTM + Schedule + LN + copylast	1.29	10K	0.41	0.25	1.64
2	HMLSTM	1.39	16K	0.23	0.15	1.53
3	HMLSTM + Schedule	1.32	12K	0.25	0.16	1.56
4	HMLSTM + Schedule + LN	1.27	12K	0.42	0.09	4.67
5	HMLSTM + Schedule + LN + α=0.125	1.28	14K	0.41	0.23	1.78
6	HMLSTM + Schedule + LN + α=0.25	1.27	12K	0.31	0.21	1.48
7	HMLSTM + Schedule + LN + α=1.0	4.32	4K	1.0	1.0	1.0
8	NoTopDown + Schedule + LN	1.28	12K	0.64	0.28	2.29
9	SimplerOutput + Schedule + LN	**1.25**	10K	0.64	0.31	2.06
10	3-layer LSTM + Schedule + LN	1.32	9K	N/A	N/A	N/A
11	3-layer LSTM + Schedule + LN + SimplerOut	1.26	12K	N/A	N/A	N/A
12	HMRNN + Schedule + LN	1.40	18K	0.0	1.0	0.0

Table 2: Ablation results on PTB

Since we did not succeed in reproducing the original results on Text8, we only perform the ablation experiments on the PTB dataset. Table 2 summarizes the results of these experiments. On the first row, we repeat our reproduction results using the most faithful replication of the original experiments (HMLSTM + Schedule + LN + CopyLast). We will compare the results from various modifications of the architecture or evaluation setup to these base results.

Layer normalization and learning-rate schedule – As is evident from the results on rows 2–4, adding learning-rate schedule and layer normalization improve the results over the base HMLSTM. Furthermore, the results on row 4 (HMLSTM + Schedule + LN) are better than the reproduction results which also implement the CopyLast feature. Therefore, in the rest

of the experiments, we consistently add layer normalization on all layers as well as learning-rate scheduling, and drop CopyLast.

Sensitivity to alpha – Rows 5–7 show results for different values of the slope α. Using the by definition hard-sigmoid slope $\alpha = 0.25$ instead of the default $\alpha = 0.5$ in the code does not degrade the performance. Lowering alpha to $\alpha = 0.125$ degrades the performance slightly. Since Chung et al. (2016a) mention that they increase the slope up to $\alpha = 2.5$, we also tested the results with a higher value of $\alpha = 1.0$ (row 7), which caused the model to diverge after 4,000 iterations.

Architectural modification: top-down connection and simpler output – Interestingly, as can be seen from row 8, removing the top-down connections (and keeping the model structure fixed otherwise) only degrades the performance by a small margin; from 1.27 bpc to 1.28. Even more surprising is the effect of using a simpler output layer: replacing the gated-output layer by our simple output module improves the results from 1.27 to 1.25. This, in fact, is the best results we have achieved. Similarly rows 10 and 11 show that the simpler output layer improves the baseline 3-layer LSTM performance from 1.32 bpc to a competitive 1.26 bpc.

Alternative architecture: HMRNN – The simplified architecture which replaces the LSTM updates with Elman RNN produces results that are much worse (1.40) than the HMLSTM counterpart (1.27). Our ablation experiments show that using layer normalization and learning-rate schedule is beneficial, high values for the slope of the sigmoid function hurt performance, but the model performance is robust otherwise to smaller α values. The LSTM updates are essential for good performance of the HMLSTM model. Finally, simplifying certain aspects of the model such as removing the top-down connection might not hurt much, and in other cases such as simplifying the output layer it can actually enhance the overall performance.

4.3 Segmentation results

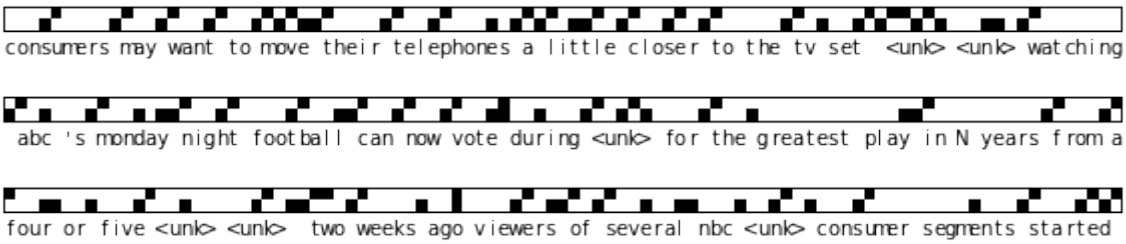

Figure 1: Segmentation examples. Black means $z_t = 1$, white $z_t = 0$.

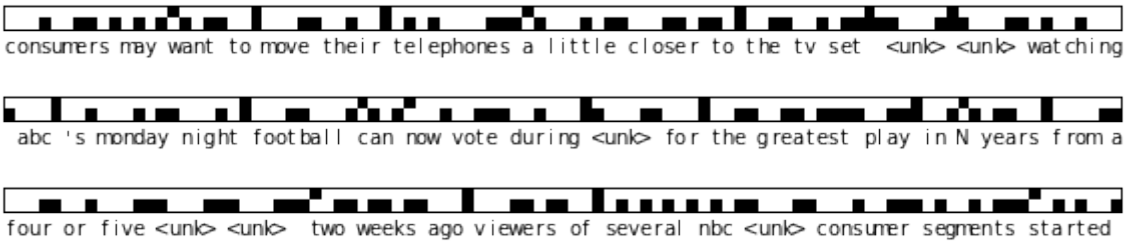

Figure 2: Segmentation examples with layer normalization. Black means $z_t = 1$, white $z_t = 0$.

The HMLSTM model predicts binary boundary variables z_t^1 and z_t^2 at each time-step, which correspond to a segment of the input utterance at each level. The frequencies of z_t^1 and z_t^2 provide a high-level description of segmentation properties of the network and are reported in Table 2. Based on the hierarchical multiscale intuition, the expected behavior is that the z_t^1

frequency is higher than z_t^2 as the former corresponds to words or morpheme-like units, whereas the latter corresponds to larger chunks. The ratio of z_t^1 to z_t^2 frequencies is reported in the last column of Table 2.

Running the HMLSTM default configuration with added layer-normalization and learning-rate schedule results in the largest separation in the time-scale of the layers as indicated by the z-ratio of 4.67. Interestingly, only changing the α value to 0.125 or 0.25 results in a much narrower gap (1.78 and 1.48 respectively), without a big impact on bpc. Furthermore, the HMLSTM with schedule, layer-norm and $\alpha = 0.125$ in row 5 performs on the same level as our NoTopDown ablation architecture, with a smaller z-ratio.

The segmentation examples reported in the original paper show the first layer of the HMLSTM segmenting the sequence at word boundaries (i.e. spaces), and the higher layer segments corresponding to multi-word chunks. Figure 1 shows segmentation results of the HMLSTM with learning-rate schedule and Figure 2 with the added layer normalization. Our runs could not reproduce the segmentation results visualized in the original paper and overall we do not find a relationship between the performance of the model and segmentation behavior.

5 Conclusion

In our attempt to reproduce the results in Chung et al. (2016a) we re-ran the HMLSTM model on two datasets: PTB and Text8. On PTB the final performance of the model almost matches the original results, but not quite. Our best result was achieved by a slight modification to the COPY operation of the last-layer provided in the source-code, but not detailed in the paper and with our added simplification to the output layer.

We could not reproduce the results on Text8 using the same code base received from the authors. This might be due to the non-availability of the pre-processed version of the dataset. Another potential source might be the lack of detail in the paper on the initialization scheme and weight penalty, which led us to keep these implementation details constant across datasets. Furthermore, the layer normalization might have been implemented on different layers across different datasets. We have made several attempts until reaching the conclusion that it needs to be implemented on every layer of the HMLSTM. This was found to perform best on PTB, but might not be the best setting for Text8. Similarly, the learning-rate schedule was applied based on the monitoring of the loss after every epoch, but this was an informed guess.

Two simplifications were applied to the architecture successfully: 1) removing top-down connections only slightly degraded performance, and 2) simplifying the output layer improved performance in our experiments. There is space for possible modifications that fell out of the scope of the current work like applying REINFORCE gradients in place of the straight-through estimator.

We could not reproduce the segmentation results provided in the paper. Furthermore, we did not observe a close relationship between the segmentation behavior and the final performance. Changing the slope variable α to 0.25 from 0.5, while keeping all other details constant, resulted in the same performance, but huge difference in segmentation behavior.

The observations made here are not specific to the work of Chung et al. (2016a) and the HMLSTM architecture. Similar results have been reported recently by Williams et al. (2017), whose re-implementation of the considered architecture did not produce the reported performances. One of their considered models learned a qualitatively different latent structure than another re-implementation by Yogatama et al. (2016) and the other architecture did not converge to the same structure across runs. The HMLSTM architecture was considered for reproduction due to its intriguing property of learning interpretable structure from character-level input. The detailed reproduction and ablation study was provided to surface some of the potential difficulties that can hinder the applicability of such models for future studies.

A Vectorized formulation of the HMLSTM

Here are the vectorized equations for the bottom, middle and top layers of the HMLSTM. Note, the computation process should be executed from top to bottom and left to right when there are multiple equations.

Bottom layer

$$\mathbf{c}_t = (1 - z_{t-1})\mathbf{c}_{t-1} \odot \sigma(\mathbf{f}_t) + \tanh(\mathbf{u}_t) \odot \sigma(\mathbf{i}_t) \tag{10}$$

Top layer

$$\begin{aligned} \hat{\mathbf{c}}_t &:= \mathbf{c}_{t-1} \odot \sigma(\mathbf{f}_t) + \tanh(\mathbf{u}_t) \odot \sigma(\mathbf{i}_t) & \hat{\mathbf{h}}_t &:= \sigma(\mathbf{o}_t) \odot \tanh(\mathbf{c}_t) \\ \mathbf{c}_t &:= z_t\hat{\mathbf{c}}_t + (1 - z_t)\mathbf{c}_{t-1} & \mathbf{h}_t &:= z_t\hat{\mathbf{h}}_t + (1 - z_t) \odot \mathbf{h}_{t-1} \end{aligned} \tag{11}$$

Middle layer

$$\begin{aligned} \mathrm{c}_m &= (1 - z_{t-1}^{\ell})(1 - z_t^{\ell-1}) & \mathbf{c}_t &= \mathbf{u}_g + \mathrm{c}_m(\mathbf{c}_{t-1} - \mathbf{u}_g) + \mathrm{u}_m(\sigma(\mathbf{f_t}) \odot \mathbf{c}_{t-1})) \\ \mathrm{u}_m &= (1 - z_{t-1}^{\ell})z_t^{\ell-1} & \mathbf{h}_t &:= \sigma(\mathbf{o}_t) \odot \tanh(\mathbf{c}_t) \\ \mathbf{u}_g &= \sigma(\mathbf{i_t}) \odot \tanh(\mathbf{u_t}) & \mathbf{h}_t &:= \mathrm{c}_m\mathbf{h}_t + \mathrm{c}_m \odot \mathbf{h}_{t-1} \end{aligned} \tag{12}$$

Variables $\mathrm{c}_m, \mathrm{u}_m$ and $\mathbf{u}_g$ stand for copy-mask, update-mask and gated-candidate activation respectively.

B Vectorized formulation of the HMRNN

Here are the vectorized equations for the bottom, middle and top layers of the HMRNN. Note, the computation process should be executed from top to bottom and left to right when there are multiple equations.

Bottom layer

$$\mathbf{h}_t = \tanh(W\mathbf{x}_t + (1 - z_{t-1}^{l})U\mathbf{h}_{t-1}^{l} + z_{t-1}^{l} \times V\mathbf{h}_{t-1}^{l+1}) \tag{13}$$

Top layer

$$\mathbf{h}_t = (1 - z_t^{l-1}) \times \mathbf{h}_{t-1} + z_t^{l-1} \times \tanh(W\mathbf{x}_t + U\mathbf{h}_{t-1}^{l}) \tag{14}$$

Middle layer

$$\begin{aligned} \mathrm{c}_m &= (1 - z_{t-1}^{\ell})(1 - z_t^{\ell-1}) & & \\ \mathrm{u}_m &= (1 - z_{t-1}^{\ell})z_t^{\ell-1} & \mathrm{h}_f &= W\mathbf{h}_t^{l-1} + V\mathbf{h}_{t-1}^{l+1} \\ \mathbf{h}_t &= \mathrm{c}_m\mathbf{h}_{t-1} + (1 - \mathrm{c}_m)\tanh((1 - \mathrm{u}_m)\mathrm{h}_f + \mathrm{u}_m\mathrm{h}_u)) & \mathrm{h}_u &= W\mathbf{h}_t^{l-1} + U\mathbf{h}_{t-1}^{l} \end{aligned} \tag{15}$$

Variables c_m and u_m stand for copy-mask and update-mask activation respectively.

Character-Level Feature Extraction with Densely Connected Networks

Abstract

Generating character-level features is an important step for achieving good results in various natural language processing tasks. To alleviate the need for human labor in generating hand-crafted features, methods that utilize neural architectures such as Convolutional Neural Network (CNN) or Recurrent Neural Network (RNN) to automatically extract such features have been proposed and have shown great results. However, CNN generates position-independent features, and RNN is slow since it needs to process the characters sequentially. In this paper, we propose a novel method of using a densely connected network to automatically extract character-level features. The proposed method does not require any language or task specific assumptions, and shows robustness and effectiveness while being faster than CNN- or RNN-based methods. Evaluating this method on three sequence labeling tasks - slot tagging, Part-of-Speech (POS) tagging, and Named-Entity Recognition (NER) - we obtain state-of-the-art performance with a 96.62 F1-score and 97.73% accuracy on slot tagging and POS tagging, respectively, and comparable performance to the state-of-the-art 91.13 F1-score on NER.

1 Introduction

Effectively extracting character-level features from words is crucial in many Natural Language Processing (NLP) tasks, such as Named Entity Recognition (NER), Part-of-Speech (POS) tagging, and Slot tagging. Thus, most state-of-the-art methods for these tasks exploit some kind of character-level features (Huang et al., 2015; dos Santos and Zadrozny, 2014). Recently, generating character-level features with neural architectures such as Convolutional Neural Network (CNN) or Recurrent Neural Network (RNN) has drawn much attention, mainly because it doesn't require human labor and shows superior performance (Ma and Hovy, 2016; dos Santos and Zadrozny, 2014). However, CNN struggles at distinguishing anagrams, and RNN is inherently slow due to its sequential nature.

In this paper, we propose an effective and efficient way of extracting character-level features using a densely connected network. The key benefits of the proposed method can be summarized as follows. First, it does not require any hand-crafted features or data preprocessing. Each word is processed based on n-gram statistics of the training data, and vectorized using bag-of-characters. Additional features are based on hexadecimal values of the character-set (e.g. UTF-16) and number of characters in the word. Second, it extracts effective character-level features while being efficient. State-of-the-art performance can be achieved using this method, and the feature extraction is done with a simple densely connected network with a single hidden layer. Third, it doesn't depend on features that are language or task specific, such as character type features or gazetteer (i.e. lists of known named entities such as cities or organization names). The only requirement for adopting this method is that the language should be processable as a sequence of words, which is made of sequence of characters. These benefits, combined with minimum requirements for application, make the proposed method an easy replacement for conventional methods such as CNN or RNN.

Proceedings of the 27th International Conference on Computational Linguistics, pages 3228–3239
Santa Fe, New Mexico, USA, August 20-26, 2018.

Our contributions are three-fold: 1) We propose an effective yet efficient method for character-level feature extraction; 2) We quantitatively show that the proposed method is superior to CNN and RNN via extensive evaluation; 3) We achieve state-of-the-art or comparable to state-of-the-art performance on three of the most popular and well-studied sequence tagging tasks - Slot tagging, Part-of-Speech (POS) tagging, and Named Entity Recognition (NER).

2 Related Work

Prior to the introduction of neural architectures for character-level feature generation, manually engineered features were designed by experts based on language and/or domain knowledge. One example is word shape, in which each word is mapped to a simplified representation that encodes information such as capitalization, numerals, and length (e.g. CoNLL-2003 to AaAAA-0000). Finkel et al. (2005) combined this feature with other information such as n-grams and gazetteers to train a conditional Markov model for identification of gene and protein names in biomedical documents. Huang et al. (2015) introduced more hand-crafted features utilizing punctuation or non-letters and used these as an input to a Bi-LSTM-CRF tagger for POS tagging, CoNLL-2000 chunking, and CoNLL-2003 NER. Even though these kinds of hand-crafted features showed strong empirical results, they are more expensive than our approach in that they require expert knowledge of the target domain and language.

In recent years, methods that utilize neural networks to automatically extract character-level features have been proposed. The most widely adopted and successful method for this is CNN. dos Santos and Zadrozny (2014) combined this approach with a window-based fully-connected neural network tagger to perform English and Portuguese POS tagging. This work achieved state-of-the-art results in Portuguese and near state-of-the-art results in English. In Ma and Hovy (2016), a Bi-LSTM-CRF model incorporated with a character-level CNN is trained in an end-to-end fashion. They evaluated this approach on English POS tagging and NER, achieving state-of-the-art performance on both tasks. However, feature vectors generated by CNN are position-independent due to the max-over-time pooling layer, and are more sensitive to model weight initialization compared to the method proposed in this paper.

Another effective way of generating feature vectors from a variable length sequence of characters is to use RNN. For instance, Lample et al. (2016) extracted character-level features using a bi-directional LSTM and used them with pre-trained word embeddings as word representations for another Bi-LSTM-CRF model. Evaluating this model for NER, they obtained state-of-the-art results for Dutch, German, and Spanish, and close to state-of-the-art results for English. Intuitively, character-level feature generation via RNN should be more effective than CNN, since RNN processes each character sequentially and thus should form a better model of character ordering. However, Reimers and Gurevych (2017) empirically showed that these two methods have no statistically significant difference in terms of performance. Furthermore, RNN has a higher time-complexity caused by its sequential nature, which makes it less favorable.

3 Proposed Method

The proposed method is built on bag-of-characters (BOC) representation. However, BOC is prone to anagrams and thus is susceptible to word collisions, i.e. different words having the same vector representation. The main focus of the proposed method is to minimize word collision while maintaining the key benefits described above. To achieve this goal, we split the word into k pieces, and each piece is vectorized using BOC. Then, two non hand-crafted-features are extracted from the word - character order and word length. These sparse vectors are concatenated and normalized to form the sparse character-level feature vector. For a n-dimensional vector $\mathbf{x} = \langle x_1, x_2, \cdots, x_n \rangle$, normalizing is done as follows:

$$x'_i = \frac{x_i}{\sum_{j=1}^{n} x_j} \tag{1}$$

This sparse vector is then fed into a densely connected network with a single hidden layer to obtain the final dense character feature vector. Note that the sparse vector representation of each word is fixed, so it can be cached for efficiency. Figure 1 illustrates the overall process.

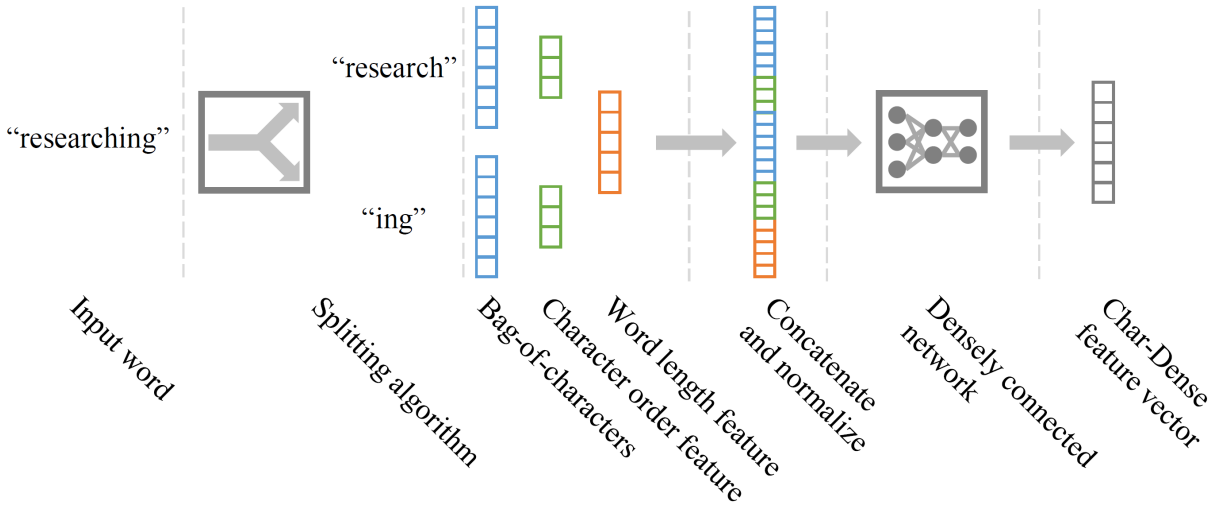

Figure 1: Process of generating the character-level feature vector of a word using the proposed method.

3.1 Splitting Words

Each word is split into k pieces to reduce the number of word collisions. To maintain the ordering of pieces, concatenation is used instead of summation or averaging to merge the vectors. Word splitting is done based on n-gram frequency. First, n-gram statistics C_{ng} is collected from the training corpus where $C_{ng}(s)$ is the number of times the n-gram s appears in the corpus. Then, the n-gram with the highest frequency gets merged into a single piece, and this merging is repeated until only k n-grams are left. The number of pieces k per word is a configurable hyperparameter. Finally, each piece is converted into a fixed length vector using BOC. The detailed algorithm is presented in Algorithm 1. This process is similar to the byte-pair encoding method in Sennrich et al. (2015), except that in the proposed method each word can only be split into k pieces whereas byte-pair encoding produces an arbitrary number of pieces. Producing a fixed number of pieces is important, since concatenation is used to merge the vectors.

Algorithm 1: Splitting word into k pieces

Input : word $w = (c_1, c_2, \cdots, c_n)$, n-gram statistics C_{ng}, number of pieces k
Output: $S = (s_1, \cdots, s_k)$ where $s_1 + s_2 + \cdots + s_k = w$

$S \leftarrow w$
while $|S| > k$ **do**
  $m = \underset{i}{\operatorname{argmax}}\, C_{ng}(c_i + c_{i+1})$
  $S \leftarrow (\cdots, s_{m-1}, s_m + s_{m+1}, s_{m+2}, \cdots)$
end
while $|S| < k$ **do**
  Append empty string to S
end
return S

3.2 Character Order Feature

Every character that has a digital representation can be converted into a numerical value via some character-set (e.g. UTF-16). Then, it is possible to numerically compare two characters. Let $T = \{c_1, c_2, \cdots, c_n\}$ be a character sequence of length n. Then $F_{asc}(T, k)$, $F_{des}(T, k)$, $C_{asc}(T)$, and $C_{des}(T)$ are defined as follows:

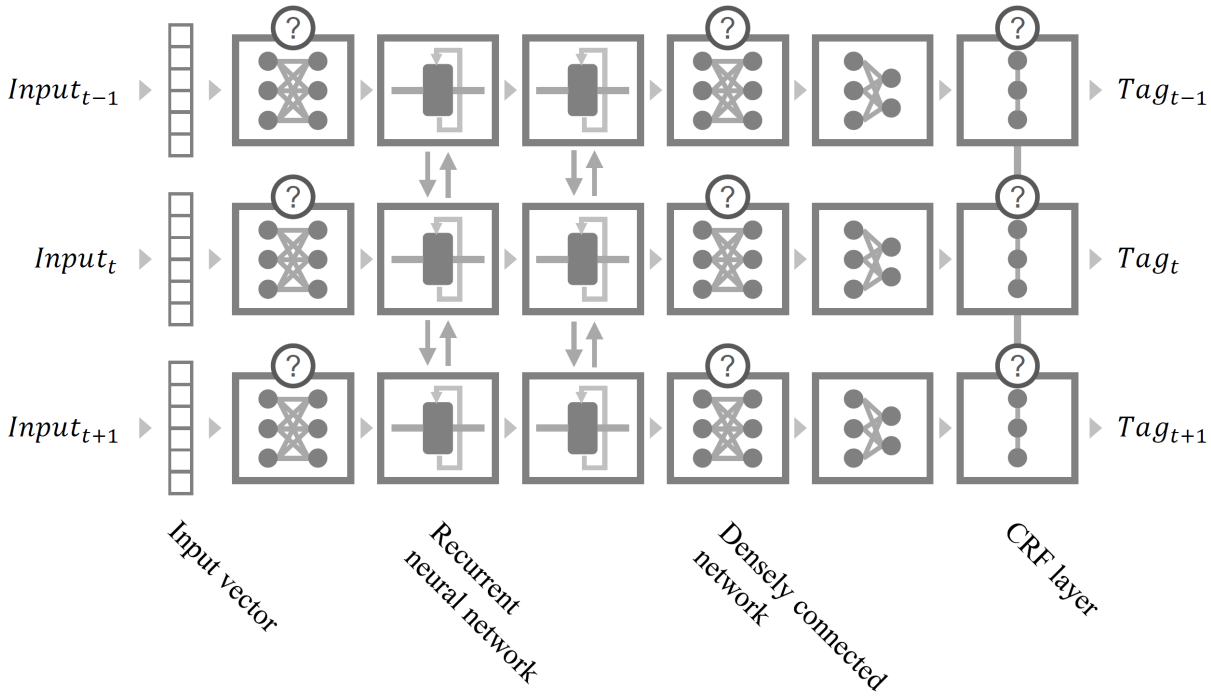

Figure 2: Overview of model architecture for sequence tagging experiments. Question mark indicates that the component is optional.

$$F_{asc}(T,k) = \begin{cases} 1, \text{if } c_k < c_{k+1} \\ 0, \text{otherwise} \end{cases}, \quad F_{des}(T,k) = \begin{cases} 1, \text{if } c_k > c_{k+1} \\ 0, \text{otherwise} \end{cases} \tag{2}$$

$$C_{asc}(T) = \sum_{k=1}^{n-1} F_{asc}(T,k), \quad C_{des}(T) = \sum_{k=1}^{n-1} F_{des}(T,k) \tag{3}$$

Bi-grams with the same character repeating are ignored. A sequence of characters can then be categorized into one of three classes: $C_{asc}(T) > C_{des}(T)$, $C_{asc}(T) = C_{des}(T)$, $C_{asc}(T) < C_{des}(T)$. This category info is calculated for each word piece, which is then converted into a 3-dimensional vector using one-hot encoding and concatenated to the sparse word piece vector.

3.3 Word Length Feature

To further reduce the number of word collisions, information about the word's length is added into the model. One-hot encoding is used to store an integer from 0 to 20, and any word exceeding 20 characters is treated as being 20 characters long.

4 Model

In this section, we describe the sequence tagging model's architecture in detail. Figure 2 illustrates the model architecture.

4.1 Sequence Tagging with Bidirectional RNN

In sequence tagging tasks, such as POS tagging or NER, both future and past input tokens are available to the model. Bidirectional RNNs (Graves and Schmidhuber, 2005) can efficiently make use of future and past features over a certain time frame. We use Long Short-Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) for our RNN cell, which is better at capturing long-term dependencies than vanilla RNN. Output of the forward and backward RNN layers are summed to form the feature vector of each time-step. Each word is tagged based on this feature vector, using either a softmax layer or CRF layer.

To capture a more abstract and higher-level representation in different layers, a densely connected layer can be added before and after the Bi-LSTM layers. The input to this network at each time-step is the concatenation of the character-level feature vector and a pre-trained word vector (described in section 5).

4.2 Conditional Random Field

Even though a Bi-LSTM layer can efficiently extract features for each time-step utilizing past and future inputs, the prediction is made on each time-step, independent of past and future tag outputs. The Conditional Random Field (CRF) layer overcomes this limitation by considering state transition probability, thereby decoding the most probable output tag sequence. It has been shown that adding a CRF layer on top of a Bi-LSTM network can lead to statistically significant performance increases (Reimers and Gurevych, 2017). We also test a variant of our model using CRF as the final layer to perform tag sequence prediction.

4.3 Stacking RNNs with Residual Connection

Increasing the depth of the neural network architecture has proven to be an effective way of improving performance. However, naively stacking layers can lead to adversarial effects due to the degradation problem. Residual connection (He et al., 2016) has shown to be an effective way to tackle this issue by creating a shortcut between layers. The same strategy is adopted to our model when there are more than one Bi-LSTM layers, in which case the input is added to the Bi-LSTM layer's output.

4.4 Dropout

Dropout is a popular and effective way of regularizing neural network models, by randomly dropping nodes (Srivastava et al., 2014). In our model, Inverted dropout is applied to all densely connected layers for regularization. For the Bi-LSTM layers, variational recurrent dropout (Gal and Ghahramani, 2016) is used, since naive dropout can deteriorate performance. The word embedding matrix is regularized using the method proposed in Gal and Ghahramani (2016), i.e. dropping words at random.

5 Training Details

Pre-trained Word Embeddings Utilizing word embeddings pre-trained on large unlabeled text has shown to be one of the most effective ways to increase performance on various NLP tasks. Our model uses the GloVe (Pennington et al., 2014) 300-dimensional vectors trained on the Common Crawl corpus with 42B tokens as word level features, as this resulted in the best performance in preliminary experiments. Words that do not appear in the training data are replaced with a special Out-of-Vocabulary (OOV) token. To train the vector of this token, we randomly swap words with OOV tokens while training with a 0.01 probability, as in Lample et al. (2016). The word vector is then concatenated with the character-level feature vector and fed into the subsequent layer.

Freezing Embeddings It is common practice to fine-tune the pre-trained word vectors through the training process. However, preliminary experiments have revealed that fine-tuning the word vectors results in lower performance than freezing the vectors, especially in the early stages of training. We hypothesize that randomly initialized weights in the model act as noise and degrade the pre-trained word vectors. To circumvent this issue, the embeddings are frozen for the first T_{freeze} phase of training so that they are not affected by untrained weights. We use $T_{freeze} = 20\%$ for all experiments.

Dynamic Batch Size Keskar et al. (2016) showed that small batch sizes lead to more global and flat minimizers, while large batch sizes lead to more local and sharp minimizers. Therefore, starting from a small batch size and increasing it during training would result in a more global, but sharp minimizer. While having similar effect to learning rate decay, this strategy also has a benefit of accelerating the training as the batch size grows (Smith et al., 2017). Adopting this method, we start from a fixed initial batch size, and increase the batch size by a factor of two on each quarter of the course of training.

Tagging Scheme It is reported that more complicated tagging schemes such as IOBES does not have statistically significant advantage over BIO scheme (Reimers and Gurevych, 2017), thus we adopt the BIO scheme for all experiments.

Dataset	ATIS		PTB WSJ		CoNLL2003	
	Sentences	Tokens	Sentences	Tokens	Sentences	Tokens
Training	4978	56591	38219	912344	14987	204567
Develop.	-	-	5527	131768	3466	51578
Test	893	9198	5462	129654	3684	46666

Table 1: Corpus statistics of each task.

Parameter Optimization Our network is trained by minimizing the cross entropy loss over the tags for the softmax model, or maximizing the log-likelihood of the tag sequence for the CRF model. The objective function is optimized using the gradient-based optimization algorithm Adam (Kingma and Ba, 2014). For all experiments, we implement the model using the TensorFlow (Abadi et al., 2016) library.
Hyperparameter Tuning Most hyperparameters, with the following exceptions, are tuned on the development sets. Hyperparameters of the character-CNN and character-RNN models are adopted from Ma and Hovy (2016) and Lample et al. (2016), respectively. The chosen hyperparameters for all experiments are summarized in Appendix A.

6 Evaluation

We evaluate the effectiveness of the proposed method using three of the most well-studied and common English sequence tagging tasks - Slot tagging, POS tagging, and NER. Note that to test the generalizability of the proposed method, we do not perform any preprocessing for all experiments. Details on each task and baseline models are described in this section. Table 1 summarizes the statistics of each task.

6.1 Slot Tagging

For slot tagging, we use the Airline Travel Information System (ATIS) dataset. This dataset has 84 types of slot labels and 127 possible tags with BIO tagging scheme. Since this corpus lacks a development set, 20% of the training data is randomly sampled and used as the development set for tuning the hyperparameters. This task's performance is measured in F1-score, which is calculated using the publicly available *conlleval.pl* script.

6.2 Part-of-Speech Tagging

For POS tagging, we use the Wall Street Journal (WSJ) portion of the Penn TreeBank dataset (Marcus et al., 1993) and adopt the standard split for part-of-speech tagging experiments - section 0-18 as training data, section 19-21 as development data, and section 22-24 as test data. This dataset contains 45 different POS tags. Model performance is measured by token-level accuracy.

6.3 Named Entity Recognition

For NER, the English portion of the CoNLL-2003 shared task (Tjong Kim Sang and De Meulder, 2003) is used for evaluation. This dataset contains four different types of named entities, which results in nine possible tags with BIO tagging scheme and an 'O' tag. Like slot tagging, the final performance is measured in F1-score using the same *conlleval.pl* script.

6.4 Baseline Models

Character-level CNN and character-level RNN are the most effective and widely adopted methods for character-level feature extraction, and thus are suitable as strong baseline methods. We implement these two methods to use them as baselines for comparison. The CRF layer has the effect of making the model robust to architectural differences (Reimers and Gurevych, 2017). Since the goal of baseline experiments is to evaluate the effect of difference in character-level feature generation methods, we use the softmax layer instead of the CRF layer for these experiments. Every aspect of the sequence tagging model except the character-level feature generation method is identical for all baseline experiments.

Method	Task		
	Slot	POS	NER
Char-CNN	96.22 (SD 0.08)	97.68 (SD 0.03)	89.08 (SD 0.20)
Char-RNN	96.25 (SD 0.09)	97.68 (SD 0.03)	**90.15** (SD 0.14)
Char-Dense (Ours)	**96.28** (SD **0.07**)	**97.69** (SD **0.02**)	90.10 (SD **0.13**)

7 Results and Discussion

7.1 Experimental Results

For a more in-depth analysis of the performance of the proposed method and two baselines, we train each model 20 times with different initial parameters, which are randomly initialized (Reimers and Gurevych, 2017). Table 2 summarizes the mean performance with standard deviation in parentheses. Performance distribution is also visualized using a violin plot in Figure 3.

7.1.1 Slot Tagging

On the task of tagging semantic slots using the ATIS dataset, the proposed method shows the best results in terms of both performance and variability. Our method has the highest mean F1-score of 96.28. Furthermore, it has the lowest standard deviation across all runs, which means it is robust to parameter initialization. On the contrary, both CNN and RNN models have lower performance and higher variability compared to the proposed method.

Analyzing the violin plot reveals that there are also differences in score distribution. While CNN models tend to have a low F1-score on average with occasional high peaks, RNN models have higher F1-score in general but suffer from a large performance drop with poor parameter initialization. This could be one of the reasons why models using CNN seem to have superior performance when only the best performance is reported. On the other hand, our model does not result in peaks or serious drops in performance with different seed values, which makes it more suitable for real-world applications.

7.1.2 Part-of-Speech Tagging
