In bilingual terminology extraction from comparable corpora, a reference list is required to evaluate the performance of the alignment. Such lists are usually composed of around 100 single terms (Hazem and Morin, 2012; Chiao and Zweigenbaum, 2002). Reference lists[6] were created for the four specialized domains and the two pairs of languages. For the French-English, reference words from the *Corporate Finance* domain were extracted from the glossary of bilingual micro-finance terms[7]. For *Breast Cancer*, the list is derived from the MESH and the UMLS thesauri[8]. Concerning *Wind Energy* and *Mobile Technology*, lists were extracted from specialized glossaries found on the Web. The Romanian-English gold standard was manually created by a native speaker starting from the French-English lists. Table 3 displays the sizes of the obtained lists. Reference terms pairs were retained if each word composing them appeared at least five times in the comparable domain corpora.

4.2 Experimental setup

Aside from those already mentioned, three parameters need to be set up: (1) the window size that defines contexts, (2) the association measure that measures the strength of the association between words and the (3) similarity measure that ranks candidate translations for state of the art methods. Context vectors are defined using a seven-word window which approximates syntactic dependencies. The association and the similarity measures (Discounted Log-Odds ratio (equation 5) and the cosine similarity) were set following Laroche and Langlais (2010), a comprehensive study of the influence of these parameters on the bilingual alignment.

$$\textit{Odds-Ratio}_{disc} = \log \frac{(O_{11} + \frac{1}{2})(O_{22} + \frac{1}{2})}{(O_{12} + \frac{1}{2})(O_{21} + \frac{1}{2})} \quad (5)$$

where O_{ij} are the cells of the 2×2 contingency matrix of a token s co-occurring with the term S within a given window size.

The F-measure of the Top 20 results (F-Measure@20), which measures the harmonic mean of precision and recall, is used as evaluation metric. Precision is the total number of correct translations divided by the number of terms for which the system returned at least one answer. Recall is equal to the ratio between the number of correct translation and the total number of words to translate (W_{cand}).

4.3 Results and discussion

In addition to the basic approach based on ESA (denoted ESA), we evaluate the performances of a method so-called Dico_{Spec} in which the translations are extracted from a generic dictionary and a method we called ESA_{Spec} which combine ESA and Dico_{Spec}. DICO_{Spec} is based on the generic dictionary we presented in subsection 3.6 and proceeds as follows: we extract a list of translations for each word to be translated from the generic dictionary. The domain specificity introduced in subsection 3.5 is then used to rank these translations. For instance, the french term *port* referring in the *Mobile Technology* domain, to the system that allows computers to receive and transmit information is translated into *port* and *seaport*. According to domain specificity values, the following ranking is obtained: the English term *port* obtain the highest specificity value (0.48). *seaport* comes next with a specificity value of 0.01. In ESA_{Spec}, the translations set out in the translations lists proposed by both ESA and the generic dictionary are weighted according to their domain specificity values. The main intuition behind this method is that by adding the information about the domain specificity, we obtain a new ranking of the bilingual extraction results.

The obtained results are displayed in table 4. The comparison of state of the art method shows that BA13 performs better than STAPP and MP11 for French-English and has comparable performances

Table 4: Results of the specialized dictionary creation on four specific domains, two pairs of languages.Three state of the art methods were used for comparison: STAPP is the standard approach, MP11 is the improvement of the standard approach introduced in (Morin and Prochasson, 2011), BA13 is a recent method that we developed (Bouamor et al., 2013). Dico$_{spec}$ exploits a generic dictionary, combined with the use of domain specificity (see Subsection 3.5). ESA stands for the ESA based approach introduced in this paper (see Figure 1). ESA$_{spec}$ combines the results of Dico$_{spec}$ and ESA.

for RO-EN. Consequently, we will use BA13 as the main baseline for discussing the newly introduced approach. The results presented in Table 4 show that ESA$_{spec}$ clearly outperforms the three baselines for the four domains and the two pairs of languages tested. When comparing ESA$_{spec}$ to BA13 for French-English, improvements range between 0.19 for *Corporate Finance* and 0.56 for *Wind Energy*. For RO-EN, the improvements vary from 0.1 for *Corporate Finance* to 0.5 for *Wind Energy*. Also, except for the *Corporate Finance* domain in Romanian, the performance variation across domains is much smaller for ESA$_{spec}$ than for the three state of the art methods. This shows that ESA$_{spec}$ is more robust to domain change and thus more generic.

The results obtained with ESA are significantly better than those obtained with Dico$_{spec}$ and ESA$_{spec}$, their combination, further improves the results. The main contribution to ESA$_{spec}$ performances comes from ESA, a finding that validates our assumption that the adequate use of a rich multilingual resource such as Wikipedia is appropriate for specialized lexicon translation. Dico$_{spec}$ is a simple method that ranks the different meanings of a candidate word available in a generic dictionary but its average performances are comparable to those of BA13 for FR-EN and higher for RO-EN. This finding advocates for the importance of good quality generic dictionaries in specialized lexicon translation approaches. However, it is clear that such dictionaries are far from being sufficient in order to cover all possible domains. There is no clear correlation between domain size and quality of results. Although richer than the other three domains, *Corporate Finance* has the lowest associated performances. This finding is probably explained by the intrinsic difficulty of each domain. When passing from FR-EN to RO-EN the average performance drop is more significant for BA13 than for the ESA based methods. The result indicates that our approach is more robust to language change.

5 Conclusion

We have presented a new approach to the creation of specialized bilingual lexicons, one of the central

building blocks of machine translation systems. The proposed approach directly tackles two of the major challenges identified in the Introduction. The scarcity of resources is addressed by an adequate exploitation of Wikipedia, a resource that is available in hundreds of languages. The quality of automatic translations was improved by appropriate domain delimitation and linking across languages, as well as by an adequate statistical processing of concepts similar to a word in a given context.

The main advantages of our approach compared to state of the art methods come from: the increased number of languages that can be processed, from the smaller sensitivity to structured resources and the appropriate domain delimitation. Experimental validation is obtained through evaluation with four different domains and two pairs of languages which shows consistent performance improvement. For French-English, two languages that have rich associated Wikipedia representations, performances are very interesting and are starting to approach those of manual translations for three domains out of four (F-Measure@20 around 0.8). For Romanian-English, a pair involving a language with a sparser Wikipedia representation, the performances of our method drop compared to French-English . However, they do not decrease to the same extent as those of the best state of the art method tested. This finding indicates that our approach is more general and, given its low language dependence, it can be easily extended to a large number of language pairs.

The results presented here are very encouraging and we will to pursue work in several directions. First, we will pursue the integration of our method, notably through comparable corpora creation using the data driven domain delimitation technique described in Subsection 3.5. Equally important, the size of the domain can be adapted so as to find enough context for all the words in domain reference lists. Second, given a word in a context, we currently exploit all similar concepts from the target language. Given that comparability of article versions in the source and the target language varies, we will evaluate algorithms for filtering out concepts from the target language that have low alignment with their source language versions. A final line of work is constituted by the use of distributional properties of texts in order to automatically rank parts of concept descriptions (i.e. articles) by their relatedness to the candidate word. Similar to the second direction, this process involves finding comparable text blocks but rather at a paragraph or sentence level than at the article level.

Abstract

Joint compression and summarization has been used recently to generate high quality summaries. However, such word-based joint optimization is computationally expensive. In this paper we adopt the 'sentence compression + sentence selection' pipeline approach for compressive summarization, but propose to perform *summary guided compression*, rather than generic sentence-based compression. To create an annotated corpus, the human annotators were asked to compress sentences while explicitly given the important summary words in the sentences. Using this corpus, we train a supervised sentence compression model using a set of word-, syntax-, and document-level features. During summarization, we use multiple compressed sentences in the integer linear programming framework to select salient summary sentences. Our results on the TAC 2008 and 2011 summarization data sets show that by incorporating the guided sentence compression model, our summarization system can yield significant performance gain as compared to the state-of-the-art.

1 Introduction

Automatic summarization can be broadly divided into two categories: extractive and abstractive summarization. Extractive summarization focuses on selecting the salient sentences from the document collection and concatenating them to form a summary; while abstractive summarization is generally considered more difficult, involving sophisticated techniques for meaning representation, content planning, surface realization, etc., and the "true abstractive summarization remains a researcher's dream" (Radev et al., 2002).

There has been a surge of interest in recent years on generating compressed document summaries as a viable step towards abstractive summarization. These compressive summaries often contain more information than sentence-based extractive summaries since they can remove insignificant sentence constituents and make space for more salient information that is otherwise dropped due to the summary length constraint. Two general strategies have been used for compressive summarization. One is a pipeline approach, where sentence-based extractive summarization is followed or proceeded by sentence compression (Knight and Marcu, 2000; Lin, 2003; Zajic et al., 2007; Wang et al., 2013). Another line of work uses joint compression and summarization. They have been shown to achieve promising performance (Daumé, 2006; Martins and Smith, 2009; Berg-Kirkpatrick et al., 2011; Chali and Hasan, 2012; Almeida and Martins, 2013; Qian and Liu, 2013). One popular approach for such joint compression and summarization is via integer linear programming (ILP). However, since words are the units in the optimization framework, solving this ILP problem can be expensive.

In this study, we use the pipeline compression and summarization method because of its computational efficiency. Prior work using such pipeline methods simply uses generic sentence-based compression for each sentence in the documents, no matter whether compression is done before or after summary sentence extraction. We propose to use sum-

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 490–500,
Seattle, Washington, USA, 18-21 October 2013.

mary guided compression combined with ILP-based sentence selection for summarization in this paper. We create a compression corpus for this purpose. Using human summaries for a set of documents, we identify salient words in the sentences. During annotation, the human annotators are given these salient words and asked to generate compressed sentences. We expect such "guided" sentence compression is beneficial for the pipeline compression and summarization task. In addition, previous research on joint modeling for compression and summarization suggested that the labeled extraction and compression data sets would be helpful for learning a better joint model (Daumé, 2006; Martins and Smith, 2009). We hope that our work on this guided compression will also be of benefit to the future joint modeling studies.

Using our created compression data, we train a supervised compression model using a variety of word-, sentence-, and document-level features. During summarization, we generate multiple compression candidates for each sentence, and use the ILP framework to select compressed summary sentences. In addition, we also propose to apply a preselection step to select some important sentences, which can both speed up the summarization system and improve performance. We evaluate our proposed summarization approach on the TAC 2008 and 2011 data sets using the standard ROUGE metric (Lin, 2004). Our results show that by incorporating a guided sentence compression model, our summarization system can yield significant performance gain as compared to the state-of-the-art reported results.

2 Related Work

Summarization research has seen great development over the last fifty years (Nenkova and McKeown, 2011). Compared to the abstractive counterpart, extractive summarization has received considerable attention due to its clear problem formulation – to extract a set of salient and non-redundant sentences from the given document set. Both unsupervised and supervised approaches have been explored for sentence selection. The supervised approaches include the Bayesian classifier (Kupiec et al., 1995), maximum entropy (Osborne, 2002), skip-chain conditional random fields (CRF) (Galley, 2006), discriminative reranking (Aker et al., 2010), among others.

The extractive summary sentence selection problem can also be formulated in an optimization framework. Previous approaches include the integer linear programming (ILP) and submodular functions, which are used to solve the optimization problem. In particular, Gillick et al. (2009) proposed a concept-based ILP approach for summarization. Li et al. (2013) improved it by using supervised stragety to estimate concept weight in ILP framework. In (Lin and Bilmes, 2010), the authors model the sentence selection problem as maximizing a submodular function under a budget constraint. A greedy algorithm is proposed to efficiently approximate the solution to this NP-hard problem.

Compressive summarization receives increasing attention in recent years, since it offers a viable step towards abstractive summarization. The compressed summaries can be generated through a joint model of the sentence selection and compression processes, or through a pipeline approach that integrates a generic sentence compression model with a summary sentence pre-selection or post-selection step.

Many studies explore the joint sentence compression and selection setting. Martins and Smith (2009) jointly perform sentence extraction and compression by solving an ILP problem; Berg-Kirkpatrick et al. (2011) propose an approach to score the candidate summaries according to a combined linear model of extractive sentence selection and compression. They train the model using a margin-based objective whose loss captures the final summary quality. Woodsend and Lapata (2012) present a method where the summary's informativeness, succinctness, and grammaticality are learned separately from data but optimized jointly using an ILP setup; Yoshikawa et al. (2012) incorporate semantic role information in the ILP model; Chali and Hasan (2012) investigate three strategies in compressive summarization: compression before extraction, after extraction, or joint compression and extraction in one global optimization framework. These joint models offer a promise for high quality summaries, but they often have high computational cost. Qian and Liu (2013) propose a graph-cut based method that improves the speed of joint compression and summarization.

The pipeline approach, where sentence-based extractive summarization is followed or proceeded by sentence compression, is also popular. Knight and Marcu (2000) utilize the noisy channel and decision tree method to perform sentence compression; Lin (2003) shows that pure syntactic-based compression may not improve the system performance; Zajic et al. (2007) compare two sentence compression approaches for multi-document summarization, including a 'parse-and-trim' and a noisy-channel approach; Galanis and Androutsopoulos (2010) use the maximum entropy model to generate the candidate compressions by removing the branches from the source sentences; Liu and Liu (2013) couple the sentence compression and extraction approaches for summarizing the spoken documents; Wang et al. (2013) design a series of learning-based compression models built on parse trees, and integrate them in query-focused multi-document summarization. Prior studies often rely heavily on the generic sentence compression approaches (McDonald, 2006; Nomoto, 2007; Clarke and Lapata, 2008; Thadani and McKeown, 2013) for compressing the sentences in the documents, yet a generic compression system may not be the best fit for the summarization purpose.

In this paper, we adopt the pipeline-based compressive summarization framework, but propose a novel *guided compression* method that is catered to the summarization task. We expect this approach to take advantage of the efficient pipeline processing while producing satisfying results as the joint models. We train a supervised guided compression model to produce n-best compressions for each sentence, and use an ILP formulation to select the best set of summary sentences. In addition, we propose to apply a sentence pre-selection step to further accelerate the processing and enhance the performance.

3 Guided Compression Corpus

The goal of guided sentence compression is to create compressed sentences that are grammatically correct and contain the important information that we would like to preserve in the final summary. Following the compression literature (Clarke and Lapata, 2008), the compression task is defined as a word deletion problem, that is, the human annotators (and also automatic compression systems) are allowed to only remove words from the original sentence to form a compression. The key difference between our proposed guided compression with generic sentence compression is that, we provide guidance to the human compression process by specifying a set of "important words" that we wish to keep for each sentence. We expect this kind of summary oriented compression would benefit the ultimate summarization task. Take the sentence shown in Table 1 as an example. For generic sentence compression, there may be multiple 'good' human compressions for this sentence, such as those listed in the table. Without guidance, a human annotator (or automatic system) is likely to use option A or B; however, if "18 hours" appears in the summary, then we want to provide this guidance in the compression process, hence option C may be the best compression choice. This guided compression therefore avoids removing the salient words that are important to the final summary.

Original Sentence:
The gas leak was contained Monday afternoon , nearly 18 hours after it was reported , Statoil spokesman Oeivind Reinertsen said .
Compression A:
The gas leak was contained
Compression B:
The gas leak was contained ***Monday afternoon***
Compression C:
The gas leak was contained ***nearly 18 hours after it was reported***

Table 1: Example sentence and three compressions.

To generate the guided compression corpus, we use the TAC 2010 data set[1] that was used for the multi-document summarization task. There are 46 topics. Each has 10 news documents, and also four human-created abstractive reference summaries. Since annotating all the sentences in this data set is time consuming and some sentences are not very important for the summarization task, we choose a set of sentences that are highly related to the human abstracts for annotation. We compare each sentence with the four human abstracts using the ROUGE-2 metric (Lin, 2004), and the sentences

[1] http://www.nist.gov/tac/2010/

Original Sentence: He said ***Vietnam veterans*** are ***presumed to have been exposed to Agent Orange*** and veterans with any of the ***10 diseases*** is presumed to have contracted it from the exposure , without individual proof .
Guided Compression: Vietnam veterans are presumed to have been exposed to Agent Orange.
Original Sentence: The ***province has*** limited the number of trees to be chopped down in the forest area in northwest Yunnan and has ***stopped building sugar factories in the Xishuangbanna region to preserve*** the only ***tropical rain forest*** in the country located there .
Guided Compression: province has stopped building sugar factories in the Xishuangbanna region to preserve tropical rain forest.

Table 2: Example original sentences and their guided compressions. The "guiding words" are italicized and marked in red.

with the highest scores are selected.

In annotation, human annotators are provided with important 'guiding words' (highlighted in the annotation interface) that we want to preserve in the sentences. We calculate the word overlap between a sentence and each of those sentences in the human abstracts, and use a set of heuristic rules to determine the "guiding words" in a sentence: the longest consecutive word overlaps (greater than 2 words) in each sentence pair are first selected; the rest overlaps that contain 2 or more words (excluding the stopwords) are also selected. We suggest the human annotators to use their best judgment to keep the guiding words as many as possible while compressing the sentence.

We use the Amazon Mechanical Turk (AMT) for data annotation[2]. In total, we select 1,150 sentences from the TAC news documents. They are grouped into about 230 human intelligence tasks (HITs) with 5 sentences in each HIT. A sentence was compressed by 3 human annotatorsand we select the shortest candidate as the goldstandard compression for each sentence. In Table 2, we show two example sentences, their guiding words (bold), and the human compressions. The first example shows that giving up some guiding words is acceptable, since more unnecessary words will be included in order to accommodate all the guiding words; the second example shows that the guided compression can lead to more aggressive word deletions since the constituents that are not important to the summary will be deleted even though they contain salient information by themselves.

For our compression corpus, which contains 1,150 sentences and their guided compressions, the average compression rate, as measured by the percentage of dropped words, is about 50%. This compression ratio is higher compared to other generic sentence compression corpora, in which the word deletion rate ranges from 24% to 34% depending on different text genres and annotation guidelines (Clarke and Lapata, 2008; Liu and Liu, 2009). This suggests that the annotators can remove words more aggressively when they are provided with a limited set of guiding words.

4 Summarization System

Our summarization system consists of three key components: we train a supervised guided compression model using our created compression data, with a variety of features.then we use this model to generate n-best compressions for each sentence; we feed the multiple compressed sentences to the ILP framework to select the best summary sentences. In addition, we propose a sentence pre-selection step that can both speed up the summarization system and improve the performance.

4.1 Guided Sentence Compression

Sentence compression has been explored in previous studies using both supervised and unsupervised approaches, including the noisy-channel and decision tree model (Knight and Marcu, 2000; Turner and Charniak, 2005), discriminative learning (McDonald, 2006), integer linear programming (Clarke and Lapata, 2008; Thadani and McKeown, 2013), conditional random fields (CRF) (Nomoto, 2007; Liu and Liu, 2013), etc. In this paper, we employ the CRF-based compression approach due to its proved performance and its flexibility to integrate different levels of discriminative features. Under this framework, sentence compression is formulated as a sequence labeling problem, where each word is

[2]http://www.mturk.com

labeled as either "0" (retained) or "1" (removed). We develop different levels of features to capture word-specific characteristics, sentence related information, and document level importance. Most of the features are extracted based only on the sentence to be compressed. However, we introduce a few document level features. These are designed to capture the word and sentence significance within the given document collection and are thus expected to be more summary related.

Word and sentence features:

- **Word n-grams**: identity of the current word and two words before and after, as well as all the bigrams and trigrams that can be formed by the adjacent words and the current word.
- **POS n-grams**: same as the word n-grams, but use the part-of-speech tags instead.
- **Named entity tags**: binary features representing whether the current word is a person, location, or temporal expression. We use the Stanford CoreNLP tools[3] for named entity tagging.
- **Stopwords**: whether the current word is a stopword or not.
- **Conjunction features**: (1) conjunction of the current word with its relative position in the sentence; (2) conjunction of the NER tag with its relative position.
- **Syntactic features**: We obtain the syntactic parsing tree using the Berkeley Parser (Petrov and Klein, 2007), then obtain the following features: (1) the last sentence constituent tag in the path from the root to the word; (2) depth: length of the path starting from the root node to the word; (3) normalized depth: depth divided by the longest path in the parsing tree; (4) whether the word is under an SBAR node; (5) depth and normalized depth of the SBAR node if the word is under an SBAR node;
- **Dependency features:** We employ the Penn2Malt toolkit [4] to convert the parse result from the Berkeley parser to the dependency parsing tree, and use these dependency features: (1) dependency relations such as 'AMOD' (adjective modifier), 'NMOD' (noun modifier), etc. (2) whether the word has a child, left child, or right child in the dependency tree.

Document-level features:

- **Sentence salience score:** We use a simple regression model to estimate a salience score for each sentence (more details in Section 4.3), which represents the importance of the sentence in the document. This score is discretized into four binary features according to the average sentence salience.
- **Unigram document frequency:** this is the current word's document frequency based on the 10 documents associated with each topic.
- **Bigram document frequency:** document frequency for the two bigrams, the current word and its previous or next word.

Some of the above features were employed in related sentence compression studies (Nomoto, 2007; Liu and Liu, 2013). In addition to these features, we explored other related features, including the absolute position of the current word, whether the word appears in the corresponding topic title and descriptions, conjunction of the syntactic tag with the tree depth, etc.; however, these features did not lead to improved performance. We train the CRF model with the Pocket CRF toolkit[5] using the guided compression corpus collected in Section 3. During summarization, we apply the model to a given sentence to generate its n-best guided compressions and use them in the following summarization step.

4.2 Summary Sentence Selection

The sentence selection process is similar to the standard sentence-based extractive summarization, except that the input to the selection module is a list of compressed sentences in our work. Many extractive summarization approaches can be applied for this purpose. In this work, we choose the integer linear programming (ILP) method, specifically, the concept-based ILP framework introduced in (Gillick

[3] http://nlp.stanford.edu/software/corenlp.shtml

[4] http://stp.lingfil.uu.se/~nivre/research/Penn2Malt.html

[5] http://sourceforge.net/projects/pocket-crf-1/

et al., 2009), mainly because it yields best performance in the TAC evaluation tasks. This ILP approach aims to extract sentences that can cover as many important concepts as possible, while ensuring the summary length is within a given constraint. We follow the study in (Gillick et al., 2009) to use word bi-grams as concepts, and assign a weight to each bi-gram using its document frequency in the given document collection for a test topic. Two differences are between our ILP setup and that in (Gillick et al., 2009). First, since we use multiple compressions for one sentence, we need to introduce an additional constraint: for each sentence, only one of the n-best compressions may be included in the summary. Second, we optimize a joint score of the concept coverage and the sentence salience. The formal ILP formulation is shown below:

$$\max \quad \sum_i w_i c_i + \sum_j v_j \sum_k s_{jk} \tag{1}$$

$$s.t. \quad \sum_k s_{jk} \leq 1 \forall j \tag{2}$$

$$s_{jk} Occ_{i\_jk} \leq c_i \tag{3}$$

$$\sum_{jk} s_{jk} Occ_{i\_jk} \geq c_i \tag{4}$$

$$\sum_{jk} l_{jk} s_{jk} \leq L \tag{5}$$

$$c_i \in \{0,1\} \ \forall i \tag{6}$$

$$s_{jk} \in \{0,1\} \ \forall j,k \tag{7}$$

where c_i and s_{jk} are binary variables indicating the presence of a concept and a sentence respectively; s_{jk} denotes the k^{th} candidate compression of the j^{th} sentence; w_i represents the weight of the concept; v_j is the sentence salience score of the j^{th} sentence, predicted using a regression model (Section 4.3), and all of its compressed candidates share this value. (1) is the new objective function we use that combines the coverage of the concepts and the sentence salience scores. (2) represents our additional constraint, which requires that for each sentence j, only one candidate compression will be chosen. Occ_{i_jk} represents the occurrence of concept i in the sentence s_{jk}. Inequalities (3) and (4) associate the sentences and the concepts. Constraint (5) controls the summary length, as measured by the total number of words in the summary. We use an open source ILP solver[6].

4.3 Sentence Pre-selection

The above ILP method can offer an exact solution to the defined objective function. However, ILP is computationally expensive when the formulation involves large quantities of variables, i.e, when we have many sentences and a large number of candidate compressions for each sentence. We therefore propose to apply a sentence pre-selection step before the compression. This kind of selection step has been used in previous ILP-based summarization systems (Berg-Kirkpatrick et al., 2011; Gillick et al., 2009). In this work, we propose to use a simple supervised support vector regression (SVR) model (Ng et al., 2012) to predict a salience score for each sentence and select the top ranked sentences for further processing (compression and summarization).

To train the SVR model, the target value for each sentence is the ROUGE-2 score between the sentence and the four human abstracts (this same value is used for sentence selection in corpus annotation (Section 3)). We employ three commonly used features: (1) sentence position in the document; (2) sentence length as indicated by a binary feature: it takes the value of 0 if the number of words in the sentence is greater than 50 or less than 10, otherwise the feature value is 1; (3) interpolated n-gram document frequency as introduced in (Ng et al., 2012), which is a weighted linear combination of the document frequency of the unigrams and bigrams contained in the sentence:

$$f(s) = \frac{\alpha \sum_{w_u \in S} DF(w_u) + (1-\alpha) \sum_{w_b \in S} DF(w_b)}{|S|}$$

where w_u and w_b represent the unigrams and bigrams contained in the sentence S; α is a balancing factor; $|S|$ denotes the number of words in the sentence.

The SVR model was trained using the SVMlight toolkit[7]. Using this model, we can predict a salience score (V_j in Eq 1) for each sentence and only select the top n sentences and supply them to the compression and summarization steps. In practice, using a fixed n may not be a good choice since the number

[6] http://www.gnu.org/software/glpk/

[7] http://svmlight.joachims.org/

of sentences varies greatly for different topics. We therefore set n heuristically based on the total number of sentences m for each topic: n=15 if $m > 150$; n=10 if $m < 100$; n=$0.1 * m$ otherwise.

5 Experimental Results

5.1 Experimental Setup

For our experiments, we use the standard TAC data sets[8], which have been used in the NIST competitions and in other summarization studies. In particular, we used the TAC 2010 data set for creating the guided compression corpus and training the SVR pre-selection model, the TAC 2009 data set as development set for parameter tuning, and the TAC 2008 and 2011 data sets as the test set for reporting the final summarization results.

We compare our pipeline summarization system against three recent studies, which have reported some of the highest published results on this task. Berg-Kirkpatrick et al. (2011) introduce a joint model for sentence extraction and compression. The model is trained using a margin-based objective whose loss captures the end summary quality; Woodsend and Lapata (2012) learn individual summary aspects from data, e.g., informativeness, succinctness, grammaticality, stylistic writing conventions, and jointly optimize the outcome in an integer linear programming framework. Ng et al. (2012) exploit category-specific information for multi-document summarization. In addition to the three previous studies, we also report the best achieved results in the TAC competitions.

5.2 Summarization Results

In Table 3 and Table 4, we present the results of our system and the aforementioned summarization studies. We use the ROUGE evaluation metrics (Lin, 2004), with R-2 measuring the bigram overlap between the system and reference summaries and R-SU4 measuring the skip-bigram with the maximum gap length of 4. "Our System" uses the pipeline setting including the three components described in Section 4. We use the SVR-based approach to preselect a set of sentences from the document set; these sentences are further fed to the guided compression module that produces n-best compressions for each sentence; the ILP-based framework is then used to select the summary sentences from these compressions.

System	R-2	R-SU4	CompR
TAC'08 Best System	11.03	13.96	n/a
(Berg-Kirkpatrick et al., 2011)	11.70	14.38	n/a
(Woodsend et al., 2012)	11.37	14.47	n/a
Our System	**12.35**†	**15.27**†	43.06%
Our System w/o Pre-selection	12.02	14.98	55.69%
Our System w/ Generic Comp	10.88	13.79	30.90%

Table 3: Results on the TAC 2008 data set. "Our System" uses the SVR-based sentence pre-selection + guided compression + ILP-based summary sentence selection. "Our System w/ Generic Comp" uses the pre-selection + generic compression + ILP summary sentence selection setting. "CompR" represents the compression ratio, i.e., percentage of dropped words. † represents our system outperforms the best previous result at the 95% significance level.

System	R-2	R-SU4	CompR
TAC'11 Best System	13.44	16.51	n/a
(Ng et al., 2012)	13.93	16.83	n/a
Our System	**14.40**	**16.89**	39.90%
Our System w/o Pre-selection	13.74	16.5	53.81%
Our System w/ Generic Comp	13.08	16.23	30.10%

Table 4: Results on the TAC 2011 data set. The systems use the same settings as for the TAC 2008 data set.

We can see from the table that in general, our system achieves considerably better results compared to the state-of-the-art on both the TAC 2008 and 2011 data sets. On the TAC 2008 data set, our system outperforms the best reported result at the 95% significance level; on the TAC 2011 data set, our system also yields considerable performance gain though not exceed the 95% significance level. In the following, we show more detailed analysis to study the effect of different system parameters.

With or without sentence pre-selection. First we evaluate the impact of sentence pre-selection step. In Table 3 and Table 4, we include the results when this step is not used ("Our System w/o Pre-selection"). That is, all of the sentences in the documents (excluding those containing less than 5 words) are compressed and used in the ILP-

based summary sentence selection module. We can see that although sentence pre-selection removes some sentences from consideration in the later summarization step, it actually significantly improves system performance. In the TAC 2008 data set, each topic contains averagely 210 sentences; while the pre-selection step chooses 13 sentences among them. These numbers are 185 and 12 for the TAC 2011 data set. Table 5 shows the average running time of each topic in TAC 2011 data for the two systems, with or without the pre-selection step. Here we fix the number of compressions to 100 in both cases for fair comparison. We can see the selection step greatly accelerates the system processing. When applying the pre-selection step, fewer sentences are used in the compression and summarization, this means we are able to use more compression candidates for each sentence (considering the complexity of ILP module). Using the TAC 2009 as development set, we tuned the number of candidate compressions generated for each sentence. Without pre-selection, we used the 100-best candidates generated from the compression model; with pre-selection, we are able to increase the number to 200-best candidate compressions and still maintain reasonable computational cost. These are the numbers used in the results in Table 3 and 4. Using more compressions helps improve summarization performance. We also notice that the compression ratios are quite different when using sentence pre-selection vs. not. This suggests that in the important sentences (those are kept after pre-selection), there is more summary related information and thus the compression model keeps more words in them (lower compression ratio).

System	Compressed Sentences	Number of Compressions	Running Time (sec)
w/o Pre-selection	185	100	3.9
w/ Pre-selection	12	100	0.85

Table 5: Average running time of our system, w/ or w/o the sentence pre-selection step. Experiments conducted on the TAC 2011 data set. Running time refers only to the execution time of the ILP module for each topic.

Number of compression candidates. This parameter (denoted as n) also impacts system performance. Figure 1 shows the R-2 scores of the two systems (with and without the sentence pre-selection step) when using different number of compressions for each sentence. In general, we find that the R-2 scores do not change much when n is large enough. For example, the 'with pre-selection' system can achieve relatively stable R-2 scores on the TAC 2008 data set (ranging from 12.2 to 12.4) when m is greater than 140; similarly, the R-2 scores on the TAC 2011 data is over 14.2 when m is greater than 100. Without the pre-selection step, the scores are less stable in regard to the changing of the m value, since the large amount of sentences plus a high volume of the compression candidates may incur huge computational cost to the ILP solver. This is also the reason that in Figure 1, for the system without pre-selection, we only vary n from 1 to 100. In general, we also notice that given more compression candidates, the R-2 score is still improving, as indicated by Figure 1. The improved performance of 'with pre-selection' over 'without pre-selection' is partly because fewer sentences are used and thus we are able to increase the number of compression candidates for these sentences in the ILP sentence extraction module.

Quality of sentence compression training data. In order to illustrate the contribution of our summary-guided sentence compression component, we train a generic sentence compression model and use this in our compression and summarization pipeline. The generic compression model was trained using the Edinburgh sentence compression corpus (Clarke and Lapata, 2008), which contains 1370 sentences collected from news articles. This data set has been widely used in other summarization studies (Martins and Smith, 2009). Each sentence has 3 compressions and we choose the shortest compression as the reference. The average compression rate of this corpus is about 28%, lower than that in our summary guided compression data. Note that in generic sentence compression, we only use those word and sentence features described in Section 4.1, not the document-level features since they are not available for the Edinburgh data set. Results of our system using the generic compression model (with sentence pre-selection) are shown in the last row of Table 3 and Table 4. We can see that the system with this generic compression model performs

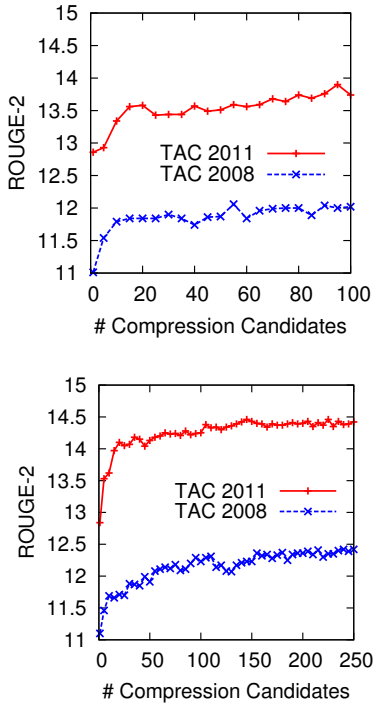

Figure 1: R-2 scores of the two systems (without and with the sentence pre-selection step) when using different number of compressions for each sentence.

worse than ours, and is also inferior to the TAC best performing system on both data sets, which signifies the importance of our proposed summary guided sentence compression approach. We can also see there is a difference in the compression ratio in the system generated compressions when using different compression corpora to train the compression models. The resulting compression ratio patterns are consistent with those in the training data, that is, using our guided compression corpus our system compressed sentences more aggressively.

Learning curve of guided compression. Since we use a supervised compression model, we further consider the relationship between the summarization performance and the number of sentence pairs used for training the guided compression model. In total, there are 1150 training sentence pairs in our corpus. We incrementally add 100 sentence pairs each time and plot the learning curve in Figure 2. In the compression step, we generate only the 1-best compression candidate in order to remove the impact caused by the downstream summary sentence selection module. As seen from Figure 2, increasing the compression training data generally improves summarization performance, although there are also fluctuations. When adding more training sentence pairs, the system performance is likely to further increase.

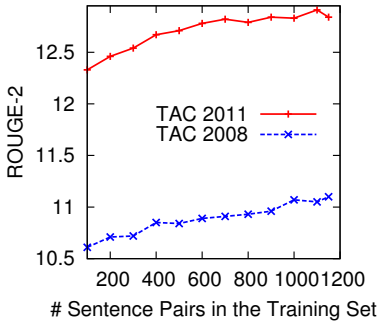

Figure 2: ROUGE-2 scores when using different number of sentences to train the guided compression model.

6 Conclusion and Future Work

In this paper, we propose a pipeline summarization approach that combines a novel *guided compression* model with ILP-based summary sentence selection. We create a guided compression corpus, where the human annotators were explicitly informed about the important summary words during the compression annotation. We then train a supervised compression model to capture the guided compression process using a set of word-, sentence-, and document-level features. We conduct experiments on the TAC 2008 and 2011 summarization data sets and show that by incorporating the guided sentence compression model, our summarization system can yield significant performance gain as compared to the state-of-the-art. In future, we would like to further explore the reinforcement relationship between keywords and summaries (Wan et al., 2007), improve the readability of the sentences generated from the guided compression system, and report results using multiple evaluation metrics (Nenkova et al., 2007; Louis and Nenkova, 2012) as well as performing human evaluations.

Abstract

Reordering poses one of the greatest challenges in Statistical Machine Translation research as the key contextual information may well be beyond the confine of translation units. We present the "Anchor Graph" (AG) model where we use a graph structure to model global contextual information that is crucial for reordering. The key ingredient of our AG model is the edges that capture the relationship between the reordering around a set of selected translation units, which we refer to as *anchors*. As the edges link anchors that may span multiple translation units at decoding time, our AG model effectively encodes global contextual information that is previously absent. We integrate our proposed model into a state-of-the-art translation system and demonstrate the efficacy of our proposal in a large-scale Chinese-to-English translation task.

1 Introduction

Reordering remains one of the greatest challenges in Statistical Machine Translation (SMT) research as the key contextual information may span across multiple translation units.[1] Unfortunately, previous approaches fall short in capturing such cross-unit contextual information that could be critical in reordering. For example, state-of-the-art translation models, such as Hiero (Chiang, 2005) or Moses (Koehn et al., 2007), are good at capturing local reordering within the confine of a translation unit, but their formulation is approximately a simple unigram model over derivation (a sequence of the application of translation units) with some aid from target language models. Moving to a higher order formulation (say to a bigram model) is highly impractical for several reasons: 1) it has to deal with a severe *sparsity issue* as the size of the unigram model is already huge; and 2) it has to deal with a *spurious ambiguity issue* which allows multiple derivations of a sentence pair to have radically different model scores.

In this paper, we develop "*Anchor Graph*" (AG) where we use a graph structure to capture global contexts that are crucial for translation. To circumvent the sparsity issue, we design our model to rely only on contexts from a set of selected translation units, particularly those that appear frequently with important reordering patterns. We refer to the units in this special set as *anchors* where they act as vertices in the graph. To address the spurious ambiguity issue, we insist on computing the model score for every anchors in the derivation, including those that appear inside larger translation units, as such our AG model gives the same score to the derivations that share the same reordering pattern.

In AG model, the actual reordering is modeled by the edges, or more specifically, by the edges' labels where different reordering around the anchors would correspond to a different label. As detailed later, we consider two distinct set of labels, namely *dominance* and *precedence*, reflecting the two dominant views about reordering in literature, i.e. the first one that views reordering as a linear operation over a sequence and the second one that views reordering as a recursive operation over nodes in a tree structure The former is prevalent in phrase-based context, while the latter in hierarchical phrase-based and

* This work was done when the authors were with IBM.

[1] We define translation units as phrases in phrase-based SMT or as translation rules in syntax-based SMT.

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 501–512,
Seattle, Washington, USA, 18-21 October 2013.

syntax-based context. More concretely, the dominance looks at the anchors' relative positions in the translated sentence, while the precedence looks at the anchors' relative positions in a latent structure, induced via a novel synchronous grammar: *Anchor-centric, Lexicalized Synchronous Grammar*.

From these two sets of labels, we develop two probabilistic models, namely the *dominance* and the *orientation* models. As the edges of AG link pairs of anchors that may appear in multiple translation units, our AG models are able to capture high order contextual information that is previously absent. Furthermore, the parameters of these models are estimated in an unsupervised manner without linguistic supervision. More importantly, our experimental results demonstrate the efficacy of our proposed AG-based models, which we integrate into a state-of-the-art syntax-based translation system, in a large scale Chinese-to-English translation task. We would like to emphasize that although we use a syntax-based translation system in our experiments, in principle, our approach is applicable to other translation models as it is agnostic to the translation units.

2 Anchor Graph Model

Formally, an AG consists of $\{\mathcal{A}, \mathcal{L}\}$ where $\mathcal{A}$ is a set of vertices that correspond to anchors, while $\mathcal{L}$ is a set of labeled edges that link a pair of anchors. In principle, our AG model is part of a translation model that focuses on the reordering within the source sentence F and its translation E. Thus, we start by first introducing $\mathcal{A}$ into a translation model (either word-based, phrase-based or syntax-based model) followed by $\mathcal{L}$. Given an F, $\mathcal{A}$ is essentially a subset of non-overlapping (word or phrase) units that make up F. As the information related to $\mathcal{A}$ is not observed, we introduce $\mathcal{A}$ as a latent variable.

Let $P(E, \sim |F)$ be a translation model where $\sim$ corresponds to the alignments between units in F and E. [2] We introduce $\mathcal{A}$ into a translation model, as follow:

$$P(E, \sim |F) = \sum_{\forall \mathcal{A}'} P(E, \sim, \mathcal{A}'|F) \quad (1)$$

$$P(E, \sim, \mathcal{A}'|F) = P(E, \sim |\mathcal{A}', F)P(\mathcal{A}') \quad (2)$$

As there can be many possible subsets of F and summing over all possible $\mathcal{A}$ is intractable, we make the following approximation for $P(\mathcal{A}')$ such that we only need to consider one particular $\mathcal{A}^*$: $P(\mathcal{A}') = \delta(\mathcal{A}' = \mathcal{A}^*)$ which returns 1 only for $\mathcal{A}^*$, otherwise 0. The exact definition of the heuristic will be described in Section 7, but in short, we equate $\mathcal{A}^*$ with units that appear frequently with important reordering patterns in training data.

Given an $\mathcal{A}^*$, we then introduce the edges of AG ($\mathcal{L}$) into the equation as follow:

$$P(E, \sim |\mathcal{A}^*, F) = P(E, \sim, \mathcal{L}|\mathcal{A}^*, F) \quad (3)$$

Note that $\mathcal{L}$ is also a latent variable but its values are derived deterministically from $(F, E, \sim)$ and $\mathcal{A}^*$, thus no extra summation is present in Eq. 3.

Then, we further simplify Eq. 3 by factorizing it with respect to each individual edges, as follow:

$$P(E, \sim, \mathcal{L}|\mathcal{A}^*, F) \approx \prod_{\substack{\forall a_m, a_n \in \mathcal{A}^* \\ m<n}} P(L_{m,n}|a_m, a_n) \quad (4)$$

where $L_{m,n} \in \mathcal{L}$ corresponds to the label of an edge that links a_m and a_n.

In principle, $L_{m,n}$ can take any arbitrary value. For addressing the reordering challenge, it should ideally correspond to some aspect of the reordering around a_m and a_n, for example, how the reordering around a_m affects the reordering around a_n. As mentioned earlier, we choose to associate $L_{m,n}$ with the dominance and the precedence relations between a_m and a_n, where the former looks at the relative positions of the two anchors when they are projected into a latent tree structure, while the latter looks at their relative positions when they are projected into the target sentence. We illustrate the two in Fig. 1.

Furthermore, we assume that dominance and precedence are independent and develop one model for each, resulting in the dominance and the orientation models, which we describe in Section 3 and 4 respectively. To make the model more compact, we

[2] Alignment ($\sim$) represents an existing latent variable. Depending on the translation units, it can be defined at different level, i.e. word, phrase or hierarchical phrase. As during translation, we are interested in the anchors that appear inside larger translation units, we set $\sim$ at word level, which information can be induced for (hierarchical) phrase units by either keeping the word alignment from the training data inside the units or inferring it via lexical translation probability. We use the former.

introduce an additional parameter O that restricts the maximum order of AG as follows:

$$\approx \prod_{o=1}^{O} \prod_{i=0}^{|\mathcal{A}^*|+o-1} P_o(L_{i-o,i}|a_{i-o}, a_i) \quad (5)$$

Thus, we only consider edges that link two anchors that are at most $O-1$ anchors apart. For $O=1$, the AG model only considers relations between neighboring anchors. Following the standard practice in the n-gram language modeling, we append O number of pseudo anchors at the beginning and at the end of F, which represent the sentence delimiter markers. We do so in a monotone order.

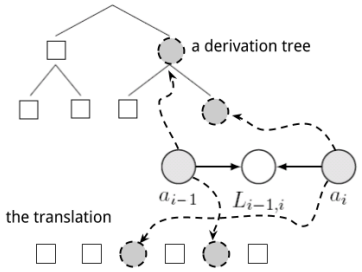

Figure 1: The illustration of the dominance and the precedence relations. The former looks at the anchors' projection on a derivation structure. The latter looks at the anchors' projection on the translated sentence.

3 Dominance Model

This section describes our dominance model where we equate $L_{m,n}$ in Eq. 4 with $dom(a_m, a_n)$ that expresses to the dominance relation between a_m and a_n in a latent tree structure. Due to reordering, anchors can only appear in specific nodes. We first describe a novel formalism of *Anchor-centric, Lexicalized Synchronous Grammar* (AL-SG), used to induce the tree structure and then discuss the probabilistic formulation of the model. Just to be clear, we introduce AL-SG mainly to facilitate the computation of $dom(a_m, a_n)$. The actual translation model at decoding time remains either phrase-based, hierarchical phrase-based or syntax-based model.

3.1 Anchor-centric, Lexicalized Synchronous Grammar

Given $(F, E, \sim)$ and $\mathcal{A}$, Anchor-centric, Lexicalized Synchronous Grammar (AL-SG) produces a tree structure where the nodes are decorated with anchors-related information. As the name alludes, the core of AL-SG is *anchor-centric constituents* (*ACC*), which corresponds to nodes, composed from merging anchors with by either their left, their right neighboring constituents or both.

More concretely, first of all, we consider a span on the source sentence F to be a *constituent* if it is consistent with the alignment ($\sim$). Second of all, we can construct a larger constituent by merging smaller constituents given that the larger constituent is also consistent with the alignment. These two constraints are similar to the heuristic applied to extract hierarchical phrases (Chiang, 2005).

Then, specific to AL-SG, we consider an anchor a to lexicalize a constituent c, if: a) we can compose c from at most three smaller constituents: c_L, a and c_R where a is the anchor while c_L,c_R are the (possibly empty) constituents immediately to the left and to the right of a; and b) we can create smaller anchors-centric constituents from concatenating a with c_L and a with c_R. If a can lexicalize c, then the node associated with c would be marked with a. In computing $dom(a_m, a_n)$, we look at the constituents that cover both anchors and check whether the anchors can lexicalized any of such constituents.

Now, we will describe AL-SG in a formal way. For simplicity, we use a simple grammar, called Inversion Transduction Grammar (ITG) (Wu, 1997), although in practice, we handle a more powerful synchronous grammar. Hence, we proceed to describe Anchor-centric, Lexicalized ITG (AL-ITG).

An AL-ITG is a quadruple $\{\Sigma, \mathcal{A}, \mathcal{V}, \mathcal{R}\}$ where:

- $\Sigma = \{(f/e)\}$ is a set of terminal symbols, which represents all possible units defined over $(F, E, \sim)$ where each pair corresponds to a link in $\sim$. We define $\sim$ at the most fine-grained level (i.e. word-level), as we insist on computing model score for each anchors even if they appear inside larger units.
- $\mathcal{A} \in \Sigma$ is a set of anchors, which is a subset of the terminal symbols.
- $\mathcal{V} = \{\{P, X, Y\} \times \{\mathcal{A}, \emptyset\}\}$ is a set of (possibly lexicalized) nonterminal symbols. P represents the terminal symbols (Σ); while X and Y correspond to the spans that are created from merging two adjacent constituents. On the tar-

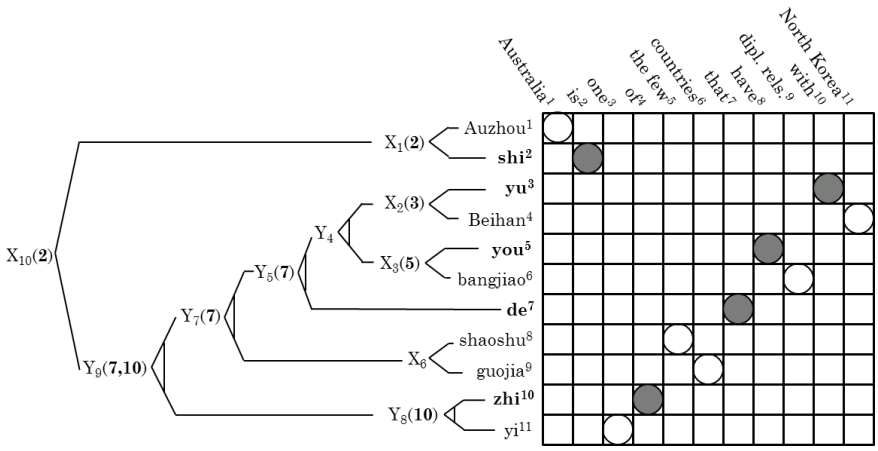

Figure 2: An illustration of an aligned Chinese-English sentence pair with one possible AL-ITG derivation obtained by applying the grammar in a left-to-right fashion. Circles represent alignment points. Black circle represents the anchor; boxes represent the anchor's neighbors. In the derivation tree, the anchors are represented by their position and in bold. For succinctness, we omit the preterminal rules in the tree.

get side, for X, the order of the two children follows the source order, while for Y, the order follows the inverse. Nonterminal symbols can be lexicalized with zero or more than one anchor. We represent a lexicalized constituent as a nonterminal symbol followed by a bracket which contains the lexicalizing anchors, e.g. $P(H)$ where H is the anchors lexicalizing P.

- $\mathcal{R}$ is a set of production rules which can be classified into the following categories:
  - Preterminal rules. We propagate the symbol if it corresponds to an anchor.

$$P(H = f/e) \rightarrow f/e, \text{ if } f/e \in \mathcal{A}^*$$
$$P(H = \emptyset) \rightarrow f/e, \text{ otherwise}$$

  - Monotone production rules, which reorder the children in monotone order, denoted by square brackets ("[","]").

$$\begin{aligned} X(H_1 \cup H_2) &\rightarrow [P(H_1)P(H_2)] \\ X(H_1 \cup H_2) &\rightarrow [X(H_1)P(H_2)] \\ X(H_1 \cup H_2) &\rightarrow [X(H_1)X(H_2)] \\ X(H_1) &\rightarrow [X(H_1)Y(H_2)] \\ X(H_2) &\rightarrow [Y(H_1)P(H_2)] \\ X(H_2) &\rightarrow [Y(H_1)X(H_2)] \\ X(\emptyset) &\rightarrow [Y(H_1)Y(H_2)] \end{aligned}$$

  - Inverse production rules, which reorder the children in the inverse order, denoted by angle brackets ("⟨","⟩").

$$\begin{aligned} Y(H_1 \cup H_2) &\rightarrow \langle P(H_1)P(H_2)\rangle \\ Y(H_1 \cup H_2) &\rightarrow \langle Y(H_1)P(H_2)\rangle \\ Y(H_1 \cup H_2) &\rightarrow \langle Y(H_1)Y(H_2)\rangle \\ Y(H_1) &\rightarrow \langle Y(H_1)X(H_2)\rangle \\ Y(H_2) &\rightarrow \langle X(H_1)P(H_2)\rangle \\ Y(H_2) &\rightarrow \langle X(H_1)Y(H_2)\rangle \\ Y(\emptyset) &\rightarrow \langle X(H_1)X(H_2)\rangle \end{aligned}$$

Like ITG, AL-ITG only permits two kind of reordering operations, namely monotone and inverse. To accommodate the lexicalization, we first assign a unique nonterminal symbol for each, i.e. X for monotone reordering and Y for inverse reordering. Then, we lexicalize Xs and Ys with anchors as long as they satisfy the constraint that the child shares the same label as the parent. This constraint guarantees that the constituents are valid ACCs. It also enables the anchors to lexicalize long constituents, although the terminal symbols are defined at word-level.

Fig. 2 illustrates an example Chinese-to-English translation with a AL-ITG derivation when the grammar is applied in a left-to-right fashion. Admittedly, AL-ITG (or more generally AL-SG) is susceptible to spurious ambiguity as it produces multiple derivation trees for a given $(F, E, \sim)$. Fortunately, the value of $dom(a_m, a_n)$ is identical for all derivations, since the computation of $dom(a_m, a_n)$ relies

only on whether a_m and a_n can lexicalize *at least one* constituent that covers both anchors. Hence, we only need to look at one derivation to compute $dom(a_m, a_n)$. Generalizing AL-ITG to a more powerful formalism is trivial; we just need to forbid the propagation for non-binarizeable production rules.

3.2 Probabilistic Model

We read-off the dominance relations $dom(a_m, a_n)$ from D obtained from the application of AL-SG to $(F, E, \sim)$. As lexicalization is a bottom-up process, for reading-off $dom(a_m, a_n)$, it is sufficient to look at the lowest common ancestor (LCA) of both anchors; if the anchors cannot lexicalize the LCA, they won't be able to lexicalize the constituents larger than LCA. To be more concrete, let's consider the D in Fig. 2. In that D, the LCA of a_m = yu^3/with^{10} and a_n = de^7/that^7 is Y_5(**7**). Then, we check the anchors that can lexicalize the LCA. Let $V(H)$ be the LCA, then $dom(a_m, a_n) \in$

$$
\begin{aligned}
(\textit{LH}) \quad & \text{, if } a_m \in H \wedge a_n \notin H \\
(\textit{RH}) \quad & \text{, if } a_m \notin H \wedge a_n \in H \\
(\textit{BL}) \quad & \text{, if } a_m \in H \wedge a_n \in H \\
(\textit{BD}) \quad & \text{, if } a_m \notin H \wedge a_n \notin H
\end{aligned}
$$

The value refers to cases where a_m and a_n can lexicalize $V(H)$ and it is useful to model spans that share a simple, uniform reordering, i.e. all-monotone or all-inverse, while the value refers to the cases where a_m and a_n cannot lexicalize $V(H)$ and it is useful to model spans that involve in a complex reordering. Meanwhile, the and refer to cases where only one anchor can lexicalize $V(H)$, i.e. a_m and a_n respectively. These values are useful for modeling cases where the surroundings of the two anchors exhibit different kind of reordering pattern.

With such definition, the edge labels $\mathcal{L}$ in Fig. 2 are indicated in Table 1. Note that in Table 1, we don't specify the relations involving pseudo anchors, although they are crucial.

The final probabilistic formulation of the dominance model is as follows:

$$
\approx \prod_{o=1}^{O} \prod_{i=0}^{|\mathcal{A}|+o-1} P_{dom_o}(dom(a_{i-o}, a_i) | a_{i-o}, a_i) \quad (6)
$$

As shown, we allocate a separate model P_{dom_o} for each separate order (o) where each P_{dom_o} will contribute as one additional feature in the log-linear model of the translation model. In allocating a separate model for each o, we conjecture that different pair of anchors contributes differently depending on how far the two anchors are.

m / n	1	2	3	4	5
1 = (shi^2/is^2)	-	-	-	-	-
2 = (yu^3/with^{10})	*LH*	-	-	-	-
3 = (you^5/have^8)	*LH*	*BD*	-	-	-
4 = (de^7/that^7)	*LH*	*RH*	*RH*	-	-
5 = (zhi^{10}/of^4)	*LH*	*RH*	*RH*	*BL*	-

Table 1: The dominance relations between pairs of anchors according to the derivation in Fig. 2.

4 Orientation Model

In this section, we introduce the orientation model (*ori*) where we equate $L_{m,n}$ with the precedence relations between a pair of anchors. Instead of directly modeling the precedence between the two anchors, we approximate it by modeling the precedence of each anchor with its neighboring constituents. Formally, we approximate $P(L_{m,n}|a_m, a_n)$ as

$$
\begin{aligned}
& P_{ori_R}(ori(a_m, M_R(a_m))|a_m) \times \\
& \quad P_{ori_L}(ori(a_n, M_L(a_n))|a_n) \qquad (7)
\end{aligned}
$$

where $M_R(a_m)$ is the largest constituent to the right of the first anchor a_m, $M_L(a_n)$ the largest constituent to the left of the second anchor a_n, and $ori()$ a function that maps the anchor and the neighboring constituent to a particular orientation.

Plugging Eq. 7 into Eq. 5 results in the following approximation of $P(\Theta|\mathcal{A})$:

$$
\begin{aligned}
C. \prod_{i=0}^{|\mathcal{A}|-1} & \{P_{ori_L}(ori(a_i, M_L(a_i))|a_i) \times \\
& P_{ori_R}(ori(a_i, M_R(a_i))|a_i)\}^O \qquad (8)
\end{aligned}
$$

where C is a constant term related to the pseudo anchors and O is the maximum order of the AG. In practice, we can safely ignore both C and O as they are constant for a given AG. As shown, the orientation model is simplified into a model that looks at the reordering of the anchors' neighboring constituents.

The exact definition of M_L and M_R will be discussed in Section 5. Their orientation, i.e.

$ori_L(C_L, a)$ and $ori_R(C_R, a)$ respectively, may take one of the following four values: (*MA*), (*RA*), (*MG*) and (*RG*). The first clause (monotone, reverse) indicates whether the target order follows the source order; the second (adjacent, gap) indicates whether the anchor and its neighboring constituent are adjacent or separated by an intervening when projected.

5 Parameter Estimation

For each $(F, E, \sim)$, the training starts with the identification of the regions in the source sentences as anchors ($\mathcal{A}$). For our Chinese-English experiments, we use a simple heuristic that equates anchors ($\mathcal{A}^*$) with constituents whose corresponding word class belongs to function words-related classes, bearing a close resemblance to (Setiawan et al., 2007). In total, we consider 21 part-of-speech tags; some of which are as follows: VC (copula), DEG, DEG, DER, DEV (*de*-related), PU (punctuation), AD (adjectives) and P (prepositions).

5.1 Extracting Events from $(F, E, \sim)$

The parameter estimation first involves extracting two statistics from $(F, E, \sim)$, namely $dom(a_m, a_n)$ for the dominance model as well as $ori(a, M_L(a))$ and $ori(a, M_R(a))$ for the orientation model. Instead of developing a separate algorithm for each, we describe a unified way to extract these statistics via the largest neighboring constituents of the anchors, i.e. $M_L(a)$ and $M_R(a)$. This approach enables the dominance model to share the same residual state information as the orientation model.[3]

Let a_m be an anchor and $M_R(a_m)$ be its largest neighboring constituent to the right. Let a_n be an anchor to the left of a_m and $M_L(a_n)$ be a_n's largest neighboring constituent to the left. According to AL-SG, we say that a_m dominates a_n if $ori(a_m, M_R(a_m)) \in \{MA, RA\}$ and $a_n \in M_R(a_m)$. By the same token, we say that a_n dominates a_m if $ori(a_n, M_L(a_n)) \in \{MA, RA\}$ and $a_m \in M_L(a_n)$. The constraints on the orientation reflect the fact that in AL-SG, anchors can only be propagated through monotone or inverse production rules, which correspond to the MA and RA respectively. The fact that we are looking at the largest neighboring constituents guarantees that if the other anchor is outside that constituent, then that other anchor is never dominated.

More formally, given an aligned sentence pair $\Theta = (F, E, \sim)$, let $\Delta(\Theta)$ be all possible constituents that can be extracted from Θ:[4]

$$\{(f_{j_1}^{j_2}/e_{i_1}^{i_2}) : \forall (j,i) \in \sim : ((j_1 \leq j \leq j_2) \wedge (i_i \leq i \leq i_2)) \vee (\neg(j_1 \leq j \leq j_2) \wedge \neg(i_i \leq i \leq i_2))$$

Then, let the anchors $\mathcal{A}$ be a subset of $\Delta(\Theta)$. Given $\mathcal{A} \subset \Delta(\Theta)$, let $a = (f_{j_1}^{j_2}/e_{i_1}^{i_2}) \in \mathcal{A}$ be a particular anchor. And, let $\mathcal{C}_L(a) \subset \Delta(\Theta)$ be a's left neighbors and let $\mathcal{C}_R(a) \subset \Delta(\Theta)$ be a's right neighbors, iff:

$$\forall C_L = (f_{j_3}^{j_4}/e_{i_3}^{i_4}) \in \mathcal{C}_L(a) : j_4 + 1 = j_1$$
$$\forall C_R = (f_{j_5}^{j_6}/e_{i_5}^{i_6}) \in \mathcal{C}_R(a) : j_2 + 1 = j_5$$

Then, let $M_L(a) \in \mathcal{C}_L(a)$ and $M_R(a) \in \mathcal{C}_R(a)$ be the largest left and right neighbors according to:

$$M_L(a) = \underset{(f_{j_3}^{j_4}/e_{i_3}^{i_4}) \in \mathcal{C}_L(a)}{\arg\max} (j_4 - j_3)$$
$$M_R(a) = \underset{(f_{j_5}^{j_6}/e_{i_5}^{i_6}) \in \mathcal{C}_R(a)}{\arg\max} (j_6 - j_5)$$

Let $M_L = (f_{j_3}^{j_4}/e_{i_3}^{i_4})$ and $M_R = (f_{j_5}^{j_6}/e_{i_5}^{i_6})$. We then proceed to extract $ori_L(a, M_L(a))$ and $ori_R(a, M_R(a))$ respectively as follows:

- *MA*, if $(i_4 + 1) = i_1$ for ori_L or if $(i_2 + 1) = i_5$ for ori_R
- *RA*, if $(i_2 + 1) = i_3$ for ori_L or if $(i_6 + 1) = i_1$ for ori_R
- *MG*, if $(i_4 + 1) < i_1$ for ori_L or if $(i_2 + 1) < i_5$ for ori_R
- *RG*, if $(i_2 + 1) < i_3$ for ori_L or if $(i_6 + 1) < i_1$ for ori_R.

Then, we proceed to extract $dom(a_m, a_n)$. Given two anchors a_m, a_n where $m < n$, we define the

[3] The analogy in an n-gram language model is the first $n-1$ words of the hypothesis that have incomplete history.

[4] We represent a constituent as a source and target phrase pair $(f_{j_1}^{j_2}/e_{i_1}^{i_2})$ where the subscript and the superscript indicate the starting and the ending indices as such $f_{j_1}^{j_2}$ denotes a source phrase that spans from j_1 to j_2.

dominance relation between a_m and a_n via $M_R(a_m)$ and $M_L(a_n)$. Let $a_m = (f_{j_1}^{j_2}/e_{i_1}^{i_2})$, $M_R(a_m) = (f_{j_3}^{j_4}/e_{i_3}^{i_4})$, $a_n = (f_{j_5}^{j_6}/e_{i_5}^{i_6})$ and $M_L(a_n) = (f_{j_7}^{j_8}/e_{i_7}^{i_8})$. Then, $ldom(a_m, a_n)$ is true only if $(j_4 \geq j_6)$ and $ori_R(a_m, M_R(a_m)) \in \{MA, RA\}$. Similarly, $rdom(a_m, a_n)$ is true only if $(j_7 \leq j_1)$ and $ori_L(a_n, M_L(a_n)) \in \{MA, RA\}$.

Hence, $dom(a_m, a_n)$ is as follows:

- *LH*, if $ldom(a_m, a_n) \wedge \neg rdom(a_m, a_n)$
- *RH*, if $\neg ldom(a_m, a_n) \wedge rdom(a_m, a_n)$
- *BL*, if $ldom(a_m, a_n) \wedge rdom(a_m, a_n)$
- *BD*, if $\neg ldom(a_m, a_n) \wedge \neg rdom(a_m, a_n)$

5.2 Parameterization and Training

After extracting events, we are now ready to train the models. To estimate them, we train a discriminative classifier for each model and use the normalized posteriors at decoding time as additional feature scores in SMT's log-linear framework.

At a high level, we use a rich set of *binary* features ranging from lexical to part-of-speech (POS) and to syntactic features. Additionally, we augment the feature set with compound features, e.g. a conjunction of the source word of the left anchor and the source word of the right anchor. Although they increase the number of features significantly, we found that they are empirically beneficial.

Suppose $a = (f_{j_1}^{j_2}/e_{i_1}^{i_2})$, $M_L(a) = (f_{j_3}^{j_4}/e_{i_3}^{i_4})$ and $M_R(a) = (f_{j_5}^{j_6}/e_{i_5}^{i_6})$, then based on the context's location, the elementary features employed in our classifiers can be categorized into:

- *anchor-related*: (the actual word of $f_{j_1}^{j_2}$), (part-of-speech (POS) tag of), ('s parent in the parse tree), ($e_{i_1}^{i_2}$'s actual target word).
- *surrounding*: (the previous word / $f_{j_1-1}^{j_1-1}$), (the next word / $f_{j_2+1}^{j_2+1}$), ('s POS tag), ('s POS tag), ('s parent), ('s parent).
- *non-local*: (the previous anchor's source word) , (the next anchor's source word), ('s POS tag), ('s POS tag).

There is a separate set of elementary features for a_m and a_n and we come up with manual combination to construct compound features.

In training the models, we manually come up with around 30-50 types of features, which consists of a combination of elementary and compound features. Due to space constraints, we will describe the actual features that we use and the classification performance of our models elsewhere. In total, we generate around one hundred millions binary features from our training data that contains six million sentence pairs. To reduce the number of features, we employ the L1-regularization in training to enforce sparse solutions, using the off-the-shelf LIBLINEAR toolkit (Fan et al., 2008). After training, the number of features in our classifiers decreases to below 1 million features for each classifier.

6 Decoding

As mentioned earlier, we wish to avoid the spurious ambiguity issue where different derivations have radically different scores although they lead to the same reordering. This section describes our decoding algorithm that avoids spurious ambiguity issue by incrementally constructing M_Ls and M_Rs thus allowing the computation of the models over partial hypotheses.

In our experiments, we integrate our dominance model as well as our orientation model into a syntax-based SMT system that uses SCFG formalism. Integrating the models into syntax-based SMT systems is non-trivial, especially since the anchors often reside within translation rules and the model doesn't always decompose naturally with the hypothesis structure. To facilitate that, we need to first induce the necessary alignment for all translation units in the hypothesis.

To describe the algorithm, let us consider a cheating exercise where we have to translate the Chinese sentence in Fig. 2 with the following set of hierarchical phrases:

$X_a \rightarrow \langle$*Aozhou*[1] *shi*[2] X_1, Australia[1] is[2] $X_1\rangle$
$X_b \rightarrow \langle$*yu*[3] *Beihan*[4] X_1, $X_1$with[3] North[4] Korea$\rangle$
$X_c \rightarrow \langle$*you*[5] *bangjiao*[6], have[5]dipl.[6] rels.$\rangle$
$X_d \rightarrow \langle X_1$ ***de***[7] *shaoshu*[8] *guojia*[9] *zhi*[10] *yi*[11],
one[11]of[10]the few[8] countries[9] **that**[7] $X_1\rangle$

As a case in point, let us consider $D = X_a \prec X_b \prec X_d \prec X_c$, which will lead to the correct English

		Target string (w/ source index)	Symbol(s) read	Op.	Stack(s)
(1)	X_c	have[5] dipl.[6] rels.	[5][6]	S,S,R	X_c:[5-6]
(2)	X_d	one[11] of[10] few[8] countries[9] **that**[7] X_c	[11][10]	S,S,R	[10-11]
(3)			[8][9]	S,S,R,R	[8-11]
(4)			[7]	S	[8-11]**[7]**
(5)			X_c:[5,6]	S	X_d:[8-11]**[7]**[5,6]

(7)			[3][4]	S,S,R,R	X_b:[8-11]**[7]**[3-6]
(8)	X_a	Australia[1] is[2] X_b	[1][2]	S,S,R	[1-2]
(9)			X_b:[8-11]**[7]**[3,6]	S,A	X_a:[1-2][8-11]**[7]**[3,6]

Table 2: The application of the shift-reduce parsing algorithm, which corresponds to the following derivation $D = X_a \prec X_b \prec X_d \prec X_c$. Anchor is in **bold**. In column Op., S, R and A refer to shift, reduce and accept operation respectively.

translation as in Fig. 2. Note that the translation rules contain internal word alignment, which we assume to have been previously inferred.

The algorithm bears a close resemblance to the shift-reduce algorithm found in phrase-based decoding (Galley and Manning, 2008; Feng et al., 2010; Cherry et al., 2012). A stack is used to accumulate (partial) information about a, M_L and M_R for each $a \in \mathcal{A}$ in the derivation. This algorithm takes an input stream and applies either the *shift* or the *reduce* operations starting from the beginning until the end of the stream. The *shift* operation advances the input stream by one symbol and push the symbol into the stack; while the *reduce* operation applies some rule to the top-most elements of the stack. The algorithm terminates at the end of the input stream where the resulting stack will be propagated to the parent for the later stage of decoding. In our case, the input stream is the target string of the rule and the symbol is the corresponding source index of the elements of the target string. The reduction rule looks at two indices and merge them if they are adjacent (i.e. has no intervening phrase). We forbid the application of the reduction rule to anchors. Table 2 shows the execution trace of the algorithm for the derivation described earlier. For conciseness, we assume that there is only one anchor and that is de[7]/that[7].

As shown, the algorithm starts with an empty stack. It then projects the source index to the corresponding target word and then enumerates the target string in a left to right fashion. If it finds a target word with a source index, it applies the shift operation, pushing the index to the stack. Unless the symbol corresponds to an anchor, it tries to apply the reduce operation. Line (4) indicates the special treatment to the anchor. If the symbol being read is a nonterminal, then we push the entire stack that corresponds to that nonterminal. For example, when the algorithm reads X_d at line (6), it pushes the entire stack from line (5).

As M_Ls and M_Rs are being incrementally constructed, we can immediately compute $P_{dom_o}(dom(a_m, a_n)|a_m, a_n)$ as soon as a partial derivation covers both a_m and a_n. For example, we can compute $P_{dom_1}(dom(\text{you}_5/\text{have}_8, \text{de}_7/\text{that}_7) =)$, $P_{dom_1}(dom(\text{de}_7/\text{that}_7, \text{zhi}_{10}/\text{of}_4) =)$ and $P_{dom_2}(dom(\text{you}_5/\text{have}_8, \text{zhi}_{10}/\text{of}_4) =)$ at partial hypothesis $X_d \prec X_c$ which corresponds to a constituent spanning from 5-11.

7 Experiments

Our baseline systems is a state-of-the-art string-to-dependency system (Shen et al., 2008). The system is trained on 10 million parallel sentences that are available to the Phase 1 of the DARPA BOLT Chinese-English MT task. The training corpora include a mixed genre of newswire, weblog, broadcast news, broadcast conversation, discussion forums and comes from various sources such as LDC, HK Law, HK Hansard and UN data.

In total, our baseline model employs more than 50 features, including from our proposed dominance and orientation models. In addition to the standard

Table 3: The NIST MT08 results on newswire (nw), weblog (wb) and combined genres. S2D is the baseline string-to-dependency system (line 1). Lines 2-7 shows the results of the dominance model with $O = 1 - 6$. Line 8 shows result on adding ori to the baseline. Lines 9-13 shows the results of the orientation complemented with the dominance model with varying O. The best BLEU, TER and Comb on each genre of the first set are in *italic* while those of the second set are in **bold**. For BLEU, higher scores are better, while for TER and Comb, lower scores are better.

features such as translation probabilities, we incorporate features that are found useful for developing a state-of-the-art baseline, such as the provenance features (Chiang et al., 2011). We use a 6-gram language model, which was trained on 10 billion English words from multiple corpora, including the English side of our parallel corpus plus other corpora such as Gigaword (LDC2011T07) and Google News. We also train a class-based language model (Chen, 2009) on two million English sentences selected from the parallel corpus. As for our string-to-dependency system, we train 3-gram models for left and right dependencies and unigram for head using the target side of the parallel corpus. To train our models, we select a set of 5 million sentence pairs.

For the tuning and development sets, we set aside 1275 and 1239 sentences selected from LDC2010E30 corpus. We tune the feature weights with PRO (Hopkins and May, 2011) to minimize (TER-BLEU)/2 metric. As for the blind test set, we report the performance on the NIST MT08 evaluation set, which consists of 691 sentences from newswire and 666 sentences from weblog. We pick the weights that produce the highest development set scores to decode the test set.

We perform two sets of experiments. The first set looks at the contribution of the dominance model with varying values of o. The second one looks at the combination of the dominance model and the orientation model. Table 3 summarizes the experimental results on NIST MT08 sets, categorized by genres. We report the results on newswire genre in columns a-c, those on weblog genre in column d-f, and those on mixed genre in column g-i. The performance of our baseline string-to-dependency syntax-based SMT is shown in the first line.

Lines 2-7 in Table 3 show the results of our first set of experiments, starting from the result of dom_1, which looks at only at pairs of adjacent anchors, to the result of dom_6, which looks at pairs of anchors that are at most 5 anchors away. As shown in line 2, our dominance model provides a nice improvement of around 0.5 point over the baseline even if it only looks at restricted context. Increasing the order of our dominance model provides an additional gain. However, the gain is more pronounced in the weblog genre (up to around 1 BLEU point) than in the newswire genre. We conjecture that this may be the artifact of our tune set, which comes from the weblog genre. We stop at dom_6 because we observe

that the weight of the feature score that corresponds to the maximum order ($o = 6$) has a negative sign, which often indicates a high correlation between the new features and existing ones.

Lines 8-13 in Table 3 shows the results of our second set of experiments. Line 8 shows the result of adding the orientation model (ori) to the baseline system. As shown, integrating ori shows a significant gain. On top of which, we then integrate dom_1 to dom_5. We see a very encouraging result as adding the dominance model increases the performance further, consistently over different value of o. This suggests that the dominance model is complementary to the orientation model. Our best result provides more than 1 BP improvement and 1 TER reduction consistently over different genres. We see this result as confirming our intuition that the global contextual information provided by our AG model can significantly improve the performance of SMT even in a state-of-the-art system.

8 Related Work

Our work intersects with existing work in many different respects. In this section, we mainly focus on work related to introducing higher-order contextual information to reordering model.

In providing global contextual information, our work is related to a large amount of literature. To name a few, Zens and Ney (2006) improves the lexicalized reordering model of Tillman (2004) by incorporating part-of-speech information. Chang et al. (2009) incorporates contexts from syntactic parse tree. Bach et al. (2009) exploits the dependency information and Xiong et al. (2012) uses the predicate-argument structure.

Vaswani et al. (2011) introduces rule markov models for a forest-to-string model in which the number of possible derivations is restricted. More recently, Durrani et al. (2013) and Zhang et al. (2013) cast reordering process as a Markov process. Similar to these models, our proposed model also provide context dependencies to the application of translation rules, however, as they focus on minimal translation units (MTU) where we focus on a selected set of translation units. (Banchs et al., 2005) introduces a bigram model for monotone phrase-based system, but their definition of translation units is suitable only for language pairs with limited reordering, such as translating Spanish to English.

In equating anchors with the function word class, our work is closely related to the function word-centered model of Setiawan et al. (2007), especially the orientation model. Our dominance model is closely related to the reordering model of Setiawan et al. (2009), except that they only look at pair of adjacent anchors, forming a chain structure instead of a graph like in our dominance model. Furthermore, we provide a discriminative treatment to the model to include a richer set of features including syntactic features. This work can be seen as modeling the identity of the neighboring of the anchors, similar to (Setiawan et al., 2013). However, instead of looking at the words at the borders, we look at whether the neighboring constituents contain other anchors.

9 Conclusion

We propose the "Anchor Graph" (AG) model to encode global contextual information. A selected set of translation units, which we call anchors, serves as the vertices of AG. And as the edges, we model two types of relations, namely the dominance and the precedence relations, where the former looks at the positions of the anchors in the derivation structure, while the latter looks at the positions of the anchors in the surface structure, resulting into two probabilistic models over edge labels. As the models look at the pairs of anchors that go beyond multiple translation units, our AG model provides global contextual information.

Our AG model embodies (admittedly crudely) some basic principles of sentence organization, namely categorization (in categorizing units into anchors and non-anchors), linear order (in modeling the precedence of anchors) and constituency structure (in modeling the dominance between anchors). We are encouraged by the facts that we learn these principles in an unsupervised way and that we can achieve a significant improvement over a strong baseline in a large-scale Chinese-to-English translation task. In the future, we hope to continue this line of research, perhaps by learning to identify anchors automatically from training data or by using our models to induce derivations directly from unaligned sentence pair.

Abstract

We present a simple and novel classifier-based preordering approach. Unlike existing preordering models, we train feature-rich discriminative classifiers that directly predict the target-side word order. Our approach combines the strengths of lexical reordering and syntactic preordering models by performing long-distance reorderings using the structure of the parse tree, while utilizing a discriminative model with a rich set of features, including lexical features. We present extensive experiments on 22 language pairs, including preordering into English from 7 other languages. We obtain improvements of up to 1.4 BLEU on language pairs in the WMT 2010 shared task. For languages from different families the improvements often exceed 2 BLEU. Many of these gains are also significant in human evaluations.

1 Introduction

Generating the appropriate word order for the target language has been one of the fundamental problems in machine translation since the ground setting work of Brown et al. (1990). Lexical reordering approaches (Tillmann, 2004; Zens and Ney, 2006) add a reordering component to standard phrase-based translation systems (Och and Ney, 2004). Because the reordering model is trained discriminatively, it can use a rich set of lexical features. However, it only has access to the local context which often times is insufficient to make the long-distance reordering decisions that are necessary for language pairs with significantly different word order.

Preordering (sometimes called pre-reordering or simply reordering) approaches (Xia and McCord, 2004; Collins et al., 2005) preprocess the input in such a way that the words on the source side appear closer to their final positions on the target side. Because preordering is performed prior to word alignment, it can improve the alignment process and can then be combined with any subsequent translation model. Most preordering models use a source-side syntactic parser and perform a series of tree transformations. Approaches that do not use a parser exist as well and typically induce a hierarchical representation that also allows them to perform long-distance changes (Tromble and Eisner, 2009; DeNero and Uszkoreit, 2011; Neubig et al., 2012).

Models that use a source-side parser differ on two main dimensions: the way tree transformations are expressed, and whether they are built manually or learned from data. One common type of tree transformation are rewrite rules. These typically involve some condition under which the transformation can be applied (e.g., a noun and an adjective found in the same clause) and the transformation itself (e.g., move the adjective after the noun). These rules can be designed manually (Collins et al., 2005; Wang et al., 2007) or learned from data (Xia and McCord, 2004; Habash, 2007; Genzel, 2010; Wu et al., 2011).

Another type of tree transformations uses ranking functions to implement precedence-based reordering. Here, a function assigns a numerical value to every word in a clause, intended to express the precedence of the word in the target language. The reordering operation is then to sort the words according to their assigned values. The ranking function

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 513–523,
Seattle, Washington, USA, 18-21 October 2013.

can be designed manually (Xu et al., 2009) or trained from data (Yang et al., 2012). This approach is particularly effective for Subject-Object-Verb (SOV) languages.

In this work we present a simple classifier-based preordering model. Our model operates over dependency parse trees and is therefore able to perform long-distance reordering decisions, as is typical for preordering models. But instead of deterministic rules or ranking functions, we use discriminative classifiers to directly predict the final word order, using rich (bi-)lexical and syntactic features.

We present two models. The first model uses a classifier to directly predict the permutation order in which a family of words (a head word and all its children) will appear on the target side. This approach is similar in spirit to the work of Li et al. (2007), except that they use constituency parse trees and consider only nodes with 2 or 3 children. We instead work with dependency trees and consider much larger head-children sets. Our second model is designed to decompose the exponential search space of all possible permutations. The prediction task is broken into two separate steps. In the first step, for each child word a binary classifier decides whether it appears before or after its parent in the target language. In the second step, we predict the best order of the words on each side of the parent. We show that the second approach is never worse than the first one and sometimes significantly better.

We present experiments on 22 language pairs from different language families using our preordering approach in a phrase-based system (Och and Ney, 2004), as well as a forest-to-string system (Zhang et al., 2011). In a first set of experiments, we use the WMT 2010 shared task data (Callison-Burch et al., 2010) and show significant improvements of up to 1.4 BLEU (Papineni et al., 2002) on three out of eight language pairs. In a second set of experiments, we use automatically mined parallel data from the web and build translation systems for languages from various language families. We obtain especially big improvements in translation quality (2-7 BLEU) when the language pairs have divergent word order (for example English to Indonesian, Japanese, Korean or Malay). In our experiments on English to and from Hungarian, Dutch, and Portuguese translation, we find that we can obtain consistent improvements in both translation directions. To additionally verify our improvements we use human raters, who confirm the significance of the BLEU score improvements.

Finally, we compare training the preordering classifiers on small amounts of manually aligned data to training on large quantities of automatically aligned data for English to Arabic, Hebrew, and Japanese. When evaluated on a pure reordering task, the models trained on manually aligned data perform slightly better, but similar BLEU scores are obtained in both scenarios on an end-to-end translation task.

2 Classifier Reordering

Our goal is to learn a model that can transform the word order of an input sentence to an order that is natural in the target language. For example, when translating the English sentence:

The black cat climbed to the tree top.

to Spanish, we would like to reorder it as:

The cat black climbed to the top tree.

When translating to Japanese, we would like to get:

The black cat the tree top to climbed.

Such a model can then be used in combination with any translation model.

In our approach we first part-of-speech (POS) tag and parse the input sentence, producing the POS tags and head-modifier dependencies shown in Figure 1. Reordering is then done by traversing the dependency tree starting at the root. For each head word we determine the order of the head and its children (independently of other decisions) and continue the traversal recursively in that order. In the example, we first need to decide on the order of the head *"climbed"* and the children *"cat"*, *"to"*, and *"."*.

2.1 Classification Model & Features

The reordering decisions are made by multi-class classifiers where class labels correspond to permutation sequences. We train a separate classifier for each number of possible children. Crucially, we do not learn explicit tree transformations rules, but let the classifiers learn to trade off between a rich set of overlapping features.

Obviously, it is possible to use any classification model and learning algorithm. We use maximum entropy classifiers with l_1/l_∞ regularization trained with the GradBoost algorithm (Duchi and Singer, 2009). We chose this setup since it naturally supports multi-class prediction and can therefore be used to select one out of many possible permutations. Additionally, the learning algorithm produces a sparse set of features. In our experiments the final models have typically only a few 100K non-zero feature weights per language pair. Given this relatively small number of features, it is possible to manually inspect the feature weights and gain insights into the behavior of the model. We show an example analysis in Section 5.

Our features encode information about the context in which a word occurs in the sentence. We model context as "informative" words:

- The head itself.
- The children. We indicate whether each child is before, immediately before, immediately after, or after the head.
- For every child, if there is a gap between it and the head, then the first and last word of that gap.
- For every pair of consecutive children, if there is a gap between them, then the first and last word of that gap.
- The head's immediate sibling to the left/right or an indication that none exists.

When extracting the features, every word can be represented by its word identity, its fine-grained POS tag from the treebank, and a coarse-grained POS category, similar to the universal categories described in Petrov et al. (2012). We also include pairs of these features, resulting in potentially bilexical features.

2.2 Training Data

The training data for the classifiers is generated from the word aligned parallel text. Since parallel data is plentiful, we can afford to be selective. We first construct the intersection of high-confidence source-to-target and target-to-source alignments. For every family in the source dependency tree we generate a training instance if and only if the intersection defines a full order on the source words:

- Every source word must be aligned to at least one target word.

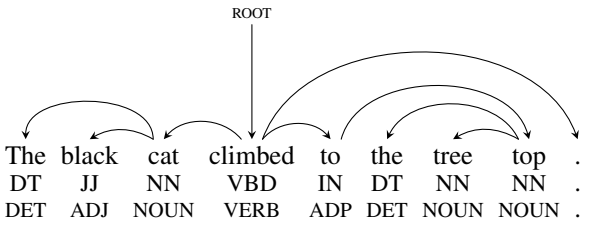

Figure 1: A sentence, its dependency parse and its fine-grained and coarse-grained POS tags.

- No two source words can be aligned to the same target word.
- If a source word is aligned to multiple target words, then no target word in this range can be aligned to a different source word.

While this might sound restrictive, we can usually generate at least some training instances from every sentence and discard the remaining families in the tree. In particular, we do not need to extract training instances for all words in a given sentence since the reordering decisions are made independently for every head word.

A potential concern might be that our method for selecting training data can exclude all instances of certain words. Consider the English phrase *"the boy"*. For languages without articles (e.g. Russian or Japanese) the determiner *"the"* may either not be aligned to any word or get aligned to the foreign word for *"boy"*. In both cases the family will be discarded according to either the first or the second condition above. The concern is therefore that we would have no training data with the English word *"the"*. In practice, however, this does not seem to be a problem. First, there are instances where the English word *"the"* gets aligned to something (perhaps a preposition), and second, since the word *"the"* is omitted in the target language its location in the reordered sentence is not very important.

Naturally we learn better classifier models from better alignments. The other direction is also true – if we run preordering on the source side then the alignment task becomes easier and tends to produce better results. Therefore it can be useful to iterate between generating the alignment and learning a preordering model. Empirically, the gains from this bootstrapping approach are not dramatic and are realized after just one iteration, i.e., create the align-

ment, train a preordering model, use the preordering model to learn a new alignment, and then train the final preordering model.

2.3 1-Step Classifier

As a first approach we use a single classifier to directly predict the correct permutation of a given family. Consider the family headed by *"climbed"* in Figure 1. There are three children and the original order of the words is *"cat"*, *"climbed"*, *"to"*, and *"."*. A possible outcome of the classifier can be the permutation 0-2-1-3, representing the order *"cat"*, *"to"*, *"climbed"*, and *"."*.

The number of permutations for the head and n children is of course $(n + 1)!$, which becomes large very quickly and causes some problems. In practice we therefore limit ourselves to the K most common permutations. Unfortunately, this means that whenever there are many children, the correct permutation order might not be available as an option. Even when the correct permutation is available, classification accuracy typically deteriorates as the number of possible classes increases.

An additional subtle issue is that the 1-step classifier cannot share useful information across different numbers of children. For example, in Spanish adjectives usually appear after the noun, but sometimes they appear before the noun. The decision depends on the adjective itself and sometimes the head noun, but does not depend on other children. Ideally, if for some adjective we have enough examples with 1 or 2 children we would like to make the same decision for a larger number of children, but these classifiers may not have enough relevant examples.

2.4 2-Step Classifier

Our 2-step approach addresses the exponential blowup of the number of children by decomposing the prediction into two steps:

1. For every child, decide whether it should appear before or after the head.
2. Determine the order of the children that appear before the head and the order of the children after the head.

The two steps make the reordering of the modifiers before and after the head independent of each other, which is reminiscent of the lexicalized parse tree generation approach of Collins (1997). In the running example, for the head *"climbed"* we might first make the following three binary decisions: the word *"cat"* should appear before the head and the words *"to"* and *"."* should appear after the head. In the second step there is only one word before the head so there is nothing to do. There are two words after the head, so we use another classifier to determine their order. The first step is implemented using a binary classifier, called the *pivot* classifier (since the head functions like the pivot in quicksort). The second step classifiers directly predict the correct permutation of the children before / after the head.

To illustrate the effectiveness of the 2-step approach, consider a head word with 4 children. The 1-step approach must predict 1 of 5! = 120 outcomes. In the 2-step approach, in the worst case the second step must predict 1 of 4! = 24 outcomes (if all the children are on one side of the head); if we are lucky and the children split evenly, then we only need two binary decisions in the second step (for the two pairs before and after the head). If we define hard cases as cases involving 5 or more words, 5.54% of the non-leaves are hard cases with the 1-step approach, but only 1.07% are hard cases with the 2-step approach.

3 Experimental Setup

To provide a through evaluation of our approach, we conduct experiments on two sets of data and with two translation systems. The first translation system is a phrase-based system (Och and Ney, 2004). In addition to the regular distance distortion model, we incorporate a maximum entropy based lexicalized phrase reordering model (Zens and Ney, 2006). Our second system is a forest-to-string system (Zhang et al., 2011). The forest-to-string system uses a one-best parse tree but factorizes it into a packed forest of binary elementary trees – hence the name forest-to-string rather than tree-to-string.

The systems are configured and tuned for each language pair to produce the best results. We then add our 1-step and 2-step preordering classifiers as preprocessing steps at training and test time. We train the reordering classifiers on up to 15M training instances. We train separate classifiers for every number of involved words, and restrict each one to the $K = 20$ most frequent outcomes.

In our implementation, in the 1-step approach we did not do any reordering for nodes with 7 or more children. In the 2-step approach we did not reorder the children on either side of the head if there were 7 or more of them. Even though there was no technical reason that prevented us from raising the thresholds, there was no good reason to do so. There were very few cases where children were not reordered because of these thresholds, many of them corresponded to bad parses, and they had very little impact on the final scores. Thus, for the 1-step approach we had 6 classifiers: 1 binary classifier for a head and a single child and 5 multi-class classifiers for 3–7 words. For the 2-step approach we had 11 classifiers: 1 pivot classifier, 5 classifiers for words before the head, and 5 for words after the head.

For a direct comparison to a strong preordering system, we compare to the system of Genzel (2010), which learns a set of unlexicalized reordering rules from automatically aligned data by minimizing the number of crossing alignments. We used a sliding window of size 3 and tried all three of their variants. There were about 40-50 rules per language pair. While conceptually possible, it is not practical to learn more rules (including lexicalized rules) with this system, because of the computational complexity of the learning algorithm and the incremental nature in which the rules are learned and applied.

3.1 WMT Setup

In our first set of experiments, we use the data provided for the WMT 2010 shared task (Callison-Burch et al., 2010). We build systems for all language pairs: English to and from Czech, French, German, and Spanish. Since this is a publicly available dataset, it is easy to compare our results to other submissions to the shared task.

During word alignment, we filter out sentences exceeding 60 words in the parallel texts and perform 6 iterations of IBM Model-1 training (Brown et al., 1993), followed by 6 iterations of HMM training (Vogel et al., 1996). We do not use Model-4 because it is slow and did not add much value to our systems in a pilot study. Standard phrase extraction heuristics (Koehn et al., 2003) are applied to extract phrase pairs with a length limit of 6 from alignments symmetrized with the "union" heuristic. Maximum jump width is set to 8. Rule extraction for the forest-to-string system is limited to 16 rules per tree node. There are no length-based reordering constraints in the forest-to-string system. We train two 5-gram language models with Kneser-Ney smoothing for each of the target languages. One is trained on the target side of the parallel text, the other on a news corpus provided by the shared task. We tune the feature weights for every configuration with 10 rounds of hypergraph-based Minimum Error Rate Training (MERT) (Kumar et al., 2009).

3.2 Additional Languages

In our second set of experiments, we explore the impact of classifier preordering for a number of languages with different word orders. Some of the languages included in our study are verb-subject-object (VSO) languages (Arabic, Irish, Welsh), subject-object-verb (SOV) languages (Japanese, Korean), and fairly free word order languages (Dutch, Hungarian). Where a parser is available, we also conduct experiments on translating into English.

Since there are no standard training sets for many of these language pairs, we use parallel data automatically mined from the web. The amount of parallel text for each language pair is between 120M and 160M words. For evaluation, we use a set of 9K English sentences collected from the web and translated by humans into each of the target languages. Each sentence has one reference translation. We use 5K sentences for evaluation and the rest for tuning.

The systems and training configurations are similar to the WMT setup. The word alignment step includes 3 iterations of IBM Model-1 training and 2 iterations of HMM training. Lexical reordering is included where it helps, but typically makes only a small difference. We again use a 5-gram language model trained on a large amount of monolingual text. Overall, we use between 20 and 30 features, whose weights are optimized using hypergraph-based MERT. All experiments for a given language pair use the same set of MERT weights. This potentially underestimates the improvements that can be obtained, but also eliminates MERT as a possible source of improvement, allowing us to trace back improvements in translation quality directly to changes in preordering of the input data.

3.3 Evaluation

We use case-sensitive BLEU (Papineni et al., 2002) to assess translation quality. For Japanese and Korean we use character-level BLEU. We use bootstrap resampling to compute confidence intervals.

Additionally, we also conduct a side-by-side human evaluation on 750 sentences for each language pair (sampled from the same sentences used for computing BLEU). For each sentence, we ask bilingual annotators to compare the translations from two different systems and say whether one is better, leading to three possible scores of -1, 0, and +1. We focus on this relative comparison since absolute scores are difficult to calibrate across languages and raters.

3.4 Syntactic Parsers

Table 1 shows our treebank sources and parsing accuracies. For English, we use the updated WSJ with OntoNotes-style annotations converted to Stanford dependencies (de Marneffe et al., 2006). The remaining treebanks are all available in dependency format. In all cases, we apply a set of heuristics to the treebank data to make the tokenization as similar as possible to the one of the bitext. Our heuristics can split treebank tokens but do not merge treebank tokens. We found that adjusting the treebank tokenization is crucial for obtaining good results. However, this makes the reported parsing accuracies not comparable to other numbers in the literature. When necessary, we projectivize the treebanks by raising arcs until the tree becomes projective, as described in Nivre and Nilsson (2005); we do not reconstruct non-projective arcs at parsing time, since our subsequent systems expect projective trees.

Our part-of-speech tagger is a conditional random field model (Lafferty et al., 2001) with simple word-identity and affix features. The parsing model is a shift-reduce dependency parser, using the higher-order features from Zhang and Nivre (2011). Additionally, we include 256 word-cluster features (Koo et al., 2008) trained on a large amount of unlabeled monolingual text (Uszkoreit and Brants, 2008).

4 Experiments

Due to the large number of experiments and language pairs we divide the experiments into groups and discuss each in turn. We only include the results from the forest-to-string system when they are better than the phrase-based results. We use * to denote results from the forest-to-string system.

	UAS	LAS	POS
en: English[1]	92.28	90.28	97.05
cs: Czech[2]	84.66	72.01	98.97
de: German[3]	89.30	86.98	97.69
es: Spanish[4]	86.24	82.32	96.62
fr: French[5]	88.57	86.40	97.48
hu: Hungarian[2]	87.66	82.51	94.47
nl: Dutch[3]	86.09	82.31	97.38
pt: Portuguese[4]	90.22	87.26	98.10

Table 1: Parsing accuracies on the retokenized treebanks. UAS is unlabeled attachment score, LAS is labeled attachment score, and POS is part-of-speech tagging accuracy. The treebank sources are (1): Marcus et al. (1993) + Judge et al. (2006) + Petrov and McDonald (2012), (2): Nivre et al. (2007), (3): Buchholz and Marsi (2006), (4): McDonald et al. (2013), (5): Abeillé et al. (2003).

4.1 WMT Experiments

Table 2 presents detailed results on the WMT setup. Lexical reordering (Zens and Ney, 2006) never hurts and is thus included in all systems. Overall, our results are a little better than the best results of the WMT 2010 shared task for two language pairs and within reach of the best results in most other cases.

The 2-step classifier preordering approach provides statistically significant improvements over the lexical reordering baseline on three out of the eight language pairs: English-Spanish (en-es: 1.4 BLEU), German-English (de-en: 1.2 BLEU), and English-French (en-fr: 1.0 BLEU). These improvements are significant in our human side-by-side evaluation. We also observe gains when combining our preordering approach with the forest-to-string system for English-Spanish and German-English. While the forest-to-string system is capable of performing long distance reordering in the decoder, it appears that an explicitly trained lexicalized preordering model can provide complementary benefits. These benefits are especially pronounced for German-English where long distance verb movement is essential. For the romance languages (Spanish and French), word ordering depends highly on lexical choice which is captured by the lexical features in our classifiers.

	base	lexical	rule	1-step	2-step	wmt best
en-cs	14.9	**15.1**	**15.2**	**15.2**	**15.2**	15.4
en-de	15.3	15.6	**15.9**	**15.9**	**15.7**	16.3
en-es	27.4	27.8♢	28.4♧	**29.0**	**28.8♠♣**	28.6
en-es*	28.9	-	28.7	29.0	29.2	28.6
en-fr	26.3	26.5♢	26.8♧	**27.2**	**27.3♠♧**	27.6
cs-en	21.6	21.6	21.5	21.6	21.7	21.9
de-en	20.6	21.1♢	**21.9**	**21.9**	**21.8♠**	22.8
de-en*	22.1	-	**22.5**	**22.5**	**22.7**	22.8
es-en	28.3	**28.7**	**28.7**	**28.8**	**28.9**	28.8
fr-en	26.8	27.0	26.9	26.9	27.0	28.3

Table 2: BLEU scores on the WMT 2010 setup. Results from the forest-to-string system are marked with * and are only included when better than the phrase-based results. The *base* system includes a distance distortion model; the *lexical* system adds lexical reordering; *rule* is the rule preordering system of Genzel (2010) plus lexical reordering; *1-step* and *2-step* are our classifier-based systems plus lexical reordering. Bolded results are statistically significantly better than non-bolded results as measured by a bootstrap sample test with a 99% confidence interval. Human evals are conducted only where indicated; we use ♠ and ♣ to indicate a significantly better result than ♢ and ♧ in the human eval at 95%. Also included are the best results from the WMT 2010 task.

Compared to a state-of-the-art preordering system, the automatic rule extraction system of Genzel (2010), we observe significant gains in several cases and no losses at all. The improvements on English-Spanish are significant also in the human evaluation, while the English-French improvements are positive, but not statistically significant.

Comparing the different languages, Czech (cs) appears the most immune to improvements from preordering (and lexical reordering). One possible explanation is that Czech has a relatively free word order with a default SVO structure. It is therefore difficult to learn reordering changes from English to Czech. Additionally, the accuracy (LAS) of our Czech parser is by far the lowest of all parsers that we used, potentially limiting the benefits that can be obtained when translating from Czech into English.

On this setup there is fairly little difference in performance between the 1-step and 2-step approaches. The main benefit of the 2-step approach is compactness: the set of 2-step classifiers has about half the number of non-zero features as the 1-step classifiers.

4.2 Additional Languages Experiments

Table 3 shows our first set of results on the additional languages, including some languages with a wide disparity in word order relative to English. The SOV languages Korean (ko) and Japanese (ja) benefit the most from preordering and gain more than 7 BLEU relative to the phrase-based baseline and still more than 3 BLEU for the forest-to-string system. Similar improvements were reported by Xu et al. (2009) with manual reordering rules. Indonesian (id) and Malay (ms) are next with gains of 2.5 BLEU. Malay does not have a grammatical subject in the sense that English does, but instead uses a concept of an agent and an object, whose order is determined by the voice of the verb. It appears that our classifiers have learned to model some of these highly lexical, but systematic ordering preferences. Welsh (cy) and Irish (ga) as VSO languages also exhibit large gains of 2.1 BLEU. For Arabic (ar) and Hebrew (iw), the gains are smaller, but still significant and exceed 1 BLEU relative to the baseline.

The benefits of our 2-step approach over the 1-step approach become apparent on this set of languages where reordering is most important. By predicting the target word order in two steps, we reduce sparsity and make two easier decisions in place of a single difficult high entropy decision. Indeed, the 2-step approach produces improvements over the 1-step approach on five out of nine language pairs. The improvements are as large as 0.9 BLEU for Korean and 0.5 BLEU for Japanese and Welsh. We performed human evaluation for all language pairs with a noticeable BLEU gain for the 2-step system over

	base	rule	1-step	2-step
en-ar	11.4	12.3	**12.5**	**12.6**
en-cy	29.3	31.1	31.9♧	**32.4**♣
en-ga	17.0	18.5	18.8♧	**19.1**♣
en-iw	18.8	19.7	**20.2**	**20.2**
en-id	31.0	33.4	**34.0**♧	**34.3**♧
en-ja	10.4	16.4	17.5♧	**18.0**♣
en-ja*	14.9	18.0	18.2♧	**18.6**♣
en-ko	24.1	31.8	31.8♧	**32.7**♣
en-ms	20.4	22.5	**22.9**	**22.9**

Table 3: BLEU scores for language from various language families: Arabic (ar), Welsh (cy), Irish (ga), Indonesian (id), Hebrew (iw), Japanese (ja), Korean (ko), and Malay (ms). Lexical reordering is not included in any of the systems. Bolded results are significant at 99%. ♣ is significantly better than ♧ in a human eval at 95%.

the 1-step system. The human judgments exactly agree with the results of the BLEU significance tests. The gains relative to the rule reordering system of Genzel (2010) and the no-preordering baseline are even larger and therefore clearly also significant.

In Table 4 we show results for Hungarian (hu), Dutch (nl), and Portuguese (pt). In all cases but English-Hungarian we observe significant improvements over the no preordering baseline. It should be noted that the gains are not symmetric – sometimes there are larger gains for translating out of English, while for Hungarian the gains are higher for translating into English. Hungarian has a free word order which is difficult to predict which might partially explain why there are no improvements for translating into Hungarian. For Dutch-English, the forest-to-string system yields the best results, which was also the case for German-English, further supporting the observation that combining different types of syntactic reordering approaches can be beneficial.

4.3 Manually Aligned Data

For Arabic (ar), Hebrew (iw), and Japanese (ja) we conducted some additional experiments with manually aligned data. We asked bilingual speakers to translate about 20K English sentences into the respective target language and to mark the alignment between the words. We reserved 20% of this data for evaluation and used the rest for training. For evaluation we used the fuzzy metric defined by Talbot et al. (2011), which counts the fraction of words that are reordered into the correct position.

	base	rule	1-step	2-step
en-hu	12.7	12.6	12.8	12.7
en-nl	25.3	26.1	**26.4**	**26.4**
en-pt	30.2	31.9	**32.6**	**32.8**
hu-en	22.0	22.2	**22.7**	**22.7**
nl-en	34.9	**35.7**	35.2	35.1
nl-en*	36.3	**36.5**	**36.6**	**36.7**
pt-en	39.8	**40.1**	**40.1**	**40.1**

Table 4: BLEU scores for translating to and from English for: Hungarian (hu), Dutch (nl), and Portuguese (pt). Lexical reordering is not used for any language pair. Bolded results are significant at 99%.

The BLEU scores in Table 5 show that training from small amounts of manually aligned data or large amounts of automatically aligned data results in models of similar quality. In terms of the fuzzy metric, the models trained from manually aligned data were better. A possible explanation is that these models were trained on data which was much more similar to the evaluation data (both were subsets of the manually aligned data), biasing the metric in their favor. In absolute terms, the reordering accuracy is around 80% for Arabic and Japanese and close to 90% for Hebrew. Most impressively, more than 60% of the Hebrew sentences are exactly in the correct word order, implying that monotonic translation may suffice.

We also examined the accuracy of the individual classifiers and found that the pivot classifier has an accuracy around 95%. It is therefore unlikely that a word is reordered to the wrong side of its head in the 2-step reordering approach. The classifiers that predict the final word order have an accuracy above 90% when there are only two words and drop to still respectable 70%-80% when there are 4 or more children or 20 possible options.

5 Analysis

In this section, we analyze an example whose translation is significantly improved by our preordering approach, demonstrating the usefulness of our lexicalized features. Consider the English sentence:

It was a real whirlwind.

	no reordering			manual			automatic		
	fuzzy	exact	BLEU	fuzzy	exact	BLEU	fuzzy	exact	BLEU
en-ar	63.2	19.8	11.4	83.5	47.6	12.4	79.0	38.9	12.6
en-iw	67.9	22.2	18.8	89.8	62.4	20.3	89.2	61.2	20.2
en-ja*	44.1	0.0	14.9	80.9	41.5	18.4	78.5	36.8	18.6

Table 5: Preordering accuracy for the 2-step classifiers using manual alignments vs. automatic alignments. Fuzzy refers to the metric defined in Talbot et al. (2011) and exact is the percentage of sentences with a perfect preordering.

taken from the WMT test set. The dependency parse tree is shown in Figure 2. In our experiments the rule-based approach of (Genzel, 2010) reordered the source sentence into:

It was a whirlwind real.

and produced the translation:

Es un torbellino real.

In comparison, our 2-step system kept the English sentence unchanged and produced the translation:

Fue un auténtico torbellino.

The second translation is better than the first because of the correct tense (which is not related directly to the preordering) and because the noun phrase *"real whirlwind"* is ordered correctly.

The main reason for the difference in the ordering is that the rule-based system can only use the unlexicalized information from the parse tree. The head *"whirlwind"* is a noun and the child *"real"* is an adjective; since adjectives typically appear after nouns in Spanish, their order is reversed.

To understand why the classifier-based system keeps *"real"* before *"whirlwind"* we can examine the features used by the classifier to make this decision. In Table 6 we consider the 3 strongest features in favor of the child *"real"* appearing after the head *"whirlwind"* and the three strongest features in favor of the child appearing before the head. Recall that the pivot is a binary classifier: positive features support one decision (in our case: the child should be after the head) and the negative features support the other decision (the child should be before the head).

The three features that have the highest positive weight encode the fact that the child is an adjective, since in general, adjectives in Spanish appear after the noun. On the other hand, the three features with the most negative weights all encode the fact that the child is the word *"real"* which unlike most adjectives tends to appear before the noun. It is interesting to note that for this particular ordering decision the child word is much more informative than the head word and indeed, all the important features contain information about the child and none of them contains any information about the head.

6 Conclusions & Future Work

We presented a simple and novel preordering approach that produces substantial improvements in translation accuracy on a large number of languages. We use a source-side syntactic parser and train discriminative classifiers to predict the order of a parent and its children in the target language, using features from the dependency tree as well as (bi-)lexical features. To decompose the exponential space of all possible permutations, we introduce the 2-step approach. We show empirically that this approach is significantly better than directly predicting the full permutation for some languages, and never significantly worse.

We obtain strong results on the WMT 2010 shared task data, observing gains of up to 1.4 BLEU over a state-of-the-art system. We also show gains of up to 0.5 BLEU over a strong directly comparable preordering system that is based on learning unlexicalized reordering rules. We obtain improvements of more than 2 BLEU in experiments on additional languages. The gains are especially large for languages where the sentence structure is very different from English. These positive results are confirmed in human side-by-side evaluations.

When comparing our approach to syntax-based translation systems (Yamada and Knight, 2001; Galley et al., 2004; Huang et al., 2006; Dyer and Resnik, 2010) we note that both approaches use syntactic information for reordering decisions. Our preordering approach has several advantages. First, be-

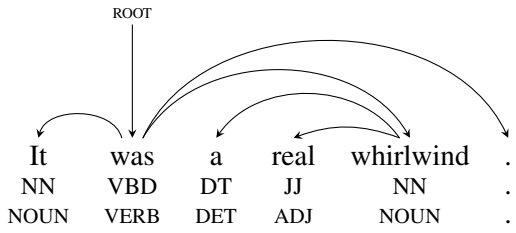

Figure 2: An example where lexical information is necessary for choosing the correct word order.

cause preordering is performed before learning word alignments, it has the potential to improve the word alignments. Second, by using discriminative classifiers we can take advantage of lexical features. Finally, preordering can be combined with syntax-based translation models and our results confirm the complementary benefits that can be obtained.

Compared to other preordering models, our approach has the obvious problem of having to make predictions over an exponential set of permutations. We show that this is not an insurmountable difficulty: our 2-step approach decomposes the exponential space, often leading to much easier prediction tasks. Even when the number of possible permutations is large we can limit ourselves to the K most popular permutations.

On the other hand, our approach provides important advantages. Compared to systems that use rewrite rules, it is much easier to encode useful knowledge that by itself is not enough to determine a full rewrite rule, such as "a determiner is unlikely to be the last word in a clause." Perhaps more importantly, our model provides an elegant answer to the question of what to do when multiple rewrite rules can be applied. Previous work has employed different heuristics: use the most specific rule (Xia and McCord, 2004), use all applicable rules (Genzel, 2010), or use the most frequent rule (Wu et al., 2011). In our model there is no need for such heuristics – all the "rules" are treated as features to a discriminative classifier, and the task of analyzing their interactions is handled by the learning algorithm.

Compared to preordering systems that use ranking functions, our model has the advantage that it can encode information about the complete permutation. For example, for three source words A, B, and C, we can naturally express the useful prior that A-B-C and C-B-A are likely orders but C-A-B is not.

Feature	Weight
`PrevChild:tag=JJ,PrevSibling:a`	`0.448`
`PrevChild:cat=ADJ,PrevSibling:a`	`0.292`
`PrevChild:cat=ADJ,NoNextSibling`	`0.212`
`...`	
`PrevChild:real,NoNextHeadSibling`	`-0.310`
`PrevChild:real,PrevSibling:cat=DET`	`-0.516`
`PrevChild:real,PrevSibling:a`	`-0.979`

Table 6: The three features with the highest and lowest weights for choosing the position of *"real"* relative to *"whirlwind."* *PrevChild* means that the child is the immediate word before the head. *PrevSibling* refers to the child's sibling immediately to the left (the determiner *"a"*). *NoNextSibling* and *NoNextHeadSibling* mean that the child and head do not have a sibling to the right.

Promising directions for future work are joint parsing and reordering models, and measuring the influence of parsing accuracy on preordering and final translation quality.

Abstract

This paper proposes a novel approach that utilizes a machine learning method to improve pivot-based statistical machine translation (SMT). For language pairs with few bilingual data, a possible solution in pivot-based SMT using another language as a "bridge" to generate source-target translation. However, one of the weaknesses is that some useful source-target translations cannot be generated if the corresponding source phrase and target phrase connect to different pivot phrases. To alleviate the problem, we utilize Markov random walks to connect possible translation phrases between source and target language. Experimental results on European Parliament data, spoken language data and web data show that our method leads to significant improvements on all the tasks over the baseline system.

1 Introduction

Statistical machine translation (SMT) uses bilingual corpora to build translation models. The amount and the quality of the bilingual data strongly affect the performance of SMT systems. For resource-rich language pairs, such as Chinese-English, it is easy to collect large amounts of bilingual corpus. However, for resource-poor language pairs, such as Chinese-Spanish, it is difficult to build a high-performance SMT system with the small scale bilingual data available.

The pivot language approach, which performs translation through a third language, provides a possible solution to the problem. The triangulation method (Wu and Wang, 2007; Cohn and Lapata, 2007) is a representative work for pivot-based machine translation. With a triangulation pivot approach, a source-target phrase table can be obtained by combining the source-pivot phrase table and the pivot-target phrase table. However, one of the weaknesses is that some corresponding source and target phrase pairs cannot be generated, because they are connected to different pivot phrases (Cui et al., 2013). As illustrated in Figure 1, since there is no direct translation between "很可口 henkekou" and "really delicious", the triangulation method is unable to establish a relation between "很可口 henkekou" and the two Spanish phrases.

To solve this problem, we apply a Markov random walk method to pivot-based SMT system. Random walk has been widely used. For example, Brin and Page (1998) used random walk to discover potential relations between queries and documents for link analysis in information retrieval. Analogous to link analysis, the aim of pivot-based translation is to discover potential translations between source and target language via the pivot language.

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 524–534,
Seattle, Washington, USA, 18-21 October 2013.

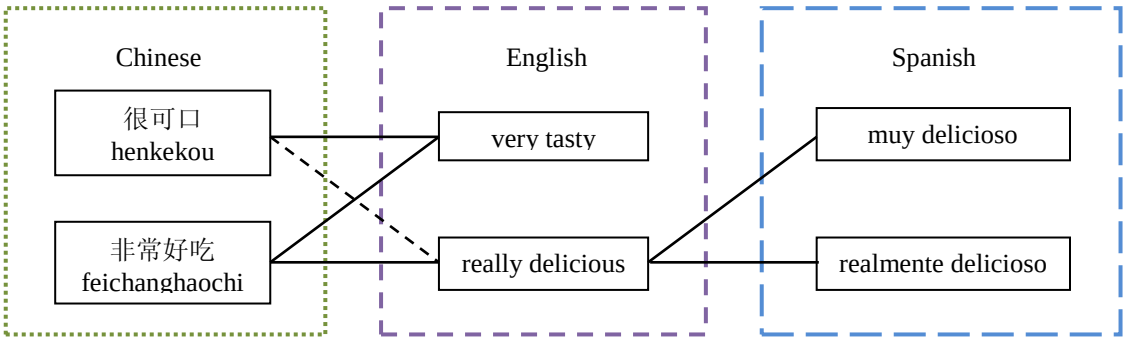

Figure 1: An example of random walk on phrase table. The dashed line indicates an implicit relation in the phrase table.

The goal of this paper is to extend the previous triangulation approach by exploring implicit translation relations using random walk method. We evaluated our approach in several translation tasks, including translations between European languages; Chinese-Spanish spoken language translation and Chinese-Japanese translation with English as the pivot language. Experimental results show that our approach achieves significant improvements over the conventional pivot-based method, triangulation method.

The remainder of this paper is organized as follows. In section 2, we describe the related work. We review the triangulation method for pivot-based machine translation in section 3. Section 4 describes the random walk models. In section 5 and section 6, we describe the experiments and analyze the performance, respectively. Section 7 gives a conclusion of the paper.

2 Related Work

Several methods have been proposed for pivot-based translation. Typically, they can be classified into 3 kinds of methods:

Transfer Method: Within the transfer framework (Utiyama and Isahara, 2007; Wang et al., 2008; Costa-jussà et al., 2011), a source sentence is first translated to *n* pivot sentences via a source-pivot translation system, and then each pivot sentence is translated to *m* target sentences via a pivot-target translation system. At each step (source to pivot and pivot to target), multiple translation outputs will be generated, thus a minimum Bayes-risk system combination method is often used to select the optimal sentence (González-Rubio et al., 2011; Duh et al., 2011). A problem with the transfer method is that it needs to decode twice. On one hand, the time cost is doubled; on the other hand, the translation error of the source-pivot translation system will be transferred to the pivot-target translation.

Synthetic Method: A synthetic method creates a synthetic source-target corpus using source-pivot translation model or pivot-target translation model (Utiyama et al., 2008; Wu and Wang, 2009). For example, we can translate each pivot sentence in the pivot-target corpus to source language with a pivot-source model, and then combine the translated source sentence with the target sentence to obtain a synthetic source-target corpus, and vice versa. However, it is difficult to build a high quality translation system with a corpus created by a machine translation system.

Triangulation Method: The triangulation method obtains source-target model by combining source-pivot and pivot-target translation models (Wu and Wang, 2007; Cohn and Lapata 2007), which has been shown to work better than the other pivot approaches (Utiyama and Isahara, 2007). As we mentioned earlier, the weakness of triangulation is that the corresponding source and target phrase pairs cannot be connected in the case that they connect to different pivot phrases.

3 The Triangulation Method

In this section, we review the triangulation method for pivot-based translation.

With the two additional bilingual corpora, the source-pivot and pivot-target translation models can be trained. Thus, a pivot model can be obtained by merging these two models. In the translation model, the phrase translation probability and the lexical weight are language dependent, which will be introduced in the next two sub-sections.

3.1 Phrase Translation Probability

The triangulation method assumes that there exist translations between phrases $\bar{s}$ and phrase $\bar{p}$ in source and pivot languages, and between phrase $\bar{p}$ and phrase $\bar{t}$ in pivot and target languages. The phrase translation probability ϕ between source and target languages is determined by the following model:

$$\begin{aligned}\phi(\bar{s} \mid \bar{t}) &= \sum_{\bar{p}} \phi(\bar{s} \mid \bar{p}, \bar{t}) \phi(\bar{p} \mid \bar{t}) \\ &= \sum_{\bar{p}} \phi(\bar{s} \mid \bar{p}) \phi(\bar{p} \mid \bar{t})\end{aligned} \quad (1)$$

3.2 Lexical Weight

Given a phrase pair $(\bar{s}, \bar{t})$ and a word alignment a between the source word positions $i = 1, \ldots, n$ and the target word positions $j = 0, 1, \ldots, m$, the lexical weight of phrase pair $(\bar{s}, \bar{t})$ can be calculated with the following formula (Koehn et al. 2003) :

$$p_{\xi}(\bar{s} \mid \bar{t}, a) = \prod_{i=1}^{n} \frac{1}{\left|\{ j \mid (i, j) \in a \}\right|} \sum_{\forall (i,j) \in a} \omega(s_i \mid t_j) \quad (2)$$

In formula 2, the lexical translation probability distribution $\omega(s \mid t)$ between source word s and target word t can be estimated with formula 3.

$$\omega(s \mid t) = \frac{count(s, t)}{\sum_{s'} count(s', t)} \quad (3)$$

Thus the alignment a between the source phrase $\bar{s}$ and target phrase $\bar{t}$ via pivot phrase $\bar{p}$ is needed for computing the lexical weight. The alignment a can be obtained as follows:

$$a = \{(s, t) \mid \exists p : (s, p) \in a_1 \,\&\, (p, t) \in a_2\} \quad (4)$$

where a_1 and a_2 indicate the word alignment between the phrase pair $(\bar{s}, \bar{p})$ and $(\bar{p}, \bar{t})$, respectively.

The triangulation method requires that both the source and target phrases connect to the same pivot phrase. Otherwise, the source-target phrase pair cannot be discovered. As a result, some useful translation relations will be lost. In order to alleviate this problem, we propose a random walk model, to discover the implicit relations among the source, pivot and target phrases.

4 Random Walks on Translation Graph

For phrase-based SMT, all source-target phrase pairs are stored in a phrase table. In our random walk approach, we first build a translation graph according to the phrase table. A translation graph contains two types of nodes: source phrase and target phrase. A source phrase $\bar{s}$ and a target phrase $\bar{t}$ are connected if exists a phrase pair $(\bar{s}, \bar{t})$ in the phrase table. The edge can be weighted according to translation probabilities or alignments in the phrase table. For the pivot-based translation, the translation graph can be derived from the source-pivot phrase table and pivot-target phrase table.

Our random walk model is inspired by two works (Szummer and Jaakkola, 2002; Craswell and Szummer,2007). The general process of random walk can be described as follows:

Let $G = (V, E)$ be a directed graph with n vertices and m edges. For a vertex $v \in V$, $\Gamma(v)$ denotes the set of neighbors of v in G. A random walk on G follows the following process: start at a vertex v_0, chose and walk along a random neighbor v_1, with $v_1 \in \Gamma(v_0)$. At the second step, start from v_1 and chose a random neighbor v_2, and so on.

Let *S* be the set of source phrases, and *P* be the set of pivot phrases. Then the nodes *V* are the union of *S* and *P*. The edges *E* correspond to the relations between phrase pairs.

Let *R* represent the binary relations between source phrases and pivot phrases. Then the 1-step translation R_{ik} from node *i* to node *k* can be directly obtained in the phrase table.

Define operator $\otimes$ to denote the calculation of relation *R*. Then 2-step translation R_{ij} from node *i* to node *j* can be obtained with the following formula.

$$R_{ij} = R_{ik} \otimes R_{kj} \quad (4)$$

We use $R_{t|0}(k \mid i)$ to denote a *t*-step translation relation from node *i* to node *k*. In order to calculate the translation relations efficiently, we use a matrix *A* to represent the graph. A *t* step translation probability can be denoted with the following formula.

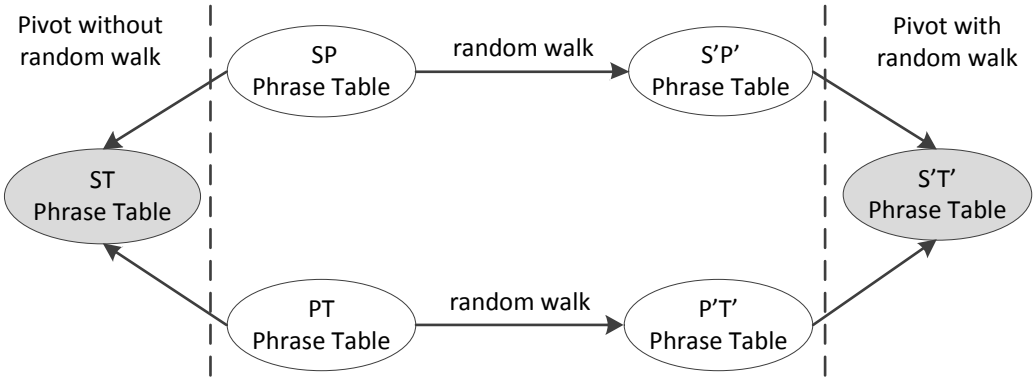

Figure 2: Framework of random walk based pivot translation. The ST phrase table was generated by combining SP and PT phrase table through triangulation method. The phrase table with superscript "'" means that it was enlarged by random walk.

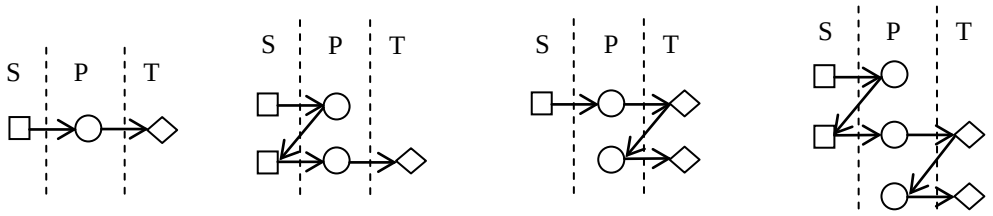

(a) Pivot without random walk (b) Random walk on source-pivot side (c) Random walk on pivot-target side (d) Random walk on both sides

Figure 3: Some possible decoding processes of random walk based pivot approach. The □ stands for the source phrase (S); the ○ represents the pivot phrase (P) and the ◇ stands for the target phrase (T).

$$P_{t|0}(k \mid i) = [A^t]_{ik} \quad (5)$$

where $\boldsymbol{A}$ is a matrix whose i,k-th element is R_{ik} .

4.1 Framework of Random Walk Approach

The overall framework of random walk for pivot-based machine translation is shown in Figure 2. Before using random walk model, we have two phrase tables: source-pivot phrase table (SP phrase table) and pivot-target phrase table (PT phrase table). After applying the random walk approach, we can achieve two extended phrase table: extended source-pivot phrase table (S'P' phrase table) and extended pivot-target phrase table (P'T' phrase table). The goal of pivot-based SMT is to get a source-target phrase table (ST phrase table) via SP phrase table and PT phrase table.

Our random walk was applied on SP phrase table or PT phrase table separately. In next 2 subsections, we will explain how the phrase translation probabilities and lexical weight are obtained with random walk model on the phrase table.

Figure 3 shows some possible decoding processes of random walk based pivot approach. In figure 3-a, the possible source-target phrase pair can be obtained directly via a pivot phrase, so it does not need a random walk model. In figure 3-b and figure 3-c, one candidate source-target phrase pair can be obtained by random walks on source-pivot side or pivot-target side. Figure 3-d shows that the possible source-target can only by obtained by random walks on source-pivot side and pivot-target side.

4.2 Phrase Translation Probabilities

For the translation probabilities, the binary relation R is the translation probabilities in the phrase table. The operator $\otimes$ is multiplication. According to formula 5, the random walk sums up the probabilities of all paths of length t between the node i and k.

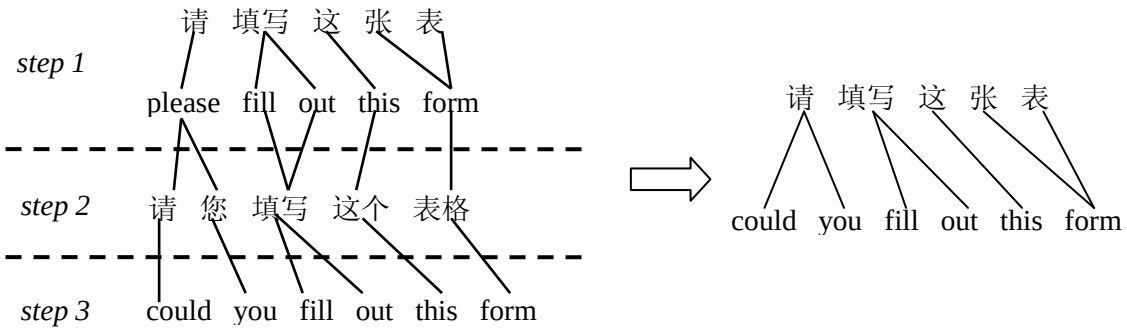

Figure 4: An example of word alignment induction with 3 steps random walks

Take source-to-pivot phrase graph as an example; denote matrix A contains $s+p$ nodes (s source phrases and p pivot phrases) to represent the translation graph.

$$A = \left[g_{ij} \right]_{(s+p)\times(s+p)} \quad (6)$$

where g_{ij} is the i,j-th elements of matrix A.

We can split the matrix A into 4 sub-matrixes:

$$A = \begin{bmatrix} 0_{s\times s} & A_{sp} \\ A_{ps} & 0_{p\times p} \end{bmatrix} \quad (7)$$

where the sub-matrix $A_{sp} = [p_{ik}]_{s\times p}$ represents the translation probabilities from source to pivot language, and A_{ps} represents the similar meaning.

Take 3 steps walks as an example:

Step1:

$$A = \begin{bmatrix} 0_{s\times s} & A_{sp} \\ A_{ps} & 0_{p\times p} \end{bmatrix}$$

Step2:

$$A^2 = \begin{bmatrix} A_{sp}\times A_{ps} & 0_{s\times p} \\ 0_{p\times s} & A_{ps}\times A_{sp} \end{bmatrix}$$

Step3:

$$A^3 = \begin{bmatrix} 0_{s\times s} & A_{sp}\times A_{ps}\times A_{sp} \\ A_{ps}\times A_{sp}\times A_{ps} & 0_{p\times p} \end{bmatrix}$$

For the 3 steps example, each step performs a translation process in the form of matrix's self-multiplication.

1. The first step means the translation from source language to pivot language. The matrix A is derived from the phrase table directly and each element in the graph indicates a translation rule in the phrase table.
2. The second step demonstrates a procedure: S-P-S'. With 2 steps random walks, we can find the synonymous phrases, and this procedure is analogous to paraphrasing (Bannard and Callison-Burch, 2005). For the example shown in figure 1 as an example, the hidden relation between "*很可口 henkekou*" and "*非常好吃 feichanghaochi*" can be found through Step 2.
3. The third step describes the following procedure: S-P-S'-P'. An extended source-pivot phrase table is generated by 3-step random walks. Compared with the initial phrase table in Step1, although the number of phrases is not increased, the relations between phrase pairs are increased and more translation rules can be obtained. Still for the example in Figure 1 , the hidden relation between "*很可口 henkekou*" and "*really delicious*" can be generated in Step 3.

4.3 Lexical Weights

To build a translation graph, the two sets of phrase translation probabilities are represented in the phrase tables. However, the two lexical weights are not presented in the graph directly. To deal with this, we should conduct a word alignment random walk model to obtain a new alignment a after t steps. For the computation of lexical weights, the relation R can be expressed as the word alignment in the phrase table. The operator $\otimes$ can be induced with the following formula.

$$a = \{(x,y) \mid \exists p : (x,z) \in a_1 \,\&\, (z,y) \in a_2\} \quad (8)$$

where a_1 and a_2 represent the word alignment information inside the phrase pairs $(\bar{x},\bar{y})$ and $(\bar{y},\bar{z})$ respectively. An example of word alignment inducing is shown in Figure 4. With a new word alignment, the two lexical weights can be calculated by formula 2 and formula 3.

5 Experiments

5.1 Translation System and Evaluation Metric

In our experiments, the word alignment was obtained by GIZA++ (Och and Ney, 2000) and the heuristics "grow-diag-final" refinement rule. (Koehn et al., 2003). Our translation system is an in-house phrase-based system using a log-linear framework including a phrase translation model, a language model, a lexicalized reordering model, a word penalty model and a phrase penalty model, which is analogous to Moses (Koehn et al., 2007). The baseline system is the triangulation method based pivot approach (Wu and Wang, 2007).

To evaluate the translation quality, we used BLEU (Papineni et al., 2002) as our evaluation metric. The statistical significance using 95% confidence intervals were measured with paired bootstrap resampling (Koehn, 2004).

5.2 Experiments on Europarl

5.2.1. Data sets

We mainly test our approach on Europarl[1] corpus, which is a multi-lingual corpus including 21 European languages. Due to the size of the data, we only select 11 languages which were added to Europarl from 04/1996 or 01/1997, including Danish (da), German (de), Greek (el), English (en), Spanish (es), Finnish (fi), French (fr), Italian (it) Dutch (nl) Portuguese (pt) and Swedish (sv). In order to avoid a trilingual scenario, we split the training corpus into 2 parts by the year of the data: the data released in odd years were used for training source-pivot model and the data released in even years were used for training pivot-target model.

We perform our experiments on different translation directions and via different pivot languages. As a most widely used language in the world (Mydans, 2011), English was used as the pivot language for granted when carrying out experiments on different translation directions. For translating Portuguese to Swedish, we also tried to perform our experiments via different pivot languages. Table 1 and Table 2 summarized the training data.

Table4. Experimental results on Europarl with different translation directions (BLEU% on WMT08). RW=Random Walk. * indicates the results are significantly better than the baseline ($p<0.05$).

Several test sets have been released for the Europarl corpus. In our experiments, we used WMT2006[2], WMT2007[3] and WMT2008[4] as our test data. The original test data includes 4 languages and extended versions with 11 languages of these test sets are available by the EuroMatrix[5] project. Table 3 shows the test sets.

5.2.2. Experiments on Different Translation Directions

We build 180 pivot translation systems[6] (including 90 baseline systems and 90 random walk based systems) using 10 source/target languages and 1 pivot language (English).

The baseline system was built following the traditional triangulation pivot approach. Table 4 lists the results on Europarl training data. Limited by the length of the paper, we only show the results on WMT08, the tendency of the results on WMT06 and WMT07 is similar to WMT08.

Several observations can be made from the table.

1. In all 90 language pairs, our method achieves general improvements over the baseline system.

2. Among 90 language pairs, random walk based approach is significantly better than the baseline system in 75 language pairs.

3. The improvements of our approach are not equal in different translation directions. The improvement ranges from 0.06 (it-es) to 1.21 (pt-da). One possible reason is that the performance is related with the source and target language. For example, when using Finnish as the target language, the improvement is significant over the baseline. This may be caused by the great divergence between Uralic language (Finnish) and Indo-European language (the other European language in Table4). From the table we can find that the translation between languages in different language family is worse than that in some language family. But our random walk approach can im-

[6] Given N languages, a total of N*(N-1) SMT systems should be build to cover the translation between each language.

prove the performance of translations between different language families.

5.2.3. Experiments via Different Pivot Languages

In addition to using English as the pivot language, we also try some other languages as the pivot language. In this sub-section, experiments were carried out from translating Portuguese to Swedish via different pivot languages.

Table 5 summarizes the BLEU% scores of different pivot language when translating from Portuguese to Swedish. Similar to Table 4, our approach still achieves general improvements over the baseline system even if the pivot language has been changed. From the table we can see that for most of the pivot language, the random walk based approach gains more than 1 BLEU score over the baseline. But when using Finnish as the pivot language, the improvement is only 0.02 BLEU scores on WMT08. This phenomenon shows that the pivot language can also influence the performance of random walk approach. One possible reason for the poor performance of using Finnish as the pivot language is that Finnish belongs to Uralic language family, and the other languages belong to Indo-European family. The divergence between different language families led to a poor performance. Thus how to select a best pivot language is our future work.

The problem with random walk is that it will lead to a larger phrase table with noises. In this sub-section, a pre-pruning (before random walk) and a post-pruning (after random walk) method were introduced to deal with this problem.

We used a naive pruning method which selects the top N phrase pairs in the phrase table. In our experiments, we set N to 20. For pre-pruning, we prune the SP phrase table and PT phrase table before applying random walks. Post-pruning means that we prune the ST phrase table after random walks. For the baseline system, we also apply a pruning method before combine the SP and PT phrase table. We test our pruning method on pt-en-sv translation task. Table 6 shows the results.

With a pre- and post-pruning method, the random walk approach is able to achieve further improvements. Our approach achieved BLEU scores of 25.11, 24.69 and 24.34 on WMT06, WMT07 and WMT08 respectively, which is much better than the baseline and the random walk approach with pruning. Moreover, the size of the phrase table is about half of the no-pruning method. When adopting a post-pruning method, the performance of translation did not improved significantly over the pre-pruning, but the scale of the phrase table dropped to 69M, which is only about 2 times larger than the triangulation method.

Phrase table pruning is a key work to improve the performance of random walk. We plan to explore more approaches for phrase table pruning. E.g. using significance test (Johnson et al., 2007) or monolingual key phrases (He et al., 2009) to filter the phrase table.

5.3 Experiments on Spoken Language

The European languages show various degrees of similarity to one another. In this sub-section, we consider translation from Chinese to Spanish with English as the pivot language. Chinese belongs to Sino-Tibetan Languages and English/Spanish belongs to Indo-European Languages, the gap between two languages is wide.

A pivot task was included in IWSLT 2008 in which the participants need to translate Chinese to Spanish via English. A Chinese-English and an English-Spanish data were supplied to carry out the experiments. The entire training corpus was tokenized and lowercased. Table 7 and Table 8 summarize the training data and test data.

Table 9 shows the similar tendency with Table 4. The random walk models achieved BLEU% scores 32.09, which achieved an absolute improvement of 2.08 percentages points on BLEU over the baseline.

Corpus	Sentence pair #	Source word #	Target word #
CE	20,000	135,518	182,793
ES	19,972	153,178	147,560

Table 7: Training Data of IWSLT2008

Table9. Results on IWSLT2008

5.4 Experiments on Web Data

The setting with Europarl data is quite artificial as the training data for directly translating between source and target actually exists in the original data sets. The IWSLT data set is too small to represent the real scenario. Thus we try our experiment on a more realistic scenario: translating from Chinese to Japanese via English with web crawled data.

All the training data were crawled on the web. The scale of Chinese-English and English-Japanese is 10 million respectively. The test set was built in house with 1,000 sentences and 4 references.

System	BLEU%	phrase pairs #
Baseline	28.76	4.5G
+pruning	28.90	273M
RW	29.13	46G
+pre-pruning	29.44	11G
+post-pruning	**29.51***	**3.4G**

Table10. Results on Web Data

Table 10 lists the results on web data. From the table we can find that the random walk model can achieve an absolute improvement of 0.75 percentages points on BLEU over the baseline.

In this subsection, the training data contains parallel sentences with different domains. And the two training corpora (Chinese-English and English-Japanese) are typically very different. It means that our random walk approach is robust in the realistic scenario.

6 Discussions

The random walk approach mainly improves the performance of pivot translation in two aspects: reduces the OOVs and provides more hypothesis phrases for decoding.

6.1 OOV

Out-of-vocabulary (OOV[7]) terms cause serious problems for machine translation systems (Zhang et al., 2005). The random walk model can reduce the OOVs. As illustrated in Figure 1, the Chinese phrase "很可口henkekou" cannot be connected to any Spanish phrase, thus it is a OOV term.

We count the OOVs when decoding with triangulation model and random walk model on IWSLT2008 data. The statistics shows that when using triangulation model, there are 11% OOVs when using triangulation model, compared with 9.6% when using random walk model. Less OOV often lead to a better result.

[7] OOV refer to phrases here.

6.2 Hypothesis Phrases

To illustrate how the random walk method helps improve the performance of machine translation, we illustrate an example as follows:

- **Source: 我 想 要 枕头**
  wo xiang yao zhentou
- **Baseline trans: Quiero almohada**
- **Random Walk trans: Quiero una almohada**

For translating a Chinese sentence "我想要枕头 wo xiang yao zhentou" to Spanish, we can get two candidate translations. In this case, the random walk translation is better than the baseline system. The key phrase in this sentence is "枕头 zhentou", figure 5 shows the extension process. In this case, the article "*a*" is hidden in the source-pivot phrase table. The same situation often occurs in articles and prepositions. Random walk is able to discover the hidden relations (hypothesis phrases) among source, pivot and target phrases.

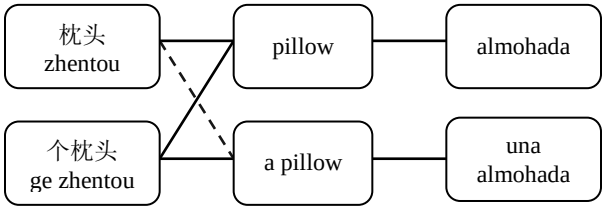

Figure 5: Phrase extension process. The dotted line indicates an implicit relation in the phrase table.

7 Conclusion and Future Work

In this paper, we proposed a random walk method to improve pivot-based statistical machine translation. The random walk method can find implicit relations between phrases in the source and target languages. Therefore, more source-target phrase pairs can be obtained than conventional pivot-based method. Experimental results show that our method achieves significant improvements over the baseline on Europarl corpus, spoken language data and the web data.

A critical problem in the approach is the noise that may bring in. In this paper, we used a simple filtering to reduce the noise. Although the filtering method is effective, other method may work better. In the future, we plan to explore more approaches for phrase table pruning.

Abstract

This paper proposes a multi-objective optimization framework which supports heterogeneous information sources to improve alignment in machine translation system combination techniques. In this area, most of techniques usually utilize confusion networks (CN) as their central data structure to compact an exponential number of an potential hypotheses, and because better hypothesis alignment may benefit constructing better quality confusion networks, it is natural to add more useful information to improve alignment results. However, these information may be heterogeneous, so the widely-used Viterbi algorithm for searching the best alignment may not apply here. In the multi-objective optimization framework, each information source is viewed as an independent objective, and a new goal of improving all objectives can be searched by mature algorithms. The solutions from this framework, termed Pareto optimal solutions, are then combined to construct confusion networks. Experiments on two Chinese-to-English translation datasets show significant improvements, 0.97 and 1.06 BLEU points over a strong Indirected Hidden Markov Model-based (IHMM) system, and 4.75 and 3.53 points over the best single machine translation systems.

1 Introduction

System combination (SC) techniques have the power of boosting translation quality in BLEU by several percent over the best among all input machine translation systems (Bangalore et al., 2001; Matusov et al., 2006; Sim et al., 2007; Rosti et al., 2007b; Rosti et al., 2007a; Huang and Papineni, 2007; He et al., 2008; Rosti et al., 2008; He and Toutanova, 2009; Li et al., 2009; Feng et al., 2009; Pauls et al., 2009). A central data structure in the SC is the confusion network, and its quality greatly affects the final performance. He et al. (2008) proposed a new hypothesis alignment algorithm for constructing high-quality confusion networks called Indirect Hidden Markov Model (IHMM), which does better in synonym matching compared with the classic translation edit rate (TER) based algorithm (Rosti et al., 2007b; Rosti et al., 2008; Sim et al., 2007). Now, current state-of-the-art SC systems have been using IHMM or variants in their alignment algorithms more or less (Li et al., 2009; Feng et al., 2009).

Our motivation derives from an observation that in an ideal alignment of a pair of sentences, many-to-many alignments often exist. For instance, "be about to" has the same meaning with "be on the point of". Because Hidden Markov Model based alignment algorithms, e.g. IHMM for system combination, HMM in GIZA++ software for statistical machine translation (SMT) (Och and Ney, 2000; Koehn et al., 2003), are designed for one-to-many alignment, and running GIZA++ from two directions to gain better performance turns into a standard operation in SMT, therefore we are seeking a way to empower IHMM by introducing bi-directional information.

However, it appears to be intractable in an IHMM model to search the optimal solution by simply defining a new goal as a product of probabilities

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 535–544,
Seattle, Washington, USA, 18-21 October 2013.

from two directions. To bypass this problem, Liang et al. (2006) adopts a simple and effective variational inference algorithm.

Further, different alignment algorithms capture different information and linguistic phenomena for a pair of sentences, hence more information would be expected to benefit the final alignment. Liang's method may not be suitable for this expected outcome.

We propose to adopt multi-objective optimization framework to support heterogeneous information sources which may induce difficulties in a conventional search algorithm. In this framework, there exist a variety of matured multi-objective optimization algorithms, e.g. evolutionary algorithm (Deb et al., 2000; Deb et al., 2002), Tabu search (Hansen, 1997), ants colony (Engelbrecht, 2005), and simulated annealing (Serafini, 1994). In this work, we select the multi-objective evolutionary algorithm because of its public open source software (http://www.iitk.ac.in/kangal/codes.shtml). On the other hand, this framework is also totally unsupervised. It prevents weights of a linearly combined goal from training even if all information is homogeneous and applicable in a Viterbi search (Forney Jr, 1973). This framework views any useful information benefiting alignment as an independent objective, and researchers just need to write short codes for objective definitions. The search algorithm seeks for potentially better solutions which are no worse than the current solution set. The output from multi-objective optimization algorithms includes a set of solutions, called *Pareto optimal solutions*, each one being a many-to-many alignment. We then combine and normalize them into a unique one-to-one alignment to perform confusion network construction (Section 3.3).

Our work is conducted on the classic pipeline which has three modules, pair-wise hypothesis alignment, confusion network construction, and training. Now many work integrates neighboring modules to avoid propagated errors to gain improved performance. For example, Rosti et al. (2008), and Li et al. (2009) combine the first and the second module, and He and Toutanova (2009) combine all modules into one directly. Nevertheless, the classic structure also owns its merits. Because of the independence between modules, a system is relatively simple to maintain, and improvements on each module might contribute to final performance additively. Based on our work, lattice-based minimum error rate training (lattice-MERT) and minimum bayes risk training techniques (Kumar et al., 2009) could be adopted on the third module. And Feng et al. (2009) in the second module adopts a different data structure called lattice which could directly use our better many-to-many alignment for construction.

Experiments on the Chinese-to-English task on two datasets use four objectives, IHMM probability (Section 3.2.1), and alignment probability from GIZA++ (Section 3.2.2) from two directions. Results show multi-objective optimization framework efficiently integrates different information to gain approximately 1 BLEU point improvement over a strong baseline.

2 Background

We briefly give an introduction to confusion networks, and because the IHMM based alignment is an important objective in our multi-objective framework, here we also provide detailed definition of formulas for completeness of content.

2.1 Confusion Network

Table 1 shows hypotheses h_1 and h_2 are aligned to selected backbone h_0. When alignment algorithm obtains good enough results, the expected output *"he prefers apples"* is included in its corresponding confusion network in Figure 1. This suggests developing better alignment algorithm may help creating high-quality confusion networks. This also motivates us to use the BLEU of oracle hypotheses to approximately measure the quality of a set of CNs. We hereafter call it an oracle BLEU of a CN. See more in Section 5.1.

h_0 :he	feels	like	apples
h_1 :he	prefer	ε	apples
h_2 :him	prefers	to	apples

Table 1: A toy example of hypothesis alignment, where h_0 is the backbone hypothesis. $h_1$and h_2 are aligned to the backbone separately. The resulting confusion network is in Figure 1.

A confusion network $G = (V, E)$ is a directed acyclic graph with a unique source and sink vertex,

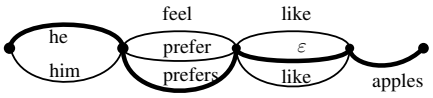

Figure 1: A classic confusion network, and the bold path the expected output.

formally a weighted finite state automation (FSA), where V is the set of nodes and E is the set of edges. Each edge is restricted to attach to a single word as well as an associated probability. A special mark ε is a place-holder denoting no word here.

2.2 IHMM-based Alignment

Indirected Hidden Markov Model (IHMM) was firstly proposed by He et. al (2008). Compared with TER-based alignment performing literal matching, IHMM supports synonym comparison in redefining emission probabilities in an IHMM model.

Let $\boldsymbol{f}^I = (f_1, \dots f_I)$ be a backbone hypothesis, and $\boldsymbol{e}^J = (e_1, \dots e_J)$ be a hypothesis aligned to the backbone, both being English sentences in our experiments. Let $\boldsymbol{a}^J = \{a_1, \dots a_j\}$ be an alignment. Suppose the a_jth word in $\boldsymbol{f}^I$ is aligned to jth word in $\boldsymbol{e}^J$, and the conditional probability that the hypothesis is generated by the backbone, shown in the upper graph of Figure 3, is given by

$$p(\boldsymbol{f}^I, \boldsymbol{e}^J) = \sum_{a^J} \prod_{j=1}^{J} \{p^t(a_j|a_{j-1}, I) p^o(e_j|f_{a_j})\} \tag{1}$$

The *distortion probability* $p^t(a_j|a_{j-1}, I)$ from position a_{j-1} to a_j, relies on jumped distance, which is computed as follows:

$$p^t(i^{'}|i, I) = \frac{c(i^{'} - i)}{\sum_{t=1}^{I} c(t - i)} \tag{2}$$

The *distortion parameters* $c(d)$ are grouped into 11 buckets, $c(\leq -4)$,$c(-3)$,$c(-2) \dots c(5)$,$c(\geq 6)$. Because all the hypotheses in system combination are in the same language, the IHMM model would support more monotonic alignments, and non-monotonic alignments will be penalized.

$$c(d) = (1 + |d - 1|)^{-K}, d = -4 \dots 6 \tag{3}$$

where K is tuned on held-out data.

Let p_0 be the probability of jumping to a $null$ word state, which is also tuned on held-out data, and the accurate transition probability becomes:

$$p^t(i^{'}|i, I) = \begin{cases} p_0 & \text{if } i^{'} = null \\ (1 - p_0) p^t(i^{'}|i, I) & \text{otherwise} \end{cases} \tag{4}$$

The *output probability* $p^o(e|f)$ from the state word f to the observation word e, also called translation probability, is a linear interpolation of semantic similarity $p^{sem}(e|f)$ and surface similarity $p^{sur}(e|f)$, and α is the interpolation factor:

$$p^o(e|f) = \alpha p^{sem}(e|f) + (1 - \alpha) p^{sur}(e|f) \tag{5}$$

When calculating *semantic similarity* $p^{sem}(e|f)$, source sentence src is needed, and a bilingual probabilistic dictionary $p^{dic}(w_1|w_2)$ is necessary.

$$p^{sem}(e|f) \approx \sum_{c \in src} p^{dic}(c|f) \cdot p^{dic}(e|c) \tag{6}$$

Note that $p^{sem}(e|f)$ has been updated with different source sentences.

The *surface similarity* $p^{sur}(e|f)$ is measured by the literal matching rate:

$$p^{sur}(e, f) = \exp\{\rho[\frac{\text{LMP}(f, e)}{\max(|f|, |e|)} - 1]\} \tag{7}$$

where $\text{LMP}(f, e)$ is the length of the longest matched prefix, and ρ is a smoothing parameter.

3 Multi-objective Optimization

Many decision making problems in the real world consider more than one objective. One natural way is to scalarize multiple objectives into one by assigning it with a weight vector. This method allows a simple optimization algorithm in many cases, while in system combination, it would cause problems.

In the first module, in order to train suitable weights of objectives, extra labeled data is needed, besides that, the efficient Viterbi algorithm for searching the optimal alignment would not work for

the alignment objectives in this work. More, the parameter training in the third module relies on the CNs constructed from the output of the first module, which increases the instability of the whole system. Therefore, an unsupervised multi-objective algorithm may be a good choice allowing for more alignment information.

There exist other alternative optimization algorithms in the multi-objective optimization framework, though the evolutionary algorithm is adopted here, we only introduce some general concepts.

3.1 Pareto Optimal Solutions

A general multi-objective optimization problem consists of a number of objectives and is associated with a number of constraints. Mathematically, the problem can be written as follows (Deb, 2001)

$$\begin{array}{lll} \text{Maximize} & f_i(x) & i = 1 \ldots M \\ \text{s.t.} & g_j(x) \leq 0 & j = 1 \ldots N \\ & h_k(x) = 0 & k = 1 \ldots K \end{array}$$

where x denotes a potential solution, its structure relying on different problems, and the number of constraints M, N, K depend on different problems. All the functions f_i, g_j, h_k map a solution x into a scalar. We will explain them in terms of system combination.

In this work, we refer to $x = \{x_{i,j} | x_{i,j} \in \{0, 1\}\}$ as a potential alignment of a pair of hypotheses, where $x_{i,j}$ is a boolean value to denote *whether the ith word in the first hypothesis is aligned to the jth word in the second hypothesis*. Here the definition of $\boldsymbol{x}$ seems different from that of $\boldsymbol{a}$ in Formula 1, and they could convert to each other. Using a line-based access style, a matrix can be unfolded as a vector. We refer to f as IHMM alignment probability (He et al., 2008) and GIZA++ alignment probability (Chen et al., 2009), total four objectives from two directions, and the larger the objectives, the better. The g_js and h_ks serve as the role of checking if $\boldsymbol{x}$ represents a legal alignment. For instance, the subscripts of $x_{i,j}$ are not in bounds.

Definition 1. *Let x, x' be two potential alignments. If $f_i(x) \geq f_i(x')$ holds for all i, we call the alignment x dominates the alignment x'. If there does not exist any alignment x'' to dominate x, we call the alignment x to be non-dominated.*

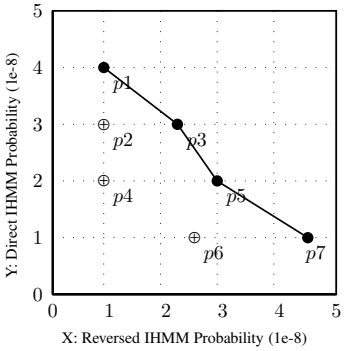

Figure 2: Sample solutions with only two objectives. Pareto Optimal Solutions p_1, p_3, p_5, p_7. Other points p_2, p_4, p_6 are dominated by at least one point in the Pareto optimal solutions.

Definition 2. *A alignment x is said to be Pareto optimal if there is no other alignment x' found to dominate x.*

In Figure 2, p_1 dominates p_2, and p_2 dominates p_4. To summarize, a point is dominated by the ones on its upper and right side with ties. In this example, p_1, p_3, p_5, p_7 are Pareto optimal.

In some cases, Pareto optimal solutions can be used for good candidate solutions. Considering the IHMM model, maximizing Y axis, the top-4 best alignments are p_1, p_2, p_3, p_4. But from the view of Pareto optimal, the top-4 alignments would be p_1, p_3, p_5, p_7 without order, which considers a greater range than a single optimization model. In our method, we just combine these Pareto optimal solutions equally into a unique alignment (Section 3.3).

Our adopted multi-objective optimization searching algorithm is the non-dominated sorting genetic algorithm II (NSGA-II) (Deb et al., 2000; Deb et al., 2002) with an open source software (http://www.iitk.ac.in/kangal/codes.shtml). NSGA-II has a complexity of $\mathrm{O}(mn^2)$, where m is the number of objectives and n is the population size in an evolutionary algorithm.

3.2 Objectives in Evolutionary Algorithm

The optimization objectives in our experiments can be categorized as an IHMM alignment probability (He et al., 2008) and GIZA++ alignment probability

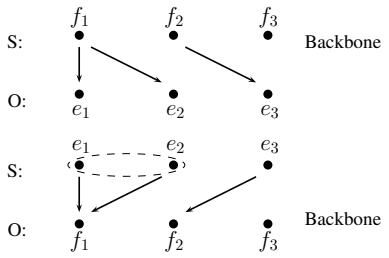

Figure 3: The same alignment $(f_1, e_1)(f_1, e_2)(f_2, e_3)$ in two IHMM models. The upper one is a typical example in IHMM, and in the bottom one, because any word in the observation is required not to correspond to two statuses, it has a minor trouble. S: status sequence, O: observation sequence.

(Chen et al., 2009), total four from two directions.

3.2.1 IHMM Probability

A typical IHMM alignment is demonstrated in the upper graph of Figure 3, where a backbone is acting the role of a status sequence. The unnormalized conditional alignment probability is $[p^t(1|null)] \cdot [p^t(1|1)p^t(2|1)] \cdot [p^o(e_1|f_1)p^o(e_2|f_1)p^o(e_3|f_2)]$. However, the same alignment $(f_1, e_1)(f_1, e_2)(f_2, e_3)$, if we change the alignment direction, the backbone being observations, would be a bit different. We offer a minor modification to Formula 1.

Look at the bottom graph of Figure 3, the observation f_1 has two statuses, e_1 and e_2 at the same time, it becomes ambiguous to compute the transitional probability between $p^t(3|1)$ and $p^t(3|2)$. This is because IHMM algorithm deals with one-to-many alignments, and MOEA permits many-to-many alignments.

We hence empirically modify the IHMM model to support many-to-many alignments. A new status is defined, rather than a single position $p^t(j|i)$, but as a set of positions $p^t(\{j\}|\{i\})$. The positions in one status need not to be adjacent to each other.

The redefined *transitional probability*

$$p^t(\{j\}|\{i\}) = \frac{1}{|\{j\}| \cdot |\{i\}|} \sum_{i,j} p^t(j|i)$$

The redefined *emission probability*

$$p^o(j|\{i\}) = \prod_i p^o(j|i)$$

We need to note that there is no guarantee on the closed property of probabilities, though these approximations prove to be effective in a practical sense. Straightforwardly, when there is only one position in a new status, the expanded IHMM degenerates to the standard IHMM.

Let us return to the second IHMM example. The new probability becomes $[p^t(1|\text{null})p^t(2|\text{null})] \cdot [\frac{1}{2}p^t(3|1)p^t(3|2) \cdot p^t(\text{null}|3)] \cdot [p^o(f_1|e_1)p^o(f_1|e_2)p^o(f_2|e_3)p^o(f_3|\text{null})]$.

3.2.2 Alignment Probability

GIZA++ considers very different and more information in alignment, we attempt to utilize them. All probabilities appearing in below formulas can be looked up in GIZA++.

Given a pair of hypotheses $\boldsymbol{f}^I = (f_1, \ldots f_I)$, $\boldsymbol{e}^J = (e_1, \ldots e_J)$, and their alignment $\boldsymbol{a}$, the alignment probability could be calculated as follows

$$p^{Giza}(\boldsymbol{e}^J|\boldsymbol{f}^I, \boldsymbol{a}) = \prod_{e_i} T(e_i|\boldsymbol{f}^I, \boldsymbol{a})$$

$$T(e_i|\boldsymbol{f}^I, \boldsymbol{a}) = \begin{cases} n(\phi_i|e_i) \sum_{(j,i)\in\boldsymbol{a}} t(e_i|f_j)a(j|i)/\phi_i & \text{if } \phi_i \neq 0 \\ n(0|e_i)t(e_i|\text{null})a(0|i) & \text{otherwise} \end{cases}$$

$$\phi_i = |\{j|(i,j) \in \boldsymbol{a}\}|$$

where ϕ_i is the fertility number, $t(e|c)$ *the translation probability* for the word pair, $z(j|i)$ *alignment probability* to show how likely a target word at position i could be translated into a source word at position j, and $n(\phi|e)$ is the *fertility probability* to show how likely a given target word e is translated into ϕ source words.

In order to increase the coverage of words, we collect all the hypothesis pairs in both the tuning set and the test set and feed them into GIZA++. This is an off-line operation, which makes it not suitable for an online translation system. In some circumstances, users submit a pile of documents in the hope of high-quality translations, thus more useful knowledge sources would be helpful. In our experiments, a pure GIZA++ based system combination does not perform as well as IHMM based, but does benefit the final translation quality if combined in our multi-objective optimization framework.

3.3 Configuration of Evolutionary Algorithm

3.3.1 Encoding

Given a sentence pair $<\boldsymbol{f}^I, \boldsymbol{e}^J>$, we define a two-dimensional matrix $\boldsymbol{x} = \{z_{i,j}|z_{ij} \in \{0,1\}\}$ to encode a set of possible alignments. Using a line-based access style, the matrix could be unfolded as a vector with $|I| \cdot |J|$ bits of length.

3.3.2 Initialization

Because in NSGA-II software the initial population are generated at random. In order to make NSGA-II more consistent and flexible, better initial seeds should be fed with, thus we combine an existing word alignment results as input. Here we use together two N-best lists generated from directional HMM and reversed HMM respectively for initialization.

3.3.3 Normalization of Pareto Optimal Solutions

Multi-objective optimization algorithms do not pose weights on objectives, thus they output a set of so-called Pareto optimal solutions, each of which is a many-to-many alignment. We can understand them as an N-best alignment list without explicit preferences. We also empirically compare it with the idea that directly cuts an N-best list from the IHMM based alignment.

We describe a two-stage strategy for normalization. Firstly, we use a simple and effective voting strategy to combine a set of many-to-many alignments into a single many-to-many alignment, and Secondly we normalize it into a one-to-one alignment for confusion network construction. In the first stage, we count the number of word-to-word alignments on each position pair (i, j). If there is more than a half number of alignments, then we output 1, otherwise 0. In the second stage, if any word relates to more than one word alignment, the one with the highest posterior probability is selected (He et al., 2008; Feng et al., 2009). The posterior probabilities can be computed in a classic forward-backward procedure in IHMM (He et al., 2008).

4 Training and Decoding

Our work does not change the classic pipeline, thus the model and features are nearly identical to the ones in (Rosti et al., 2007b; He et al., 2008), which are modeled in a log-linear fashion in Eq. 8. Translation on a CN is just a concatenation of edges traversed, on which 4 categories of features are defined.

1. word posterior probabilities. In Eq. 8, $p(w|sys, span)$ are word confidence scores. If the word w comes from the kth hypothesis of thesys-th system, the raw score should be $\frac{1}{k+1}$, and then it would be normalized by the same sys and $span$. The same word coming from different systems owns a different score, so there are sys system weights λ_{sys}.

2. logarithm of language model score, $L(h)$.

3. number of $null$ edge, Num_{null}.

4. number of words, Num_w.

$$\begin{aligned} log(h) &= \sum_{span} \log(\sum_{sys} \lambda_{sys} p(w|sys, span)) \\ &+ w_0 L(h) + w_1 Num_{null} + w_2 Num_w \end{aligned} \quad (8)$$

Decoding a confusion network is straightforward, traversing each node from left to right, and the beam search algorithm will retain for each node an N-best list. The final N-best can be acquired following (Huang and Chiang, 2005).

The training process follows minimum error rate training (MERT) described in (Och, 2003; Koehn et al., 2003). In each iteration, the Powell algorithm would attempt to predict the optimal parameters on the cumulative N-best list.

5 Experiments

We evaluate our method in two datasets in the Chinese-to-English task. In the first one, NIST MT 2002 and 2005 are used for tuning and testing respectively, and in the second, the newswire part of MT 2006 and 2008 are for tuning and testing. A 5-gram language model is trained on the Xinhua portion of the Gigaword corpus. We report the case-sensitive NIST-BLEU score.

Four single machine translation systems participating in the system combination consist of a BTG-based system using a Max-Entropy based reordering model, a hierarchical phrase-based system, a Moses decoder and a syntax-based system. 10-best unique hypotheses from a single system on the development

SYSTEM	MT 2005	MT 2008(news)
best single	0.3207	0.3016
IHMM*	0.3585(+3.78%)	0.3263(+2.47%)
IncIHMM	0.3639(+4.32%)	0.3320(+3.04%)
GIZA++	0.3438(+2.31%)	0.3166(+1.50%)
PPBD	0.3619(+4.10%)	0.3306(+2.90%)
N-best IHMM	0.3590(+3.83%)	0.3270(+2.54%)
dH+rH	0.3604	0.3284
dH+dT	0.3610	0.3290
dH+rH+dT	0.3609	0.3289
dH+rH+rT	0.3630*(+4.27%)	0.3320$*$(+3.04%)
dH+rH+dT+rT	**0.3682****(+4.75%)	**0.3369****(+3.53%)

Table 2: PPBD is a posterior probabilistic-based decoding (section 5.3). N-best IHMM simulates the Pareto optimal solutions in our method (section 5.3). The last five systems adopt different objective combinations. The improvement percents in parentheses are compared to the best single. dH: directed IHMM, rH: reversed IHMM, dT: directed translation probability, rT: reversed translation probability. ** significance at 0.01 level, and * significance at 0.05 level over the IHMM model.

and test sets are collected as the input of the system combination.

Our baseline systems are described as follows. Two main baseline systems are IHMM based and incremental IHMM (Li et al., 2009). The first system differs from our method just in hypothesis alignment algorithm, and the second combines the first and second module of the system combination pipeline.

Because our method utilizes bidirectional information, we also provide another two alternative systems for comparison, which are GIZA++ based alignment and the posterior probability based alignment (Liang et al., 2006). Finally, we also provide an N-best alignment IHMM system, which combines an N-best alignment list to simulate the Pareto optimal solutions in our method.

The method that linearly combines all objectives is not listed as our baseline like (Duh et al., 2012) does, because their algorithm finds the best weighted solution in a fixed and small solution set, while in our problem, the solution space is a trellis-style structure consisting of an exponential number of solutions, and no efficient algorithms apply here.

The IHMM based alignment utilizes typical settings (He et al., 2008; Feng et al., 2009). The smoothing factor for the surface similarity model, and $\rho = 3$ the controlling factor for the distortion model, $K = 2$. The bilingual probabilistic dictionary is trained in the FBIS corpus which includes about 230k parallel sentence pairs. GIZA++ based system is to run GIZA++ from two directions to align all the hypotheses, and make the intersection using grow-diag-final heuristics (Koehn et al., 2003). The many-to-many alignments are normalized with the same method with ours. Our system employs NSGA-II software to realize the MOEA algorithm. The main parameters, generation number, cross probability and mutation probability, and population size, are empirically set as 100, 0.9, 0.001 and 40, and we examine the influence of difference populations sizes in the full system combination.

5.1 The Quality of Confusion Networks

This experiment shows the relationship between hypothesis alignment and confusion network. Intuitively, we expect a better hypothesis alignment would reduce the error in constructing confusion networks, and then improve the final translation quality.

We first use the *alignment error rate* (AER) (Och and Ney, 2000), which is widely used to measure the quality of hypothesis alignment. The smaller, the better. For convenience, we only examine exact literal matching. IHMM based alignment reaches around 0.15 in AER, and our method 0.145.

As the AER may not vividly reflect the relations between alignment and the final BLEU of systems, and the quality of confusion network is hard to measure directly, we assume that the quality of confusion networks could be measured by the oracle hypotheses that could be generated from them. We test the BLEU of the oracle hypotheses.

From this angle, we demonstrate several oracle BLEU of CNs generated from some conventional alignment algorithms. The results are shown in Table 3.

We find the confusion network from IHMM based alignment (He et al., 2008) is better than that from TER based alignment (Rosti et al., 2007b) by about 1 point in both two datasets. These quantities agree with the final improvements in the BLEU score in (He et al., 2008). As confusion networks from MOEA based alignment also show superiority over

alignment	MT02	MT05
GIZA++	0.5690	0.5228
TER	0.5720	0.5270
IHMM	0.5883	0.5382
IncIHMM	0.5931	0.5453
MOEA	**0.6017**	**0.5526**

Table 3: Oracle BLEUs of CNs. GIZA++: invoking GIZA++ software. TER: minimum translation edit rate. IHMM: indirect hidden markov model. IncIHMM: incremental indirect hidden markov model. MOEA: multi-objective evolution algorithm.

that from IHMM based in the oracle BLEU, we expect our final translation quality would be improved.

In Table 3, GIZA++ and TER perform similarly, because the former is more capable of tackling many-to-many alignments over the latter, while latter based might obtain relatively more precise alignment information. Both of the two do not consider synonym matching compared to IHMM.

Our method and IncIHMM overpass IHMM on this metric due to different strategies. Obtaining better hypothesis alignment or better construction of confusion networks benefit the quality of CNs.

5.2 Different Objective Combinations

As our framework is convenient to support different alignment information, we test the influence of different objective combinations to the final translation quality. We adopt four objectives to depict the candidate alignment, directed IHMM probability (dH), reversed IHMM probability (rH), directed alignment probability (dT), and reversed alignment probability (rT). Table 2 demonstrates all the results.

We can see that the IHMM based system outperforms the GIZA++ based system by about 1-1.5 points in BLEU, which agrees with the difference of oracle BLEU in Table 1. From (He et al., 2008), the IHMM based system outperforms the TER based by 1 point, which also agrees with our results in Table 1. Our system, using dH + rH + dT + rT, improves BLEU score by about 1 points over the IHMM based system. This comparison verifies our assumption, improving the quality of the confusion network does improve system performance.

The different feature combinations exhibit interesting results. The system with dH + rH + dT is 0.05 point better than the system with dH + rH, and the system dH + rH + rT is 0.3 point better than system with dH + rH, so the contributions of feature dT and rT are 0.05 and 0.3 respectively. While the two features are used together in the fourth system, the contribution is about 0.8 point, rather than 0.35. This phenomenon also proves the correlations between different features.

Our method explores a way to integrate GIZA++ and IHMM, and is supportive of useful features. Compared to the classic and powerful IHMM based system, we obtained an improvement of 0.97 points on MT 05 and 1.06 points on news of MT 2008, and equivalently over the best single system by 4.75 points and 3.53 points respectively. More, compared with the incremental IHMM, our system also shows moderate improvement, though not much. We hope these two ideas could be effectively combined in the future work.

5.3 Comparison with Other Bi-directional Alignment Methods

Our method introduces multiple alignment information into system combination to obtain improvements, thus it would be interesting to explore other alternative methods for utilizing this information. We provide three alternative methods similar to our motivations, and they fall into two categories.

The first category is from the angle of bi-directional alignment. We use GiZA++ alignment and the posterior probability decoding-based alignment for comparison. The basic idea for the latter is setting a word-to-word alignment $x_{i,j}$ as 1, if its approximate posterior marginal probability $q(x_{i,j}, x) = p_d(x_{i,j}|x, \theta_d) \cdot p_r(x_{i,j}|x, \theta_r)$ is greater than a threshold δ, where p_d and p_r are posterior marginal probabilities from directed and reversed IHMM models, which could be conveniently computed with a forward-backward algorithm, and the δ is tuned on a validation-set optimized data. We just list some δ values to examine its best performance shown in Table 4.

The second class is because our method combines the Pareto optimal solutions that consist of several candidate alignments, thus for fairness we also use a 100-best outputs from the directed IHMM model and conduct the same normalization technique.

The general results are shown in Table 2. We can

δ	**MT 2005**	**MT 2008**
IHMM	0.3585	0.3263
0.15	0.3556	**0.3391**
0.2	**0.3619**	**0.3306**
0.25	0.3575	0.3278
0.3	0.3608	0.3259

Table 4: Posterior decoding. When threshold δ are set to suitable values, simple bi-directional alignment could overpass the baseline.

see that, GIZA++ leads to the worst performance, which can be explained as GIZA++ does not support synonym matching like IHMM. The N-best IHMM has a minor improvement over the IHMM method. We found differences in the N-best list are not obvious enough. In comparison, the posterior decoding method brings relatively significant improvements on both datasets. However, the threshold δ must be selected suitably. Table 4 lists the ideal results, which will be hampered when tuning on a validation set.

All of the three candidate methods can not conveniently support extra alignment information, and a linear model poses restrictions on features to get an efficient decoding, the multi-objective optimization may be a good selection as an inference algorithm in many circumstances.

5.4 Population Size

We test the influence of final translation quality and time consumed by different population size.

population size	**BLEU** MT 2005
20	0.3597
40	0.3682
60	0.3655

Table 5: Big population size consumes more CPU time. In our experiments, we use a multi-thread technique to speed up the alignment, and choose 40 as the parameter to leverage the time and BLEU.

We expect enlarging the population size would improve the translation quality, but the BLEU in population size set as 60 does not overpass when set as 40. We conjecture that, in our code, if the N-best size from IHMM (we set as 50-best) does not reach the population size, we would use randomly generated seeds, which may hamper the performance of MOEA. We also tried a larger population in MOEA, but did not receive obvious improvement on performance.

We exerted a hard restriction on the genes in evolutionary algorithm, that is many-to-many discontiguous alignment is forbidden. This trick speeds up running by about 20 times, and does not harm system performance. Now our method runs about 0.9 seconds to align a pair of hypotheses. In practice, we utilize multi-thread to speed up.

6 Conclusion

In this paper, we explore a multi-objective framework to conveniently support more useful alignment objectives to improve the hypothesis alignment. By a minor modification of the first module in the classic pipeline, we successfully combine GIZA++ and IHMM to obtain significant improvement over a powerful and state-of-the-art IHMM based system. In comparison with another genre of improving system combination by combing adjacent modules of the pipeline, more powerful incremental IHMM here, our system also show moderate improvement. Though, our best system may not overpass He and Toutanova (2009) who combine all the modules into a unified training procedure, we believe our method could boost many work on the higher modules of the pipeline to obtain a further improvement to match their work.

Abstract

Machine translation benefits from system combination. We propose *flexible interaction of hypergraphs* as a novel technique combining different translation models within one decoder. We introduce features controlling the interactions between the two systems and explore three interaction schemes of hiero and forest-to-string models—specification, generalization, and interchange. The experiments are carried out on large training data with strong baselines utilizing rich sets of dense and sparse features. All three schemes significantly improve results of any single system on four testsets. We find that specification—a more constrained scheme that almost entirely uses forest-to-string rules, but optionally uses hiero rules for shorter spans—comes out as the strongest, yielding improvement up to 0.9 (T -B)/2 points. We also provide a detailed experimental and qualitative analysis of the results.

1 Introduction

Recent years have witnessed the success of various statistical machine translation (SMT) models using different levels of linguistic knowledge–phrase (Koehn et al., 2003), hiero (Chiang, 2005), and syntax-based (Liu et al., 2006; Galley et al., 2006). System combination became a promising way of building up synergy from different SMT systems and their specific merits.

Numerous efforts that have been proposed in this field recently can be broadly divided into two categories: *Offline system combination* (Rosti et al., 2007; He et al., 2008; Watanabe and Sumita, 2011; Denero et al., 2010) aims at producing consensus translations from the outputs of multiple individual systems. Those outputs usually contain k-best lists of translations, which only explore a small portion of the entire search space of each system. This issue is well addressed in *joint decoding* (Liu et al., 2009), or *online system combination*, showing comparable improvements to the offline combination methods. Rather than finding consensus translations from the outputs of individual systems, joint decoding works with different grammars at the decoding time. Although limited to individual systems sharing the same search paradigm (e.g. *left-to-right* or *bottom-up*), joint decoding offers many potential advatages: search through a larger space, better efficiency, features designed once for all subsystems, potential cross-system features, online sharing of partial hypotheses, and many others.

Different approaches have different strengths in general–hiero rules are believed to provide reliable lexical coverage, while tree-to-string rules are good at non-local reorderings. Different contexts present different challenges–noun phrases usually follow the adjacency principle, while verb phrases require more challenging reorderings. In this work, we study different schemes of interaction between translation models, reflecting their specific strengths at different (syntactic) contexts. We make five new contributions:

> **First**, we propose a framework for joint decoding by means of flexible combination of translation hypergraphs, allowing for detailed con-

*M. Č and H. M. contributed equally to this work.

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 545–555,
Seattle, Washington, USA, 18-21 October 2013.

trol of interactions between the different systems using soft constraints (Section 3).

Second, we study three interaction schemes– special cases of joint decoding: *generalization*, *specification*, and *interchange* (Section 3.3).

Third, instead of using a tree-to-string system, we use a much stronger forest-to-string system with fuzzy match of nonterminal categories (Section 2.1).

Fourth, we train strong systems on a large-scale data set, and test all methods on four test sets. Experimental results (Section 6) show that our new approach brings improvement of up to 0.9 points in terms of (T − B)/2 over the best single system.

Fifth, we conduct a comprehensive experimental analysis, and find that joint decoding actually prefers tree-to-string rules in both shorter and longer spans. (Section 6.3).

The paper is organized as follows: We briefly review the individual models in Section 2, describe the method of joint decoding using three alternative interaction schemes in Section 3, describe the features controlling the interactions and fuzzy match in Section 4, review the related work in Section 5, and finally, describe our experiments and give detailed discussion of the results in Section 6.

2 Individual Models

Our individual models are two state-of-the-art systems: a hiero model (Chiang, 2005), and a forest-to-string model (Mi et al., 2008; Mi and Huang, 2008).

We will use the following example from Chinese to English to explain both individual and joint decoding algorithms throughout this paper.

tǎolùn	hùi	zěnmeyàng
discussion/NN	will/VV	how/VV
discuss/VV	meeting/NN	

There are several possible meanings based on the different POS tagging sequences:

1: NN VV VV: *How is the discussion going?*
2: VV NN VV: *Discuss about the meeting.*
3: NN NN VV: *How was the discussion meeting?*
4: VV VV VV: *Discuss what will happen.*

id	rule
r_1	VV(tǎolùn) → discuss
r_2	NP(tǎolùn) → the discussion
r_3	NP(hùi) → the meeting
r_4	VP(zěnmeyàng) → how
r'_4	VP(zěnmeyàng) → about
r_5	IP(x_1:NP x_2:VP) → x_2 x_1
r_6	IP(x_1:VV x_2:IP) → x_1 x_2
r_7	IP(x_1:NP VP(VV(hùi) x_2:VP)) → x_2 is x_1 going
r_{11}	X(x_1:X zěnmeyàng) → how was x_1
r_{12}	X(zěnmeyàng) → what
r_{13}	X(tǎolùn hùi) → the discussion meeting
r_{14}	X(hùi x_1:X) → x_1 will happen
r_{15}	S(x_1:S x_2:X) → x_1 x_2

Table 1: Translation rules. Tree-to-string (r_1–r_7), hiero (r_{11}–r_{14}), vanilla glue (r_{15}).

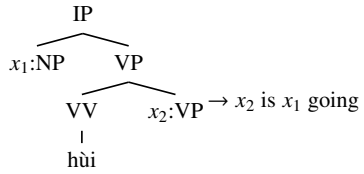

Figure 1: Tree-to-string rule r_7.

Table 1 shows translation rules that can generate all four translations. We will use those rules in the following sections.

2.1 Forest-to-string

Forest-to-string translation (Mi et al., 2008) is a linguistic syntax-based system, which significantly improves the translation quality of the tree-to-string model (Liu et al., 2006; Huang et al., 2006) by using a packed parse forest as the input instead of a single parse tree.

Figure 1 shows a tree-to-string **translation rule** (Huang et al., 2006), which is a tuple $\langle lhs(r), rhs(r), \psi(r)\rangle$, where $lhs(r)$ is the source-side tree fragment, whose internal nodes are labeled by nonterminal symbols (like NP and VP), and whose frontier nodes are labeled by source-language words (like "hùi") or variables from a set $\mathcal{X} = \{x_1, x_2, \ldots\}$; $rhs(r)$ is the target-side string expressed in target-language words (like "going") and variables; and $\psi(r)$ is a mapping from $\mathcal{X}$ to nonterminals. Each

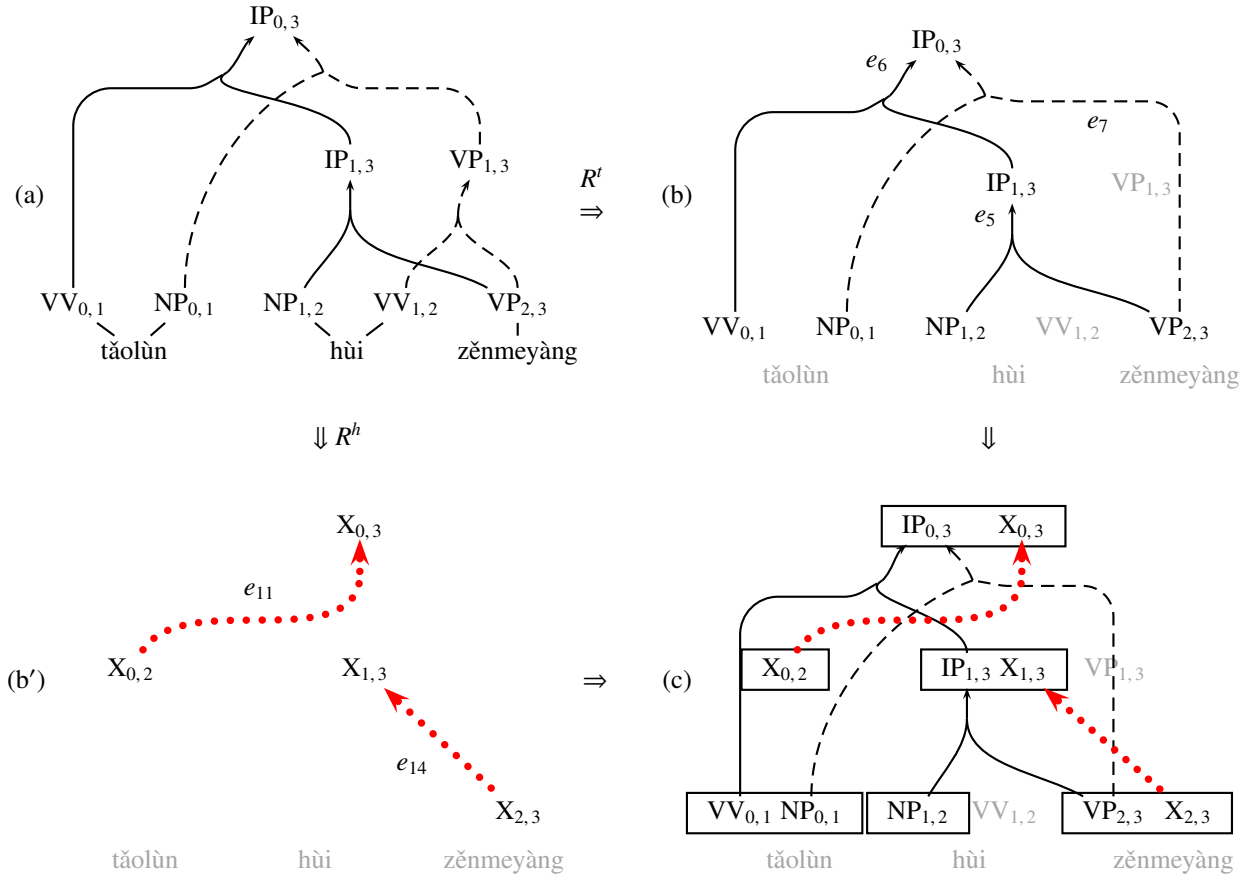

Figure 2: Parse and translation hypergraphs. (a) The parse forest of the example sentence. Solid hyperedges denote the 1-best parse. (b) The corresponding translation forest F^t after applying the tree-to-string translation rule set R^t. Target lexical content is not shown. Each translation hyperedge (e.g. e_7) has the same index as the corresponding rule (r_7). Gray nodes (e.g. $\text{VP}_{1,3}$) became inaccessible due to the insufficient rule coverage. (b′) The translation forest F^h after applying the hierarchical rule set R^h to the input sentence. (c) The combined translation forest H^m obtained by superimposing b and b′. The nodes within each solid box share the same span. See Figure 3 for an example of the internal structure of a box. The forest-to-string system can produce the translation 1 (dashed derivation: r_2, r_4 and r_7) and 2 (solid derivation: r_1, r_3, r'_4, r_5, and r_6). Hierarchical rules generate the translation 3 (r_{11} and r_{13}). The translation 4 is available by using joint decoding at $\text{X}_{1,3} \rightarrow \text{IP}_{1,3}$ with the derivation: r_1, r_6, r_{12}, and r_{14}.

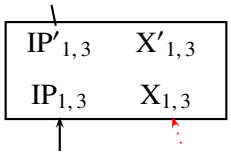
variable $x_i \in \mathcal{X}$ occurs *exactly once* in $lhs(r)$ and *exactly once* in $rhs(r)$. Take the rule r_7 in Figure 1 for example, we have:

$$lhs(r_7) = \text{IP}(x_1\text{:NP VP(VV(hùi) } x_2\text{:VP)}),$$
$$rhs(r_7) = x_2 \text{ is } x_1 \text{ going},$$
$$\psi(r_7) = \{x_1 \mapsto \text{NP}, x_2 \mapsto \text{VP}\}.$$

Typically, a forest-to-string system performs translation in two steps (shown in Figure 2): parsing and decoding. In the parsing step, we convert the source language input into a *parse forest* (a). In the decoding step, we first convert the parse forest into a *translation forest* F^t in (b) by using the fast pattern-matching technique (Zhang et al., 2009). For example, we pattern-match the rule r_7 rooted at $\text{IP}_{0,3}$, in such a way that x_1 spans $\text{NP}_{0,1}$ and x_2 spans $\text{VP}_{2,3}$, and add a translation hyperedge e_7 in (b). Then the decoder searches for the best derivation on the translation forest and outputs the target string.

2.2 Hiero

Hiero (hierarchical phrase-based) model (Chiang, 2005) acquires rules of synchronous context-free grammars (SCFGs) from word-aligned parallel data, and uses plain sequences of words as the input, without any syntactic information.



scheme	interaction edges in supernode
Generalization	IP′1, 3 X′1, 3 / IP1, 3 X1, 3
Specification	IP′1, 3 X′1, 3 / IP1, 3 X1, 3
Interchange	IP′1, 3 X′1, 3 / IP1, 3 X1, 3

Figure 3: Three interaction schemes for joint decoding. Details of the interaction supernode for span $(1, 3)$ shown in Figure 2 (c). Soft constraints control the transitions.

SCFG can be formalized as a set of tuples $\langle lhs(r), rhs(r), \phi(r)\rangle$, where $lhs(r)$ is the source-side one-level CFG, whose root is X or S, and whose frontier nodes are labeled by source-language words (like "hùi") or variables from a set $\mathcal{X} = \{x_1, x_2, \ldots\}$; $rhs(r)$ is the target-side string expressed in target-language words (like "going") and variables; and $\phi(r)$ is a mapping from $\mathcal{X}$ to nonterminals. Table 1 shows examples of hiero rules r_{11}–r_{15}.

Although different on source side, hiero decoding can be formalized equally as forest-to-string decoding: First, pattern-match the input sentence into a *translation forest* F^h. For example, since the rule r_{11} matches "zěnmeyàng" such that x_1 spans the first two words, add a hyperedge e_{11} in Figure 2 (b′). Then search for the best derivation over the translation forest.

3 Joint Decoding

The goal of joint decoding is to let different MT models collaborate within the framework of a single decoder. This can be done by combining translation hypergraphs of the different models at the decoding time, so that online sharing of partial hypotheses overcomes weaknesses and boosts strengths of the systems combined.

As both forest-to-string and hiero produce translation forests that share the same *hypergraph* structure, we first formalize the hypergraph, then we introduce an algorithm to combine different hypergraphs, and finally we describe three joint decoding schemes over the merged hypergraph.

3.1 Hypergraphs

More formally, a hypergraph H is a pair $\langle V, E\rangle$, where V is the set of **nodes**, and E the set of **hyperedges**. For a given sentence $w_{1:l} = w_1 \ldots w_l$, each node $v \in V$ is in the form of $Y_{i,j}$, where Y is a nonterminal in the context-free grammar[1] and i, j, $0 \le i < j \le l$, are string positions in the sentence $w_{1:l}$, which denote the recognition of nonterminal Y spanning the substring from positions i through j (that is, $w_{i+1} \ldots w_j$). Each hyperedge $e \in E$ is a tuple $\langle tails(e), head(e), target(e)\rangle$, where $head(e) \in V$ is the *consequent node* in the deductive step, $tails(e) \in V^*$ is the list of *antecedent nodes*, and $target(e)$ is a list of $rhs(r)$ for rules r such that each rule r has the same $lhs(r)$ pattern-matched at the node $head(e)$. For example, the hyperedge e_7 in Figure 2 (b) is

$$e_7 = \langle (\mathrm{NP}_{0,1}, \mathrm{VP}_{2,3}), \mathrm{IP}_{0,3}, (\mathrm{x}_2 \text{ is } x_1 \text{ going})\rangle,$$

where we can infer the mapping to be

$$\{x_1 \mapsto \mathrm{NP}_{0,1}, x_2 \mapsto \mathrm{VP}_{2,3}\}.$$

We also denote $BS(v)$ to be the set of **incoming hyperedges** of node v, which represent the different ways of deriving v. For example, $BS(\mathrm{IP}_{0,3})$ is a set of e_7 and e_6.

There is also a distinguished **root node** TOP in each hypergraph, denoting the goal item in translation, which is simply $\mathrm{TOP}_{0,l}$.

3.2 Combining Hypergraphs

We enable interaction between translation hypergraphs, such as hiero $F^h = \langle V^h, E^h\rangle$ and forest-to-string $F^t = \langle V^t, E^t\rangle$, on nodes covering the same span (e.g. $\mathrm{IP}_{1,3}$ and $\mathrm{X}_{1,3}$ in Figure 2 (c) grouped in a box). We call such groups *interaction supernodes* and show a detailed example of a supernode for span $(1, 3)$ in Figure 3.

The combination runs in four steps:

[1] In this paper, nonterminal labels X and S denote hiero derivations, other labels are tree-to-string labels.

1. For each node $v = Y_{i,j}, v \in V^h \cup V^t$, we create a new *interaction node* $v' = Y'_{i,j}$ with empty $BS(v')$. For example, we create two nodes, $\mathrm{IP}'_{1,3}$ and $\mathrm{X}'_{1,3}$, at the top of Figure 3.

2. For each hyperedge $e \in BS(v)$, $v \in V^t \cup V^h$, we replace each v in $tails(e)$ with v'. For example, e_7 becomes $\langle(\mathrm{NP}'_{0,1}, \mathrm{VP}'_{2,3}), \mathrm{IP}_{0,3}, (\mathrm{x}_2 \text{ is } x_1 \text{ going})\rangle$.

3. All the nodes and hyperedges form the merged hypergraph F^m, such as in Figure 2 (c).

4. Insert *interaction hyperedges* connecting nodes within each interaction supernode to make F^m connected again.

In the following subsection we present details of interactions and introduce three alternative schemes.

3.3 Three Schemes of Joint Decoding

Interaction hyperedges within each supernode allow the decoder either to stay within the same system (e.g. in hiero using $\mathrm{X}_{1,3} \rightarrow \mathrm{X}'_{1,3}$ in Figure 3), or to switch to the other (e.g. to forest-to-string using $\mathrm{X}_{1,3} \rightarrow \mathrm{IP}'_{1,3}$).

For example, translation 4 can be produced as follows: The source string "zěnmeyàng" is translated by the phrase rule r_{12}. The hiero hyperedge e_{14} combines it with the translation of "hùi", reaching the hiero node $\mathrm{X}_{1,3}$. Using the interaction edge $\mathrm{X}_{1,3} \rightarrow \mathrm{IP}'_{1,3}$ will switch into the tree-to-string model, so that the translation can be completed with the tree-to-string edge e_6 that connects it with a partial tree-to string translation of "tǎolùn" done by r_1.

In order to achieve more precise control over the interaction between tree-to-string and hiero derivations, we propose the following three basic interaction schemes: **generalization**, **specification**, **interchange**. The schemes control the interaction between hiero and tree-to-string models by means of soft constraints. Some schemes may even restrict certain types of transitions. The schemes are depicted in Figure 3 and their details are discussed in the following three subsections.

3.3.1 Specification

The *specification* decoding scheme reflects the intuition of using hiero rules to translate shorter spans and tree-to-string rules to reorder higher-level sentence structures. In other words, the scheme allows one-way switching from the hiero general nonterminal into the more *specific* nonterminal of a tree-to-string rule. Transitions in reverse directions are not allowed. This is achieved by inserting *specification interaction hyperedges e* leading from hiero nodes $\mathrm{X}_{i,j}$ or $\mathrm{S}_{i,j}$ into all tree-to-string interaction nodes $\mathrm{Y}'_{i,j}$ within the same supernode.

3.3.2 Generalization

In some translation domains, hiero outperforms tree-to-string systems, as was shown in experiments in Section 6. While local hiero or tree-to-string reorderings perform well, long distance reorderings proposed by tree-to-string may be too risky (e.g. due to parsing errors), so that monotone concatenation of long sequences[2] is the more reliable strategy. The *generalization* decoding scheme, complementary to the specification, is motivated by the idea of incorporating reliable tree-to-string translations for some sequences into a strong hiero translation system. This is achieved by inserting *generalization interaction hyperedges e* leading from tree-to-string nodes $\mathrm{Y}_{i,j}$ nodes into *general* hiero interaction nodes $\mathrm{X}'_{i,j}$ and $\mathrm{S}'_{i,j}$ within the same supernode.

3.3.3 Interchange

The *interchange* decoding scheme is a union of the two previous approaches. Any derivation can freely combine hiero and tree-to-string productions. Both *specification* and *generalization interaction hyperedges* are inserted leading from all hiero and tree-to-string nodes $\mathrm{X}_{i,j}$, $\mathrm{S}_{i,j}$, and $\mathrm{Y}_{i,j}$ into all interaction nodes $\mathrm{X}'_{i,j}$, $\mathrm{S}'_{i,j}$, and $\mathrm{Y}'_{i,j}$.

3.4 Fuzzy match

The translation rule set cannot usually cover all hyperedges in the parse forest, thus some nodes become inaccessible in the translation forest (e.g. $\mathrm{VP}_{1,3}$ in Figure 2). However, in the parse forest, as opposed to a 1-best tree, we can find other nodes spanning the same sequence $w_{i:j}$ (e.g. node $\mathrm{IP}_{1,3}$). In order to re-enable inaccessible nodes and to increase the variability of the translation forest, we allow reaching them from the other tree-to-string

[2]Monotone glue is the only possibility for very long spans exceeding the hiero *maxParse* treshold.

nodes within the same interaction node. This can be achieved by adding *fuzzy hyperedges* between every tree-to-string state $Y_{i,j}$ and a differently labeled tree-to-string interaction state $Z'_{i,j}$. For example, in the span (0,1), we have a fuzzy hyperedge $\mathrm{VV}_{0,1} \rightarrow \mathrm{NP}'_{0,1}$.

While interaction hyperedges combine different translation models, fuzzy hyperedges combine different derivations within the same (tree-to-string) model.

4 Interaction Features

Our baseline systems use the log-linear framework to estimate the probability $P(D)$ of a derivation D from features ϕ_i and their weights λ_i as $P(D) \propto \exp\left(\sum_i \lambda_i \phi_i\right)$. Similarly as Chiang et al. (2009), our systems use tens of dense (e.g. language models, translation probabilities) and thousands of sparse (e.g. lexical, fertility) features.

The features related to the joint decoding experiments are the costs for *specification*, *generalization*, *interchange*, and the *fuzzy match*. Let L^t be the set of the labels used by the source language parser and $L^h = \{\mathrm{S},\mathrm{X}\}$ be the labels used by hiero.

The **generalization feature**

$$\phi_{Y \rightarrow Z} = |\{e; e \in D, \exists i, j \; tails(e) = \{\mathrm{Y}_{i,j}\} \wedge head(e) = \mathrm{Z}'_{i,j}\}| \quad (1)$$

is the total number of generalization hyperedges in D going from tree-to-string states $Y \in L^t$ to hiero states $Z' \in L^h$.

The **specification feature**

$$\phi_{Z \rightarrow Y} = |\{e; e \in D, \exists i, j \; tails(e) = \{\mathrm{Z}_{i,j}\} \wedge head(e) = \mathrm{Y}'_{i,j}\}| \quad (2)$$

is the total number of specification hyperedges in D going from hiero states $Z \in L^h$ to tree-to-string states $Y' \in L^t$.

The **interchange feature** is implemented by enabling the generalization and specification features at the same time for both tuning and testing.

The **fuzzy match feature**

$$\phi_{U \rightarrow W} = |\{e; e \in D, \exists i, j \; tails(e) = \{\mathrm{U}_{i,j}\} \wedge head(e) = \mathrm{W}'_{i,j}\}| \quad (3)$$

is the total number of fuzzy match hyperedges in D going from tree-to-tree states $U \in L^t$ to tree-to-string states $W' \in L^t$. [3]

We use MIRA to obtain weights for the new features by tuning on the development set. The number of new parameters to tune can be estimated as $|L^h| \times |L^t|$ for generalization and specification, and $2 \times |L^h| \times |L^t|$ for interchange. For the fuzzy match of tree-to-string nonterminals we have $|L^t| \times |L^t|$ parameters organized as a sparse matrix, since we only consider combinations on nonterminal labels that cooccur in the data.[4]

5 Related Work

From the previous explorations of online translation model combination, we see the work of Liu et al. (2009) proposing an unconstrained combination of hiero and tree-to-string models as a special configuration of our framework, and we also replicate it.

Denero et al. (2010) combine translation models even with different search paradigms. Their approach is different, since their component systems do not interact at decoding time, instead, each of them provides its weighted translation forest first, the forests are then combined to infer a new combination model.

6 Experiment

In this section we describe the setup, present results, and analyze the experiments. Finally, we propose future directions of research.

[3] Here we allow $U = W$, which can be viewed in such a way that exact match is a special case of fuzzy match.

[4] We also carried out an alternative experiment with only three fuzzy match features estimated from the training data parse forest by Naïve Bayes by observing all spans in the training data, accumulating counts $C_s(U)$ and $C_s(U, W)$ of nonterminals (or pairs of nonterminals) heading the same span s. The first two features (one for each direction) are based on conditional probabilities:

$$\phi_{(U|W)} = -\log\left(\frac{\sum_{s \in spans} C_s(U, W)}{\sum_{s \in spans} C_s(W)}\right). \quad (4)$$

The third feature is based on joint probability:

$$\phi_{(U,W)} = -\log\left(\frac{\sum_{s \in spans} C_s(U, W)}{\sum_{s \in spans, A, B \in L^t} C_s(A, B)}\right). \quad (5)$$

The average performance drops by 0.1 (T -B)/2 points, compared to the interchange eperiment.

Table 2: All results of single and joint decoding systems.

6.1 Setup

The training corpus consists of 16 million sentence pairs available within the DARPA BOLT Chinese-English task. The corpus includes a mix of newswire, broadcast news, webblog and comes from various sources such as LDC, HK Law, HK Hansard and UN data. The Chinese text is segmented with a segmenter trained on CTB data using conditional random fields (CRF). Language models are trained on the English side of the parallel corpus, and on monolingual corpora, such as Gigaword (LDC2011T07) and Google News, altogether comprising around 10 billion words.

We use a modified version of the Berkeley parser (Petrov and Klein, 2007) to obtain a parse forest for each training sentence, then we prune it with the marginal probability-based inside-outside algorithm to contain only $3n$ CFG nodes, where n is the sentence length. Finally, we apply the forest-based GHKM algorithm (Mi and Huang, 2008; Galley et al., 2004) to extract tree-to-string translation rules from forest-string pairs.

In the decoding step, we prune the input hypergraphs to $10n$ nodes before we use fast pattern-matching (Zhang et al., 2009) to convert the parse forest into the translation forest.

We tune on 1275 sentences, each with 4 references, from the LDC2010E30 corpus, initially released under the DARPA GALE program.

All MT experiments are optimized with MIRA (Crammer et al., 2006) to maximize (T -B)/2.

We test on four different test sets: GALE-web test set from LDC2010E30 corpus (1239 sentences, 4 references), P1R6-web test set from LDC2012E124 corpus (1124 sentences, 1 reference), NIST MT08 newswire portion (691 sentences, 4 references), and NIST MT08 web portion (666 sentences, 4 references).

6.2 Results

Table 2 shows all results of single and joint decoding systems. The B score of the single hiero baseline is 39.2 on MT08-news, showing that it is a strong system. The single F2S baseline achieves comparable scores on all four test sets.

Then, for reference, we present results of joint Hiero and T2S decoding, which is, to our knowledge, a strong and competitive reimplementaion of the work described by Liu et al. (2009). Finally, we present results of joint decoding of hiero and F2S in three interaction schemes: generalization, specification, and interchange.

All three combination schemes significantly improve results of any single system on all four testsets. On average and measured in (T -B)/2, our systems improve the best single system by 0.4 (generalization), 0.7 (specification), and 0.6 (interchange).

The specification comes out as the strongest interaction scheme, beating the second interchange on 2 testsets by 0.1 and 0.4 (T -B)/2 points and on 3 testsets by 0.2 B points.

6.3 Discussion of Results

Interpretations of model behavior with thousands of parameters that may possibly overlap and interfere should be always attempted with caution. In this section we highlight some interesting observations, ac-

companying them with our subjective judgements and speculations.

Table 3 shows the specification and generalization features tuned for the three combination schemes, then sorted by their weights $\lambda_{X\to Y}$ or $\lambda_{Y\to X}$. Features shown at the top of the table are very expensive (the system tries to avoid them), while inexpensive features are at the bottom (the system is encouraged to use them).

The most expensive interactions for the **specification** belong to constituents (IP, VP) that usually occur higher in a syntactic tree (see Figure 4 for average span lengths of selected syntactic labels), and often require non-local reorderings. This indicates that the decoder is discouraged from switching from hiero into F2S derivation at these higher-level spans.

rule type	Generalization		Specification		Interchange	
F2S	18,807	58%	19,399	70%	18,400	61%
Hiero	3,730	12%	2,330	8%	3,133	10%

total	32,178		27,784		30,115	

Table 4: Rule counts on GALE-web test set.

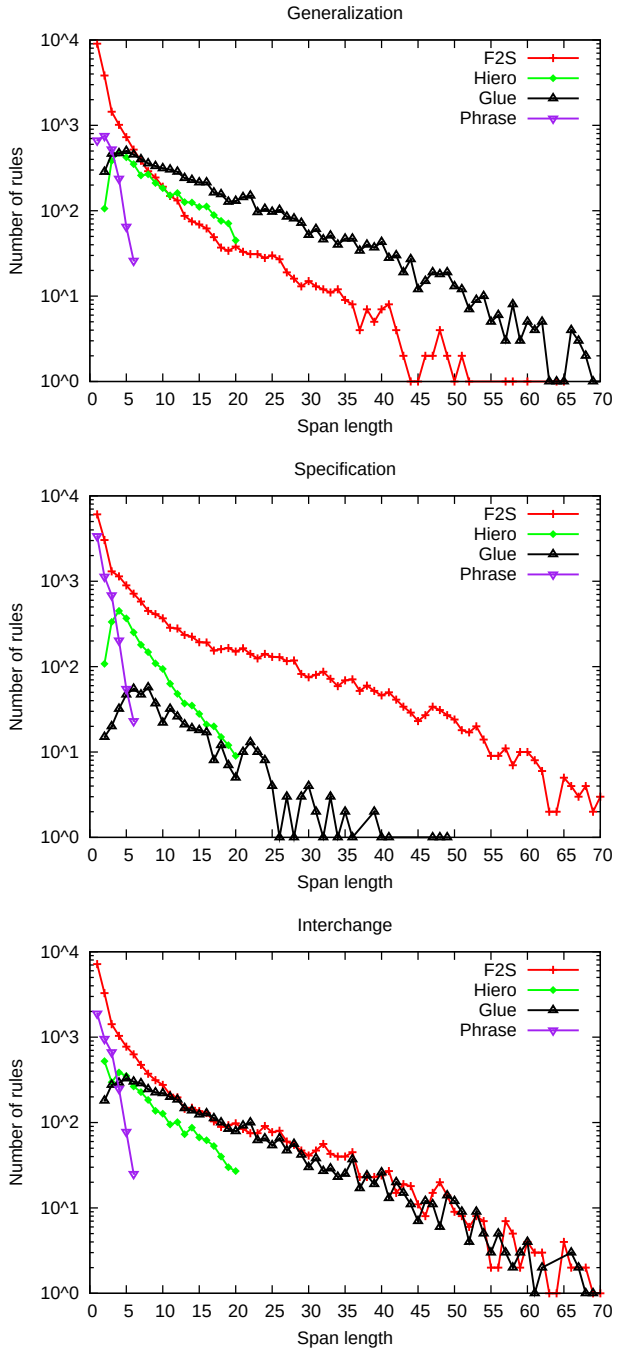

Figure 5: Rule distributions on GALE-web test set.

The third most expensive feature belongs to a part-of-speech tag—the preterminal VV. We may hypothesize that it shows the importance of lexical information for the precision of reordering typically carried out within (parent) VP nodes, and/or the importance of POS information for succesful disambiguation of word senses in translation. Ideally, the system can use a VP rule with a lexicalized VV. Less preferably, the VV part has to be translated by another T2S rule (losing the lexical constraint). In the worst case, the system has to use a hiero hypothesis to translate the VV part (losing the syntactic constraint), risking imprecise translation, since the hiero rule is not constrained to senses corresponding to the source POS VV. Again, the high penalty discourages from using the hiero derivation in this context.

On the other hand, the bottom of the table shows labels that encourage using hiero–DP, PP, DNP, ADJP, etc.–shorter phrases that tend to be monotone and less ambiguous.

Similar interpretations seem plausible when examining the **generalization** experiment. Expensive features related to preterminals (NR, NN, CD) may suggest two alternative principles: First, using F2S rules for thes POS categories and then switching to hiero is discouraged, since these contexts are more reliably handled by hiero due to better lexical coverage and common adjacency in nominal categories. Second, since there is only one attempt to switch from F2S derivation to hiero, letting F2S complete even larger spans (and maybe switching to hiero later) is favorable.

The tail of generalization feature weights is more difficult to interpret. The discount on VP encourages decoder to use F2S for entire verb phrases before switching to hiero, on the other hand, other verb-related preterminals occupy the tail as well, hurrying into early switching from F2S to hiero.

Finally, the feature weights tuned for the **interchange** experiment are divided into two subcolumns. Both generalization and specification weights show similar trends as in the previous two interaction schemes, although blurred (VP and IP descending from the absolute top). Since transitions in both ways are allowed, the search space is bigger and the system may behave differently. It is even possible for a path in the hypergraph to zigzag between F2S and hiero nodes to collect interaction discounts, "diluting" the syntactic homogeneity of the hypothesis.

Figure 5 and Tables 4 and 5 show rule distributions, total rule counts, and numbers of interactions of different types for the three interaction schemes on the GALE-web test set. The scope of phrase rules is limited to 6 words. The scope of hiero rules is limited to 20 words by the commonly used maxParse parameter, leaving longer spans to the glue rule.

The trends of F2S and glue rules show the most obvious difference. In the generalization, F2S rules translate spans of up to 50 words. Glue rules prevail on spans longer then 7 words. The specification is reversed, pushing the longest scope of hiero and glue rules down to 40 words, completing the longest sentences entirely with F2S. The interchange comes out as a mixture of the previous two trends.

All three schemes prefer using F2S rules at shorter spans, to the contrary of our original assumption of phrasal and hiero rules being stronger on local contexts *in general*. Here we may refer again to the specification feature weights for preterminals VV, NR, CC and P in Table 3 and to our previously stated hypothesis about the importance of preserving lexical and syntactic context.

Hiero rules usage on longer spans drops fastest for specification, slowest for generalization, and in between for interchange.

It is also interesting to notice the trends on very short spans (2–4 words) shown by rule distributions and reflected in numbers of interaction types. While specification often transitions from a single phrase rule directly into F2S, the interchange has relatively higher counts of hiero rules, another sign of the hiero and F2S interaction.

Synthesizing from several sources of indications is difficult, however, we arrive at the conclusion that joint decoding of hiero and F2S significantly improves the performance. While the single systems show similar performance, their roles are not balanced in joint decoding. It seems that the role of hiero consists in enabling F2S in most contexts.

We have focused on three special cases of interaction. We see a great potential in further studies of other schemes, allowing more flexible interaction than simple specification, but still more constrained than the interchange. It seems also promising to refine the interaction modeling with features taking into account more information than a single syntactic label, and to explore additional ways of parameter estimation.

7 Conclusion

We have proposed *flexible interaction of hypergraphs* as a novel technique combining hiero and forest-to-string translation models within one decoder. We have explored three basic interaction schemes—*specification*, *generalization*, and *interchange*—and described soft constraints controlling the interactions. We have carried out experiments on large training data and with strong baselines. Of the three schemes, the specification shows the highest gains, achieving improvements from 0.5 to 0.9 (T -B)/2 points over the best single system. We have conducted a detailed analysis of each system output based on different indications of interactions, discussed possible interpretations of results, and finally offered our conclusion and proposed future lines of research.

Abstract

This paper describes a factored approach to incorporating soft source syntactic constraints into a hierarchical phrase-based translation system. In contrast to traditional approaches that directly introduce syntactic constraints to translation rules by explicitly decorating them with syntactic annotations, which often exacerbate the data sparsity problem and cause other problems, our approach keeps translation rules intact and factorizes the use of syntactic constraints through two separate models: 1) a syntax mismatch model that associates each nonterminal of a translation rule with a distribution of tags that is used to measure the degree of syntactic compatibility of the translation rule on source spans; 2) a syntax-based reordering model that predicts whether a pair of sibling constituents in the constituent parse tree of the source sentence should be reordered or not when translated to the target language. The features produced by both models are used as soft constraints to guide the translation process. Experiments on Chinese-English translation show that the proposed approach significantly improves a strong string-to-dependency translation system on multiple evaluation sets.

1 Introduction

Hierarchical phrase-based translation models (Chiang, 2007) are widely used in machine translation systems due to their ability to achieve local fluency through phrasal translation and handle non-local phrase reordering using synchronous context-free grammars. A large number of previous works have tried to introduce grammaticality to the translation process by incorporating syntactic constraints into hierarchical translation models. Despite some differences in the granularity of syntax units (e.g., tree fragments (Galley et al., 2004; Liu et al., 2006), treebank tags (Shen et al., 2008; Chiang, 2010), and extended tags (Zollmann and Venugopal, 2006)), most previous work incorporates syntax into hierarchical translation models by explicitly decorating translation rules with syntactic annotations. These approaches inevitably exacerbate the data sparsity problem and cause other problems such as increased grammar size, worsened derivational ambiguity, and unavoidable parsing errors (Hanneman and Lavie, 2013).

In this paper, we propose a factored approach that incorporates soft source syntactic constraints into a hierarchical string-to-dependency translation model (Shen et al., 2008). The general ideas are applicable to other hierarchical models as well. Instead of enriching translation rules with explicit syntactic annotations, we keep the original translation rules intact, and factorize the use of source syntactic constraints through two separate models.

The first is a *syntax mismatch model* that introduces source syntax into the nonterminals of translation rules, and measures the degree of syntactic compatibility between a translation rule and the source spans it is applied to during decoding. When a hierarchical translation rule is extracted from a parallel training sentence pair, we determine a tag for each nonterminal based on the dependency parse of the source sentence. Instead of fragmenting rule statistics by directly labeling nonterminals with tags,

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 556–566,
Seattle, Washington, USA, 18-21 October 2013.

we keep the original string-to-dependency translation rules intact and associate each nonterminal with a distribution of tags. That distribution is then used to measure the syntactic compatibility between the syntactic context from which the translation rule is extracted and the syntactic analysis of a test sentence.

The second is a *syntax-based reordering model* that takes advantage of phrasal cohesion in translation (Fox, 2002). The reordering model takes a pair of sibling constituents in the source parse tree as input, and uses source syntactic clues to predict the ordering distribution (straight vs. inverted) of their translations on the target side. The resulting ordering distribution is used in the decoder at the word pair level to guide the translation process. This separate reordering model allows us to utilize source syntax to improve reordering in hierarchical translation models without having to explicitly annotate translation rules with source syntax.

Our results show that both the syntax mismatch model and the syntax-based reordering model are able to achieve significant gains over a strong Chinese-English MT baseline. The rest of the paper is organized as follows. Section 2 discusses related work in the literature. Section 3 provides an overview of our baseline string-to-dependency translation system. Section 4 describes the details of the syntax mismatch and syntax-based reordering models. Experimental results are presented in Section 5. The last section concludes the paper.

2 Related Work

Attempts to use rich syntactic annotations do not always result in improved performance when compared to purely hierarchical models that do not use linguistic guidance. For example, as shown in (Mi and Huang, 2008), tree-to-string translation models (Huang et al., 2006) only start to outperform purely hierarchical models when significant efforts were made to alleviate parsing errors by using forest-based approaches in both rule extraction and decoding. Using only syntactic phrases is too restrictive in phrasal translation as many useful phrase pairs are not syntactic constituents (Koehn et al., 2003). The syntax-augmented translation model of Zollmann and Venugopal (2006) annotates nonterminals in hierarchical rules with thousands of extended syntactic categories in order to capture the syntactic variations of phrase pairs. This results in exacerbated data sparsity problems, partially due to the requirement of exact matches in nonterminal substitutions between translation rules in the derivation. Several solutions were proposed. Shen et al. (2009) and Chiang (2010) used soft match features to explicitly model the substitution of nonterminals with different labels; Venugopal et al. (2009) used a preference grammar to soften the syntactic constraints through the use of a preference distribution of syntactic categories; and recently Hanneman and Lavie (2013) proposed a clustering approach to reduce the number of syntactic categories. Our proposed syntax mismatch model associates nonterminals with a distribution of tags. It is similar to the preference grammar in (Venugopal et al., 2009); however, we use treebank tags and focus on the syntactic compatibility between translation rules and the source sentence. The work of Huang et al. (2010) is most similar to ours, with the main difference being that their syntactic categories are latent and learned automatically in a data driven fashion while we simply use treebank tags based on dependency parsing. Marton and Resnik (2008) also exploited soft source syntax constraints without modifying translation rules. However, they focused on the quality of translation spans based on the syntactic analysis of the source sentence, while our method explicitly models the syntactic compatibility between translation rules and source spans.

Most research on reordering in machine translation focuses on phrase-based translation models as they are inherently weak at non-local reordering. Previous efforts to improve reordering for phrase-based systems can be largely classified into two categories. Approaches in the first category try to reorder words in the source sentence in a preprocessing step to reduce reordering in both word alignment and MT decoding. The reordering decisions are either made using manual or automatically learned rules (Collins et al., 2005; Xia and McCord, 2004; Xia and McCord, 2004; Genzel, 2010) based on the syntactic analysis of the source sentence, or constructed through an optimization procedure that uses feature-based reordering models trained on a word-aligned parallel corpus (Tromble and Eisner, 2009;

Khapra et al., 2013). Approaches in the second category try to explicitly model phrase reordering in the translation process. These approaches range from simple distance based distortion models (Koehn et al., 2003) that globally penalizes reordering based on the distorted distance, to lexicalized reordering models (Koehn et al., 2005; Al-Onaizan and Papineni, 2006) that assign reordering preferences of adjacent phrases for individual phrases, and to hierarchical reordering models (Galley and Manning, 2008; Cherry, 2013) that handle reordering preferences beyond adjacent phrases. Although hierarchical translation models are capable of handling non-local reordering, their accuracy is far from perfect. Xu et al. (2009) showed that the syntax-augmented hierarchical model (Zollmann and Venugopal, 2006) also benefits from reordering source words in a pre-processing step. Explicitly adding syntax to translation rules helps with reordering in general, but it introduces additional complexities, and is still limited by the context-free nature of hierarchical rules. Our work exploits an alternative direction that uses an external reordering model to improve word reordering of hierarchical models. Gao et al. (2011), Xiong et al. (2012), and Li et al. (2013) also studied external reordering models for hierarchical models. However, they focused on specific word pairs such as a word and its dependents or a predicate and its arguments, while our proposed general framework considers all word pairs in a sentence. Our syntax-based reordering model exploits phrasal cohesion in translation (Fox, 2002) by modeling the reordering of sibling constituents in the source parse tree, which is similar to the recent work of Yang et al. (2012). However, the latter focuses on finding the optimal reordering of sibling constituents before MT decoding, while our proposed model generates reordering features that are used together with other MT features to determine the optimal reordering during MT decoding.

3 String-to-Dependency Translation

Our baseline translation system is based on a string-to-dependency translation model similar to the implementation in (Shen et al., 2008). It is an extension of the hierarchical translation model of Chiang et al. (2006) that requires the target side of a phrase pair to have a well-formed dependency structure, defined as either of the two types:

- *fixed structure*: a single rooted dependency sub-tree with each child being a complete constituent. In this case, the phrase has a unique head word inside the phrase, i.e., the root of the dependency sub-tree. Each dependent of the head word, together with all of its descendants, is either completely inside the phrase or completely outside the phrase. For example, the phrase *give him* in Figure 1 (a) has a fixed dependency structure with head word *give*.

- *floating structure*: a sequence of siblings with each being a complete constituent. In this case, the phrase is composed of a sequence of sibling constituents whose common parent is outside the phrase. For example, the phrase *him that brown coat* in Figure 1 is a floating structure whose common parent *give* is not in the phrase.

Requiring the target side to have a well-formed dependency structure is less restrictive than requiring it to be a syntactic constituent, allowing more translation rules to be extracted. However, it still results in fewer rules than pure hierarchical translation models and might hurt MT performance. The well-formed dependency structure on the target side makes it possible to introduce syntax features during decoding. Shen et al. (2008) obtained significant improvements from including a dependency language model score in decoding, outweighing the negative effect of the dependency constraint. Shen et al. (2009) proposed an approach to label each nonterminal, which can be either on the left-hand-side (LHS) or the right-hand-side (RHS) of the rule, with the head POS tag of the underlying target phrase if it has a fixed dependency structure[1], and measure the mismatches between nonterminal labels when a RHS nonterminal of a rule is substantiated with the LHS nonterminal of another rule during decoding. This also resulted in further improvements in MT performance. Figure 1 (c) shows an example string-to-dependency translation rule in our baseline system.

[1]Nonterminals corresponding to floating structures keep their default label "X" as experiments show that it is not beneficial to label them differently.

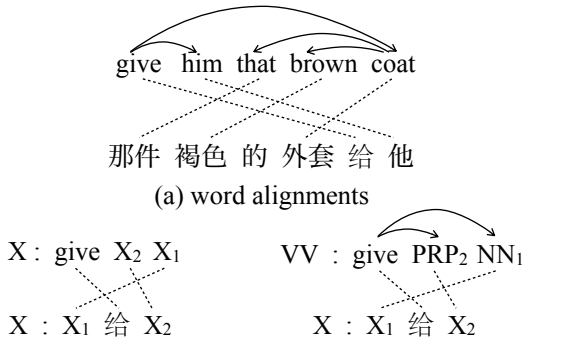

Figure 1: An example of extracting a string-to-dependency translation rule from word alignments. The nonterminals on the target side of the hierarchical rule (b) all correspond to fixed dependency structures and so they are labeled by the respective head tag in the string-to-dependency rule (c).

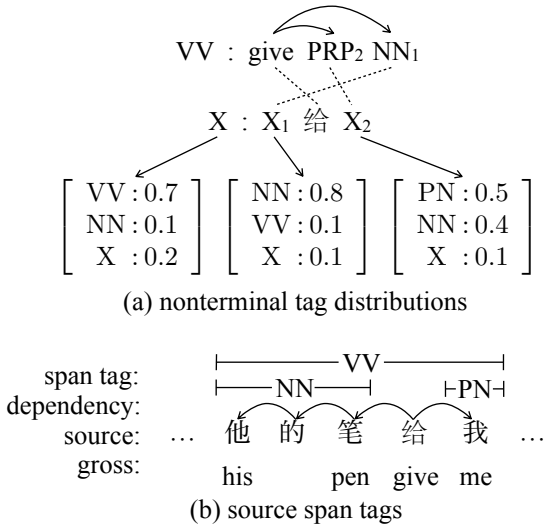

Figure 2: Example distribution of tags for nonterminals on the source side (a) and example tags for source spans (b)

4 Factored Syntactic Constraints

Although the string-to-dependency formulation helps to improve the grammaticality of translations, it lacks the ability to incorporate source syntax into the translation process. We next describe a factored approach to address this problem by utilizing source syntax through two models: one that introduces syntactic awareness to translation rules themselves, and another that focuses on reordering based on the syntactic analysis of the source.

4.1 Syntax Mismatch Model

A straightforward method to introduce awareness of source syntax to translation rules is to apply the same well-formed dependency constraint and head POS annotation on the target side of string-to-dependency translation rules to the source side. However, as discussed earlier, this would significantly reduce the number of rules that can be extracted, exacerbate data sparsity, and cause other problems, especially given that the target side is already constrained by the dependency requirement.

A relaxed method is to bypass the dependency constraint and only annotate source nonterminals whose underlying phrase is a fixed dependency structure with the head POS tag of the phrase. This method would still extract all of the rules that can be extracted from the baseline string-to-dependency translation model, but the extra annotation on nonterminals can split a rule into multiple rules, with the only difference being the nonterminal labels on the source side. Unfortunately, our experiments have shown that even this moderate annotation results in significantly lower translation quality due to the fragmentation of translation rules, and the increased derivational ambiguity. We have also tried to include some source tag mismatch features (with details described later) to measure the syntactic compatibility between the nonterminal labels of a translation rule and the corresponding tags of source spans. This improves translation accuracy, but not enough to compensate for the performance drop caused by annotating source nonterminals.

Our proposed method introduces syntax to translation rules without sacrificing performance. Instead of imposing dependency constraints or explicitly annotating source nonterminals, we keep the original string-to-dependency translation rules intact and associate each nonterminal on the source side with a distribution of tags. The tags are determined based on the dependency structure of training samples. If the underlying source phrase of a nonterminal is a fixed dependency structure in a training sample, we use the head POS tag of the phrase as the tag. Otherwise, we use the default tag "X" to denote float-

Feature	Condition	Value
f_1	t_s = X	P(t_r = X)
f_2	t_s = X	P($t_r \neq$ X)
f_3	$t_s \neq$ X	P(t_r = X)
f_4	$t_s \neq$ X	P($t_r = t_s$)
f_5	$t_s \neq$ X	P($t_r \neq$ X, $t_r \neq t_s$)

Table 1: Source tag mismatch features. The default value of each feature is zero if the source span tag t_s does not match the condition

ing structures and dependency structures that are not well formed. As a result, we still extract the same set of rules as in the baseline string-to-dependency translation model, and also obtain a distribution of tags for each nonterminal. Figure 2 (a) illustrates the example tag distributions of a string-to-dependency translation rule. The tag distributions provide an approximation of the source syntax of the training data from which the translation rules are extracted. They are used to measure the syntactic compatibility between a translation rule and the source spans it is applied to. At decoding time, we parse the source sentence and assign each span a tag in the same way as it is done during rule extraction, as shown in the example in Figure 2 (b). When a translation rule is used to expand a derivation, for each nonterminal (which can be on the LHS or RHS) on the source side of the rule, five source tag mismatch features are computed based on the distribution of tags P(t_r) on the rule nonterminal, and the tag t_s on the corresponding source span. The features are defined in Table 1. We use soft features instead of hard syntactic constraints, and allow the tuning process to choose the appropriate weight for each feature. As shown in Section 5, these source syntax mismatch features help to improve the baseline system.

4.2 Syntax-based Reordering Model

Most previous research on reordering models has focused on improving word reordering for statistical phrase-based translation systems (e.g., (Collins et al., 2005; Al-Onaizan and Papineni, 2006; Tromble and Eisner, 2009)). There has been less work on improving the reordering of hierarchical phrase-based translation systems (see (Xu et al., 2009; Gao et al., 2011; Xiong et al., 2012) for a few exceptions), except through explicit syntactic annotation of translation rules. It is generally assumed that hierarchical models are inherently capable of handling both local and non-local reorderings. However, many hierarchical translation rules are noisy and have limited context, and so may not be able to produce translations in the right order.

We propose a general framework that incorporates external reordering information into the decoding process of hierarchical translation models. To simplify the presentation, we make the assumption that every source word translates to one or more target words, and that the translations for a pair of source words is either straight or inverted. We discuss the general case later. Given a sentence $w_1, \cdots, w_n$, suppose we have a separate reordering model that predicts $\mathrm{P}_{\text{order}}(o_{ij})$, the probability distribution of ordering $o_{ij} \in \{\text{straight}, \text{inverted}\}$ between the translations of any source word pair (w_i, w_j). We can measure the goodness of a given hypothesis h with respect to the ordering predicted by the reordering model as the sum of log probabilities[2] for ordering each pair of source words, as defined in Equation 1:

$$f_{\text{order}}(h) = \sum_{1 \leq i < j \leq n} \log \mathrm{P}_{\text{order}}(o_{ij} = o_{ij}^h) \qquad (1)$$

where o_{ij}^h is the ordering between the translations of source word pair (w_i, w_j) in hypothesis h. The reordering score $f_{\text{order}}(h)$ can be computed efficiently through recursion during hierarchical decoding as follows:

- Base case: for phrasal (i.e. non-hierarchical) rules, the ordering of translations for any word pair covered by the source phrase can be determined based on the word alignment of the rule. The value of the reordering score can be simply computed according to Equation 1.
- Recursive case: when a hierarchical rule is used to expand a partial derivation, two types of word pairs are encountered: a) word pairs that are covered exclusively by one of the nonterminals on the RHS of the rule, and b) other

[2] In practice, the log probability is thresholded to avoid negative infinity, which would otherwise result in a hard constraint.

(他, 我)	inverted
(的, 给)	inverted
(的, 我)	inverted
(笔, 给)	inverted
(笔, 我)	inverted
(给, 我)	straight
(他, 的)	previously considered
(他, 笔)	previously considered
(的, 笔)	previously considered

Figure 3: An example rule application (a) with the translation order of new source word pairs covered by the rule shown in (b). The translation order of word pairs covered by X_1 is previously considered and is thus not shown.

word pairs. The reordering scores of the former would be already computed in previous rule applications, and can simply be retrieved from the partial derivation. Word pairs of the latter case are new word pairs introduced by the hierarchical rule, and their ordering can be determined based on the alignment of the hierarchical rule. The value of the reordering score of the new derivation is the sum of the reordering scores retrieved from the partial derivations for the nonterminals and the reordering scores of the new word pairs.

Figure 3 shows an example of determining the ordering of translations when applying a string-to-dependency rule. The alignment in the translation rule is able to fully determine the translation order for all new word pairs introduced by the rule. For example, "笔/pen" is covered by X_1 in the rule and the translation order for X_1 and "给/give" is inverted on the target side. Since "笔/pen" is translated together with other words covered by X_1 as a group, we can determine that the translation order between the source word pair "笔/pen" and "给/give" is also inverted on the target side. The words "他/his", "的", "笔 /pen" are all covered by the same nonterminal X_1 and thus their pairwise reordering scores have already been considered in previous rule applications.

Table 2: Features in the reordering model

In practice, not all source words in a translation rule are translated to a target word; sometimes there is no clear ordering between the translations of two source words. In such cases we use a binary discount feature instead of the reordering feature.

This reordering framework relies on an external model to provide the ordering probability distribution of source word pairs. In this paper, we investigate a simple maximum-entropy reordering model based on the syntactic parse tree of the source sentence. This allows us to take advantage of the source syntax to improve reordering without using syntactic annotations in translation rules. The syntax-based reordering model attempts to predict the reordering probability of a pair of sibling constituents in the source parse tree, building on the fact that syntactic phrases tend to move in a group during translation (Fox, 2002). The reordering model is trained on a word-aligned corpus. For each pair of sibling constituents in the source parse tree, we determine the translation order on the target side based on word alignments. If there is a clear ordering[3], i.e., either straight or inverted, on the target side, we include the context of the constituent pair and its translation order as a sample for training or evaluating the maximum entropy reordering model. Table 2 lists the features of the reordering model.

The ordering distributions of source word pairs are determined based on the ordering distributions of sibling constituent pairs. For each pair of sib-

[3]If the translations overlap with other, the non-overlapping parts are used to determine the translation order.

ling constituents[4] in the parse tree of a source sentence, we compute its distribution of translation order using the reordering model. The distribution is shared among all word pairs covered by the respective constituents, which guarantees that the ordering distribution of any source word pair is computed exactly once. The ordering distributions of source word pairs are then used through the general reordering framework in the decoder to guide the decoding process.

5 Experiments

5.1 Experimental Setup

Our main experiments use the Chinese-English parallel training data and development sets released by the LDC, and made available to the DARPA GALE and BOLT programs. We train the translation model on 100 million words of parallel data. We use a 8 billion words of English monolingual data to train two language models: a trigram language model used in chart decoding, and a 5-gram language model used in n-best rescoring. The systems are tuned and evaluated on a mixture of newswire and web forum text from the development sets available for the DARPA GALE and BOLT programs, with up to 4 independent references for each source sentence. We also evaluate our final systems on both newswire and web text from the NIST MT06 and MT08 evaluations using an experimental setup compatible with the NIST MT12 Chinese-English constrained track. In this setup, the translation and language models are trained on 35 million words of parallel data and 3.8 billion words of English monolingual data, respectively. The systems are tuned on the MT02-05 development sets. All systems are tuned and evaluated on IBM BLEU (Papineni et al., 2002). The baseline string-to-dependency translation system uses more than 10 core features and a large number of sparse binary features similar to the method described in (Chiang et al., 2009). It achieves translation accuracies comparable to the top ranked systems in the NIST MT12 evaluation.

GIZA++ (Och and Ney, 2003) is used for automatic word alignment in all of the experiments. We use Charniak's parser (Charniak and Johnson, 2005) on the English side to obtain string-to-dependency translation rules, and use a latent variable PCFG parser (Huang and Harper, 2009) to parse the source side of the parallel training data as well as the test sentences for extracting syntax mismatch and reordering features. For both languages, dependency structures are read off constituency trees using manual head word percolation rules. We use a lexicon-based longest-match-first word segmenter to tokenize source Chinese sentences. Since the source tokenization used in our MT system is different from the treebank tokenization used to train the Chinese parser, the source sentences are first tokenized using the treebank-trained Stanford Chinese segmenter (Tseng et al., 2005), then parsed with the Chinese parser, and finally projected to MT tokenization based on the character alignment between the tokens. The syntax-based reordering model is trained on a set of Chinese-English manual word alignment corpora released by the LDC[5].

5.2 Syntax Mismatch Model

We first conduct experiments on the GALE/BOLT data sets to evaluate different strategies of incorporating source syntax into string-to-dependency translation rules. As mentioned in Section 4.1, constraining the source side of translation rules to only well-formed dependency structures is too restrictive given that our baseline system already has dependency constraint on the target side. We evaluate the relaxed method that only annotates source nonterminals with the head POS tag of the underlying phrase if the phrase is a fixed dependency structure. As shown in Table 3, nonterminal annotation results in a big drop in performance, decreasing the BLEU score of the baseline from 27.82 to 25.54. This suggests that it is undesirable to further fragment the translation rules. Introducing the syntax mismatch features described in Section 4.1 helps to improve

[4]Note that the constituent pairs used to train the reordering model are filtered to only contain these with clear ordering on the target side, while no such pre-filtering is applied to constituent pairs when applying the reordering model in translation. We leave it to future work to address this mismatch problem.

[5]The alignment corpora are LDC2012E24, LDC2012E72, LDC2012E95, and LDC2013E02. The reordering model can also be trained on automatically aligned data; however, our experiments show that using manual alignments results in a better accuracy for the reordering model itself and more improvements for the MT system.

	BLEU
baseline	27.82
+ tag annotation only	25.54
+ tag annotation, mismatch feat.	25.90
+ tag distribution, mismatch feat.	28.23

Table 3: Effects of tag annotation, tag distribution, and syntax mismatch features on MT performance on the GALE/BOLT data set.

BLEU from 25.54 to 25.90. This improvement is not large enough to compensate for the performance drop caused by annotating the nonterminals.

Our proposed approach, on the other hand, does not modify the translation rules in the baseline system, but only associates each nonterminal with a distribution of tags. For that reason, it does not suffer from the aforementioned problem. It achieves exactly the same performance as the baseline system if no source syntactic constraints are imposed during decoding. When the source syntax mismatch features are used, the proposed approach is able to achieve a gain of 0.41 in BLEU over the baseline system. Table 4 lists the learned weights of the syntax mismatch features after MT tuning. The negative weights of f_1 and f_2 mean that the MT system penalizes source spans that do not have a fixed dependency structure, and it assigns a higher penalty to rules whose nonterminals have a high probability of being extracted from source phrases that do not have a fixed dependency structure. When the source span has a fixed dependency structure, the MT system prefers translation rules that have a high probability of matching the tag on the source span (feature f_4) over the ones that do not match (features f_3 and f_5). This result is consistent with our expectations of the syntax mismatch features.

Feature	Description	Weight
f_1	t_s = X, t_r = X	−1.543
f_2	t_s = X, $t_r \neq$ X	−0.676
f_3	$t_s \neq$ X, t_r = X	0.380
f_4	$t_s \neq$ X, $t_r \neq$ X, $t_r = t_s$	1.677
f_5	$t_s \neq$ X, $t_r \neq$ X, $t_r \neq t_s$	0.232

Table 4: Learned syntax mismatch feature weight

5.3 Syntax-based Reordering Model

Before evaluating the syntax-based reordering model, we would like to establish the upper bound improvement that could be achieved using the general reordering framework for hierarchical translation models. Towards that goal, we conduct an oracle experiment on the GALE/BOLT development set that uses the oracle translation order from the reference as the external reordering model. For each source sentence in the development set, we pair it with the first reference translation (out of up to 4 independent translations). We then add the sentence pairs from the development set to the parallel training data and run GIZA++ to obtain word alignments. We consider the GIZA++ word alignments for the development set to be all correct, and use it to determine the oracle order in the reference translation. For the ordering distribution, we set the log probability of the reference translation order to 0 and the reverse order to -1 to avoid negative infinity. As shown in Table 5, the system tuned and evaluated with the oracle reordering model significantly outperforms the baseline by a large margin of 2.32 in BLEU on the GALE/BOLT test set. This suggests that there is room for potential improvement by using a fairly trained reordering model.

	BLEU
baseline	27.82
+ oracle reorder	30.14
+ syntax reorder	28.40

Table 5: Effects of external reordering features on MT performance on the GALE/BOLT test set.

We next evaluate the syntax-based reordering model. We train the model on manually aligned Chinese-English corpora. Since the tokenization used in the manual alignment corpora is different from the tokenization used in our MT system, the manual alignment is projected to the MT tokenization based on the character alignment between the tokens. Some extraneously tagged alignment links in the manual alignment corpora are not useful for machine translation and are thus removed before projecting the alignment. As described in Section 4.2, the syntax-based reordering method mod-

els the translation order of sibling constituent pairs in the source parse tree. As a result of strong phrasal cohesion (Fox, 2002), we find that 94% of constituent pairs have a clear ordering on the target side. We only retain these constituent pairs for training and evaluating the reordering model. In order to evaluate the accuracy of the maximum entropy reordering model, we divide the manual alignment corpora into 2/3 for training and 1/3 for evaluation. A baseline that only chooses the majority order (i.e. straight) has an accuracy of 69%, while the syntax-based reordering model improves the accuracy to 79%.

The final reordering model used in MT is trained on all of the samples extracted from the manual alignment corpora. As shown in Table 5, the syntax-based reordering feature improves the baseline by 0.58 in BLEU, which is a good improvement given our strong baseline. Table 6 lists the number of shifting errors in TER measurement (Snover et al., 2006) of various systems on the GALE/BOLT test set. The syntax-based reordering model achieves a 6.1% reduction in the number of shifting errors in the baseline system, and its combination with the syntax mismatch model achieves an additional reduction of 0.6%. This suggests that the proposed method helps to improve word reordering in translation.

	Shifting errors
baseline	3205
+ syntax mismatch	3089
+ syntax reorder	3010
+ syntax mismatch and reorder	2990

Table 6: Number of shifting errors in TER measurement of multiple systems on the GALE/BOLT test set

5.4 Final Results

Table 7 shows the final results on the GALE/BOLT test set, as well as the NIST MT06 and MT08 test sets. Both the syntax mismatch and the syntax-based reordering features improve the baseline system, resulting in moderate to significant gains in all of the five test sets. The two features are complementary to each other and their combination results in better improvement in four out of the five test sets compared to adding them separately. In three out of the five test sets, the improvement from the combination of the two features is statistically significant at the 95% confidence level over the baseline, with the largest absolute improvement of 1.43 in BLEU obtained on MT08 web.

6 Conclusion

In this paper, We have discussed problems resulting from explicitly decorating translation rules with syntactic annotations. We presented a factored approach to incorporate soft source syntax mismatch and reordering constraints to hierarchical machine translation, and showed how our models avoid the pitfalls of the explicit decoration approach. Experiments on Chinese-English translation show that the proposed approach significantly improves a strong string-to-dependency translation baseline on multiple evaluation sets. There are many directions in which this work can be continued. The syntax mismatch model can be extended to dynamically adjust the translation distribution based on the syntactic compatibility between a translation rule and a source sentence. It also might be beneficial to look beyond syntactic constituent pairs when modeling reordering, given that phrasal cohesion does not always hold in translation. The general framework that uses an external reordering model in hierarchical models via features can also be naturally extended to use multiple reordering models.

Abstract

While inversion transduction grammar (ITG) is well suited for modeling ordering shifts between languages, how to make applying the two reordering rules (i.e., straight and inverted) dependent on actual blocks being merged remains a challenge. Unlike previous work that only uses boundary words, we propose to use recursive autoencoders to make full use of the entire merging blocks alternatively. The recursive autoencoders are capable of generating vector space representations for variable-sized phrases, which enable predicting orders to exploit syntactic and semantic information from a neural language modeling's perspective. Experiments on the NIST 2008 dataset show that our system significantly improves over the MaxEnt classifier by 1.07 BLEU points.

1 Introduction

Phrase-based models (Koehn et al., 2003; Och and Ney, 2004) have been widely used in practical machine translation (MT) systems due to their effectiveness, simplicity, and applicability. First, as sequences of consecutive words, phrases are capable of memorizing local word selection and reordering, making them an effective mechanism for translating idioms or translations with word insertions or omissions. Moreover, n-gram language models can be seamlessly integrated into phrase-based decoders since partial translations grow left to right in decoding. Finally, phrase-based systems can be applicable to most domains and languages, especially for resource-scarce languages without high-accuracy parsers.

However, as phrase-based decoding casts translation as a string concatenation problem and permits arbitrary permutations, it proves to be NP-complete (Knight, 1999). Therefore, phrase reordering modeling has attracted intensive attention in the past decade (e.g., Och et al., 2004; Tillman, 2004; Zens et al., 2004; Al-Onaizan and Papineni, 2006; Xiong et al., 2006; Koehn et al., 2007; Galley and Manning, 2008; Feng et al., 2010; Green et al., 2010; Bisazza and Federico, 2012; Cherry, 2013).

Among them, reordering models based on **inversion transduction grammar (ITG)** (Wu, 1997) are one of the important ongoing research directions. As a formalism for bilingual modeling of sentence pairs, ITG is particularly well suited to predicting ordering shifts between languages. As a result, a number of authors have incorporated ITG into left-to-right decoding to constrain the reordering space and reported significant improvements (e.g., Zens et al., 2004; Feng et al., 2010). Along another line, Xiong et al. (2006) propose a maximum entropy (MaxEnt) reordering model based on ITG. They use the CKY algorithm to recursively merge two blocks (i.e., a pair of source and target strings) into larger blocks, either in a straight or an inverted order. Unlike lexicalized reordering models (Tillman, 2004; Koehn et al., 2007; Galley and Manning, 2008) that are defined on individual bilingual phrases, the MaxEnt ITG reordering model is a two-category classifier (i.e., straight or inverted) for two arbitrary bilingual phrases of which the source phrases are adjacent. This potentially alleviates the data sparseness

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 567–577,
Seattle, Washington, USA, 18-21 October 2013.

problem since there are usually a large number of reordering training examples available (Xiong et al., 2006). As a result, the MaxEnt ITG model and its extensions (Xiong et al., 2008; Xiong et al., 2010) have achieved competing performance as compared with state-of-the-art phrase-based systems.

Despite these successful efforts, the ITG reordering classifiers still face a major challenge: how to extract features from training examples (i.e., a pair of bilingual strings). It is hard to decide which words are representative for predicting reordering, either manually or automatically, especially for long sentences. As a result, Xiong et al. (2006) only use boundary words (i.e., the first and the last words in a string) to predict the ordering. What if we look inside? Is it possible to avoid manual feature engineering and learn semantic representations from the data?

Fortunately, the rapid development of intersecting deep learning with natural language processing (Bengio et al., 2003; Collobert and Weston, 2008; Collobert et al., 2011; Glorot et al., 2011; Bordes et al., 2011; Socher et al., 2011a; Socher et al., 2011b; Socher et al., 2011c; Socher et al., 2012; Bordes et al., 2012; Huang et al., 2012; Socher et al., 2013; Hermann and Blunsom, 2013) brings hope for alleviating this problem. In these efforts, natural language words are represented as real-valued vectors, which can be naturally fed to neural networks as input. More importantly, it is possible to learn vector space representations for multi-word phrases using **recursive autoencoders** (Socher et al., 2011c), which opens the door to leveraging semantic representations of phrases in reordering models from a neural language modeling point of view.

In this work, we propose an ITG reordering classifier based on recursive autoencoders. The neural network consists of four autoencoders (i.e., the first source phrase, the first target phrase, the second source phrase, and the second target phrase) and a softmax layer. The recursive autoencoders, which are trained on reordering examples extracted from word-aligned bilingual corpus, are capable of producing vector space representations for arbitrary multi-word strings in decoding. Therefore, our model takes the whole phrases rather than only boundary words into consideration when predicting phrase permutations. Experiments on the NIST 2008 dataset show that our system significantly improves over the MaxEnt classifier by 1.07 in terms of case-insensitive BLEU score.

2 Recursive Autoencoders for ITG-based Translation

2.1 Inversion Transduction Grammar

Inversion transduction grammar (ITG) (Wu, 1997) is a formalism for synchronous parsing of bilingual sentence pairs. Xiong et al. (2006) apply bracketing transduction grammar (BTG), which is a simplified version of ITG, to phrase-based translation using the following production rules:

$$X \rightarrow [X^1, X^2] \quad (1)$$

$$X \rightarrow \langle X^1, X^2 \rangle \quad (2)$$

$$X \rightarrow f/e \quad (3)$$

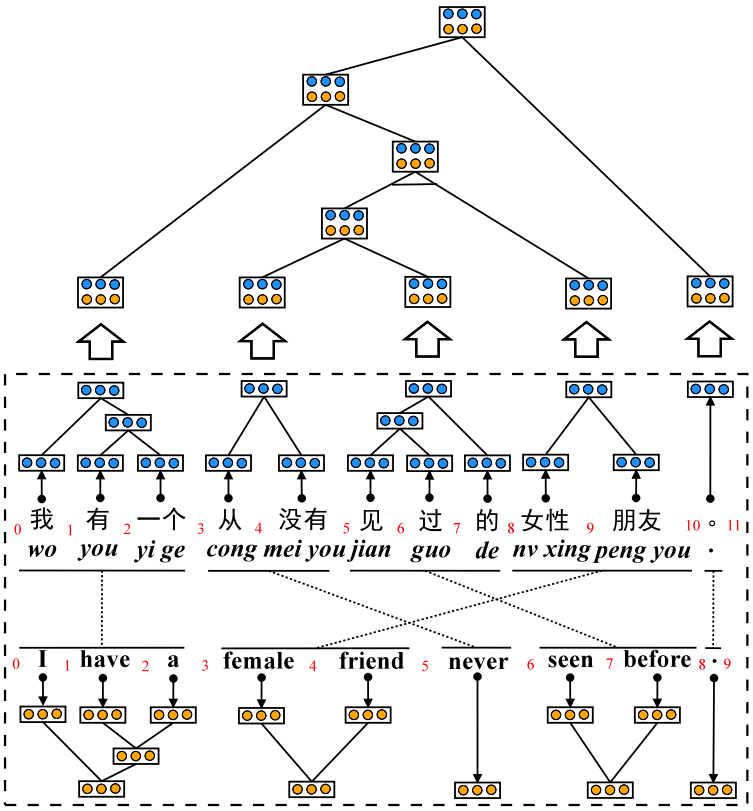
where X is a **block** that consists of a pair of source and target strings, f is a source phrase, and e is a target phrase. X^1 and X^2 are two neighboring blocks of which the two source phrases are adjacent. While rule (1) merges two target phrases in a **straight** order, rule (2) merges in an **inverted** order. Besides these two **reordering rules**, rule (3) is a **lexical rule** that translates a source phrase f into a target phrase e. This is exactly a bilingual phrase used in conventional phrase-based systems.

An ITG derivation, which consists of a sequence of production rules, explains how a sentence pair is generated simultaneously. Figure 1 shows an ITG derivation for a Chinese sentence and its English translation. We distinguish between two types of blocks:

1. **atomic blocks**: blocks generated by applying lexical rules,
2. **composed blocks**: blocks generated by applying reordering rules.

In Figure 1, the sentence pair is segmented into five atomic blocks:

$X_{0,3,0,3}$: *wo you yi ge* $\leftrightarrow$ I have a
$X_{3,5,5,6}$: *cong mei you* $\leftrightarrow$ never
$X_{5,8,6,8}$: *jian guo de* $\leftrightarrow$ seen before
$X_{8,10,3,5}$: *nv xing peng you* $\leftrightarrow$ female friend
$X_{10,11,8,9}$: . $\leftrightarrow$.



(1)	$X_{0,11,0,9} \rightarrow [X_{0,10,0,8}, X_{10,11,8,9}]$
(2)	$X_{0,10,0,8} \rightarrow [X_{0,3,0,3}, X_{3,10,3,8}]$
(3)	$X_{0,3,0,3} \rightarrow$ *wo you yi ge* / I have a
(4)	$X_{3,10,3,8} \rightarrow \langle X_{3,8,5,8}, X_{8,10,3,5} \rangle$
(5)	$X_{3,8,5,8} \rightarrow [X_{3,5,5,6}, X_{5,8,6,8}]$
(6)	$X_{3,5,5,6} \rightarrow$ *cong mei you* / never
(7)	$X_{5,8,6,8} \rightarrow$ *juan guo de* / seen before
(8)	$X_{8,10,3,5} \rightarrow$ *nv xing peng you*/ female friend
(9)	$X_{10,11,8,9} \rightarrow$. / .

Figure 1: An ITG derivation for a Chinese sentence and its translation. We use $X_{i,j,k,l} = \langle f_i^j, e_k^l \rangle$ to represent a block. Our neural ITG reordering model first assigns vector space representations to single words and then produces vectors for phrases using recursive autoencoders, which form atomic blocks. The atomic blocks are recursively merged into composed blocks, the vector space representations of which are produced by recursive autoencoders simultaneously. The neural classifier makes decisions at each node using the vectors of all its descendants.

where $X_{3,5,5,6}$ indicates that the block consists of a source phrase spanning from position 3 to position 5 (i.e., *"cong mei you"*) and a target phrase spanning from position 5 to position 6 (i.e., "never"). More formally, a block $X_{i,j,k,l} = \langle f_i^j, e_k^l \rangle$ is a pair of a source phrase $f_i^j = f_{i+1} \dots f_j$ and a target phrase $e_k^l = e_{k+1} \dots e_l$. Obviously, these atomic blocks are generated by lexical rules.

Two blocks of which the source phrases are adjacent can be merged into a larger one in two ways: concatenating the target phrases in a straight order using rule (1) or in an inverted order using rule (2). For example, atomic blocks $X_{3,5,5,6}$ and $X_{5,8,6,8}$ are merged into a composed block $X_{3,8,5,8}$ in a straight order, which is further merged with an atomic block $X_{8,10,3,5}$ into another composed block $X_{3,10,3,8}$ in an inverted order. This process recursively proceeds until the entire sentence pair is generated.

The major challenge of applying ITG to machine translation is to decide when to merge two blocks in a straight order and when in an inverted order. Therefore, the ITG reordering model can be seen as a two-category classifier $P(o|X^1, X^2)$, where $o \in \{straight, inverted\}$.

A naive way is to assign fixed probabilities to two reordering rules, which is referred to as *flat model* by Xiong et al. (2006):

$$P(o|X^1, X^2) = \begin{cases} p & o = straight \\ 1-p & o = inverted \end{cases} \quad (4)$$

The drawback of the flat model is ignoring the actual blocks being merged. Intuitively, different blocks should have different preferences between the two orders.

To alleviate this problem, Xiong et al. (2006) propose a maximum entropy (MaxEnt) classifier:

$$P(o|X^1, X^2) = \frac{\exp(\theta \cdot h(o, X^1, X^2))}{\sum_{o'} \exp(\theta \cdot h(o', X^1, X^2))} \quad (5)$$

where $h(\cdot)$ is a vector of features defined on the blocks and the order, θ is a vector of feature weights.

While MaxEnt is a flexible and powerful framework for including arbitrary features, feature engineering becomes a major challenge for the MaxEnt classifier. Xiong et al. (2006) find that boundary words (i.e., the first and the last words in a string) are informative for predicting reordering. Actually, it is hard to decide which internal words in a long composed blocks are representative and informative. Therefore, they only use boundary words as the main features.

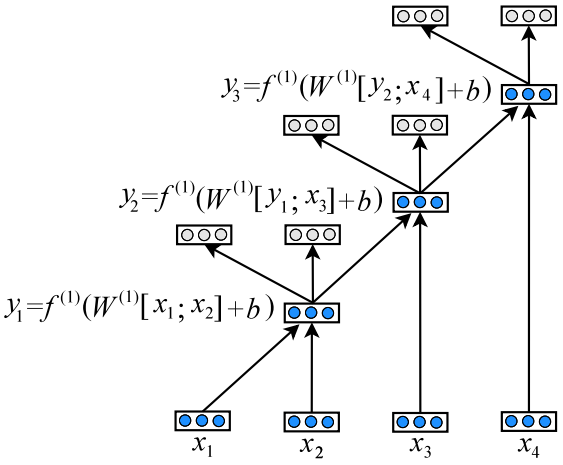


Figure 2: A recursive autoencoder for multi-word strings. The example is adapted from (Socher et al., 2011c). Blue and grey nodes are original and reconstructed ones, respectively.

However, it seems not enough to just consider boundary words and ignore all internal words when making order predictions, especially for long sentences.[1] Indeed, Xiong et al. (2008) find that the MaxEnt classifier with boundary words as features is prone to make wrong predictions for long composed blocks. As a result, they have to impose a hard constraint to always prefer merging long composed blocks in a monotonic way.

Therefore, it is important to consider more than boundary words to make more accurate reordering predictions. We need a new mechanism to achieve this goal.

2.2 Recursive Autoencoders

2.2.1 Vector Space Representations for Words

In neural networks, a natural language word is represented as a real-valued vector (Bengio et al., 2003; Collobert and Weston, 2008). For example, we can use $[0.1\ 0.8\ 0.4]^T$ to represent "female" and

[1] Strictly speaking, the ITG reordering model is not a phrase reordering model since phrase pairs are only the atomic blocks. Instead, it is defined to work on arbitrarily long strings because composed blocks become larger and larger until the entire sentence pair is generated.

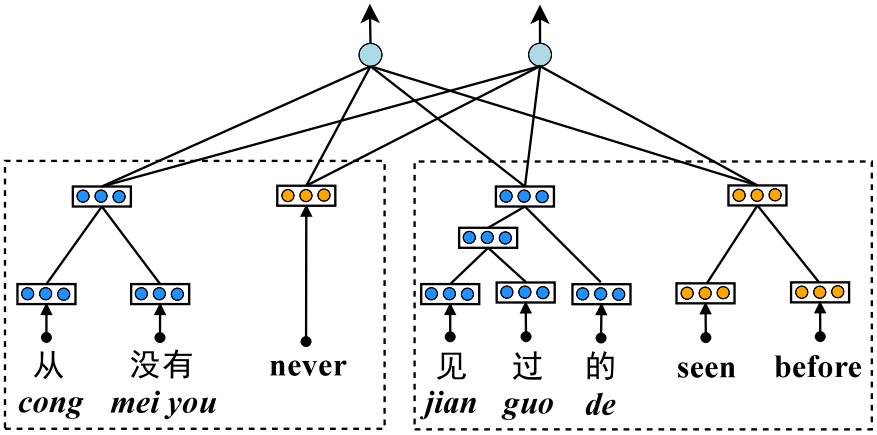

Figure 3: A neural ITG reordering model. The binary classifier makes decisions based on the vector space representations of the source and target sides of merging blocks.

$[0.7\ 0.1\ 0.5]^T$ to represent "friend". Such vector space representations enable natural language words to be fed to neural networks as input.

Formally, we denote each word as a vector $x \in \mathbb{R}^n$. These word vectors are then stacked into a word embedding matrix $L \in \mathbb{R}^{n \times |V|}$, where $|V|$ is the vocabulary size. Given a sentence that is an ordered list of m words, each word has an associated vocabulary index k into the word embedding matrix L that we use to retrieve the word's vector space representation. This look-up operation can be seen as a simple projection layer:

$$x_i = Lb_k \in \mathbb{R}^n \tag{6}$$

where b_k is a binary vector which is zero in all positions except for the kth index.

In Figure 1, we assume $n = 3$ for simplicity and can retrieve vectors for Chinese and English words from two embedding matrices, respectively.

2.2.2 Vector Space Representations for Multi-Word Strings

To apply neural networks to ITG-based translation, it is important to generate vector space representations for atomic and composed blocks.

For example, since the vector of "female" is $[0.1\ \ 0.8\ \ 0.4]^T$ and the vector of "friend" is $[0.7\ 0.1\ 0.5]^T$, what is the vector of the phrase "female friend"? If we denote "female friend" as p (i.e., parent), "female" as c_1 (i.e., the first child), and "friend" as c_2 (i.e., the second child), this can be done by applying a function $f^{(1)}$:

$$p = f^{(1)}(W^{(1)}[c_1; c_2] + b^{(1)}) \tag{7}$$

where $[c_1; c_2] \in \mathbb{R}^{2n \times 1}$ is the concatenation of c_1 and c_2, $W^{(1)} \in \mathbb{R}^{n \times 2n}$ is a parameter matrix, $b^{(1)} \in \mathbb{R}^{n \times 1}$ is a bias term, and $f^{(1)}$ is an element-wise activation function such as $\tanh(\cdot)$, which is used in our experiments.

Note that the resulting vector for the parent is also an n-dimensional vector, e.g, $[0.6\ 0.9\ 0.2]^T$. The same neural network can be recursively applied to two strings until the vector of the entire sentence is generated. As ITG derivation builds a binary parse tree, the neural network can be naturally integrated into CKY parsing.

To assess how well the learned vector p represents its children, we can **reconstruct** the children in a reconstruction layer:

$$[c_1'; c_2'] = f^{(2)}(W^{(2)}p + b^{(2)}) \tag{8}$$

where c_1' and c_2' are the reconstructed children, $W^{(2)}$ is a parameter matrix for reconstruction, $b^{(2)}$ is a bias term for reconstruction, and $f^{(2)}$ is an element-wise activation function, which is also set as $\tanh(\cdot)$ in our experiments. Similarly, the same reconstruction neural network can be applied to each node in an ITG parse.

These neural networks are called **recursive autoencoders** (Socher et al., 2011c). Figure 2 illustrates an application of a recursive autoencoder to a

binary tree. The blue and grey nodes are the original and reconstructed nodes, respectively. The autoencoder is re-used at each node of the tree. The binary tree is composed of a set of triplets in the form of $(p \rightarrow c_1\ c_2)$, where p is a parent vector and c_1 and c_2 are children vectors of p. Each child can be either an input word vector or a multi-word vector. Therefore, the tree in Figure 2 can be represented as three triplets: $(y_1 \rightarrow x_1\ x_2)$, $(y_2 \rightarrow y_1\ x_3)$, and $(y_3 \rightarrow y_2\ x_4)$.

In Figure 1, we use recursive autoencoders to generate vector space representations for Chinese and English phrases, which form the atomic blocks for further block merging.

2.2.3 A Neural ITG Reordering Model

Once the vectors for blocks are generated, it is straightforward to introduce a neural ITG reordering model. As shown in Figure 3, the neural network consists of an input layer and a softmax layer. The input layer is composed of the vectors of the first source phrase, the first target phrase, the second source phrase, and the second target phrase. Note that all phrases in the same language use the the same recursive autoencoder. The softmax layer outputs the probabilities of the two merging orders:

$$P(o|X^1, X^2) = \frac{\exp(g(o, X^1, X^2))}{\sum_{o'} \exp(g(o', X^1, X^2))} \quad (9)$$

$$g(o, X^1, X^2) = f(W^o c(X^1, X^2) + b^o) \quad (10)$$

where $o \in \{straight, inverted\}$, $W^o \in \mathbb{R}^{1\times 4n}$ is a parameter matrix, $b^o \in \mathbb{R}$ is a bias term, and $c(X^1, X^2) \in \mathbb{R}^{4n\times 1}$ is the concatenation of the vectors of the four phrases.

3 Training

There are three sets of parameters in our recursive autoencoders:

1. θ_L: word embedding matrix L for both source and target languages (Section 2.2.1);
2. θ_{rec}: recursive autoencoder parameter matrices $W^{(1)}$, $W^{(2)}$ and bias terms $b^{(1)}$, $b^{(2)}$ for both source and target languages (Section 2.2.2);
3. θ_{reo}: neural ITG reordering model parameter matrix W^o and bias term b^o (Section 2.2.3).

All these parameters are learned automatically from the training data. For clarity, we will use θ to denote all these parameters in the rest of the paper.

For training word embedding matrix, there are two settings commonly used. In the first setting, the word embedding matrix is initialized randomly. This works well in a supervised scenario, in which a neural network updates the matrix in order to optimize some task-specific objectives (Collobert et al., 2011; Socher et al., 2011c). In the second setting, the word embedding matrix is pre-trained using an unsupervised neural language model (Bengio et al., 2003; Collobert and Weston, 2008) with huge amount of unlabeled data. In this work, we prefer to the first setting because the word embedding matrices can be trained to minimize errors with respect to reordering modeling.

There are two kinds of errors involved

1. **reconstruction error**: how well the learned vector space representations represent the corresponding strings?
2. **reordering error**: how well the classifier predicts the merging order?

As described in Section 2.2.2, the input vector c_1 and c_2 of a recursive autoencoder can be reconstructed using Eq. 8 as c_1' and c_2'. We use Euclidean distance between the input and the reconstructed vectors to measure the *reconstruction error*:

$$E_{rec}([c_1; c_2]; \theta) = \frac{1}{2} \left\| [c_1; c_2] - [c_1'; c_2'] \right\|^2. \quad (11)$$

Given a sentence, there are exponentially many ways to obtain its vector space representation. Note that each way corresponds to a binary tree like Figure 2. To find a binary tree with minimal reconstruction error, we follow Socher et al. (2011c) to use a greedy algorithm. Taking Figure 2 as an example, the greedy algorithm begins with computing the reconstruction error $E_{rec}(\cdot)$ for each pair of consecutive vectors, i.e., $E_{rec}([x_1; x_2]; \theta)$, $E_{rec}([x_2; x_3]; \theta)$ and $E_{rec}([x_3; x_4]; \theta)$. Suppose $E_{rec}([x_1; x_2]; \theta)$ is the smallest, the algorithm will replace x_1 and x_2 with their vector representation y_1 produced by the recursive autoencoder. Then, the algorithm evaluates $E_{rec}([y_1; x_3]; \theta)$ and $E_{rec}([x_3; x_4]; \theta)$ and repeats the above replacing steps until only one vector

remains. Socher et al. (2011c) find that the greedy algorithm runs fast without significant loss in performance as compared with CKY-style algorithms.

Given a training example set $S = \{t_i = (o_i, X_i^1, X_i^2)\}$, the average reconstruction error on the source side on the training set is defined as

$$E_{rec,s}(S;\theta) = \frac{1}{N_s}\sum_i \sum_{p\in T_R^\theta(t_i,s)} E_{rec}([p.c_1, p.c_2];\theta) \quad (12)$$

where $T_R^\theta(t_i, s)$ denotes all the intermediate nodes on the source side in binary trees, N_s is the number of these intermediate nodes, and $p.c_k$ is the kth child vector of p. The average reconstruction error on the target side, denoted by $E_{rec,t}(S;\theta)$, can be computed in a similar way.

Therefore, the reconstruction error is defined as

$$E_{rec}(S;\theta) = E_{rec,s}(S;\theta) + E_{rec,t}(S;\theta). \quad (13)$$

Given a training example $t_i = (o_i, X_i^1, X_i^2)$, we assume the probability distribution d_{t_i} for its label is $[1, 0]$ when $o_i = straight$, and $[0, 1]$ when $o_i = inverted$. Then the cross-entropy error is

$$E_c(t_i;\theta) = -\sum_o d_{t_i}(o)\log\left(P_\theta(o|X^1, X^2)\right) \quad (14)$$

where $o \in \{straight, inverted\}$. As a result, the reordering error is defined as

$$E_{reo}(S;\theta) = \frac{1}{|S|}\sum_i E_c(t_i;\theta). \quad (15)$$

Therefore, the joint training objective function is

$$J = \alpha E_{rec}(S;\theta) + (1-\alpha)E_{reo}(S;\theta) + R(\theta) \quad (16)$$

where α is a parameter used to balance the preference between reconstruction error and reordering error, $R(\theta)$ is the regularizer and defined as [2]

$$R(\theta) = \frac{\lambda_L}{2}\|\theta_L\|^2 + \frac{\lambda_{rec}}{2}\|\theta_{rec}\|^2 + \frac{\lambda_{reo}}{2}\|\theta_{reo}\|^2. \quad (17)$$

As Socher et al. (2011c) stated, a naive way for lowering the reconstruction error is to make the magnitude of the hidden layer very small, which is not desirable. In order to prevent such behavior, we normalize all the output vectors of the hidden layers to have length 1 in the same way as (Socher et al., 2011c). Namely we set $p = \frac{p}{||p||}$ after computing p as in Eq. 7, and $c_1' = \frac{c_1'}{||c_1'||}$, $c_2' = \frac{c_2'}{||c_2'||}$ in Eq. 8.

Following Socher et al. (2011c), we use L-BFGS to estimate the parameters with respect to the joint training objective. Given a set of parameters, we construct binary trees for all the phrases using the greedy algorithm. The derivatives for these fixed binary trees can be computed via backpropagation through structures (Goller and Kuchler, 1996).

4 Experiments

4.1 Data Preparation

We evaluated our system on Chinese-English translation. The training corpus contains 1.23M sentence pairs with 32.1M Chinese words and 35.4M English words. We used SRILM (Stolcke, 2002) to train a 4-gram language model on the Xinhua portion of the GIGAWORD corpus, which contains 398.6M words. We used the NIST 2006 MT Chinese-English dataset as the development set and NIST 2008 dataset as the test set. The evaluation metric is case-insensitive BLEU. Because of the expensive computational cost for training our neural ITG reordering model, only the reordering examples extracted from about 1/5 of the entire parallel training corpus were used to train our neural ITG reordering model.

For the neural ITG reordering model, we set the dimension of the word embedding vectors to 25 empirically, which is a trade-off between computational cost and expressive power. We use the early stopping principle to determine when to stop L-BFGS. The hyper-parameters α, λ_L, λ_{rec} and λ_{reo} are optimized by random search (Bergstra and Bengio, 2012). As preliminary experiments show that classification accuracy has a high correlation with BLEU score, we optimize these hyper-parameters with respect to classification accuracy instead of BLEU to reduce computational cost. We randomly select 400,000 reordering examples as training set, 500 as development set, and another 500 as test set. The numbers of straight and inverted reordering examples in the development/test set are set to be equal to avoid biases. We draw α uniformly from 0.05

[2] The bias terms $b^{(1)}$, $b^{(2)}$ and b^o are not regularized. We do not exclude them from the equation explicitly just for clarity.

System	NIST 2006 (tune)	NIST 2008
maxent	30.40	23.75
neural	**31.61***	**24.82***

Table 1: BLEU scores on the NIST 2006 and 2008 datasets. *: significantly better ($p < 0.01$). "maxent" denotes the baseline maximum entropy system and "neural" denotes our recursive autoencoder system.

length	$>$	$=$	$<$
$[1, 10]$	43	121	57
$[11, 20]$	181	67	164
$[21, 30]$	170	11	152
$[31, 40]$	105	3	90
$[41, 50]$	69	1	53
$[51, 119]$	40	0	30

Table 2: Number of sentences that our system has a higher ($>$), equal ($=$) or lower ($<$) sentence-level BLEU-4 score on the NIST 2008 dataset.

to 0.3, and λ_L, λ_{rec}, λ_{reo} exponentially from 10^{-8} to 10^{-2}. We use the following hyper-parameters in our experiments: $\alpha = 0.11764$, $\lambda_L = 7.59 \times 10^{-5}$, $\lambda_{rec} = 1.30 \times 10^{-5}$ and $\lambda_{reo} = 3.80 \times 10^{-4}$. [3]

The baseline system is a re-implementation of (Xiong et al., 2006). Our system is different from the baseline by replacing the MaxEnt reordering model with a neural model. Both the systems have the same pruning settings: the threshold pruning parameter is set to 0.5 and the histogram pruning parameter to 40. For minimum-error-rate training, both systems generate 200-best lists.

4.2 MT Evaluation

Table 1 shows the case-insensitive BLEU-4 scores of the baseline system and our system on the development and test sets. Our system outperforms the baseline system by 1.21 BLEU points on the development set and 1.07 on the test set. Both the differences are statistically significant at $p = 0.01$ level (Riezler and Maxwell, 2005).

Table 2 shows the number of sentences that our system has a higher ($>$), equal ($=$) or lower ($<$) BLEU score on the NIST 2008 dataset. We find that our system is superior to the baseline system for long sentences.

[3]The choice of α is very important for achieving high BLEU scores. We tried a number of intervals and found that the classification accuracy is most stable in the interval [0.100,0.125].

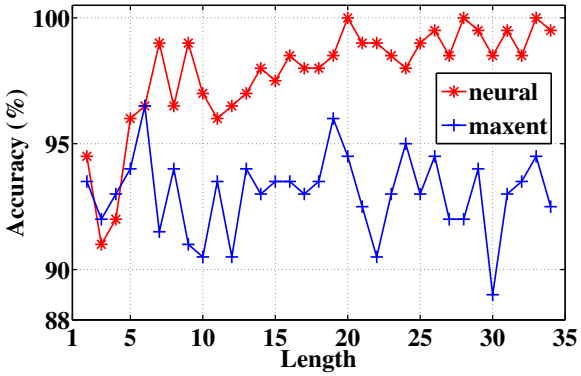

Figure 4: Comparison of reordering classification accuracies between the MaxEnt and neural classifiers over varying phrase lengths. "Length" denotes the sum of the lengths of two source phrases in a reordering example. Our classifier (neural) outperforms the MaxEnt classifier (maxent) consistently, especially for predicting long-distance reordering.

# of examples	NIST 2006 (tune)	NIST 2008
100,000	30.88	23.78
200,000	30.75	23.89
400,000	30.80	24.35
800,000	31.01	24.45
6,004,441	31.61	24.82

Table 3: The effect of reordering training data size on BLEU scores. The BLEU scores rise with the increase of training data size. Due to the computational cost, we only used 1/5 of the entire bilingual corpus to train our neural reordering model.

Figure 4 compares classification accuracies of the neural and MaxEnt classifiers. "Length" denotes the sum of the lengths of two source phrases in a reordering example. For each length, we randomly select 200 unseen reordering examples to calculate the classification accuracy. Our classifier outperforms the baseline consistently, especially for long composed blocks.

Xiong et al. (2008) find that the performance of the baseline system can be improved by forbidding inverted reordering if the phrase length exceeds a pre-defined distortion limit. This heuristic increases the BLEU score of the baseline system significantly to 24.46 but is still significantly worse ($p < 0.05$) than our system without the heuristic. We find that imposing this heuristic fails to improve our system

cluster 1	cluster 2	cluster 3	cluster 4	cluster 5

Table 4: Words and phrases that are close in the Euclidean space. The words and phrases in the same cluster have similar behaviors from a reordering point of view rather than relatedness, suggesting that the vector representations produced by the recursive autoencoders are helpful for capturing reordering regularities.

significantly. One possible reason is that there is limited room for improvement as our system makes fewer wrong predictions for long composed blocks.

The above results suggest that our system does go beyond using boundary words and make a better use of the merging blocks by using vector space representations.

Table 3 shows the effect of training dataset size on BLEU scores. We find that BLEU scores on both the development and test sets rise with the increase of the training dataset size. As the training process is very time-consuming, only the reordering examples extracted from 1/5 of the entire parallel training corpus are used in our experiments to train our model. Obviously, with more efficient training algorithms, making full use of all the reordering examples extracted from the entire corpus will result in better results. We leave this for future work.

4.3 Qualitative Analysis on Vector Representations

Table 4 shows a number of words and phrases that are close (measured by Euclidean distance) in the n-dimensional space. We randomly select about 370K target side phrases used in our experiments and cluster them into 983 clusters using k-means algorithm (MacQueen, 1967). The distance between two phrases are measured by the Euclidean distance between their vector representations. As shown in Table 4, cluster 1 mainly consists of nouns, cluster 2 mainly contains verb/noun+preposition structures, cluster 3 contains compound phrases, cluster 4 consists of phrases which should be followed by a clause, and cluster 5 mainly contains the beginning parts of prepositional phrases that tend to be followed by a noun phrase or word. We find that the words and phrases in the same cluster have similar behaviors from a reordering point of view rather than relatedness. This indicates that the vector representations produced by the recursive autoencoders are helpful for capturing reordering regularities.

5 Conclusion

We have presented an ITG reordering classifier based on recursive autoencoders. As recursive autoencoders are capable of producing vector space representations for arbitrary multi-word strings in decoding, our neural ITG system achieves an absolute improvement of 1.07 BLEU points over the baseline on the NIST 2008 Chinese-English dataset.

There are a number of interesting directions we would like to pursue in the near future. First, replacing the MaxEnt classifier with a neural one redefines the conditions for risk-free hypothesis recombination. We find that the number of hypotheses that can be recombined reduces in our system. Therefore, we plan to use forest reranking (Huang, 2008) to alleviate this problem. Second, it is interesting to follow Socher et al. (2013) to combine linguistically-motivated labels with recursive neural networks. Another problem with our system is that the decoding speed is much slower than the baseline system because of the computational overhead introduced by RAEs. It is necessary to investigate more efficient decoding algorithms. Finally, it is possible to apply our method to other phrase-based and even syntax-based systems.

Abstract

In this paper, we analyze a novel set of features for the task of automatic edit category classification. Edit category classification assigns categories such as spelling error correction, paraphrase or vandalism to edits in a document. Our features are based on differences between two versions of a document including meta data, textual and language properties and markup. In a supervised machine learning experiment, we achieve a micro-averaged F1 score of .62 on a corpus of edits from the English Wikipedia. In this corpus, each edit has been multi-labeled according to a 21-category taxonomy. A model trained on the same data achieves state-of-the-art performance on the related task of fluency edit classification. We apply pattern mining to automatically labeled edits in the revision histories of different Wikipedia articles. Our results suggest that high-quality articles show a higher degree of homogeneity with respect to their collaboration patterns as compared to random articles.

1 Introduction

Due to its ever-evolving and collaboratively built content, Wikipedia has been the subject of many NLP studies. While the number of newly created articles in the online encyclopedia declined in the last few years (Suh et al., 2009), the number of edits in existing articles is rather stable.[1] It is reasonable to assume that the latter will not change in the near future. One of the major reasons for the popularity of Wikipedia is its up-to-dateness (Keegan et al., 2013), which in turn requires constant editing activity. Wikipedia's revision history stores all changes made to any page in the encyclopedia in separate revisions. Previous studies have exploited revision history data in tasks such as preposition error correction (Cahill et al., 2013), spelling error correction (Zesch, 2012) or paraphrasing (Max and Wisniewski, 2010). However, they all use different approaches to extract the information needed for their task. Ferschke et al. (2013) outline several applications benefiting from revision history data. They argue for a unified approach to extract and classify edits from revision histories based on a predefined edit category taxonomy.

In this work, we show how the extraction and automatic multi-label classification of any edit in Wikipedia can be handled with a single approach. Therefore, we use the 21-category edit classification taxonomy developed in previous work (Daxenberger and Gurevych, 2012). This taxonomy enables a fine-grained analysis of edit activity in revision histories. We present the results from an automatic classification experiment, based on an annotated corpus of edits in the English Wikipedia. Additional information necessary to reproduce our results, including word lists and training, development and test data, is released online.[2] To the best of our knowledge, this is the first approach allowing to classify each single edit in Wikipedia into one or more of 21 different edit categories using a supervised machine learning

approach.

We define our task as edit category classification. An *edit* is a coherent, local change which modifies a document and which can be related to certain meta data (e.g. its author, time stamp etc.). In edit category classification, we aim to detect all n edits $e^k_{v-1,v}$ with $0 \leq k < n$ in adjacent versions r_{v-1}, r_v of a document (we refer to the older revision as r_{v-1} and to the newer as r_v) and assign each of them to one or more edit categories. There exist at least two main applications of edit category classification: First, a fine-grained classification of edits in collaboratively created documents such as Wikipedia articles, scientific papers or research proposals, would help us to better understand the collaborative writing process. This includes answers to questions about the kind of contribution of individual authors (Who has added substantial contents?, Who has improved stylistic issues?) and about the kind of collaboration which characterizes different articles (Liu and Ram, 2011). Second, automatic classification of edits generates huge amounts of training data for the above mentioned NLP systems.

Edit category classification is related to the better known task of document pair classification. In *document pair classification*, a pair of documents has to be assigned to one or more categories (e.g. paraphrase/non-paraphrase, plagiarism/non-plagiarism). Here, the document may be a very short text, such as a sentence or a single word. Applications of document pair classification include plagiarism detection (Potthast et al., 2012), paraphrase detection (Madnani et al., 2012) or text similarity detection (Bär et al., 2012). In *edit category classification*, we also have two documents. However, these documents are different versions of the same text. This scenario implies certain characteristics for a well-designed feature set as we will demonstrate in this study.

The main contributions of this paper are: First, we introduce a novel feature set for edit category classification. Second, we evaluate the performance of this feature set on different tasks within a corpus of Wikipedia edits. We propose the new task of edit category classification and show that our model is able to classify edits from a 21-category taxonomy. Furthermore, our model achieves state-of-the-art performance in a fluency edit classification task (Bronner and Monz, 2012). Third, we analyze collaboration patterns based on edit categories on two subsets of Wikipedia articles, namely featured and non-featured articles. We detect correlations between collaboration patterns and high-quality articles. This is demonstrated by the fact that featured articles have a higher degree of homogeneity with respect to their collaboration patterns as compared to random articles.

The rest of this paper is structured as follows. In Section 2, we motivate our experiments based on previous work. Section 3 explains our training data and the features we use for the machine learning experiments. In Section 4, we present and discuss the results of our experiments. We also demonstrate an application of our classifier model in Section 5 by mining frequent collaboration patterns in the revision histories of different articles. Finally, we draw a conclusion in Section 6.

2 Related Work

Wikipedia is a huge data source for generating training data for edit category classification, as all previous versions of each page in the encyclopedia are stored in its revision history. Unsurprisingly, the number of studies extracting certain kinds of Wikipedia edits keeps growing. Most of these use manually defined rules or filters find the right kind of edits. Among the latter, there are NLP applications such as the detection of lexical errors (Nelken and Yamangil, 2008), spelling error correction (Max and Wisniewski, 2010; Zesch, 2012), preposition error correction (Cahill et al., 2013), sentence compression (Nelken and Yamangil, 2008; Yamangil and Nelken, 2008), summarization (Nelken and Yamangil, 2008), simplification (Yatskar et al., 2010; Woodsend and Lapata, 2011), paraphrasing (Max and Wisniewski, 2010; Dutrey et al., 2011), textual entailment (Zanzotto and Pennacchiotti, 2010; Cabrio et al., 2012), information retrieval (Aji et al., 2010; Nunes et al., 2011) and bias detection (Recasens et al., 2013).

Bronner and Monz (2012) define features for the supervised classification of factual and fluency edits. Their features are calculated both on character- and word-level. Furthermore, they use features based on POS tags, named entities, acronyms, and a lan-

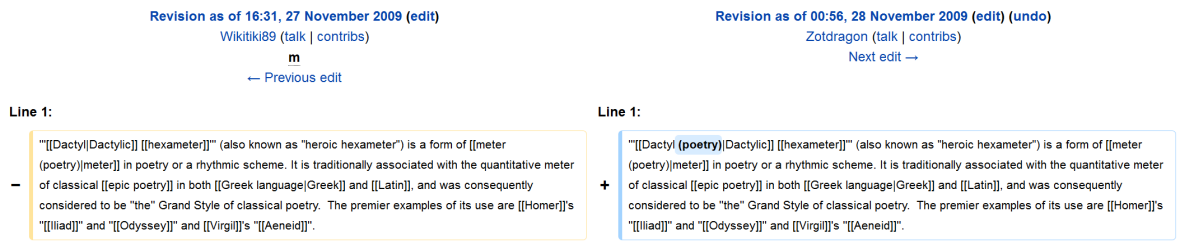

Figure 1: An example edit from WPEC labeled with REFERENCE-M, as displayed by Wikimedia's diff page tool.

guage model (word n-grams). In their experiments, character-level features and named entity features show the highest improvement over the baseline.

Vandalism detection in Wikipedia has mostly been defined as a binary machine learning task, where the goal is to classify a pair of adjacent revisions as vandalized or not-vandalized based on edit category features. In Adler et al. (2011), the authors group these features into meta data (author, comment and time stamp of a revision), reputation (author and article reputation), textual (language independent, i.e. token- and character-based) and language features (language dependent, mostly dictionary-based). They carry out cross-validation experiments on the PAN-WVC-10 corpus (Potthast and Holfeld, 2011). Classifiers based on reputation and text performed best. Adler et al. (2011) use Random Forests as classifier (Breiman, 2001) in their experiments. This classifier was also used in the vandalism detection study of Javanmardi et al. (2011) where it outperformed the classifiers based on Logistic Regression and Naive Bayes.

Different to the approach of Bronner and Monz (2012) and previous vandalism classification studies, we built a model which accounts for multi-labeling and a fine-grained edit category system. Our feature set builds upon existing work while adding a substantial number of new features.

3 Experiments

3.1 Wikipedia Edit Category Corpus

For our experiments, we used the freely available Wikipedia Edit Category Corpus (WPEC) compiled in previous work (Daxenberger and Gurevych, 2012). In this corpus, each pair of adjacent revisions is segmented into one or more edits. This enables an accurate picture of the editing process, as an author may perform several independent edits in the same revision. Furthermore, edits are multi-labeled, i.e. each edit is assigned one or more categories. This is important for a precise description of major edits, e.g. when an entire new paragraph including text, references and markup is added. There are four basic types of edits, namely Insertions, Deletions, Modifications and Relocations. These are calculated via a line-based diff comparison on the source text (including wiki markup). As previously suggested (Daxenberger and Gurevych, 2012), inside modified lines, only the span of text which has actually been changed is marked as edit (either Insertion, Deletion or Modification), not the entire line. We extracted the data which is not contained in WPEC (meta data and plain text of r_{v-1} and r_v) using the Java Wikipedia Library (JWPL) with the Revision Toolkit (Ferschke et al., 2011).

In Daxenberger and Gurevych (2012), we divide the 21-category taxonomy into text-base (meaning-changing edits), surface (non meaning-changing edits) and Wikipedia policy (VANDALISM and REVERT) edits. Among the text-base edits, we include categories for templates, references (internal and external links), files and information, each of which is further divided into an insertion (I), deletion (D) and modification (M) category. Surface edits consist of paraphrases, spelling and grammar corrections, relocations and markup edits. The latter category contains all edits which affect markup elements that are not covered by any of the other categories and is divided into insertions, deletions and modifications. This includes, for example, apostrophes in '''bold text'''. We also suggested an OTHER category, which is intended for edits which cannot be labeled due to segmentation errors. Figure 1 shows an example edit from WPEC, labeled with the REFERENCE-

	Feature	Value	Explanation
Meta Data	Author group	user	Wikimedia user group of the author
	Author is registered*	true	Author is registered (otherwise: IP user)
	Same author*	false	Authors of r_v and r_{v-1} are the same
	Comment length*	0	Number of characters in the comment
	Vulgarism in comment	false	Comment contains a word from in the vulgarism word list
	Comment is auto-generated	false	Entire comment has been auto-generated
	Auto-generated comment ratio	0	Auto-generated part of comment divided by length of the comment
	Incorrect comment ratio	0	Out-of-dictionary word count divided by word count in the comment
	Comment n-grams[1]	—	Presence or absence of token n-grams in the comment
	Is revert*	false	Comment contains a word from in the revert word list
	Is minor	false	Revision has been marked as minor change
	Time difference*	505	Time difference between r_{v-1} and r_v (in minutes)
	Number of edits	1	Absolute number of edits in the (r_{v-1}, r_v)-pair
Textual	Diff capitals*	0	Difference in the number of capitals
	Diff digits*	0	Difference in the number of digits
	Diff special characters*	2	Difference in the number of non-alphanumeric characters
	Diff whitespace characters	1	Difference in the number of whitespace characters
	Diff characters*	9	Difference in the number of characters
	Diff tokens*	1	Difference in the number of whitespace-separated tokens
	Diff repeated characters	0	Difference in the number of repeated characters
	Diff repeated tokens	0	Difference in the number of repeated white-space separated tokens
	Cosine similarity	0	Cosine similarity
	Levenshtein distance*	9	Levenshtein distance
	Optimal string alignment distance	9	Optimal string alignment distance (Damerau-Levenshtein distance)
	Ratio diff to paragraph characters	0.02	Diff characters divided by the length of the edited paragraph
	Ratio diff to revision characters	0.0005	Diff characters divided by the length of r_{v-1}
	Ratio diff to paragraph tokens	0.04	Diff tokens divided by the length of the edited paragraph
	Ratio diff to revision tokens	0.0003	Diff tokens divided by the length of r_{v-1}
	Ratio old to new paragraph	0	Difference in the number of characters in the edited paragraph
	Character n-grams[1]	p,o,e,t,r,y[2]	Presence or absence of n-grams of edited characters
	Token n-grams[1]	poetry[2]	Presence or absence of n-grams of edited tokens
	Simple edit type	Insertion	Modification, Insertion, Deletion or Relocation
Markup	Diff number m	0	Difference in the number of m
	Diff type m	false	Different types of m
	Diff type context m	true[3]	Different types of m within the immediate context of the edit
	Is covered by m	true[3]	Edit is covered by m in r_{v-1}
	Covers m	false	Edit covers m in r_{v-1}
Language	Diff spelling errors*	0	Difference in the number of out-of-dictionary words
	Diff vulgar words*	0	Difference in the number of tokens contained in vandalism word list
	Semantic similarity	-1	Explicit Semantic Analysis with vector indexes from Wiktionary
	Diff POS tags*	false	POS tag sets are symmetrically different
	Diff type POS tags*	0	Number of distinct POS tags

[1] N-gram features are represented as boolean features.
[2] In this example, n = 1 (unigrams).
[3] True if m corresponds to internal link, false otherwise.

Table 1: List of edit category classification features with explanations. The values correspond to the the example edit from Figure 1. m may refer to internal link, external link, image, template or markup element. Features marked with * have previously been mentioned in Adler et al. (2011), Javanmardi et al. (2011) or Bronner and Monz (2012).

M category. WPEC was created in a manual annotation study with three annotators. The overall inter-annotator agreement measured as Krippendorf's α is .67 (Daxenberger and Gurevych, 2012). The experiments in this study are based on the gold standard annotations in WPEC, which have been derived by means of a majority vote for each edit.

WPEC consists of 981 revision pairs, segmented into 1,995 edits. We define edit category classification as a multi-label classification task. For the sake of readability, in the following we will refer to an edit $e^k_{v-1,v}$ as e_i, with $e_i \in E$, where $0 \leq i < 1995$ and E is the set of all edits. An edit e_i is the basic classification unit in our task. Each e_i has to be labeled with a set of categories $y \subseteq C$, where C is the set of all edit categories, $|C| = 21$.

3.2 Features for Edit Category Classification

We grouped our features into *meta data*, *textual*, *markup* and *language* features. An overview and explanation of all features can be found in Table 1. The scheme we apply to group edit category classification features is similar to the system used by Adler et al. (2011). We re-use some of the features suggested by Adler et al. (2011), Javanmardi et al. (2011) and Bronner and Monz (2012), as marked in Table 1. Features are calculated on edited text spans. We label the edited text span corresponding to e_i in r_{v-1} as t_{v-1} and the edited text span in r_v as t_v. In edits which are insertions, we consider t_{v-1} to be empty, while t_v is considered empty for deletions. For Relocations, $t_{v-1} = t_v$.

Table 1 includes the value of each feature for the example edit from Figure 1. This edit modifies the link `[[Dactyl|Dactylic]]` by adding a specification to the target of that link. For spell-checking, we use British and US-American English Jazzy dictionaries.[3] Markup elements are detected by the Sweble Wikitext parser (Dohrn and Riehle, 2011).

Meta data features We consider the comment, author, time stamp or any other flag ("minor change") of r_v as meta data. The Wikimedia user group[4] of an author specifies the edit permissions of this user (e.g. bot, administrator, blocked user). We indicate whether the revision comments or parts of it have been auto-generated. This happens when a page is blanked, i.e. all of its content has been deleted or replaced or when a new page or redirect is created (denoted by the *Comment is auto-generated* feature). Furthermore, edits within a specific section of an article are automatically marked by adding a prefix with the name of this section to the comment of the revision (denoted by the *Auto-generated comment ratio* feature). Meta data features have the same value for all edits in a (r_{v-1}, r_v)-pair.

Textual features Textual features are calculated based on a certain property of the changed text. In a preprocessing step, any wiki markup inside t_{v-1} and t_v is deleted. As for the example edit from Figure 1, t_{v-1} would correspond to an empty string and t_v would be represented as " (poetry)". The n-gram feature spaces are composed of n-grams that are present either in t_{v-1} but not t_v, or vice verse. Character n-grams only contain English alphabet characters, token n-grams consist of words excluding special characters.

Markup features As opposed to textual features, wiki markup features account for the Wikimedia specific markup elements. Markup features are calculated based on the number and type of a markup element m and the surrounding context of an edit. Here, m can be a template, an external or internal link, an image or any other element used to describe markup including HTML tags. The type of m is defined by the link target for internal and external links and images, by the name of the template for templates and by the wiki markup element name for markup elements. Markup features are calculated on text spans t_{v-1} and t_v. Naturally, wiki markup is not deleted beforehand. The edited text spans t_{v-1} and t_v may be located inside a markup element m (e.g. a link or a template). In such cases, our diff algorithm will not label the entire element m, but rather the actually modified text. However, such an edit may change the name of a template or the target of a link (as in the example edit from Figure 1). We therefore include the immediate context s_{v-1} and s_v of each edit and compare the type of potential markup elements m in s_{v-1} and s_v. Here, s_v (s_{v-1}) is defined as t_v (t_{v-1}) including all preceding and follow-

ing characters in r_v (r_{v-1}) which are not separated from t_v (t_{v-1}) by a boundary character (whitespace or line break). The above described features model *what* is actually edited in the text. A number of features are calculated on t_{v-1} only. These features are more likely to inform about *where* an edit is conducted. They specify whether t_{v-1} covers (i.e. contains) a certain wiki markup element and vice versa, i.e. whether t_{v-1} is located inside a text span that belongs to a markup element.

Language Language features are calculated on the context s_{v-1} and s_v of edits, any wiki markup is deleted. For the Explicit Semantic Analysis, we use Wiktionary (Zesch et al., 2008) and not Wikipedia assuming that the former has a better coverage with respect to different lexical classes. POS tagging was carried out using the OpenNLP POS tagger.[5] The vandalism word list contains a hand-crafted set of around 100 vandalism and spam words from various places in the web.

3.3 Experimental Setup

We extract features with the help of ClearTK (Ogren et al., 2008). For the machine learning part, we use Weka (Hall et al., 2009) with the Meka[6] and Mulan (Tsoumakas et al., 2010) extensions for multi-label classification. We use DKPro Lab (Eckart de Castilho et al., 2011) to test different parameter combinations. We randomly split the gold standard data from WPEC into 80% training, 10% test and 10% development set, as shown in Table 2.

Multi-label Classification We report the performance of various machine learning algorithms. A comprehensive overview of multi-label classification algorithms and evaluation measures can be found in Madjarov et al. (2012). Multi-label classification problems are solved by either transforming the multi-label classification task into one or more single-label classification tasks (problem transformation method) or by adapting single-label classification algorithms (algorithm adaption method). Several algorithms have been developed on top of the former methods and use ensembles of such classifiers (ensemble methods). We applied the Binary Relevance approach (BR), a simple transformation method which converts the multi-label problem into $|C|$ binary single-label problems, where $|C|$ is the number of categories. Hence, this method trains a classifier for each category in the corpus (one-against-all). It is the most straightforward approach when dealing with multi-labeled data. However, it does not consider possible relationships or dependencies between categories. Therefore, we tested two more sophisticated methods. Hierarchy of multi-label classifiers HOMER (Tsoumakas et al., 2008) is a problem transformation method. It accounts for possibly hierarchical relationships among categories by dividing the overall category set into a tree-like structure with nodes of small category sets of size k and leaves of single categories. Subsequently, a multi-label classifier is applied to each node in the tree. Random k-labelsets RAKEL (Tsoumakas et al., 2011) is an ensemble method, which randomly chooses l typically small subsets with k categories from the overall set of categories. Subsequently, all k-labelsets which are found in the multi-labeled data set are converted into new categories in a single-labeled data set using the la-

[6] `http://meka.sourceforge.net`

bel powerset transformation (Trohidis et al., 2008). HOMER and BR are among the multi-label classifiers, which Madjarov et al. (2012) recommend as benchmark methods. As underlying single-label classification algorithm, we used a C4.5 decision tree classifier (Quinlan, 1993), as decision tree classifiers yield state-of-the-art performance in the related work.

Multi-label Evaluation We denote the set of relevant categories for each edit $e_i \in E$ as $y_i \in C$ and the set of predicted categories as $h(e_i)$. Evaluation measures for multi-label classification systems are based on either bipartitions or rankings. Among the former, we report example-based (weighting each edit equally) and label-based (weighting each edit category equally) measures. The accuracy of a multi-label classifier is defined as $\frac{1}{|E|}\sum_{i=1}^{|E|}\frac{|h(e_i)\cap y_i|}{|h(e_i)\cup y_i|}$, which corresponds to the Jaccard similarity of $h(e_i)$ and y_i averaged over all edits. We report subset accuracy (exact match), calculated as $\frac{1}{|E|}\sum_{i=1}^{|E|} I$, with $I = 1$ if $h(e_i) = y_i$ and $I = 0$ otherwise. Example-based precision is defined as $\frac{1}{|E|}\sum_{i=1}^{|E|}\frac{|h(e_i)\cap y_i|}{|h(e_i)|}$, recall as $\frac{1}{|E|}\sum_{i=1}^{|E|}\frac{|h(e_i)\cap y_i|}{|y_i|}$, and F1 as $\frac{1}{|E|}\sum_{i=1}^{|E|}\frac{2\times|h(e_i)\cap y_i|}{|h(e_i)|+|y_i|}$. For the label-based measures, we report macro- and micro-averaged F1 scores. As a ranking-based measure, we report one error, which is defined as $\frac{1}{|E|}\sum_{i=1}^{|E|}[\![[arg\ \underset{c\in C}{max} f(e_i,c)] \notin y_i]\!]$, $[\![expr]\!] = 1$ if $expr$ is true and $[\![expr]\!] = 0$ otherwise. $f(e_i, c)$ denotes the rank of category $c \in C$ as predicted by the classifier. The one error measure evaluates the number of edits where the highest ranked category in the predictions is not in the set of relevant categories. It becomes smaller when the performance of the classifier increases.

Table 3 shows the overall classification scores. We calculated a random baseline, which multi-labels edits at random considering the label powerset frequencies it has learned from the training data. Furthermore, we calculated a majority category baseline, which labels all edits with the most frequent edit category in the training data. In Figure 2, we list the results for each category, together with the average pair-wise inter-rater agreement (F1 scores). The F1 scores are calculated based on the study we carried out in Daxenberger and Gurevych (2012).

Parameters and Feature selection All parameters have been adjusted on the development set using the RAKEL classifier, aiming to optimize accuracy. With respect to the n-gram features, we tested values for n = 1, 2 and 3. For comment n-grams, unigrams turned out to yield the best overall performance, and bigrams for character and token n-grams. The word and character n-gram spaces are limited to the 500 most frequent items, the comment n-gram space is limited to the 1,500 most frequent items. To transform ranked output into bipartitions, it is necessary to set a threshold. This threshold is reported in Table 3 and has been optimized for each classifier with respect to label cardinality (average number of labels assigned to edits) on the development set. Since most of the traditional feature selection methods cannot be applied directly to multi-labeled data, we used the label powerset approach to transform the multi-labeled data into single-labeled data and subsequently applied χ^2. Feature reduction to the highest-ranked features clearly improved the classifier performance on the development set. We therefore limited the feature space to the 150 highest-ranked features in our experiments.

For the RAKEL classifier, we set $l = 42$ (twice the size of the category set) and $k = 3$. In HOMER, we used BR as transformation method, random distribution of categories to the children nodes and $k = 3$. For all other classifier parameters, we used the default settings as configured in Meka respective Mulan.

4 Discussion

The classifiers significantly outperformed both baselines. RAKEL shows best performance for almost all measures in Table 3. The simpler BR approach, which assumes no dependencies between categories, still outperforms HOMER.

We trained and tested the classifier with different feature groups (see Table 1), to analyze the importance of single types of features. As shown in Figure 2, textual features had the highest impact on classification performance. On the opposite, language features played a minor role in our experiments. Among the highest ranked individual features for the entire set of categories, we find textual (*Levenshtein distance*, *Simple edit type*), markup (*Diff number*

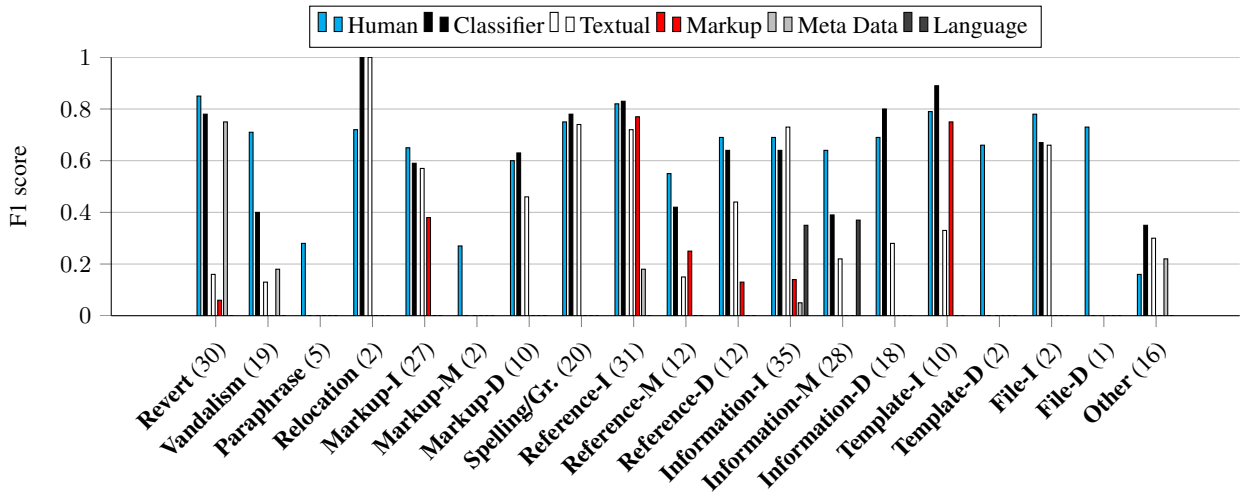

Figure 2: F1 scores of RAKEL with C4.5 as base classifier for individual categories. We add human inter-annotator agreement as average pair-wise F1 scores as well as F1 scores for classifiers trained and tested on single feature groups, cf. Table 1. The number of edits labeled with each category in the test set is given in brackets. The FILE-M and TEMPLATE-M categories are omitted in this Figure, as they had no examples in the development or test set.

markup elements) and meta data (*Number of edits*) features.

Bronner and Monz (2012) report an accuracy of .88 for their best performing system on the binary classification task of distinguishing fluency and factual edits. The best performing classifier in their study was Random Forests (Breiman, 2001). To compare our features with their approach, we mapped the 21 edit categories from Daxenberger and Gurevych (2012) to the binary category set (factual vs. fluency) of Bronner and Monz (2012). Edits labeled as SPELLING/GRAMMAR, MARKUP, RELOCATION and PARAPHRASE are considered fluency edits, the remaining categories factual edits. We removed all edits labeled as OTHER, REVERT or VANDALISM from WPEC. After applying the category mapping, we deleted all edits which were labeled with both the fluency and factual category. The latter may happen due to multi-labeling. This resulted in 1,262 edits labeled as either fluency or factual. On the 80% training split from Table 2, we trained a Random Forests classifier with the optimized feature set and feature reduction as described in Section 3.3. The number of trees was set to 100, with unlimited depth. On the remaining data (test and development split), we achieved an accuracy of .90. Although we did not use the same data set as Bronner and Monz (2012), this result suggests that our feature set is suited for related tasks such as fluency detection.

With respect to vandalism detection in Wikipedia, state-of-the-art systems have a performance of around .82 to .85 AUC-PR on the English Wikipedia (Adler et al., 2011). We suspect that the low performance of our system for Vandalism edits is mostly due to a lower amount of training data, a higher skew in the training and test data and the fact that we did not include features which inform about future actions (e.g. whether a revision is reverted).

Error Analysis Sparseness is a major problem for some of the 21 categories, as shown in Figure 2 by categories such as FILE-D, TEMPLATE-D, MARKUP-M or PARAPHRASE which have only very few examples in training, development and test set. Categories with low inter-annotator agreement in WPEC such as MARKUP-M, PARAPHRASE or OTHER also yielded low classification accuracy. We analyzed frequent errors of the classifier with the help of a confusion matrix. PARAPHRASE edits have been confused with INFORMATION-M by the classifier. Furthermore, the classifier had problems to distinguish between VANDALISM and REVERT as well as INFORMATION-I. Generally, modifications as compared to insertions or deletions perform worse. All of the classifiers we tested, build

their predictions by thresholding over a ranking, cf. Table 3. This generates a source of errors, because the classifier is not able to make a prediction, if it does not have enough confidence for any of the categories. The imbalance of the data, because of the high skew in the category distribution, is another reason for classification errors. In ambiguous cases, the classifier will be biased toward the category with more examples in the training data.

5 A closer look at edit sequences: Mining collaboration patterns

An edit category classifier allows us to label entire article revision histories. We applied the best-performing model from Section 3.3 trained on the entire WPEC to automatically classify all edits in the Wikipedia Quality Assessment Corpus (WPQAC) as presented in previous work (Daxenberger and Gurevych, 2012). WPQAC consists of 10 featured and 10 non-featured articles[7], with an overall number of 21,578 revisions (9,986 revisions from featured articles and 11,592 from non-featured articles), extracted from the April 2011 English Wikipedia dump. The articles in WPQAC are carefully chosen to form comparable pairs of featured and non-featured articles, which should reduce the noise of external influences on edit activity such as popularity or visibility. In Daxenberger and Gurevych (2012), we have shown significant differences in the edit category distribution of articles with featured status before and after the articles were featured. We concluded that articles become more stable after being featured, as shown by the higher number of surface edits and lower number of meaning-changing edits.

Different to our previous approach which is based on the mere distribution of edit categories, in the present study we include the chronological order of edits and use a 10 times larger amount of data for our experiments. We segmented all adjacent revisions in WPQAC into edits, following the approach explained in Daxenberger and Gurevych (2012). During the classification process, we discarded revisions where the classifier could not assign any of the 21 edit categories with a confidence higher than the threshold, cf. Table 3. This resulted in 17,640 remaining revisions. We applied a sequential pattern mining algorithm with time constraints (Hirate and Yamana, 2006; Fournier-Viger et al., 2008) to the data. The latter is based on the PrefixSpan algorithm (Pei et al., 2004). Calculations have been carried out within the open-source SPMF Java data mining platform.[8]

We created one time-extended sequence database for the 10 featured articles and one for the 10 non-featured articles. The sequence databases consist of one row per article. Each row is a chronologically ordered list of revisions. Each revision is represented by the itemset of all edit categories for all edits in that revision (in alphabetical order).

The output of the algorithm are sequential patterns with time constraints. To obtain meaningful results, we constrained the output with the following parameters:

- Minimum support: 1 (the patterns have to be present in each article)
- Time interval allowed between two successive itemsets in the patterns: 1 (patterns are extracted only from adjacent revisions)
- Minimum time interval between the first itemset and the last itemset in the patterns: 1 (the length of the patterns is 2 or higher)

As this output reflects recurring sequences of adjacent revisions labeled with edit categories, we refer to it as *collaboration patterns*. With these parameters, the algorithm discovered 1,358 sequential patterns for featured articles and 968 for non-featured articles. The number of shared patterns in featured and non-featured articles is 427, this corresponds to the number of frequent patterns in a sequence database which contains all 20 featured and non-featured articles. The maximum length of patterns which were found was 6 for featured articles, and 5 for non-featured articles. These numbers show that the defined collaboration patterns seem to have discriminative power for different kinds of articles. Featured articles can be characterized by a higher

Table 4: Examples of collaboration patterns which have been found in either all featured or all non-featured articles of WPQAC.

degree of homogeneity with respect to their collaborative patterns due to a higher number and length of frequent sequential patterns in featured articles as compared to non-featured articles.

In Table 4, we list some examples of collaboration patterns with a minimum support of 1 which we found in featured, but not non-featured articles, or vice verse. Unsurprisingly, patterns which contain combinations of the most frequent categories (INFORMATION-I, REFERENCE-I), have a high overall frequency. The diversity inside collaboration patterns measured by the number of different edit categories was higher in non-featured articles. For example, the VANDALISM - REVERT pattern was only found in non-featured articles. Patterns in featured articles tended to be more homogeneous, as shown by the first pattern in Table 4, a repetition of additions of information. We conclude that distinguished, high-quality articles, show a higher degree of homogeneity as compared to a subset of non-featured articles and the overall corpus.

6 Conclusion

In this study, we evaluated a novel feature set for building a model to automatically classify Wikipedia edits. Using a freely available corpus (Daxenberger and Gurevych, 2012), our model achieved a micro-averaged F1 score of .62 classifying edits within a range of 21 categories. Textual features had the highest impact on classifier performance, whereas language features play a minor role. The same classifier model obtained state-of-the-art performance on the related task of fluency edit classification. Applications which potentially benefit from our work include the analysis of the writing process in collaboratively created documents, such as wikis or research papers. We have demonstrated how our model can be used to detect collaboration patterns in article revision histories. On a subset of articles from the English Wikipedia, we found that high-quality articles show a higher degree of homogeneity in their collaborative patterns as compared to random articles. Furthermore, automatic edit category classification allows to generate huge amounts of category-filtered training data for NLP tasks, e.g. spelling and grammar correction or vandalism detection. With respect to future work, we plan to include more resources, e.g. the PAN-WVC-10 (Potthast and Holfeld, 2011) or WiCoPaCo (Max and Wisniewski, 2010) to increase the size of training data. A larger amount of labeled data would certainly help to improve the classifier performance for weak categories (e.g. VANDALISM and PARAPHRASE) and sparse categories (e.g. TEMPLATE-D, MARKUP-M). Based on our trained classifier, annotating more examples can be alleviated with the help of active learning.

Abstract

We introduce a novel discriminative model for phrase-based monolingual alignment using a semi-Markov CRF. Our model achieves state-of-the-art alignment accuracy on two phrase-based alignment datasets (RTE and paraphrase), while doing significantly better than other strong baselines in both non-identical alignment and phrase-only alignment. Additional experiments highlight the potential benefit of our alignment model to RTE, paraphrase identification and question answering, where even a naive application of our model's alignment score approaches the state of the art.

1 Introduction

Various NLP tasks can be treated as an alignment problem: machine translation (aligning words in one language with words in another language), question answering (aligning question words with the answer phrase), textual entailment recognition (aligning premise with hypothesis), paraphrase detection (aligning semantically equivalent words), etc. Even though most of these tasks involve only a single language, alignment research has primarily focused on the bilingual setting (i.e., machine translation) rather than monolingual. Moreover, most work has considered token-based approaches over phrase-based.[1] Here we seek to address this imbalance by proposing better phrase-based models for monolingual word alignment.

Most token-based alignment models can extrinsically handle phrase-based alignment to some extent. For instance, in the case of `NYC` aligning to `New York City`, the single source word `NYC` may align three times separately to the target words: `NYC`↔`New`, `NYC`↔`York`, `NYC`↔`City`. Or in the case of identical alignment, `New York City` aligning to `New York City` is simply `New`↔`New`, `York`↔`York`, `City`↔`City`. However, it is not as clear how to token-align `New York` (as a city) with `New York City`. The problem is more prominent when aligning phrasal paraphrases or multiword expressions, such as `pass away` and `kick the bucket`. This suggests an intrinsically phrase-based alignment model.

The token aligner jacana-align (Yao et al., 2013a) has achieved state-of-the-art result on the task of monolingual alignment, based on previous work of Blunsom and Cohn (2006). It employs a Conditional Random Field (Lafferty et al., 2001) to align tokens from the source sentence to tokens in the target sentence, by treating source tokens as "observation" and target tokens as "hidden states". However, it is not designed to handle phrase-based alignment, largely due to the Markov nature of the underlying model: a state can only span one token each time, making it unable to align multiple consecutive tokens (i.e. a phrase). We extend this model by introducing semi-Markov states for phrase-based alignment: a state can instead span multiple consecutive time steps, thus aligning phrases on the source side. Also, we merge phrases on the target side to phrasal states, allowing the model to align phrases on the target side as well. We evaluate the resulting semi-Markov

[1] In this paper we use the term token-based alignment for one-to-one alignment and phrase-based for non one-to-one alignment, and word alignment in general for both.

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 590–600,
Seattle, Washington, USA, 18-21 October 2013.

CRF model on the task of phrase-based alignment, and then show a basic application in the NLP tasks of recognizing textual entailment, paraphrase identification, and question answering sentence ranking. The final phrase-based aligner is open-source.[2]

2 Related Work

Most work in monolingual alignment employs dependency tree/graph matching algorithms, including tree edit distance (Punyakanok et al., 2004; Kouylekov and Magnini, 2005; Heilman and Smith, 2010; Yao et al., 2013b), Particle Swarm Optimization (Mehdad, 2009), linear regression/classification models (Chambers et al., 2007; Wang and Manning, 2010), and min-cut (Roth and Frank, 2012). These works inherently only support token-based alignment, with phrase-like alignment achieved by first merging tokens to phrases as a *preprocessing* step.

The MANLI aligner (MacCartney et al., 2008) and its derivations (Thadani and McKeown, 2011; Thadani et al., 2012) are the first known phrase-based aligners specifically designed for aligning English sentence pairs. It applies discriminative perceptron learning with various features and handles phrase-based alignment of arbitrary phrase lengths. MANLI suffers from slow decoding time due to its large search space. This was optimized by Thadani and McKeown (2011) through Integer Linear Programming (ILP), where benefiting from modern ILP solvers they showed an order-of-magnitude speedup in decoding. Also, various syntactic constraints can be easily added, significantly improving exact alignment match rate for whole sentence pairs. Besides the common application of textual entailment and question answering, monolingual alignment has also been applied in the field of text generation (Barzilay and Lee, 2003; Pang et al., 2003).

Word alignment has been more explored in machine translation. The IBM models (Brown et al., 1993) allow many-to-one alignment and are essentially asymmetric. Phrase-based MT historically relied on heuristics (Koehn, 2010) to merge two sets of word alignment in opposite directions to yield phrasal alignment. Later, researchers explored non-heuristic phrase-based methods. Among them, Marcu and Wong (2002) described a joint probability model that generates both the source and target sentences simultaneously. All possible pairs of phrases in both sentences are enumerated and then pruned with statistical evidence. Deng and Byrne (2008) explored token-to-phrase alignment based on HMM models (Vogel et al., 1996) by explicitly modeling the token-to-phrase probability and phrase lengths. However, the token-to-phrase alignment is only in one direction: each target state still only spans one source word, and thus alignment on the source side is limited to tokens. Andrés-Ferrer and Juan (2009) extended the HMM-based method to Hidden Semi-Markov Models (HSMM) (Ostendorf et al., 1996), allowing phrasal alignments on the source side. Finally, Bansal et al. (2011) unified the HSMM models with the alignment by agreement framework (Liang et al., 2006), achieving phrasal alignment that agreed in both directions.

Despite successful usage of generative semi-Markov models in bilingual alignment, this has not been followed with models in discriminative monolingual alignment. Essentially monolingual alignment would benefit more from discriminative models with various feature extractions (just like those defined in MANLI) than generative models without any predefined feature (just like how they were used in bilingual alignment). To combine the strengths of both semi-Markov models and discriminative training, we propose to use the semi-Markov Conditional Random Field (Sarawagi and Cohen, 2004), which was first used in information extraction to tag continuous segments of input sequences and outperformed conventional CRFs in the task of named entity recognition. We describe this model in the following section.

3 The Alignment Model

Our objective is to define a model that supports phrase-based alignment of arbitrary phrase length. In this section we first describe a regular CRF model that supports one-to-one token-based alignment (Blunsom and Cohn, 2006; Yao et al., 2013a), then extend it to phrase-based alignment with the semi-Markov model.

[2] http://code.google.com/p/jacana/

3.1 Token-based Model

Given a source sentence $\mathbf{s}$ of length M, and a target sentence $\mathbf{t}$ of length N, the alignment from $\mathbf{s}$ to $\mathbf{t}$ is a sequence of target word indices $\mathbf{a}$, where $a_{i\in[1,M]} \in [0, N]$. We specify that when $a_i = 0$, source word s_i is aligned to a NULL state, i.e., deleted. This models a many-to-one alignment from source to target: multiple source words can be aligned to the same target word, but not vice versa. One-to-many alignment can be obtained by running the aligner in the other direction. The probability of alignment sequence $\mathbf{a}$ conditioned on both $\mathbf{s}$ and $\mathbf{t}$ is then:

$$p(\mathbf{a} \mid \mathbf{s}, \mathbf{t}) = \frac{\exp(\sum_{i,k} \lambda_k f_k(a_{i-1}, a_i, \mathbf{s}, \mathbf{t}))}{Z(\mathbf{s}, \mathbf{t})}$$

This assumes a first-order Conditional Random Field (Lafferty et al., 2001). Since the word alignment task is evaluated over F_1, instead of directly optimizing it, we choose a much easier objective (Gimpel and Smith, 2010) and add a cost function to the normalizing function $Z(\mathbf{s}, \mathbf{t})$ in the denominator:

$$Z(\mathbf{s}, \mathbf{t}) = \sum_{\hat{\mathbf{a}}} \exp(\sum_{i,k} \lambda_k f_k(\hat{a}_{i-1}, \hat{a}_i, \mathbf{s}, \mathbf{t}) + cost(\mathbf{a_y}, \hat{\mathbf{a}}))$$

where $\mathbf{a_y}$ is the true alignments. $cost(\mathbf{a_y}, \hat{\mathbf{a}})$ can be viewed as special "features" that encourage decoding to be consistent with true labels. It is only computed during training in the denominator because in the numerator $cost(\mathbf{a_y}, \mathbf{a_y}) = 0$. Hamming cost is used in practice without learning the weights (i.e., uniform weights). The more inconsistence there is between $\mathbf{a_y}$ and $\hat{\mathbf{a}}$, the more penalized is the decoding sequence $\hat{\mathbf{a}}$ through the cost function.

3.2 Phrase-based Model

The token-based model supports $1 : 1$ alignment. We first extend it in the direction of $l_s : 1$, where a target state spans l_s words on the source side (l_s source words align to 1 target word). Then we extend it in the direction of $1 : l_t$, where l_t is the target phrase length a source word aligns to (1 source word aligns to l_t target words). The final combined

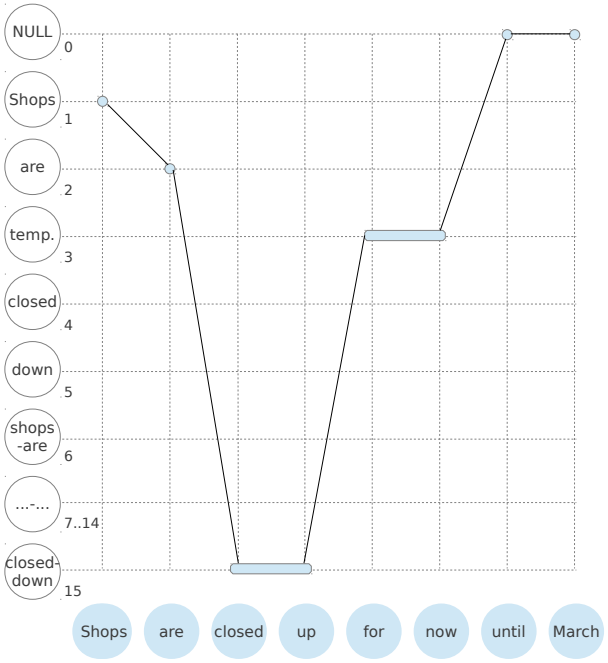

Figure 1: A semi-Markov phrase-based model example and the desired Viterbi decoding path. Shaded horizontal circles represent the source sentence (`Shops are closed up for now until March`) and hollow vertical circles represent the hidden states with state IDs for the target sentence (`Shops are temporarily closed down`). State 0, a NULL state, is designated for deletion. One state (e.g. state 3 and 15) can span multiple consecutive source words (a semi-Markov property) for aligning phrases on the source side. States with an ID larger than the target sentence length indicate "phrasal states" (states 6-15 in this example), where consecutive target tokens are merged for aligning phrases on the target side. Combining the semi-Markov property and phrasal states yields for instance, a 2×2 alignment between `closed up` in the source and `closed down` in the target.

model supports $l_s : l_t$ alignment. Throughout this section we use Figure 1 as an illustrative example, which shows phrasal alignment between the source sentence: (`Shops are closed up for now until March`) and the target sentence: (`Shops are temporarily closed down`).

$1 : 1$ alignment is a special case of $l_s : 1$ alignment where the target side state spans $l_s = 1$ source word, i.e., at *each* time step i, the source side word

s_i aligns to one state a_i and the next aligned state a_{i+1} only depends on the current state a_i. This is the Markovian property of the CRF. When $l_s > 1$, during the time frame $[i, i + l_s)$, all source words $[a_i, a_{i+l_s})$ share the same state a_i. Or in other words, the state a_i "spans" the following l_s time steps. The Markovian property still holds "outside" the time frame l_s, i.e., a_{i+l_s} still only depends on a_i, the previous state l_s time steps ago. But "within" the time frame l_s, the Markovian property does not hold any more: $[a_i, ..., a_{i+l_s-1}]$ are essentially the same state a_i. This is the semi-Markov property . States can be distinguished by this property into two types: *semi-Markovian states* and *Markovian states*.

We have generalized the regular CRF to a semi-Markov CRF. Now we define it by generalizing the feature function:

$$p(\mathbf{a} \mid \mathbf{s}, \mathbf{t}) = \frac{\exp(\sum_{i,k,l_s} \lambda_k f_k(a_{i-l_s}, a_i, \mathbf{s}, \mathbf{t}))}{Z(\mathbf{s}, \mathbf{t})}$$

At time i, the k-th feature function f_k mainly extracts features from the pair of source words $(s_{i-l_s}, ..., s_i]$ and target word t_{a_i} (still with a special case that $a_i = 0$ marks for deletion). Inference is still Viterbi-like: except for the fact during maximization, the Viterbi algorithm not only checks the previous *one* time step, but *all* l_s time steps. Suppose the allowed maximal source phrase length is L_s, define $V_i(a \mid \mathbf{s}, \mathbf{t})$ as the highest score along the decoding path until time i ending with state a:

$$V_i(a \mid \mathbf{s}, \mathbf{t}) = \max_{a_1, a_2, ... a_{i-1}} p(a_1, a_2, \ldots, a_i = a \mid \mathbf{s}, \mathbf{t})$$

then the recursive maximization is:

$$\begin{aligned} V_i(a \mid \mathbf{s}, \mathbf{t}) &= \max_{a'} \max_{l_s = 1 ... L_s} [V_{i-l_s}(a' \mid \mathbf{s}, \mathbf{t}) \\ &\quad + \Psi_i(a', a, l_s, \mathbf{s}, \mathbf{t})] \end{aligned}$$

with factor:

$$\Psi_i(a', a, l_s, \mathbf{s}, \mathbf{t}) = \sum_k \lambda_k f_k(a'_{i-l_s}, a_i, \mathbf{s}, \mathbf{t})$$

and the best alignment $\mathbf{a}$ can be obtained by backtracking the last state a_M from $V_M(a_M \mid \mathbf{s}, \mathbf{t})$.

Training a semi-Markov CRF is very similar to the inference, except for replacing maximization with summation. The forward-backward algorithm should also be used to dynamically compute the normalization function $Z(\mathbf{s}, \mathbf{t})$. Compared to regular CRFs, a semi-Markov CRF has a decoding time complexity of $O(L_s M N^2)$, a constant factor L_s (usually 3 or 4) slower.

To extend from $1:1$ alignment to $1:l_t$ alignment with one source word aligning to l_t target words, we simply explode the state space by L_t times with L_t the maximal allowed target phrase length. Thus the states can be represented as an $N \times L_t$ matrix. The state at (j, l_t) represents the target phrase $[t_j, ..., t_{j+l_t})$. In this paper we distinguish states by three types: NULL state ($j = 0, l_t = 0$), *token state* ($l_t = 1$) and *phrasal state* ($l_t > 1$).

To efficiently store and compute these states, we linearize the two dimensional matrix with a linear function mapping uniquely between the state ID and the target phrase offset/span. Suppose the target phrase t_j of length $l_{t_j} \in [1, L_t]$ holds a position $p_{t_j} \in [1, N]$, and the source word s_i is aligned to this state (p_{t_j}, l_{t_j}), a tuple for (position, span). Then state ID a_{s_i} is computed as:

$$a_{s_i}(p_{t_j}, l_{t_j}) = \begin{cases} p_{t_j} & l_{t_j} = 1 \\ N + (p_{t_j} - 1) \times L_t + l_{t_j} & 1 < l_{t_j} \leq L_t \end{cases}$$

Assume in Figure 1, $L_t = 2$, then the state ID for the phrasal state (5, 2) `closed-down` with $p_{t_j} = 5$ for the position of word `down` and $l_{t_j} = 2$ for the span of 2 words (looking "backward" from the word `down`) is: $5 + (5 - 1) \times 2 + 2 = 15$.

Similarly, given a state id a_{s_i}, the original target phrase position and length can be recovered through integer division and modulation. Thus during decoding, if one output state is 15, we would know that it uniquely comes from the phrasal state (5,2), representing the target phrase `closed down`.

This two dimensional definition of state space expands the number of states from $1 + N$ to $1 + L_t N$. Thus the decoding complexity becomes $O(M(L_t N)^2) = O(L_t^2 M N^2)$ with a usual value of 3 or 4 for L_t.

Now we have defined separately the $l_s : 1$ model and the $1 : l_t$ model. We can simply merge them to

have an $l_s : l_t$ alignment model. The semi-Markov property makes it possible for any target states to align phrases on the source side, while the two dimensional state mapping makes it possible for any source words to align phrases on the target side. For instance, in Figure 1, the phrasal state a_{15} represents the two-word phrase `closed down` on the target side, while still spanning for two words on the source side, allowing a 2×2 alignment. State a_{15} is phrasal, and at source word position 3 and 4 (spanning `closed up`) it is semi-Markovian. The final decoding complexity is $O(L_s L_t^2 M N^2)$, a factor of $30 \sim 60$ times slower than the token-based model (with a typical value of 3 or 4 for L_s and L_t).

In the following we describe features.

3.3 Feature Design

We reused features in the original token-based model based on string similarity, POS tags, position, WordNet, distortion and context. Then we used an additional chunker to mark phrase boundaries *only* for feature extraction:

Chunking Features are binary indicators of whether the phrase types of two phrases match. Also, we added indicators for mappings between source phrase types and target phrase types, such as "vp2np", meaning that a verb phrase in the source is mapped to a noun phrase in the target.

Moreover, we introduced the following lexical features:

PPDB Features (Ganitkevitch et al., 2013) include various similarity scores derived from a paraphrase database with 73 million phrasal and 8 million lexical paraphrases. Various paraphrase conditional probability was employed. For instance, for the ADJP/VP phrase pair `capable of` and `able to`, there are the following minus-log probabilities:

$$p(lhs|e1) = 0.1, p(lhs|e2) = 0.3, p(e1|lhs) = 5.0$$
$$p(e1|e2) = 1.3, p(e2|lhs) = 6.7, p(e2|e1) = 2.8$$
$$p(e1|e2, lhs) = 0.6, p(e2|e1, lhs) = 2.3$$

where $e1/e2$ are the phrase pair, and lhs is the left hand side syntactic non-terminal symbol. We did not use the syntactic part (e.g., `the` NP `of` NNS $\leftrightarrow$ `the` NNS `of` NP) of PPDB as we did not make the assumption that the input sentence pairs were well-formed (and newswire-like) English, or even of a language with a parser available. Also, for phrasal alignments, we ruled out those paraphrases spanning multiple syntactic structures, or of different syntactic structures (indicated as `[X]` in PPDB), for instance, `and crazy` $\leftrightarrow$ `, mad`.

Semantic Relatedness Feature is a single scaled number in $[0, 1]$ from the best performing system (Han et al., 2013) of the *Sem 2013 Semantic Textual Similarity (STS) task. We included this feature mainly to deal with cases where "related" words cannot be well measured by either paraphrases or distributional similarities. For instance, in one alignment dataset annotators aligned `married` with `wife`. Adding a few other words as comparison, the Han et al. (2013) system gives the following similarity scores:

```
married/wife:  0.85
married/husband:  0.84
married/child:  0.10
married/stone:  0.01
```

Name Phylogeny Feature (Andrews et al., 2012) is a similarity feature with a string transducer to model how one name evolves to another. Examples below show how similar is the name `Bill` associated with other names in log probability:

```
Bill/Bill:  -0.8
Bill/Billy:  -5.2
Bill/William:  -13.6
Bill/Mary:  -18.6
```

Finally, one decision we made during feature design was not to use any parsing-based features, with a permissive assumption that the input might not be well-formed English, or even not complete sentences (such as fragmented snippets from web search). The "deepest" linguistic processing stays at the level of tagging and chunking, making the model more easily extendable to other languages.

3.4 Feature Value

In this phrase-based model, the width of a state span over the source words depends on the competition between features fired on the phrases as a whole vs. the consecutive but individual tokens. We found it critical to assign feature values "fairly" among tokens and phrases to make sure that semi-Markov states and phrasal states fire up often enough for phrasal alignments.

	train	test	length	%align.
MSR06	800	800	29/11	36%
Edinburgh++	715	305	22/22	78%

Table 1: Statistics of the two manually aligned corpora, divided into training and test in sentence pairs. The length column shows average lengths of source and target sentences in a pair. %align. is the percentage of aligned tokens.

	1x1	1x2	1x3	2x2	2x3	3x3	more
MSR06	89.2	1.9	0.3	5.7	0.0	1.9	0.8
EDB++	81.9	3.5	0.8	8.3	0.4	3.0	2.1

Table 2: Percentage of various alignment sizes (undirectional, e.g., 1x2 and 2x1 are merged) after synthesizing phrasal alignment from token alignment in the *training* portion of two corpora.

To illustrate this in a simplified way, take `closed up↔closed down` in Figure 1, and assume the only feature is the normalized number of matching tokens in the pair. Then this feature firing on the following pairs would have values (the normalization factor is the maximal phrase length):

`closed↔closed`	1.0
`closed up↔closed`	0.5
`closed up↔up`	0.5
`closed up↔closed down`	0.5
`...↔...`	...

The desired alignment `closed up↔closed down` would not have survived the state competition due to its weak feature value. In this case the model would simply prefer a token alignment `closed↔closed` and up↔`...` (probably NULL).

Thus we upweighted feature values by the maximum source or target phrase length to encourage phrasal alignments, in this case `closed up ↔closed down`:1.0. Then this alignment would have a better chance to be picked out with additional features, such as with the PPDB and Semantic Relatedness Features, which are also upweighted by maximum phrase lengths.

4 Experiment

4.1 Data Preparation

There are two annotated datasets for training and testing. **MSR06**[3] (Brockett, 2007) has annotated alignments on the 2006 PASCAL RTE2 development and test corpora, with 1600 pairs in total. Semantically equivalent words and phrases in the premise and hypothesis sentences are aligned in a manner analogous to alignments in statistical machine translation. This dataset is asymmetric: on average the premises contain 29 words and the hypotheses 11 words. **Edinburgh++**[4] (Thadani et al., 2012) is a revised version of the Edinburgh paraphrase corpus(Cohn et al., 2008) with sentences from the following resources: 1. the Multiple-Translation Chinese corpus; 2. Jules Verne's novel Twenty Thousand Leagues Under the Sea. 3. the Microsoft Research paraphrase corpus (Dolan et al., 2004). The corpus is more balanced and symmetric: the source and target sentences are both 22 words long on average. Table 1 shows some statistics.

Both corpora contain mostly token-based alignment. For MSR06, MacCartney et al. (2008) showed that setting the allowable phrase size to be greater than one only increased F_1 by 0.2%. For Edinburgh++, the annotation guideline[5] explicitly instructs to "prefer smaller alignments whenever possible". Statistics shows that single token alignment counts 96% and 95% of total alignments in these two corpora separately. With such a heavy imbalance towards only token-based alignment, a phrase-based aligner would learn feature weights that award token alignments more than phrasal alignments.

Thus we synthesized phrasal alignments from continuous monotonic token alignments in these two corpora. We first ran the OpenNLP chunker through the corpora. Then for each phrase pair, if each token in the source phrase is aligned to a token in the target phrase in a monotonic way, and vice versa, we

[3] `http://www.cs.biu.ac.il/~nlp/files/RTE_2006_Aligned.zip`

[4] `http://www.ling.ohio-state.edu/~scott/#edinburgh-plusplus`

[5] `http://staffwww.dcs.shef.ac.uk/people/T.Cohn/paraphrase_guidelines.pdf`

merge these alignments to form one single phrasal alignment.[6] Table 2 lists the percentage of various alignment sizes after the merge. Two observations can be made: first, the portion of phrasal alignments increases to $10\% \sim 20\%$ after merging; second, allowing a maximal phrase length of 3 covers $98\% \sim 99\%$ of total alignments, thus a phrase length larger than 3 would be a bad trade-off for coverage vs speed.

4.2 Baselines and Evaluation Metrics

MacCartney et al. (2008) and Yao et al. (2013a) showed that the traditional MT bilingual aligner GIZA++ (Och and Ney, 2003) presented weak results on the task of monolingual alignment. Thus we instead used four other strong baselines:

Meteor (Denkowski and Lavie, 2011): a system for evaluating machine translation by aligning MT output with reference sentences. It is designed for the task of monolingual alignment and supports phrasal alignment. We used version 1.4 and default weights to optimize by maximum accuracy.

MANLI-constraint (Thadani and McKeown, 2011): a re-implemented MANLI system with ILP-powered decoding for speed and hard syntactic constraints to boost exact match rate, with reported numbers on MSR06.

MANLI-joint (Thadani et al., 2012): an improved version of MANLI-constraint that not only models phrasal alignments, but also alignments between dependency arcs, with reported numbers on the original Edinburgh paraphrase corpus.

jacana-token (Yao et al., 2013a): a token-based aligner with state-of-the-art performance on MSR06.

Note that the jacana-token aligner is open-source, so we were able to re-train it with exactly the same feature set used by our phrase-based model. This allows a fair comparison of model performance (token-based vs. phrase-based). The MANLI* systems are not available, thus we only reported their numbers from published papers.

The standard evaluation metrics for alignments are precision (P), recall (R), F_1, and exact matching rate (E) based on either tokens (two tokens are considered aligned iff they are aligned) or phrases (two tokens are considered aligned iff they are contained within phrases that are aligned). Following Thadani et al. (2012), we only report the results based on token alignments (which allows a partial credit if their containing phrases are not aligned), even for the phrase-based alignment task. The reasoning is that if a phrase-based aligner is already doing better than a token aligner in terms of token alignment scores, then the difference in terms of phrase alignment scores will be even larger. Thus showing the superiority of token alignment scores is sufficient.

4.3 Implementation and Training

The elements in the phrase-based model: dynamic state indices, semi-Markov and phrasal states, are not typically found in standard CRF implementations. Thus we implemented the phrase-based model in the Scala programming language, which is fully interoperable with Java, using one semi-Markov CRF package[7] as a reference. We used the L2 regularizer and LBFGS for optimization. OpenNLP[8] provided the POS tagger and chunker and JWNL[9] interfaced with WordNet (Fellbaum, 1998).

4.4 Results

Table 3 gives scores (in bigger fonts) of different aligners on MSR06 and Edinburgh++ and their corresponding phrasal versions. Overall, the token-based aligner did the best on the original corpora, in which single token alignment counts more than 95% of total alignment. The phrase-based aligner did slightly worse. We think the main reason was that it output more phrasal alignment, which in turn harms scores in token-based evaluation (for instance, if the gold alignment is `New`↔`New`, `York`↔`York`, then the phrasal alignment of `New York`↔`New York` would only have half the precision because it inherently also aligns `New` in the source with `York` in the target.). Further investigation showed that on the Edinburgh++ corpus, over-generated phrase-based alignment, when evaluated under just token alignment, contributed hurting about 1.1% of overall F_1,

[6] a few examples: `two Atlanta-based companies`↔`two Atlanta companies`, `the UK`↔`the UK`, `the 17-year-old`↔`the teenager`, `was held`↔`was held`.

[7] `http://crf.sf.net`

[8] `http://opennlp.apache.org/`

[9] `http://jwordnet.sf.net/`

a gap that would make the phrase aligner (85.9%) outperform the token aligner (86.4%).

On the phrasal alignment corpora (represented by MSR06P and EDB++P in Table 3), the phrase-based aligner did significantly better. Note that the overall F_1 and exact match rate are still much lower than those scores obtained from the original corpora, suggesting that the phrasal corpora present a much harder task. Furthermore, as a more "fair" comparison between the two aligners, we synthesized phrasal alignments from the output of the token-based aligner, just as how the phrased-based corpora were prepared, then evaluated its performance again. Still, on the EDB++P corpus, the token aligner was about 1.6% (current difference is 69.1% vs. 72.8%) worse than the phrase-based aligner.

Also, we want to emphasize that since the token-based aligner and the phrase-based aligner shared exactly the same features and lexical resources, the performance boost of the phrase-based aligner on the phrasal corpora results from a better model design: it is the semi-Markov property and phrasal states making the phrase-based aligner better.

To further investigate the performance of aligners with respect to different types of alignment, we divided the scores into those for identical alignments (such as `New`↔`New`) and non-identical alignments (such as `wife`↔`spouse`), indicated by the subscripts *i* and *n* in Table 3. In terms of identical alignment, most aligners were able to score more than 90%, but for non-identical alignment there was noticeable decrease. Still, on the phrasal alignment corpora, the phrase-based model has a much larger recall score for non-identical alignment than others.

We also divided scores with respect to token-only alignment and phrase-only alignment. Due to space limit, we only show results on synthesized Edinburgh++, in Table 4. Meteor and the token aligner inherently have either very limited or no support for phrasal alignment, thus they had very low scores on phrase-only alignment. We then ran the aligners in two directions and merged the results with the "union" MT heuristic to get better phrase support. But that still did not bring F_{1p}'s up to over 5%.

The phrase-based aligner baseline Meteor did worse than our aligners. We think there are two reasons: First, Meteor was not trained on these corpora. Second, Meteor only does strict word, stem, synonym and paraphrase matching but does not use any string similarity measures; this can be supported by the large difference between, for instance, F_{1i} and F_{1n}. In general Meteor did well on identical alignment, but not so well on non-identical alignment.

	System	P% P_i/P_n	R% R_i/R_n	F1% F_{1i}/F_{1n}	E%

Table 3: Results on original (mostly token) and phrasal (P) alignment corpora, where (x%) indicates how much alignment is identical alignment, such as `New`↔`New`. E% stands for exact (perfect) match rate. Subscript *i* stands for corresponding scores for "identical" alignment and *n* for "non-identical". *: scores of MANLI-joint were for the original Edinburgh corpus instead of Edinburgh++ (with hand corrections) so it is not a direct comparison.

5 Applications

Natural language alignment can be applied to various NLP tasks. While how to most effectively apply

	System	P% P_t/P_p	R% R_t/R_p	F1% F_{1t}/F_{1p}	E%
EDB++P	Meteor	88.4 59.5/14.9	60.6 90.6/1.1	71.9 71.8/2.0	**2.9**
	token	**90.7** 59.4/21.4	55.8 85.5/0.9	69.1 70.1/1.7	2.3
	phrase	82.3 73.3/48.0	**65.3** 73.5/44.2	**72.8** 73.4/46.0	1.6

Table 4: Same results on the phrasal Edinburgh++ corpus but with scores divided by token-only alignment (subscript t) and phrase-only alignment (subscript p).

it is another topic, we simply show in this section using *just* alignment scores in binary prediction problems. Specifically, we pick the tasks of recognizing textual entailment (RTE), paraphrase identification (PP), and question answering sentence ranking (QA) described in Heilman and Smith (2010):

RTE: predicting whether a hypothesis can be inferred from the premise, with training data from RTE-1/2 and RTE-3 dev, and test from RTE-3 test.

PP: predicting whether two sentences are paraphrases, with training and test data from the MSR Paraphrase Corpus (Dolan et al., 2004).

QA: predicting whether a sentence contains the answer to the question, with training data from TREC-8 to TREC-12 and test data from TREC-13.

For each aligned pair, we can compute a normalized decoding score. Following MacCartney et al. (2008), we select a threshold score and predict true if the decoding score is above this threshold. For the tasks of RTE and PP, we tuned this threshold w.r.t the maximal accuracy on the training set, then reported performance on the test set. For the task of QA, since the evaluation methods in Mean Average Precision and Mean Reciprocal Rank only need a ranked list of answer sentences, and the scores on the test set are sufficient to provide the ranking, we did not tune anything on training but instead directly ran the aligner on the test set. All three tasks shared the same aligner model trained on the superset of MSR06 and Edinburgh++. Results are reported in Table 5. We could not report on Meteor as Meteor does not explicitly output alignment scores.

We did not expect the aligners to beat any of the

state-of-the-art result since no sophisticated models were additionally used but only the alignment score. Still, the aligners showed competitive performance. It still follows the pattern from the alignment experiment that the phrasal aligner had higher recall and lower precision than the token aligner in the task of RTE and PP. In the QA task, the phrasal aligner performed better than all systems except for the top one.

6 Conclusion

We have introduced a phrase-to-phrase alignment model based on semi-Markov Conditional Random Fields. The combination of semi-Markov states and phrasal states makes phrasal alignment on both the source and target sides possible. The final phrase-

based aligner performed the best on two phrasal alignment corpora and showed its potential usage in three NLP tasks. Future work includes aligning discontinuous (gappy) phrases and integrating alignment more closely in NLP applications.

A Constrained Latent Variable Model for Coreference Resolution

Kai-Wei Chang Rajhans Samdani Dan Roth
University of Illinois at Urbana-Champaign
{kchang10|rsamdan2|danr}@illinois.edu

Abstract

Coreference resolution is a well known clustering task in Natural Language Processing. In this paper, we describe the Latent Left Linking model (L^3M), a novel, principled, and linguistically motivated latent structured prediction approach to coreference resolution. We show that L^3M admits efficient inference and can be augmented with knowledge-based constraints; we also present a fast stochastic gradient based learning. Experiments on ACE and Ontonotes data show that L^3M and its constrained version, CL^3M, are more accurate than several state-of-the-art approaches as well as some structured prediction models proposed in the literature.

1 Introduction

Coreference resolution is a challenging task, that involves identification and clustering of noun phrases mentions that refer to the same real-world entity. Most machine learning approaches to coreference resolution learn a scoring function to estimate the compatibility between two mentions or two sets of previously clustered mentions. Then, a decoding algorithm is designed to aggregate these scores and find an optimal clustering assignment.

The most popular of these frameworks is the pairwise mention model (Soon et al., 2001; Ng and Cardie, 2002; Bengtson and Roth, 2008), which learns a compatibility score of mention-pairs and uses these pairwise scores to obtain a global clustering. Recently, efforts have been made (Haghighi and Klein, 2010; Rahman and Ng, 2011b; Rahman and Ng, 2011c) to consider models that capture higher order interactions, in particular, between mentions and previously identified entities (that is, between mentions and clusters). While such models are potentially more expressive, they are largely based on heuristics to achieve computational tractability.

This paper focuses on a novel and principled machine learning framework that pushes the state-of-the-art while operating at a mention-pair granularity. We present two models — the Latent Left-Linking Model (L^3M), and a version of that is augmented with domain knowledge-based constraints, the Constrained Latent Left-Linking Model (CL^3M). L^3M admits efficient inference, linking each mention to a previously occurring mention to its left, much like the existing best-left-link inference models (Ng and Cardie, 2002; Bengtson and Roth, 2008). However, unlike previous best-link techniques, learning in our case is performed jointly with decoding — we present a novel latent structural SVM approach, optimized using a fast stochastic gradient-based technique. Furthermore, we present a probabilistic generalization of L^3M that is more expressive in that it is capable of considering mention-entity interactions using scores at the mention-pair granularity. We augment this model with a temperature-like parameter (Samdani et al., 2012) to provide additional flexibility.

CL^3M augments L^3M with knowledge-based constraints following (Roth and Yih, 2004; Denis and Baldridge, 2007). This capability is very desirable as shown by the success of the rule-based deterministic approach of Raghunathan et al. (2010) in the CoNLL shared task 2011 (Pradhan et al., 2011). In L^3M, domain-specific constraints are incorporated into learning and inference in a straightforward way. CL^3M scores a mention's contribution to its cluster by combining the corresponding score

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 601–612,
Seattle, Washington, USA, 18-21 October 2013.

of the underlying L^3M model with that from a set of constraints.

Most importantly, in our experiments on benchmark coreference datasets, we show that CL^3M, with just five constraints, compares favorably with other, more complicated, state-of-the-art algorithms on a variety of evaluation metrics. Overall, the main contribution of this paper is a principled machine learning model operating at mention-pair granularity, using easy to implement constraint-augmented inference and learning, that yields competitive results on coreference resolution on Ontonotes-5.0 (Pradhan et al., 2012) and ACE 2004 (NIST, 2004).

2 Related Work

The idea of Latent Left-linking Model (L^3M) is inspired by a popular inference approach to coreference which we call the *Best-Left-Link* approach (Ng and Cardie, 2002; Bengtson and Roth, 2008). In the best-left-link strategy, each mention i is connected to the best antecedent mention j with $j < i$ (i.e. a mention occurring to the left of i, assuming a left-to-right reading order), thereby creating a *left-link*. The "best" antecedent mention is the one with the highest pairwise score, w_{ij}; furthermore, if w_{ij} is below some threshold, say 0, then i is not connected to any antecedent mention. The final clustering is a transitive closure of these "best" links. The intuition behind best-left-link strategy is based on how humans read and decipher coreference links – they mostly rely on information to the left of the mention when deciding whether to add it to a previously constructed cluster or not. This strategy has been successful and commonly used in coreference resolution (Ng and Cardie, 2002; Bengtson and Roth, 2008; Stoyanov et al., 2009). However, most works have developed ad-hoc approaches to implement this idea. For instance, Bengtson and Roth (2008) train a model $\mathbf{w}$ on binary training data generated by taking for each mention, the closest antecedent coreferent mention as a positive example, and all the other mentions as negative examples. Similar approaches to training and, additionally, decoupling the training stage from the clustering stage were used by other systems. In this paper, we formalize the learning problem of the best-left-link model as a structured prediction problem and analyze our system with detailed experiments. Furthermore, we generalize this approach by considering multiple pairwise left-links instead of just the best link, efficiently capturing the notion of a mention-to-cluster link.

Many techniques in the coreference literature break away from the mention pair-based, best-left-link paradigm. Denis and Baldridge (2008) and Ng (2005) learn a local ranker to rank the mention pairs based on their compatibility. While these approaches achieve decent empirical performance, it is unclear why these are the right ways to train the model. Some techniques consider a more expressive model by using features defined over mention-cluster or cluster-cluster (Rahman and Ng, 2011c; Stoyanov and Eisner, 2012; Haghighi and Klein, 2010). For these models, the inference and learning algorithms are usually complicated. Very recently, Durrett et al. (2013) propose a probabilistic model which enforces structural agreement constraints between specified properties of mention cluster when using a mention-pair model. This approach is very related to the probabilistic extension of our method as both models attempt to leverage entity-level information from mention-pair features. However, our approach is simpler because it directly considers the probabilities of multiple links. Furthermore, while their model performs only slightly better than the Stanford rule-based system (Lee et al., 2011), we significantly outperform this system. Most importantly, our model obtains state-of-the-art performance on OntoNotes-5.0 while still operating at the mention-pair granularity. We believe that this is due to our novel and principled structured prediction framework which results in accurate (and efficient) training.

Several structured prediction techniques have been applied to coreference resolution in the machine learning literature. For example, McCallum and Wellner (2003) and Finley and Joachims (2005) model coreference as a correlational clustering problem (Bansal et al., 2002) on a complete graph over the mentions with edge weights given by the pairwise classifier. However, correlational clustering is known to be NP Hard (Bansal et al., 2002); nonetheless, an ILP solver or an approximate inference algorithm can be used to solve this problem. Another approach proposed by Yu and Joachims (2009) formu-

lates coreference with latent spanning trees. However, their approach has no directionality between mentions, whereas our latent structure captures the natural left-to-right ordering of mentions. In our experiments (Sec. 5), we show that our technique vastly outperforms both the spanning tree and the correlational clustering techniques. We also compare with (Fernandes et al., 2012) and the publicly available Stanford coreference system (Raghunathan et al., 2010; Lee et al., 2011), a state-of-the-art rule-based system.

Finally, some research (Ratinov and Roth, 2012; Bansal and Klein, 2012; Rahman and Ng, 2011a) has tried to integrate world knowledge from web-based statistics or knowledge bases into a coreference system. World knowledge is potentially useful for resolving coreference and can be injected into our system in a straightforward way via the constraints framework. We will show an example of incorporating our system with name-entity and WordNet-based similarity metric (Q. Do, 2009) in Sec. 5. Including massive amount of information from knowledge resources is not the focus of this paper and may distort the comparison with other relevant models but our results indicate that this is doable in our model, and may provide significant improvements.

3 Latent Left-Linking Model with Constraints

In this section, we describe our Constrained Latent Left-Linking Model (CL^{3}M). CL^{3}M is inspired by a few ideas from the literature: (a) the popular *Best-Left-Link* inference approach to coreference (Ng and Cardie, 2002; Bengtson and Roth, 2008), and (b) the injection of domain knowledge-based constraints for structured prediction (Roth and Yih, 2004; Clarke and Lapata, 2006; Chang et al., 2012b; Ganchev et al., 2010; Koo et al., 2010; Pascal and Baldridge, 2009).

We first introduce the notion of a pairwise mention-scorer, then introduce our Left-Linking Model (L^{3}M), and finally describe how to inject constraints into our model.

Let d be a document with m_d mentions. Mentions are denoted solely using their indices, ranging from 1 to m_d. A coreference clustering $\mathcal{C}$ for document d is a collection of disjoint sets partitioning the set $\{1, \ldots, m_d\}$. We represent $\mathcal{C}$ as a binary function with $\mathcal{C}(i, j) = 1$ if mentions i and j are coreferent, otherwise $\mathcal{C}(i, j) = 0$. Let $s(\mathcal{C}; \mathbf{w}, d)$ be the score of a given clustering $\mathcal{C}$ for a given document and a given pairwise weight vector $\mathbf{w}$. Then, during inference, a clustering $\mathcal{C}$ is predicted by maximizing the scoring function $s(\mathcal{C}; \mathbf{w}, d)$, over all valid (i.e. satisfying symmetry and transitivity) clustering binary functions $\mathcal{C} : \{1, \ldots, m_d\} \times \{1, \ldots, m_d\} \rightarrow \{0, 1\}$.

3.1 Mention Pair Scorer

We model the task of coreference resolution using a pairwise scorer which indicates the compatibility of a pair of mentions. The inference routine then predicts the final clustering — a structured prediction problem — using these pairwise scores.

Specifically, for any two mentions i and j (w.l.o.g. $j < i$), we produce a pairwise compatibility score w_{ji} using extracted features $\phi(j, i)$ as

$$w_{ji} = \mathbf{w} \cdot \phi(j, i) \ , \qquad (1)$$

where $\mathbf{w}$ is a weight parameter that is learned.

3.2 Latent Left-Linking Model

Our inference algorithm is inspired by the best-left-link approach. In particular, the score $s(\mathcal{C}; d, \mathbf{w})$ is defined so that each mention links to the antecedent mention (to its left) with the highest score (as long as the score is above some threshold, say, 0). Specifically:

$$s(\mathcal{C}; d, \mathbf{w}) = \sum_{i=1}^{m_d} \max_{0 \leq j < i, \mathcal{C}(i,j)=1} \mathbf{w} \cdot \phi(j, i) \ . \qquad (2)$$

In order to simplify the notation, we introduce a dummy mention with index 0, which is to the left (i.e. appears before) of all other mentions and has $w_{0i} = 0$ for all *actual* mentions $i > 0$. For a given clustering $\mathcal{C}$, if a mention i is not co-clustered with any previous actual mention $j, 0 < j < i$, then we assume that i links to 0 and $\mathcal{C}(i, 0) = 1$. In other words, $C(i, 0) = 1$ *iff* i is the first actual item of a cluster in $\mathcal{C}$. However, such an item i is **not** considered to be co-clustered with 0 and for any valid clustering, item 0 is always in a singleton dummy cluster, which is eventually discarded. The important property of the score s is that it is exactly maximized

by the best-left-link inference, as it maximizes individual left link scores and the creation of one left-link does not affect the creation of other left-links.

3.3 Learning

We use a max-margin approach to learn $\mathbf{w}$. We are given a training set D of documents where for each document $d \in D$, $\mathcal{C}_d$ refers to the annotated ground truth clustering. Then we learn $\mathbf{w}$ by minimizing

$$L(\mathbf{w}) = \frac{\lambda}{2}\|\mathbf{w}\|^2 + \frac{1}{|D|}\sum_{d\in D}\frac{1}{m_d}\Big(\max_{\mathcal{C}}\big(s(\mathcal{C};d,\mathbf{w}) + \Delta(\mathcal{C},\mathcal{C}_d)\big) - s(\mathcal{C}_d;d,\mathbf{w})\Big)\ ,$$

where $\Delta(\mathcal{C},\mathcal{C}_d)$ is a loss function used in coreference. In order to achieve tractable loss-augmented minimization — something not possible with standard loss functions used in coreference (e.g. B^3 (Bagga and Baldwin, 1998)) — we use a decomposable loss function that just counts the number of mention pairs on which $\mathcal{C}$ and $\mathcal{C}_d$ disagree: $\Delta(\mathcal{C},\mathcal{C}_d) = \sum_{i,j=0,j<i}^{m_d}\mathbb{I}_{\mathcal{C}(i,j)=\mathcal{C}_d(i,j)}$, where $\mathbb{I}$ is a binary indicator function. This loss function is equivalent to the numerator of the Rand index loss (Rand, 1971). With this form of loss function and using the scoring function in Eq. (2), we can write $L(\mathbf{w})$ as

$$\frac{\lambda}{2}\|\mathbf{w}\|^2 + \frac{1}{|D|}\sum_{d\in D}\frac{1}{m_d}\sum_{i=1}^{m_d}\Big(\max_{0\le j<i}\big(\mathbf{w}\cdot\phi(j,i) + \delta(\mathcal{C}_d,i,j)\big) - \max_{0\le j<i, C(i,j)=1}(\mathbf{w}\cdot\phi(j,i))\Big)\ , \quad (3)$$

where $\delta(\mathcal{C}_d,i,j) = 1 - \mathcal{C}_d(i,j)$ is the loss-based margin that is 1 if i and j are not coreferent in $\mathcal{C}_d$, and is 0 otherwise. In the above objective function, the left-links remain latent while we get to observe the clustering. This objective function is related to latent structural SVMs (Yu and Joachims, 2009). However Yu and Joachims (2009) use a spanning tree based latent structure which does not have the left-to-right directionality we exploit. We can minimize the above function using Concave Convex Procedure (Yuille and Rangarajan, 2003), which is guaranteed to reach the local minima. However, such a procedure is costly as it requires doing inference on all the documents to compute a single gradient update. Consequently, we choose a faster stochastic sub-gradient descent (SGD) approach. Since $L(\mathbf{w})$ in Eq. (3) decomposes not only over training documents, but also over individual mentions in each document, we can perform SGD on a per-mention basis. The stochastic sub-gradient w.r.t. mention i in document d is given by

$$\begin{aligned}\nabla L(\mathbf{w})_d^i &\propto \phi(j',i) - \phi(j'',i) + \lambda\mathbf{w}, \text{ where} \quad (4)\\ j' &= \arg\max_{0\le j<i}(\mathbf{w}\cdot\phi(j,i) + 1 - \mathcal{C}_d(i,j))\\ j'' &= \arg\max_{0\le j<i, C(i,j)=1}\mathbf{w}\cdot\phi(j,i)\end{aligned}$$

While SGD has no theoretically convergence guarantee, it works excellently in our experiments. Specifically, we observe that SGD achieves similar training performance to CCCP with a speed-up of around 10,000.

3.4 Incorporating Constraints

Next, we show how to incorporate domain knowledge-based constraints into L^3M and generalize it to CL^3M. In CL^3M, we obtain a clustering by maximizing a constraint-augmented scoring function f given by

$$s(\mathcal{C};d,\mathbf{w}) + \sum_{p=1}^{n_c}\rho_p\psi_p(d,\mathcal{C}),$$

where the second term on the R.H.S. is the score contributed by domain specific constraints $\psi_1,\ldots,\psi_{n_c}$ with their respective scores $\rho_1,\ldots,\rho_{n_c}$. In particular, $\psi_p(d,\mathcal{C})$ measures the extent to which a given clustering $\mathcal{C}$ satisfies the p^{th} constraint. Note that this framework is general and can be applied to inject mention-to-cluster or cluster-to-cluster level constraints too. However, for simplicity, we consider here only constraints between mention pairs. This allows us derive fast greedy algorithm to solve the inference problem. The details of our constraints are presented in Sec. 5.

All of our constraints can be categorized into two groups: "must-link" and "cannot-link"."Must-link" constraints encourage a pair of mentions to connect, while "cannot-link" constraints discourage mention pairs from being linked. Consequently, the coefficients ρ_p associated with "must-link" constraints are positive while ρ_p for "cannot-link" constraints are negative. In the following, we briefly discuss how to

solve the inference problem with these two types of constraints.

We slightly abuse notations and use $\psi_p(j,i)$ to indicate the p^{th} constraint on a pair of mentions (i,j). $\psi_p(j,i)$ is a binary function that is 1 *iff* two mentions i and j satisfy the conditions specified in constraint p. Chang et al. (2011) shows that best-left-link inference can be formulated as an ILP problem. When we add constraints, the ILP becomes:

$$\begin{aligned} \underset{B,C\in\{0,1\}}{\arg\max} \quad & \sum_{i,j:j<i} w_{ji}B_{ji} + \sum_{i,j} \rho_p \psi_p(j,i) C_{ij} \\ \text{s.t} \quad & C_{kj} \geq C_{ij} + C_{ki} - 1,\ \forall i,j,k, \\ & \sum_{j=0}^{i-1} B_{ji} = 1,\ \forall i \\ & B_{ji} < C_{ji}, C_{ji} = C_{ji}, \forall i,j, \end{aligned} \tag{5}$$

where $C_{ij} \equiv C(i,j)$ is a binary variable indicating whether i and j are in the same cluster or not and B_{ji} is an auxiliary variable indicating the best-left-link for mention i. The first set of inequality constraints in (5) enforces the transitive closure of the clustering. The constraints $B_{ji} < C_{ji}, \forall i,j$ enforce the consistency between these two sets of variables.

One can use an off-the-shelf solver to solve Eq. (5). However, when the absolute values of the constraint scores ($|\rho_p|$) are high (the hard constraint case), then the following greedy algorithm approximately solves the inference efficiently. We scan the document from left-to-right (or in any other arbitrary order). When processing mention i, we find

$$j^* = \underset{j<i}{\arg\max} \quad w_{ji} + \sum_{k:\hat{C}(k,j)=1} \sum_p \rho_p \psi_p(k,i), \tag{6}$$

where $\hat{C}$ is the current clustering obtained from the previous inference steps. Then, we add a link between mention i and j^*. The rest of the inference process is the same as in the original best-left-link inference. Specifically, this inference procedure combines the classifier score for mention pair i,j, with the constraints score of all mentions currently co-clustered with j. We discuss this further in Section 5.

4 Probabilistic Latent Left-Linking Model

In this section, we extend and generalize our left-linking model approach to a probabilistic model, Probabilistic Latent Left-Linking Model (PL^{3}M), that allows us to naturally consider mention-to-entity (or mention-to-cluster) links. While in L^{3}M, we assumed that each mention links deterministically to the max-scoring mention on its left, in PL^{3}M, we assume that mention i links to mention j, $j \leq i$, with probability given by

$$Pr[j \leftarrow i; d, \mathbf{w}] = \frac{e^{\frac{1}{\gamma}(\mathbf{w}\cdot\phi(i,j))}}{Z_i(\mathbf{w},\gamma)} \ . \tag{7}$$

Here $Z_i(\mathbf{w},\gamma) = \sum_{0\leq k<i} e^{\frac{1}{\gamma}(\mathbf{w}\cdot\phi(i,k))}$ is a normalizing constant and $\gamma \in (0,1]$ is a constant temperature parameter that is tuned on a development set (Samdani et al., 2012). We assume that the event that mention i links to a mention j is independent of the event that mention i' links to j' for $i \neq i'$.

Inference with PL^{3}M: Given the probability of a link as in Eq. (7), the probability that mention i joins an existing cluster c, $Pr[c \odot i; d, \mathbf{w}]$, is simply the sum of the probabilities of i linking to the mentions inside c:

$$\begin{aligned} Pr[c \odot i; d, \mathbf{w}] &= \sum_{j\in c, 0\leq j<i} Pr[j \leftarrow i; d, \mathbf{w}] \\ &= \sum_{j\in c, 0\leq j<i} \frac{e^{\frac{1}{\gamma}(\mathbf{w}\cdot\phi(i,j))}}{Z_i(d,\mathbf{w},\gamma)} \ . \end{aligned} \tag{8}$$

Based on Eq. (8) and making use of the independence assumption of left-links, we follow a simple greedy clustering (or inference) algorithm: sequentially add each mention i to a previously formed cluster c^*, where $c^* = \arg\max_c Pr[c \odot i; d, \mathbf{w}]$. If the $\arg\max$ cluster is the singleton cluster with the dummy mention 0 (i.e. the score of all other clusters is below the threshold of 0), then i starts a new cluster and is not included in the dummy cluster. Note that we link a mention to a cluster taking into account all the mentions inside that cluster, mimicking the notion of a mention-to-cluster link. This provides more expressiveness than the Best-Left-Link inference, where a mention connects to a cluster solely based on a single pairwise link to some antecedent mention (the best-link mention) in that cluster.

The case of $\gamma = 0$: As γ approaches zero, it is easy to show that the probability $P[j \leftarrow i; d, w]$

in Eq. (7) approaches a Kronecker delta function that puts probability 1 on the *max-scoring mention* $j = \arg\max_{0 \leq k < i} \mathbf{w} \cdot \phi(i, j)$ (assuming no ties), and 0 everywhere else (Pletscher et al., 2010; Samdani et al., 2012). Consequently, as $\gamma \to 0$, $Pr[c \odot i; d, \mathbf{w}]$ in Eq. 8 approaches a Kronecker delta function centered on the cluster containing the max-scoring mention, thus reducing to the best-link case of L^3M. Thus, PL^3M, when tuning the value of γ, is a strictly more general model than L^3M.

Learning with PL^3M We use a likelihood-based approach to learning with PL^3M, and first compute the probability $Pr[\mathcal{C}; d, \mathbf{w}]$ of generating a clustering $\mathcal{C}$, given $\mathbf{w}$. We then learn $\mathbf{w}$ by minimizing the regularized negative log-likelihood of the data, augmenting the partition function with a loss-based margin (Gimpel and Smith, 2010). We omit the details of likelihood computation due to lack of space.

With PL^3M, we again follow a stochastic gradient descent technique instead of CCCP for the same reasons mentioned in Sec. 3.3. The stochastic gradient (subgradient when $\gamma = 0$) w.r.t. mention i in document d is given by

$$\nabla LL(\mathbf{w})^i_d \propto \sum_{0 \leq j < i} p_j \phi(i, j) - \sum_{0 \leq j < i} p'_j \phi(i, j) + \lambda \mathbf{w},$$

where p_j and p'_j, $j = 0, \ldots, i-1$, are non-negative weights that sum to one and are given by

$$p_j = \frac{e^{\frac{1}{\gamma}(\mathbf{w} \cdot \phi(i,j) + \delta(\mathcal{C}_d, i, j))}}{\sum_{0 \leq k < i} e^{\frac{1}{\gamma}(\mathbf{w} \cdot \phi(i,k) + \delta(\mathcal{C}_d, i, k))}} \text{ and}$$

$$p'_j = \frac{\mathcal{C}_d(i, j) Z_i(d, \mathbf{w}, \gamma)}{Z_i(\mathcal{C}_d; d, \mathbf{w}, \gamma)} Pr[j \leftarrow i; d, \mathbf{w}] \ .$$

Interestingly, the above update rule generalizes the one for L^3M, as we are incorporating a weighted sum of all previous mentions in the update rule. With $\gamma \to 0$, the SGD in Eq. (4) converges to the SGD update in L^3M (Eq. (4)). Finally, in the presence of constraints, we can fold them inside the pairwise link probabilities as in Eq. (6).

5 Experiments and Results

In this section, we present our experiments on the two commonly used benchmarks for coreference — Ontonotes-5.0 (Pradhan et al., 2012) and ACE 2004 (NIST, 2004). Table 1 exhibits our bottom line results: CL^3M achieves the best result reported on Ontonotes-5.0 development set and essentially ties with (Fernandes et al., 2012) on the test set. As shown in Table 3, CL^3M is also the best algorithm on ACE and when evaluated on the gold mentions of Ontonotes. We show that CL^3M performs particularly well on clusters containing named entity mentions, which are more important for many information extraction applications. In the rest of this section, after describing our experimental setting, we provide careful analysis of our algorithms and compare them to competitive coreference approaches in the literature.

5.1 Experimental Setup

Datasets: ACE 2004 contains 443 documents — we used a standard split of these documents into 268 training, 68 development, and 106 testing documents used by Culotta et al. (2007) and Bengtson and Roth (2008). OntoNotes-5.0 dataset, released for the CoNLL 2012 Shared Task (Pradhan et al., 2012), is by far the largest annotated corpus on coreference. It contains 3,145 annotated documents drawn from a wide variety of sources — newswire, bible, broadcast transcripts, magazine articles, and web blogs. We report results on both development set and test set. To test on the development set, we further split the training data into training and development sets.

Classifier details: For each of the pairwise approaches, we assume the pairwise score is given by $\mathbf{w} \cdot \phi(\cdot, \cdot) + t$ where ϕ are the features, $\mathbf{w}$ is the weight vector learned by the approach, and t is a threshold which we set to 0 during learning (as in Eq. (1)), but use a tuned value (tuned on a development set) during testing. For learning with L^3M, we do stochastic gradient descent with 5 passes over the data. Empirically, we observe that this is enough to generate a stable model. For PL^3M (Sec. 4), we tune the value of γ using the development set picking the best γ from $\{0.0, 0.2, \ldots, 1.0\}$. Recall that when $\gamma = 0$, PL^3M is the same as L^3M. We refer to L^3M and PL^3M with incorporating constraints during inference as CL^3M and CPL^3M (Sec. 3.4), respectively.

Metrics: We compare the systems using three popular metrics for coreference — MUC (Vilain et al., 1995), BCUB (Bagga and Baldwin, 1998), and

Entity-based CEAF (CEAF$_e$) (Luo, 2005). Following, the CoNLL shared tasks (Pradhan et al., 2012), we use the average F1 scores of these three metrics as the main metric of comparison.

Features: We build our system on the publicly available Illinois-Coref system[1] primarily because it contains a rich set of features presented in Bengtson and Roth (2008) and Chang et al. (2012a) (the latter adds features for pronominal anaphora resolution). We also compare with the Best-Left-Link approach described by Bengtson and Roth (2008).

Constraints: We consider the following constraints in CL^{3}M and CPL^{3}M.

- SameSpan: two mentions must be linked to each other if they share the same surface text span and the number of words in the text span is larger than a threshold (set as 5 in our implementation).
- SameDetNom: two mentions must be linked to each other if both mentions start with a determiner and the [0,1] wordnet-based similarity score between the mention head words is above a threshold (set to 0.8).
- SameProperName: two mentions must be linked if they are both proper names and the similarity score measured by a named entity-based similarity metric, Illinois NESim[2], are higher than a threshold (set to 0.8). For a person entity we add additional rules to extract the first name, last name and professional title as properties.
- ModifierMismatch: the constraint prevents two mentions to be linked if the head modifiers conflict. For example, the constraint prevents "northern Taiwan" from linking to "southern Taiwan". We gather a list of mutual exclusive modifiers from the training data.
- PropertyMismatch: the constraint prevents two mentions to be linked if their properties conflict. For example, it prevents male pronouns to link to female pronouns and "Mr. Clinton" to link to "Mrs. Clinton" by checking the gender property. The properties we consider are gender, number, professional title and the nationality.

CL^{3}M	69.64	**71.93**	48.32	63.30

Table 1: Performance on OntoNotes-5.0 with predicted mentions. We report the F1 scores (%) on various coreference metrics (MUC, BCUB, CEAF). The column AVG shows the average scores of the three. We observe that PL^{3}M and CPL^{3}M (see Sec. 4) yields the same performance as L^{3}M and CL^{3}M, respectively as the tuned γ for all the datasets turned out to be 0.

While the "must-link" constraints described in the paper can be treated as features, due to their high precision, treating them as hard constraints (set ρ to a high value) is a safe and direct way to inject human knowledge into the learning model. Moreover, our framework allows a constraint to use information from previous decisions (such as "cannot-link" constraints). Treating such constraints as features will complicate the learning model.

5.2 Performance of the End-to-End System

We compare our system with the top systems reported in the CoNLL shared task 2012 as well as with the Stanford's publicly released rule-based system (Lee et al., 2013; Lee et al., 2011), which won the CoNLL 2011 Shared Task (Pradhan et al., 2011). Note that all the systems use the same annotations (e.g., gender prediction, part-of-speech tags, name entity tags) provided by the shared task organizers.

However, each system implements its own mention detector and pipelines the identified mentions into the coreference clustering component. Moreover, different systems use a different set of features. In order to partially control for errors on mention detection and better evaluate the clustering component in our coreference system, we will also present results on correct (gold) mentions in the next section.

Table 1 shows the end-to-end results. On the development set, only the best performing system of Fernandes et al. (2012) is better than L^{3}M, but this difference disappears when we use our system with constraints, CL^{3}M. Although our system is much simple, it achieves the best B^3 score on the test set and is competitive with the best system participated in the CoNLL shared task 2012.

Performance on named entities: The coreference annotation in Ontonotes 5.0 includes various types of mentions. However, not all mention types are equally interesting. In particular, clusters which contain at least one proper name or a named entity mention are more important for information extraction tasks like Wikification (Mihalcea and Csomai, 2007; Ratinov et al., 2011), cross-document coreference resolution (Bagga and Baldwin, 1998), and entity linking and knowledge based population (Ji and Grishman, 2011).

Inspired by this, we compare our system to the best systems in the CoNLL shared task of 2011 (Stanford (Lee et al., 2011)) and 2012 (Fernandes (Fernandes et al., 2012)) on the following specific tasks on Ontonotes-5.0.

- **ENT-C**: Evaluate the system on clusters that contain at least one proper name mention. We generate the gold annotation and system outputs by using the gold and predicted name entity tag annotations provided by the CoNLL shard task 2012. That is, if a cluster does not include any name entity mention, then it will be removed from the final clustering.
- **PER-C**: As in the construction of ENT-C, but here we only consider clusters which contain at least one "Person (PER)" entity.
- **ORG-C**: As in the construction of Entity-C, but here we only consider clusters which contain at least one "Organization (ORG)" entity.

Typically, the clusters that get ignored in the above definitions contain only first and second person pronouns (which often happens in transcribed discourse.) Also note that all the systems are trained with the same name entity tags, provided by the shared task organizers, and we use the same name entity tags to construct the specific clustering. Also, in order to further ensure fairness, we do not tune our system to favor the evaluation of these specific types of clusters. We chose to do so because we only have access to the system output of Fernandes et al. (2012).

Task	Stanford	Fernandes	L^{3}M	CL^{3}M
ENT-C	44.06	47.05	46.63	**48.02**
PER-C	34.04	36.43	37.01	**37.57**
ORG-C	25.02	26.23	26.22	**27.01**

Table 2: Performance on named entities for OntoNotes-5.0 data. We compare our system to Fernandes (Fernandes et al., 2012) and Stanford (Lee et al., 2013) systems.

Table 2 shows the results. The performance of all systems degrades when considering only clusters that contain name entities, indicating that ENT-C is actually a harder task than the original coreference resolution problem. In particular, resolving ORG coreferent clusters is hard, because names of organizations are sometimes confused with person names, and they can be referred to using a range of pronouns (including "we" and "it"). Overall, CL^{3}M outperforms all the competing systems on the clusters that contain at least one specific type of entity by a margin larger than that for the overall coreference.

5.3 Analysis on Gold Mentions

To better understand the contribution of our joint learning and clustering model, we present experiments assuming that gold mentions are given. The definitions of gold mentions in ACE and Ontonotes are different because Ontonotes-5.0 excludes singleton clusters in the annotation. In addition, Ontonotes includes longer mentions; for example, it includes NP and appositives in the same mention. We compare with the publicly available Stanford (Lee et al., 2011) and IllinoisCoref (Chang et al., 2012a) systems; the system of Fernandes et al. (2012) is not publicly available. In addition, we also compare with the following two structured prediction baselines that use the same set of features as L^{3}M and PL^{3}M.

	MUC	BCUB	CEAF$_e$	AVG
ACE 2004 Gold Ment.				
All-Link-Red.	77.45	81.10	77.57	78.71
Spanning	73.31	79.25	74.66	75.74
IllinoisCoref	76.02	81.04	77.6	78.22
Stanford	75.04	80.45	76.75	77.41
(Stoyanov and Eisner, 2012)	**80.1**	81.8	-	-
L^{3}M	77.57	81.77	78.15	79.16
PL^{3}M	78.18	82.09	79.21	79.83
CL^{3}M	78.17	81.64	78.45	79.42
CPL^{3}M	78.29	**82.20**	**79.26**	**79.91**
Ontonotes 5.0 Gold Ment.				
All-Link-Red.	83.72	75.59	64.00	74.44
Spanning	83.64	74.83	61.07	73.18
IllinoisCoref	80.84	74.29	65.96	73.70
Stanford	82.26	76.82	61.69	73.59
L^{3}M	83.44	78.12	64.56	75.37
PL^{3}M	83.97	78.25	65.69	75.97
CL^{3}M	84.10	78.30	68.74	77.05
CPL^{3}M	**84.80**	**78.74**	**68.75**	**77.43**

Table 3: Performance on ACE 2004 and OntoNotes-5.0. All-Link-Red. is based on correlational clustering; Spanning is based on latent spanning forest based clustering (see Sec. 2). Our proposed approach is L^{3}M (Sec. 3) and PL^{3}M (sec. 4). CL^{3}M and CPL^{3}M are the version with incorporating constraints.

1. **All-Link-Red:** a reduced and faster alternative to the correlational clustering based approach (Finley and Joachims, 2005). We implemented this algorithm as an ILP and droped one of the three transitivity constraints for each triplet of mention variables. Following Pascal and Baldridge (2009) and Chang et al. (2011) we observe that this slightly improves the accuracy over a pure correlation clustering approach, in addition to speeding up inference.
2. **Spanning:** the latent spanning forest based approach presented by Yu and Joachims (2009). We use the publicly available implementation provided by the authors[3] for the ACE data; since their CCCP implementation is slow, we implemented our own stochastic gradient descent version to scale it to the much larger Ontonotes data.

[3]Available at http://www.cs.cornell.edu/ cnyu/latentssvm/

Table 3 lists the results. Although L^{3}M is simple and use only the features defined on pairwise mentions, it compares favorably with all recently published results. Moreover, the probabilistic generalization of L^{3}M, PL^{3}M, achieves even better performance. For example, L^{3}M with $\gamma = 0.2$ improves L^{3}M with $\gamma = 0$ by 0.7 points in ACE 2004. In particular, This shows that considering more than a one left-links is helpful. This is in contrast with the predicted mentions where $\gamma = 0$ performed best. We suspect that this is because noisy mentions can hurt the performance of PL^{3}M that takes into account not just the best scoring links, but also weaker links which are likely to be less reliable (more false positives). Also, as opposed to what is reported by Yu and Joachims (2009), the correlation clustering approach performs better than the spanning forest approach. We think that this is because we compare the systems on different metrics than they did and also because we use exact ILP inference for correlational clustering whereas Yu and Joachims (2009) used approximate greedy inference.

Both L^{3}M and PL^{3}M can be benefit from using constraints. However, The constraints improve only marginally on the ACE 2004 data because ACE uses shorter phrases as mentions. Consequently, constraints designed for leveraging information from long mention spans are less effective. Overall, the experiments show that L^{3}M and PL^{3}M perform well on modeling coreference clustering.

5.4 Ablation Study of Constrains

Finally, we study the value of individual constraints by adding one constraint at a time to the coreference system starting with the simple L^{3}M model. The system with all the constraints added is the CL^{3}M model introduced in Table 1. We then remove individual constraints from CL^{3}M to assess its contribution. Table 4 shows the results on the Ontonotes dataset with predicted mentions. Overall, it is shown that each one of the constraints has a contribution, and that using all the constraints improves the performance of the system by 1.29% in the AVG F1 score. In particular, most of this improvement (1.19%) is due to the must-link constraints (the first four constraints in the table). The must-link constraints are more useful for L^{3}M as L^{3}M achieves higher precision than recall (e.g., the precision and

	MUC	BCUB	$CEAF_e$	AVG

-SameSpan	68.91	72.66	48.36	63.31
-SameDetNom	68.62	72.51	48.06	63.06
-SameProperName	68.97	72.69	48.50	63.39
-ModifierMismatch	69.12	72.80	48.63	63.52
-PropertyMismatch	69.11	72.81	48.58	63.50

Table 4: Ablation study on constraints. We first show cumulative performance on OntoNotes-5.0 data with predicted mentions as constraints are added one at a time into the coreference system. Then we demonstrate the value of individual constraints by leaving out one constraint at each time.

recall of L^3M are 78.38% and 67.96%, respectively in B^3). As a result, the must-link constraints, which aim at improving the recall, do better when optimizing F1.

6 Conclusions

We presented a principled yet simple framework for coreference resolution. Furthermore, we showed that our model can be augmented in a straightforward way with knowledge based constraints, to improve performance. We also presented a probabilistic generalization of this model that can take into account entity-mention links by considering multiple possible coreference links. We proposed a fast stochastic gradient-based learning technique for our model. Our model, while operating at mention pair granularity, obtains state-of-the-art results on OntoNotes-5.0, and performs especially well on mention clusters containing named entities. We provided a detailed analysis of our experimental results.

Abstract

The performance of nearest neighbor methods is degraded by the presence of *hubs*, i.e., objects in the dataset that are similar to many other objects. In this paper, we show that the classical method of *centering*, the transformation that shifts the origin of the space to the data centroid, provides an effective way to reduce hubs. We show analytically why hubs emerge and why they are suppressed by centering, under a simple probabilistic model of data. To further reduce hubs, we also move the origin more aggressively towards hubs, through weighted centering. Our experimental results show that (weighted) centering is effective for natural language data; it improves the performance of the k-nearest neighbor classifiers considerably in word sense disambiguation and document classification tasks.

1 Introduction

1.1 Background

The k-nearest neighbor (kNN) algorithm is a simple nonparametric method of classification. It has been applied to various natural language processing (NLP) tasks such as document classification (Masand et al., 1992; Yang and Liu, 1999), part-of-speech tagging (Søgaard, 2011), and word sense disambiguation (Navigli, 2009).

To apply the kNN algorithm, data is typically represented as a vector object in a feature space, and (dis)similarity between data is measured by the distance between the vectors, their inner product, or cosine of the angle between them (Jurafsky and Martin, 2008). With such a (dis)similarity measure, the unknown class label of a test object is predicted by a majority vote of the classes of its k most similar objects in the labeled training set.

Recent studies (Radovanović et al., 2010a; Radovanović et al., 2010b) have shown that if the feature space is high-dimensional, some objects in the dataset emerge as *hubs*; i.e., these objects frequently appear in the k nearest neighbors of other objects.

The emergence of hubs may deteriorate the performance of kNN classification and nearest neighbor search in general:

- If hub objects exist in the training set, they have a strong chance to be a kNN of many test objects. Because the class of a test object is predicted by a majority vote from its k nearest neighbors, prediction is biased toward the labels of the hubs.
- In information retrieval, nearest neighbor search finds objects in the database that are most relevant, or similar, to user-provided queries. If particular objects, such as hubs, are nearly always returned for any query, the retrieved results are probably not very useful.

These drawbacks may hinder application of nearest neighbor methods in NLP, as typical natural language data are extremely high-dimensional (Jurafsky and Martin, 2008) and thus prone to produce hubs.

1.2 Contributions

Centering (Mardia et al., 1979; Fisher and Lenz, 1996; Eriksson et al., 2006) is a standard technique

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 613–623,
Seattle, Washington, USA, 18-21 October 2013.

for removing observation bias in the data. It is a transformation of feature space in a way that the origin of the space is moved to the data centroid (sample mean). The distance between data objects is not changed by centering, but their inner product and cosine are affected; see Section 3 for detail.

In this paper, we advocate the use of centering as a means of reducing hubs. Specifically, we propose to measure the similarity of objects by the inner product (not distance or cosine) in the centered feature space.

Our approach is motivated by the observation that the objects similar to the data centroid tend to become hubs (Radovanović et al., 2010a). This observation suggests that the number of hubs may be reduced if we can define a similarity measure that makes all objects in a dataset equally similar to the centroid (Suzuki et al., 2012). The inner product in the centered space indeed enjoys this property.

In Section 4, we analyze why hubs emerge under a simple probabilistic model of data, and also give an account of why they are suppressed by centering.

Using both synthetic and real datasets, we show that objects similar to the centroid also emerge as hubs in multi-cluster data (Section 5), so the application of centering is wider than expected. To further reduce hubs, we also propose to move the origin of the space more aggressively towards hubs, through *weighted* centering (Section 6).

In Section 7, we show that centering and weighted centering are effective for natural language data. these methods markedly improve the performance of kNN classifiers in word sense disambiguation and document classification tasks.

2 Related work

Centering is a classical technique widely used in many fields of science. For instance, centering forms a preprocessing step in principal component analysis and Fisher linear discriminant analysis.

In NLP, however, centering is seldom used; the use of cosine and inner product similarities is quite common, but they are nearly always used uncentered. Non-centered cosine is used, for instance, in word sense disambiguation (Schütze, 1998; Navigli, 2009), paraphrasing (Erk and Padó, 2008; Thater et al., 2010), and compositional semantics (Mitchell and Lapata, 2008), to name a few.

There have been several approaches to improving kNN classification: learning similarity/distance measures from training data (metric learning) (Weinberger and Saul, 2009; Qamar et al., 2008), weighting nearest neighbors for similarity-based classification (Chen et al., 2009), and neighborhood size selection (Wang et al., 2006; Guo and Chakraborty, 2010). However, none of these have addressed the reduction of hubs.

More recently, Schnitzer et al. (2012) proposed the *Mutual Proximity* transformation that rescales distance measures to decrease hubs in a dataset. Suzuki et al. (2012) showed that kernels based on graph Laplacian, such as the commute-time kernels (Saerens et al., 2004) and the regularized Laplacian (Chebotarev and Shamis, 1997; Smola and Kondor, 2003), make all objects equally similar to the data centroid, which in turn reduce hubs.

In Section 7, we evaluate centering, Mutual Proximity, and Laplacian kernels in NLP tasks, and demonstrate that centering is equally or even more effective. Section 4 presents a theoretical justification for using centering to reduce hubs, but this kind of analysis is missing for the Laplacian kernels.

Centering is easier to compute as well. For a dataset of n objects, it takes $O(n^2)$ time to compute, whereas computing a Laplacian-based kernel requires $O(n^3)$ time for matrix inversion. Mutual Proximity also has a time complexity of $O(n^2)$.

3 Centering

Consider a dataset of n objects in an m-dimensional feature space, $\boldsymbol{x}_1, \cdots, \boldsymbol{x}_n \in \mathbb{R}^m$. Throughout this paper, we use the inner product $\langle \boldsymbol{x}_i, \boldsymbol{x}_j \rangle$ as a measure of similarity between $\boldsymbol{x}_i$ and $\boldsymbol{x}_j$. Let $\mathbf{K}$ be the Gram matrix of the n feature vectors, i.e., the $n \times n$ matrix whose (i, j) element holds $\langle \boldsymbol{x}_i, \boldsymbol{x}_j \rangle$. Using $m \times n$ data matrix $\mathbf{X} = [\boldsymbol{x}_1, \cdots, \boldsymbol{x}_n]$, we can write $\mathbf{K}$ as

$$\mathbf{K} = \mathbf{X}^{\mathrm{T}}\mathbf{X},$$

where $\mathbf{X}^{\mathrm{T}}$ represents the matrix transpose of $\mathbf{X}$.

Centering is a transformation in which the origin of the feature space is shifted to the data centroid

$$\bar{\boldsymbol{x}} = \frac{1}{n}\sum_{i=1}^{n} \boldsymbol{x}_i, \tag{1}$$

and object $\boldsymbol{x}$ is mapped to the centered feature vector

$$\boldsymbol{x}^{\mathsf{cent}} = \boldsymbol{x} - \bar{\boldsymbol{x}}. \tag{2}$$

The similarity between two objects $\boldsymbol{x}$ and $\boldsymbol{x}'$ is now measured by $\langle \boldsymbol{x}^{\mathsf{cent}}, \boldsymbol{x}'^{\mathsf{cent}} \rangle = \langle \boldsymbol{x} - \bar{\boldsymbol{x}}, \boldsymbol{x}' - \bar{\boldsymbol{x}} \rangle$.

After centering, the inner product between any object and the data centroid (which is a zero vector because $\bar{\boldsymbol{x}}^{\mathsf{cent}} = \bar{\boldsymbol{x}} - \bar{\boldsymbol{x}} = \mathbf{0}$) is uniformly 0; in other words, all objects in the dataset have an equal similarity to the centroid. According to the observation that the objects similar to the centroid become hubs (Radovanović et al., 2010a), we can expect hubs to be reduced after centering.

Intuitively, centering reduces hubs because it makes the length of the feature vector $\boldsymbol{x}^{\mathsf{cent}}$ short for (hub) objects $\boldsymbol{x}$ that lie close to the data centroid $\bar{\boldsymbol{x}}$; see Eq. (2). And since we measure object similarity by inner product, shorter vectors tend to produce smaller similarity scores. Hence objects close to the data centroid become less similar to other objects after centering, and no longer be hubs. In Section 4, we analyze the effect of centering on hubness in more detail.

3.1 Centered Gram matrix

Let $\mathbf{I}$ be an $n \times n$ identity matrix and $\mathbb{1}$ be an n-dimensional all-ones vector. The symmetric matrix $\mathbf{H} = \mathbf{I} - (1/n)\mathbb{1}\mathbb{1}^{\mathrm{T}}$ is called *centering matrix*, because the centered data matrix $\mathbf{X}^{\mathsf{cent}} = [\boldsymbol{x}_1^{\mathsf{cent}}, \cdots, \boldsymbol{x}_n^{\mathsf{cent}}]$ can be computed by $\mathbf{X}^{\mathsf{cent}} = \mathbf{XH}$ (Mardia et al., 1979).

The Gram matrix $\mathbf{K}^{\mathsf{cent}}$ of the centered feature vectors, whose (i, j) element holds the inner product $\langle \boldsymbol{x}_i^{\mathsf{cent}}, \boldsymbol{x}_j^{\mathsf{cent}} \rangle$, can be calculated from the original Gram matrix $\mathbf{K}$ by

$$\mathbf{K}^{\mathsf{cent}} = \left(\mathbf{X}^{\mathsf{cent}}\right)^{\mathrm{T}} \left(\mathbf{X}^{\mathsf{cent}}\right) = \mathbf{H}\mathbf{X}^{\mathrm{T}}\mathbf{X}\mathbf{H} = \mathbf{HKH}. \tag{3}$$

Eq. (3) implies that the original data matrix $\mathbf{X}$ is not needed to compute the centered Gram matrix $\mathbf{K}^{\mathsf{cent}}$, provided that $\mathbf{K}$ is given. It is hence possible to use the so-called *kernel trick*; i.e., centering can be applied even if data matrix $\mathbf{X}$ is not available but the similarity of objects can be measured by a kernel function in an implicit feature space.

4 Theoretical analysis of the effect of centering on hubness

We now analyze why objects most similar to the centroid tend to be hubs in the dataset, and give an explanation as to why centering may suppress the emergence of hubs.

4.1 Before centering

Consider a dataset of m-dimensional feature vectors, with each vector $\boldsymbol{x} \in \mathbb{R}^m$ generated independently from a distribution with a finite mean vector $\boldsymbol{\mu}$. In other words, objects $\boldsymbol{x}$ in this dataset are drawn from a distribution $P(\boldsymbol{x})$, i.e.,

$$\boldsymbol{x} \sim P(\boldsymbol{x}),$$

and

$$\boldsymbol{\mu} = \mathbb{E}[\boldsymbol{x}] = \int \boldsymbol{x}\, dP(\boldsymbol{x}) \tag{4}$$

where $\mathbb{E}[\cdot]$ denotes the expectation of a random variable.

We will use the following elementary lemma on the distributions of inner product subsequently.

Lemma 1. *Let $\boldsymbol{a} \in \mathbb{R}^m$ be a fixed vector, and $\boldsymbol{x} \in \mathbb{R}^m$ be an object sampled according to distribution $P(\boldsymbol{x})$. Then the inner product $\langle \boldsymbol{a}, \boldsymbol{x} \rangle$ follows a distribution with mean $\langle \boldsymbol{a}, \boldsymbol{\mu} \rangle$.*

Proof. From the linearity of the inner product and Eq. (4), we obtain

$$\begin{aligned} \mathbb{E}[\langle \boldsymbol{a}, \boldsymbol{x} \rangle] &= \int \langle \boldsymbol{a}, \boldsymbol{x} \rangle\, dP(\boldsymbol{x}) \\ &= \langle \boldsymbol{a}, \int \boldsymbol{x}\, dP(\boldsymbol{x}) \rangle = \langle \boldsymbol{a}, \boldsymbol{\mu} \rangle. \end{aligned}$$

□

Now, imagine that we have an object $\boldsymbol{x}$ sampled from $P(\boldsymbol{x})$, and we want to compute its nearest neighbor in a dataset. Let $\boldsymbol{h}$ and $\boldsymbol{\ell}$ be two fixed objects in the dataset, such that the inner product to the true mean $\boldsymbol{\mu}$ is higher for $\boldsymbol{h}$ than for $\boldsymbol{\ell}$, i.e.,

$$\langle \boldsymbol{h}, \boldsymbol{\mu} \rangle - \langle \boldsymbol{\ell}, \boldsymbol{\mu} \rangle > 0. \tag{5}$$

We are interested in which of $\boldsymbol{h}$ and $\boldsymbol{\ell}$ is more similar to $\boldsymbol{x}$ (in terms of inner product), or in other words, the difference of two inner products

$$z = \langle \boldsymbol{h}, \boldsymbol{x} \rangle - \langle \boldsymbol{\ell}, \boldsymbol{x} \rangle = \langle \boldsymbol{h} - \boldsymbol{\ell}, \boldsymbol{x} \rangle. \tag{6}$$

Because $\boldsymbol{x}$ is a random variable, so is z. Let $Q(z)$ be the distribution of z; i.e., $z \sim Q(z)$.

Using Lemma 1 with $\boldsymbol{a} = \boldsymbol{h} - \boldsymbol{\ell}$, together with Eq. (5), we have

$$\mathbb{E}[z] = \langle \boldsymbol{h} - \boldsymbol{\ell}, \boldsymbol{\mu} \rangle = \langle \boldsymbol{h}, \boldsymbol{\mu} \rangle - \langle \boldsymbol{\ell}, \boldsymbol{\mu} \rangle > 0. \quad (7)$$

Note that the above statement is only concerned about the mean, so it does not in general assure that

$$\langle \boldsymbol{h}, \boldsymbol{x} \rangle > \langle \boldsymbol{\ell}, \boldsymbol{x} \rangle \quad (8)$$

holds with high probability; there is a chance that a small number of outliers are inflating the mean. To assure that inequality (8) holds with probability greater than $1/2$ for instance, the median rather than the mean of the distribution $Q(z)$ must be greater than 0.

If the distribution $Q(z)$ is symmetric, the median occurs at the same point as the mean, and the above claim holds. Indeed, if the components of $\boldsymbol{x}$ are generated independently from (possibly non-identical) normal distributions, we can show that $Q(z)$ also obeys a normal distribution. Because it is a symmetric distribution, we can safely say that in this case, Eq. (8) holds with probability greater than $1/2$.

For a general non-symmetric distribution with a finite variance, the median is known to be within the standard deviation of the mean (Mallows, 1991), so we could still say that Eq. (8) is likely to hold if $\langle \boldsymbol{h} - \boldsymbol{\ell}, \boldsymbol{\mu} \rangle$ is sufficiently large compared to the standard deviation.

Now, if we let $\boldsymbol{h}$ be the object in a given dataset with the highest similarity (inner product) to the mean $\boldsymbol{\mu}$, and let $\boldsymbol{\ell}$ be any other object in the set, then we see from the above discussion that $\boldsymbol{h}$ is likely to have higher similarity to $\boldsymbol{x}$, a test sample drawn from distribution $P(\boldsymbol{x})$. Because this holds for any $\boldsymbol{\ell}$ in the dataset, the conclusion is that the objects in the dataset most similar to $\boldsymbol{\mu}$ are likely to become hubs.

4.2 After centering

Next let us investigate what happens if the dataset is centered. Let $\bar{\boldsymbol{x}}$ be the sample (empirical) mean given by Eq. (1). After centering, the similarity of $\boldsymbol{x}$ with each of the two fixed objects $\boldsymbol{h}$ and $\boldsymbol{\ell}$ are evaluated by $\langle \boldsymbol{h} - \bar{\boldsymbol{x}}, \boldsymbol{x} - \bar{\boldsymbol{x}} \rangle$ and $\langle \boldsymbol{\ell} - \bar{\boldsymbol{x}}, \boldsymbol{x} - \bar{\boldsymbol{x}} \rangle$, respectively. Their difference z^{cent} is given by

$$\begin{aligned} z^{\mathsf{cent}} &= \langle \boldsymbol{h} - \bar{\boldsymbol{x}}, \boldsymbol{x} - \bar{\boldsymbol{x}} \rangle - \langle \boldsymbol{\ell} - \bar{\boldsymbol{x}}, \boldsymbol{x} - \bar{\boldsymbol{x}} \rangle \\ &= \langle \boldsymbol{h} - \boldsymbol{\ell}, \boldsymbol{x} - \bar{\boldsymbol{x}} \rangle \\ &= \langle \boldsymbol{h} - \boldsymbol{\ell}, \boldsymbol{x} \rangle - \langle \boldsymbol{h} - \boldsymbol{\ell}, \bar{\boldsymbol{x}} \rangle \\ &= z - \langle \boldsymbol{h} - \boldsymbol{\ell}, \bar{\boldsymbol{x}} \rangle. \end{aligned}$$

The last equality follows from Eq. (6). By definition we have $z \sim Q(z)$, and since $\langle \boldsymbol{h} - \boldsymbol{\ell}, \bar{\boldsymbol{x}} \rangle$ is a constant,

$$z^{\mathsf{cent}} = z - \langle \boldsymbol{h} - \boldsymbol{\ell}, \bar{\boldsymbol{x}} \rangle \sim Q(z + \langle \boldsymbol{h} - \boldsymbol{\ell}, \bar{\boldsymbol{x}} \rangle).$$

In other words, the shape of the distribution does not change, but the mean is shifted to

$$\begin{aligned} \mathbb{E}[z^{\mathsf{cent}}] &= \mathbb{E}[z] - \langle \boldsymbol{h} - \boldsymbol{\ell}, \bar{\boldsymbol{x}} \rangle \\ &= \langle \boldsymbol{h} - \boldsymbol{\ell}, \boldsymbol{\mu} \rangle - \langle \boldsymbol{h} - \boldsymbol{\ell}, \bar{\boldsymbol{x}} \rangle \\ &= \langle \boldsymbol{h} - \boldsymbol{\ell}, \boldsymbol{\mu} - \bar{\boldsymbol{x}} \rangle, \end{aligned}$$

where $\mathbb{E}[z]$ is given by Eq. (7). If the sample mean $\bar{\boldsymbol{x}}$ is close enough to the true mean $\boldsymbol{\mu}$, i.e., $\bar{\boldsymbol{x}} \approx \boldsymbol{\mu}$, we have an approximation

$$\mathbb{E}[z^{\mathsf{cent}}] = \langle \boldsymbol{h} - \boldsymbol{\ell}, \boldsymbol{\mu} - \bar{\boldsymbol{x}} \rangle \approx 0. \quad (9)$$

Thus, if the median and the mean of distribution $Q(z)$ are again not far apart, Eq. (9) suggests that $\boldsymbol{h} - \bar{\boldsymbol{x}}$ and $\boldsymbol{\ell} - \bar{\boldsymbol{x}}$ are about equally likely to be more similar to $\boldsymbol{x} - \bar{\boldsymbol{x}}$; i.e., neither has a greater chance to become a hub.

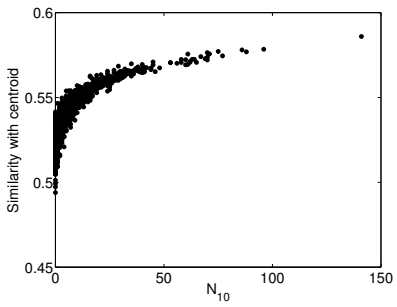
5 Hubs in multi-cluster data

In this section, we discuss emergence of hubs when the data consists of multiple clusters. In fact, the analysis of Section 4 is distribution-free, and thus also applies to the case of multi-modal $P(\boldsymbol{x})$. However, one might still argue that objects similar to the data centroid should hardly occur in that case. Using both synthetic and real datasets, we demonstrate below that even in multi-cluster data, objects that are only slightly more similar to the data mean (centroid) may emerge as hubs.

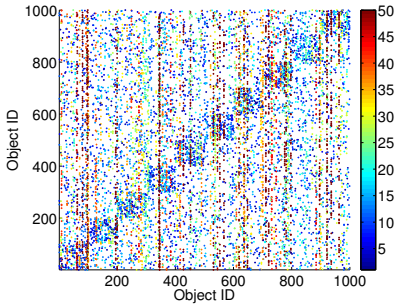
5.1 Synthetic data

5.1.1 Data generation

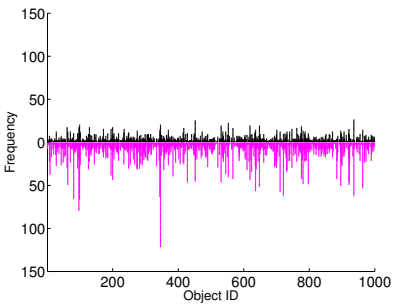
We generated a high-dimensional multi-cluster dataset by modeling it as a mixture of ten von Mises-Fisher distributions (Mardia and Jupp, 2000) in



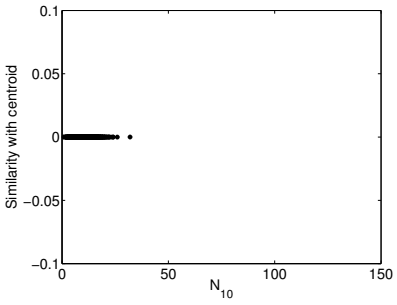
(a) Before centering: N_{10} vs. inner product similarity to the data centroid



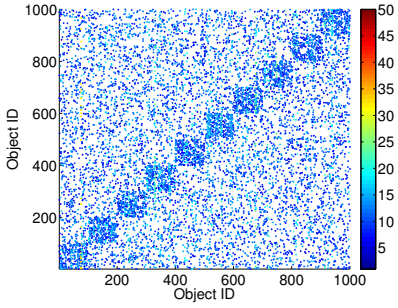
(b) Before centering: kNN matrix



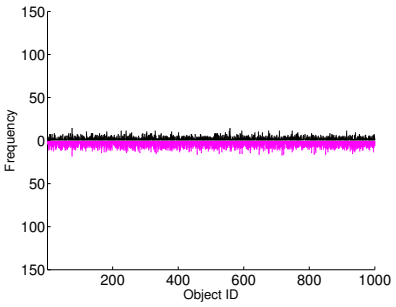
(c) Before centering: Breakdown of N_{10} by cluster match/mismatch between objects and neighbors



(d) After centering: N_{10} vs. inner product similarity to the data centroid



(e) After centering: kNN matrix



(f) After centering: Breakdown of N_{10} by cluster match/mismatch between objects and neighbors

Figure 1: 300-dimensional synthetic data. (a), (d): scatter plot of the N_{10} value of objects and their similarity to centroid. (b), (e): kNN matrices. The points are colored according to the N_{10} value of object x; warmer colors indicate higher N_{10} values. (c), (f): the number of times (y-axis) an object (whose ID is on the x-axis) appears in the 10 nearest neighbors of objects of the same cluster (black bars), and those of different clusters (magenta).

$\mathbb{R}^{300}$. The von Mises-Fisher distribution is a distribution of unit vectors (it can roughly be thought of as a normal distribution on a unit hypersphere), so for objects (feature vectors) sampled from this distribution, inner product reduces to cosine similarity.

We sampled[1] 100 objects from each of the ten distributions (clusters), and made a dataset of 1,000 objects in total.

The von Mises-Fisher distribution has two parameters, the mean direction vector $\boldsymbol{\mu}$, and the concentration parameter κ characterizing how strongly the population is concentrated around the direction $\boldsymbol{\mu}$. We set $\kappa = 500$ for all ten distributions, but the mean directions $\boldsymbol{\mu}$ were made distinct; all mean direction vectors had 30 components set to 0.5 while the remaining 270 components were set to 1, but the 30 components with value 0.5 were chosen to be distinct among the ten clusters. This configuration assures that all ten mean directions have the same angle from the all-ones vector $[1, \ldots, 1]^{\mathrm{T}}$, which is the direction of the mean of the entire data distribution.

Note that even though all sampled objects reside on the surface of the unit hypersphere, the data centroid lies not on the surface but inside the hypersphere. And after centering, the length of the feature vectors may vary from one another, but we do not normalize these vectors; i.e., object similarity is measured by raw inner product, not by cosine.

[1]We used the random sampling code available at http://people.kyb.tuebingen.mpg.de/suvrit/work/progs/movmf.html (Banerjee et al., 2005).

5.1.2 Correlation between hubness and centroid similarity

The scatter plot in Figure 1(a) shows the correlation between the degree of hubness (N_{10}) of an object and its inner product similarity to the data centroid. The N_{10} value of an object is defined as the number of times the object appears in the 10 nearest neighbors of other objects in the dataset. It was used in (Radovanović et al., 2010a) to measure the degree of hubness of individual objects.

The plot clearly shows that the hub objects (i.e., those with high N_{10}) consist of objects that are similar to the centroid. Figure 1(d) shows the scatter plot after the data is centered, created in the same way as Figure 1(a). The similarity to the centroid is uniformly 0 as a result of centering, and no objects have an N_{10} value greater than 33.

5.1.3 Influence of hubs on objects in different clusters

The kNN matrix of Figure 1(b) depicts the kNN relations with $k = 10$ among objects before centering. In this matrix, both the x- and y- axes represent the ID of the objects. If object x is in the 10 nearest neighbors of object y, a point is plotted at coordinates (x, y). As a result, there are exactly $k = 10$ points in each row. The color of points indicates the degree of hubness of object x; warmer color represents higher N_{10} value of the object.

In this matrix, object IDs are sorted by the cluster the objects belong to. Hence in the ideal case in which the k nearest neighbors of every object consist genuinely of objects from the same cluster, only the diagonal blocks would be colored, and off-diagonal areas would be left blank.

As Figure 1(b) shows, the actual situation is far from ideal, even though ten diagonal blocks are still identifiable. The presence of many warm colored vertical lines suggests that many hub objects appear in the 10 nearest neighbors of other objects that are not in the same cluster as the hubs. Thus these hubs may have a strong influence on the kNN prediction of other objects.

Figure 1(e) shows the kNN matrix after centering. The warm colored lines have disappeared, and the diagonal blocks are now more visible.

The bar graphs of Figures 1(c) and (f) plot the N_{10} value of each object (whose ID is on the x-axis). Recall that N_{10} is the number of times an object appears in the 10 nearest neighbors of other objects. The bar for each object is broken down by whether the object and its neighbors belong to the same cluster (black bar) or in different clusters (magenta bar). In terms of kNN classification, having a large number of nearest neighbors with the same class improves the classification performance, so longer black bars and shorter magenta bars are more desirable.

Before centering (Figure 1(c)), hub objects with large N_{10} values are similar not only to objects belonging to the same cluster (as indicated by black bars), but also to objects belonging to different clusters (magenta bars). After centering (Figure 1(f)), the number of tall magenta bars decreases.

Before centering, 22.7% of the 10 nearest neighbors of an object have the same class label as the object (as indicated by the ratio of the total height of black bars relative to that of all bars in Figure 1(c)). After centering, the percentage increases to 31.6%.

5.2 Real dataset

We did the same analysis as Sections 5.1.2–5.1.3 to a real dataset with multiple-cluster structure: the Reuters Transcribed dataset. This multi-class document classification dataset has ten classes, and each class roughly forms a cluster. We will also use this dataset in an experiment in Section 7.2.

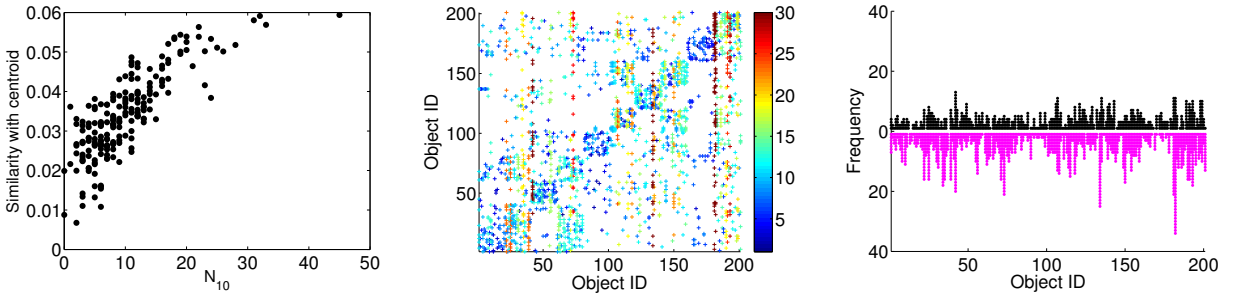
The results are shown in Figure 2. We can observe the same trends as we saw in Figure 1 for the synthetic data: positive correlation between hubness (N_{10}) and inner product with the data centroid before centering; hubs appearing in the nearest neighbors of many objects of different classes; and both are reduced after centering.

The ratio of the height of black bars to that of all bars in Figure 2(c) is 38.4% before centering, whereas it improves to 41.0% after centering (Figure 2(f)).

6 Hubness weighted centering

Centering shifts the origin of the space to the data centroid, and objects similar to the centroid tend to become hubs. Thus in a sense, centering can be interpreted as an operation that shifts the origin towards hubs.

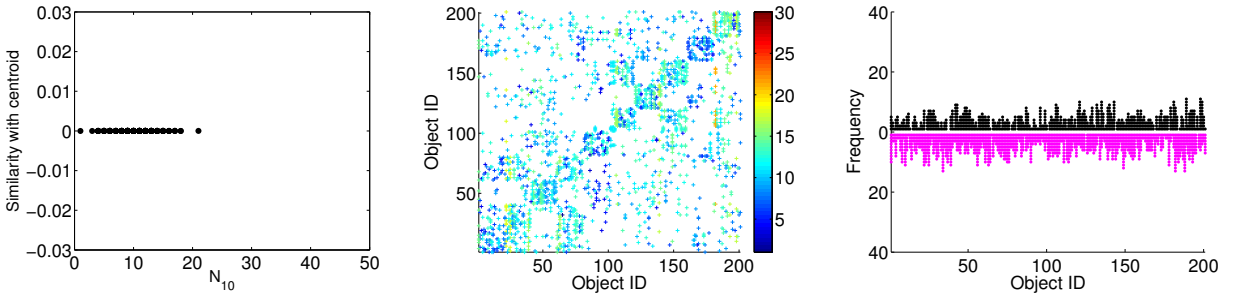
In this section, we extrapolate this interpretation,



(a) Before centering: N_{10} vs. inner product similarity to the data centroid

(b) Before centering: kNN matrix

(c) Before centering: Breakdown of N_{10} by class match/mismatch between objects and neighbors



(d) After centering: N_{10} vs. inner product similarity to the data centroid

(e) After centering: kNN matrix

(f) After centering: Breakdown of N_{10} by class match/mismatch between objects and neighbors

Figure 2: Reuters Transcribed data.

and move the origin more actively towards hub objects in the dataset, rather than towards the data centroid. To this end, we consider *weighted centering*, a variation of centering in which each object is associated with a weight, and the origin is shifted to the weighted mean of the data. Specifically, we define the weight of an object as the sum of the similarities (inner products) between the object and all objects, regarding this sum as the index of how likely the object can be a hub.

6.1 Weighted centering

In weighted centering, we associate weight w_i to each object i in the dataset, and move the origin to the weighted centroid

$$\bar{\boldsymbol{x}}^{\text{weighted}} = \sum_{i=1}^{n} w_i \boldsymbol{x}_i$$

where $\sum_{i=1}^{n} w_i = 1$ and $0 \le w_i \le 1$ for $i = 1, \ldots, n$. Thus, object $\boldsymbol{x}$ is mapped to a new feature vector

$$\boldsymbol{x}^{\text{weighted}} = \boldsymbol{x} - \bar{\boldsymbol{x}}^{\text{weighted}} = \boldsymbol{x} - \sum_{i=1}^{n} w_i \boldsymbol{x}_i.$$

Notice that the original centering formula (2) is recovered by letting $w_i = 1/n$ for all $i = 1, \ldots, n$.

Weighted centering can also be kernelized by using the weighted centering matrix $\mathbf{H}(\boldsymbol{w}) = \mathbf{I} - \mathbb{1}\boldsymbol{w}^{\mathrm{T}}$ in place of $\mathbf{H}$ in Eq. (3). The resulting Gram matrix is

$$\mathbf{K}^{\text{weighted}} = \mathbf{H}(\boldsymbol{w})\mathbf{K}\mathbf{H}(\boldsymbol{w})^{\mathrm{T}}. \tag{10}$$

6.2 Similarity-dependent weighting

To move the origin towards hubs more aggressively, we place more weights on objects that are more likely to become hubs. This likelihood is estimated by the similarity of individual objects to all objects in the data set.

Let d_i be the sum of the similarity between object $\boldsymbol{x}_i$ and all objects in the dataset. So,

$$d_i = \sum_{j=1}^{n} \langle \boldsymbol{x}_i, \boldsymbol{x}_j \rangle = n \, \langle \boldsymbol{x}_i, \frac{1}{n} \sum_{j=1}^{n} \boldsymbol{x}_j \rangle.$$

As seen from the last equation, d_i is proportional to the similarity (inner product) between object $\boldsymbol{x}_i$ and the data centroid.

Now we define $\{w_i\}_{i=1}^n$ from $\{d_i\}_{i=1}^n$ by

$$w_i = \frac{d_i^\gamma}{\sum_{j=1}^n d_j^\gamma},$$

where γ is a parameter controlling how much we emphasize the effect of d_i. Setting $\gamma = 0$ results in $w_i = 1$ for every i, and hence is equivalent to normal centering. When $\gamma > 0$, weighted centering moves the origin closer to the objects with a large d_i than normal centering would.

7 Experiments

We evaluated the effect of centering in two natural language tasks: word sense disambiguation (WSD) and document classification. We are interested in whether hubs are actually reduced after centering, and whether the performance of kNN classification is improved.

Throughout this section, $\mathbf{K}$ denotes cosine similarity matrix; i.e., inner product of feature vectors normalized to unit length; $\mathbf{K}^{\mathsf{cent}}$ denotes the centered similarity matrix computed by Eq. (3) from $\mathbf{K}$; $\mathbf{K}^{\mathsf{weighted}}$ denotes its hubness weighted variant given by Eq. (10). Depending on context, these symbols are also used to denote kNN classifiers using respective similarity measures.

For comparison, we also tested two recently proposed approaches to hub reduction: transformation of the base similarity measure (in our case, $\mathbf{K}$) by Mutual Proximity (Schnitzer et al., 2012)[2], and the one (Suzuki et al., 2012) based on graph Laplacian kernels. Since the Laplacian kernels are defined for graph nodes, we computed them by taking the cosine similarity matrix $\mathbf{K}$ as the weighted adjacency (affinity) matrix of a graph. For Laplacian kernels, we computed both the regularized Laplacian kernel (Chebotarev and Shamis, 1997; Smola and Kondor, 2003) with several parameter values, as well as the commute-time kernel (Saerens et al., 2004), but present only the best results among these kernels.

7.1 Word sense disambiguation

7.1.1 Task and dataset

In the WSD experiment, we used the dataset for the Senseval-3 English Lexical Sample (ELS) task (Mihalcea et al., 2004). It is a collection of sentences containing 57 polysemous words, and each of these sentences is annotated with a gold standard sense of the target word. The goal of the ELS task is to build a classifier for each target word, which, given a context around the word, predicts a sense from the known set of senses.

We used a basic bag-of-words representation for the context surrounding a target word (Mihalcea, 2004; Navigli, 2009). A context is thus represented as a high-dimensional feature vector holding the tf-idf weighted frequency of words[3] in context.

7.1.2 Compared methods

We applied kNN classification using cosine similarity $\mathbf{K}$, and its four transformed similarity measures: centered similarity $\mathbf{K}^{\mathsf{cent}}$, its weighted variant $\mathbf{K}^{\mathsf{weighted}}$, Mutual Proximity and graph Laplacian kernels. The sense of a test object was predicted by voting from the k training objects most similar to the test object, as measured by the respective similarity measures.

We used leave-one-out cross validation within the training data to tune neighborhood size k for the kNN classification and the voting scheme, i.e., either (unweighted) majority vote, or weighted vote in which votes from individual objects are weighted by their similarity score to the test objects. We also selected parameter γ in $\mathbf{K}^{\mathsf{weighted}}$ and the best graph Laplacian kernel among the regularized Laplacian and commute time kernels using the training data.

7.1.3 Evaluation

We computed two indices for each similarity measure: (i) skewness of the N_{10} distribution to evaluate

[2] We used the Matlab script downloaded from http://www.ofai.at/~dominik.schnitzer/mp/.

[3] We removed stop words listed in the on-line appendix of (Lewis et al., 2004).

Method	F1 score	Skewness
$\mathbf{K}$	60.3	4.55
$\mathbf{K}^{\mathsf{cent}}$	64.0	1.19
$\mathbf{K}^{\mathsf{weighted}}$	**64.8**	1.02
Mutual Proximity	63.0	1.00
Graph Laplacian	61.2	4.51
GAMBL (Decadt et al., 2004)	64.5	—

Table 1: WSD results: Macro-averaged F1 score (points) of the compared methods (larger is better) and empirical skewness of the N_{10} distribution for each similarity measure (smaller is better).

the emergence of hubs, and (ii) macro-averaged F1 score to evaluate the classification performance.

Skewness To evaluate the degree of hub emergence for each similarity measure, we followed (Radovanović et al., 2010a) and counted $N_k(\boldsymbol{x})$, the number of times object $\boldsymbol{x}$ occurs in the kNN lists of other objects in the dataset (we fix $k = 10$ below). The emergence of hubs in a dataset can then be quantified with *skewness*, defined as follows:

$$S_{N_k} = \frac{\mathbb{E}\left[(N_k - \mu_{N_k})^3\right]}{\sigma_{N_k}^3}.$$

In this equation, $\mathbb{E}[\cdot]$ denotes expectation, and μ_{N_k} and σ_{N_k} are the mean and the standard deviation of the N_k distribution, respectively.

When hubs exist in a dataset, the distribution of N_k is expected to skew to the right, and yields a large S_{N_k} (Radovanović et al., 2010a). In other words, similarity measures that yield smaller S_{N_k} are more desirable in terms of hub reduction.

Skewness can only be computed for each dataset, and in the WSD task, each target word has its own dataset. Hence we computed the skewness $S_{N_{10}}$ for each word and then took average.

Macro-averaged F1 score Classification performance was measured by the F1 score macro-averaged over all the 57 target words in the Senseval-3 ELS dataset. The standard Senseval-3 ELS scoring method is based on micro average, but we used macro average to make the evaluation consistent with skewness computation, which, as mentioned above, can only be computed for each dataset (i.e., word).

Dataset	#classes	#objects	#features
Reuters Transcribed	10	201	2730
Mini Newsgroups	20	2000	8811

Table 2: Document classification datasets: Number of classes, data size, and number of features.

7.1.4 Result

Table 1 shows the F1 scores and the skewness of the N_{10} distributions, macro averaged over the 57 target words. The table also includes the macro-averaged F1 score[4] of the GAMBL system, the best memory-based system participated in the Senseval-3 ELS task. Note however that GAMBL uses more elaborate features (e.g., part-of-speech of words) than just a plain bag-of-words used by other methods in this comparison. GAMBL also employs complex post-processing of the kNN outputs.

After centering ($\mathbf{K}^{\mathsf{cent}}$ and $\mathbf{K}^{\mathsf{weighted}}$) skewness became markedly smaller than that of the non-centered cosine $\mathbf{K}$. F1 score also improved with the decrease in skewness. In particular, weighted centering ($\mathbf{K}^{\mathsf{weighted}}$) slightly outperformed GAMBL, though the difference was small. Recall however that $\mathbf{K}^{\mathsf{cent}}$ and $\mathbf{K}^{\mathsf{weighted}}$ only use naive bag-of-words features, unlike GAMBL.

7.2 Document classification

7.2.1 Task and dataset

Two multiclass document classification datasets were used: Reuters Transcribed and Mini Newsgroups, distributed at http://archive.ics.uci.edu/ml/. The properties of the datasets are summarized in Table 2.

7.2.2 Evaluation

The performance was evaluated by the F1 score (equivalent to accuracy in this task) of prediction using leave-one-out cross validation, due to the limited number of documents.

7.2.3 Compared methods

We used the cosine similarity as the base similarity matrix ($\mathbf{K}$). The centered similarity matrix ($\mathbf{K}^{\mathsf{cent}}$) and its weighted variant ($\mathbf{K}^{\mathsf{weighted}}$), Mutual

[4]The macro-averaged F1 of GAMBL was calculated from the per-word F1 scores listed in Table 1 of (Decadt et al., 2004).

Method	F1 score	Skewness
$\mathbf{K}$	56.7	1.61
$\mathbf{K}^{\mathsf{cent}}$	**61.2**	0.11
$\mathbf{K}^{\mathsf{weighted}}$	60.2	0.04
Mutual Proximity	60.2	−0.10
Graph Laplacian	57.2	0.37

(a) Reuters Transcribed

Method	F1 score	Skewness
$\mathbf{K}$	76.5	4.37
$\mathbf{K}^{\mathsf{cent}}$	79.0	1.56
$\mathbf{K}^{\mathsf{weighted}}$	**79.4**	1.68
Mutual Proximity	79.0	0.49
Graph Laplacian	77.6	2.13

(b) Mini Newsgroups

Table 3: Document classification results: F1 score (%) (larger is better) and skewness of the N_{10} distribution for each similarity measure (smaller is better).

Proximity, and graph Laplacian based kernels were computed from $\mathbf{K}$.

kNN classification was done in a standard way: The class of object $\boldsymbol{x}$ is predicted by the majority vote from $k = 10$ objects most similar to $\boldsymbol{x}$, measured by a specified similarity measure. The parameter k for the kNN classification, the voting scheme (i.e., either unweighted or weighted majority vote), γ in $\mathbf{K}^{\mathsf{weighted}}$, and the best graph Laplacian kernel were selected by leave-one-out cross validation.

7.2.4 Result

Table 3 shows the F1 score and the skewness of the N_{10} distribution of the respective methods in document classification. Centered cosine ($\mathbf{K}^{\mathsf{cent}}$) outperformed uncentered cosine similarity $\mathbf{K}$, and achieved an F1 score comparable to Mutual Proximity. Weighted centering ($\mathbf{K}^{\mathsf{weighted}}$) further improved F1 on the Mini Newsgroups data.

8 Conclusion

We have shown that centering similarity matrices reduces the emergence of hubs in the data, and consequently improves the accuracy of nearest neighbor classification. We have theoretically analyzed why objects most similar to the mean tend to make hubs, and also proved that centering cancels the bias in the distribution of inner products, and thus is expected to reduce hubs.

In WSD and document classification tasks, kNN classifiers showed much better performance with centered similarity measures than non-centered ones. Weighted centering shifts the origin towards hubs more aggressively, and further improved the classification performance in some cases.

In future work, we plan to exploit the class distribution in the dataset to make more effective similarity measures; notice that the hubness weighted centering of Section 6 is an unsupervised method, in the sense that class information was not used for determining weights. We will investigate if more effective weighting can be done using this information.

Abstract

We derive a spectral method for unsupervised learning of Weighted Context Free Grammars. We frame WCFG induction as finding a Hankel matrix that has low rank and is linearly constrained to represent a function computed by inside-outside recursions. The proposed algorithm picks the grammar that agrees with a sample and is the simplest with respect to the nuclear norm of the Hankel matrix.

1 Introduction

Weighted Context Free Grammars (WCFG) define an important class of languages. Their expressivity makes them good candidates for modeling a wide range of natural language phenomena. This expressivity comes at a cost: unsupervised learning of WCFG seems to be a particularly hard task. And while it is a well-studied problem, it is still to a great extent unsolved.

Several methods for unsupervised learning of WCFG have been proposed. Some rely on heuristics that are used to build incrementally an approximation of the unknown grammar (Adriaans et al., 2000; Van Zaanen, 2000; Tu and Honavar, 2008). Other methods are based on maximum likelihood estimation, searching for the grammar that has the largest posterior given the training corpus (Baker, 1979; Lari and Young, 1990; Pereira and Schabes, 1992; Klein and Manning, 2002). Several Bayesian inference approaches have also been proposed (Chen, 1995; Kurihara and Sato, 2006; Liang et al., 2007; Cohen et al., 2010). These approaches perform parameter estimation by exploiting Markov sampling techniques.

Recently, for the related problem of unsupervised dependency parsing, Gormley and Eisner (2013) proposed a new way of framing the max-likelihood estimation. In their formulation the problem is expressed as an integer quadratic program subject to non-linear constraints. They exploit techniques from mathematical programming to solve the resulting optimization.

In spirit, the work by Clark (2001; 2007) is probably the most similar to our approach since both approaches share an algebraic view of the problem. In his case the key idea is to work with an algebraic representation of a WCFG. The problem of recovering the constituents of the grammar is reduced to the problem of identifying its syntactic congruence.

In the last years, multiple spectral learning algorithms have been proposed for a wide range of models (Hsu et al., 2009; Bailly et al., 2009; Bailly et al., 2010; Balle et al., 2011; Luque et al., 2012; Cohen et al., 2012). Since the spectral approach provides a good thinking tool to reason about distributions over Σ^*, the question of whether they can be used for unsupervised learning of WCFG seems natural. Still, while spectral algorithms for unsupervised learning of languages can learn regular languages, tree languages and simple dependency grammars, the frontier to WCFG seems hard to reach.

In fact, the most recent theoretical results on spectral learning of WCFG do not seem to be very encouraging. Recently, Hsu et al. (2012) showed that the problem of recovering the joint distribution over PCFG derivations and their yields is not identifiable.

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 624–635,
Seattle, Washington, USA, 18-21 October 2013.

Although, for some simple grammar subclasses (e.g. independent left and right children), identification in the weaker sense (over the yields of the grammar) implies strong identification (e.g. over joint distribution of yields and derivations). In their paper, they propose a spectral algorithm based on a generalization of the method of moments for these restricted subclasses.

Thus one open direction for spectral research consists on defining subclasses of context free languages that can be learned (in the strong sense) from observations of yields. Yet, an alternative research direction is to consider learnability in the weaker sense. In this paper we take the second road, and focus on the problem of approximating the distribution over yields generated by a WCFG.

Our main contribution is to present a spectral algorithm for unsupervised learning of WCFG. Following ideas from Balle et al. (2012), the algorithm is framed as a convex optimization where we search for a low-rank matrix satisfying two types of constraints: (1) Constraints derived from observable statistics over yields; and (2) Constraints derived from certain recurrence relations satisfied by a WCFG. Our derivations of the learning algorithm illustrate the main ingredients behind the spectral approach to learning functions over Σ^* which are: (1) to exploit the recurrence relations satisfied by the target family of functions and (2) provide algebraic formulations of these relations.

We alert the reader that although we are able to frame the problem as a convex optimization, the number of variables involved is quite large and prohibits a practical implementation of the method on a realistic scenario. The experiments we present should be regarded as examples designed to illustrate the behavior of the method. More research is needed to make the optimization more efficient, and we are optimistic that such improvements can be achieved by exploiting problem-specific properties of the optimization. Regardless of this, ours is a novel way of framing the grammatical inference problem.

The rest of the paper is organized as follows. Section 2 gives preliminaries on WCFG and the type of functions we will learn. Section 3 establishes that spectral methods can learn a WCFG from a Hankel matrix containing statistics about context-free cuts. Section 4 presents the unsupervised algorithm, where we formulate grammar induction as a low-rank optimization. Section 5 presents experiments, and finally we conclude the paper.

Notation Let Σ be an alphabet. We use σ to denote an arbitrary symbol in Σ. The set of all finite strings over Σ is denoted by $\Sigma^\star$, where we write λ for the empty string. We also use the set $\Sigma^+ = \Sigma^\star \setminus \{\lambda\}$.

We use bold letters to represent column vectors $\boldsymbol{v}$ and matrices $\boldsymbol{M}$. We use $\boldsymbol{I}_n$ to denote the n-dimensional identity matrix. We use $\boldsymbol{M}^+$ to denote the *Moore-Penrose pseudoinverse* of some matrix $\boldsymbol{M}$. $\boldsymbol{M} \otimes \boldsymbol{M}'$ is the Kronecker product between matrices $\boldsymbol{M} \in \mathbb{R}^{m \times n}$ and $\boldsymbol{M}' \in \mathbb{R}^{p \times q}$ resulting in a matrix in $\mathbb{R}^{mp \times nq}$. The rest of notation will be given as needed.

2 Weighted Context Free Grammars

In this section we define Weighted Context Free Grammars (WCFG). We start with a classic definition and then describe an algebraic form of WCFG that will be used throughout the paper. We also describe the fundamental recursions in WCFG.

2.1 WCFG in Classic Form

A WCFG over Σ is a tuple $\bar{G} = \langle V, R, T, w_\star, w_T, w_R \rangle$ where

- V is the set of non-terminal symbols. We assume that $V = \{1, \ldots, n\}$ for some natural number n, and that $V \cap \Sigma = \emptyset$.
- R is a set of binary rules of the form $i \to j\ k$ where $i, j, k \in V$.
- T is a set of unary rules of the form $i \to \sigma$ where $i \in V$ and $\sigma \in \Sigma$.
- $w_\star : V \to \mathbb{R}$, with $w_\star(i)$ being the weight of starting a derivation with non-terminal i.
- $w_T : V \times \Sigma \to \mathbb{R}$, with $w_T(i \to \sigma)$ being the weight of rule rewriting i into σ.
- $w_R : V \times V \times V \to \mathbb{R}$, with $w_R(i \to j\ k)$ being the weight of rewriting i into $j\ k$.

A WCFG $\bar{G}$ computes a function $g_{\bar{G}} : \Sigma^+ \to \mathbb{R}$ defined as

$$g_{\bar{G}}(x) = \sum_{i \in V} w_\star(i) \bar{\beta}_{\bar{G}}(i \overset{\star}{\Rightarrow} x) \quad , \qquad (1)$$

where we define the *inside* function $\bar{\beta}_{\bar{G}} : V \times \Sigma^+ \rightarrow \mathbb{R}$ recursively:

$$\bar{\beta}_{\bar{G}}(i \overset{\star}{\Rightarrow} \sigma) = w_T(i \rightarrow \sigma) \tag{2}$$

$$\bar{\beta}_{\bar{G}}(i \overset{\star}{\Rightarrow} x) = \sum_{\substack{j,k \in V \\ x_1,x_2 \in \Sigma^+ \\ \text{s.t. } x = x_1 x_2}} w_R(i \rightarrow j\ k)\ \bar{\beta}_{\bar{G}}(j \overset{\star}{\Rightarrow} x_1) \bar{\beta}_{\bar{G}}(k \overset{\star}{\Rightarrow} x_2)\ , \tag{3}$$

where in the second case we assume $|x| > 1$. The inside function $\bar{\beta}_{\bar{G}}(i \overset{\star}{\Rightarrow} x)$ exploits the fundamental inside recursion in WCFG (Baker, 1979; Lari and Young, 1990). We will find useful to define the *outside* function $\bar{\alpha}_{\bar{G}} : \Sigma^\star \times V \times \Sigma^\star \rightarrow \mathbb{R}$ defined recursively as:

$$\bar{\alpha}_{\bar{G}}(\lambda; i; \lambda) = w_\star(i) \tag{4}$$

$$\begin{aligned} \bar{\alpha}_{\bar{G}}(x; i; y) = &\sum_{\substack{j,k \in V \\ x_1 \in \Sigma^\star, x_2 \in \Sigma^+ \\ \text{s.t. } x = x_1 x_2}} w_R(j \rightarrow k\ i) \cdot \\ &\bar{\alpha}_{\bar{G}}(x_1; j; y) \cdot \bar{\beta}_{\bar{G}}(k \overset{\star}{\Rightarrow} x_2) \\ &+ \sum_{\substack{j,k \in V \\ y_1 \in \Sigma^+, y_2 \in \Sigma^\star \\ \text{s.t. } y = y_1 y_2}} w_R(j \rightarrow i\ k) \cdot \\ &\bar{\alpha}_{\bar{G}}(x; j; y_2) \cdot \bar{\beta}_{\bar{G}}(k \overset{\star}{\Rightarrow} y_1)\ , \end{aligned} \tag{5}$$

where in the second case we assume that either $x \neq \lambda$ or $y \neq \lambda$.

For $x, z \in \Sigma^\star$ and $y \in \Sigma^+$ we have that

$$\sum_{i \in V} \bar{\alpha}_{\bar{G}}(x; i; z) \cdot \bar{\beta}_{\bar{G}}(i \overset{\star}{\Rightarrow} y) \tag{6}$$

is the weight that the grammar $\bar{G}$ assigns to a string xyz that has a *cut* or bracketing around y. Technically, it corresponds to the sum of the weights of all derivations that have a constituent spanning y. In particular we have that

$$g_{\bar{G}}(x) = \sum_i \bar{\alpha}_{\bar{G}}(\lambda; i; \lambda) \cdot \bar{\beta}_{\bar{G}}(i \overset{\star}{\Rightarrow} x)\ .$$

If x is a string of length m, and $x_{[t:t']}$ is the substring of x from positions t to t', it also happens that

$$g_{\bar{G}}(x) = \sum_i \bar{\alpha}_{\bar{G}}(x_{[1:t-1]}; i; x_{[t+1:m]}) \cdot \bar{\beta}_{\bar{G}}(i \overset{\star}{\Rightarrow} x_{[t]}))$$

for any t between 1 and m.

In this paper we will make frequent use of inside and outside quantities. Notationally, for outsides the semi-colon between two strings, i.e. $x; z$, will simbolize a cut where we can insert an inside string y.

Finally, we note that Probabilistic Context Free Grammars (PCFG) are a special case of WCFG where: $w_\star(i)$ is the probability to start a derivation with non-terminal i; $w_R(i \rightarrow j\ k)$ is the conditional probability of rewriting nonterminal i into j and k; $w_T(i \rightarrow \sigma)$ is the probability of rewriting i into symbol σ; $\sum_i w_\star(i) = 1$; and for each $i \in V$, $\sum_{j,k} w_R(i \rightarrow j\ k) + \sum_\sigma w_T(i \rightarrow \sigma) = 1$. Under these conditions the function $g_{\bar{G}}$ is a probability distibution over Σ^+.

2.2 WCFG in Algebraic Form

We now define a WCFG in algebraic form. A Weighted Context Free Grammar (WCFG) over Σ with n states is a tuple $G = \langle \boldsymbol{\alpha}_\star, \{\boldsymbol{\beta}_\sigma\}, \boldsymbol{A} \rangle$ with:

- An initial vector $\boldsymbol{\alpha}_\star \in \mathbb{R}^n$.
- Terminal vectors $\boldsymbol{\beta}_\sigma \in \mathbb{R}^n$ for $\sigma \in \Sigma$.
- A bilinear operator $\boldsymbol{A} \in \mathbb{R}^{n \times n^2}$.

A WCFG G computes a function $g_G : \Sigma^\star \rightarrow \mathbb{R}$ defined as

$$g_G(x) = \boldsymbol{\alpha}_\star^\top \beta_G(x) \tag{7}$$

where the *inside* function $\beta_G : \Sigma^+ \rightarrow \mathbb{R}^n$ is

$$\beta_G(\sigma) = \boldsymbol{\beta}_\sigma \tag{8}$$

$$\beta_G(x) = \sum_{\substack{x_1,x_2 \in \Sigma^+ \\ x = x_1 x_2}} \boldsymbol{A}(\beta_G(x_1) \otimes \beta_G(x_2)) \tag{9}$$

We will define the *outside* function $\alpha_G : \Sigma^\star \times \Sigma^\star \rightarrow \mathbb{R}^n$ as:

$$\alpha_G(\lambda; \lambda) = \boldsymbol{\alpha}_\star \tag{10}$$

$$\begin{aligned} \alpha_G(x; z)^\top = &\sum_{\substack{x_1 \in \Sigma^\star, x_2 \in \Sigma^+ \\ x = x_1 x_2}} \alpha_G(x_1; z)^\top \boldsymbol{A}(\beta_G(x_2) \otimes \boldsymbol{I}_n) \\ &+ \sum_{\substack{z_1 \in \Sigma^+, z_2 \in \Sigma^\star \\ z = z_1 z_2}} \alpha_G(x; z_2)^\top \boldsymbol{A}(\boldsymbol{I}_n \otimes \beta_G(z_1)) \end{aligned} \tag{11}$$

For $x, z \in \Sigma^\star$ and $y \in \Sigma^+$ we have that

$$\alpha_G(x; z)^\top \beta_G(y) \tag{12}$$

is the weight that the grammar assigns to the string xyz with a cut around y. In particular, $g_G(x) = \alpha_G(\lambda; \lambda)^\top \beta_G(x)$.

Let us make clear that a WCFG is the same device in classic or algebraic forms. If $\bar{G} = \langle V, R, T, w_\star, w_T, w_R \rangle$ and $G = \langle \boldsymbol{\alpha}_\star, \{\boldsymbol{\beta}_\sigma\}, \boldsymbol{A} \rangle$, the mapping is:

$$w_\star(i) = \boldsymbol{\alpha}_\star(i) \tag{13}$$
$$w_T(i \to \sigma) = \boldsymbol{\beta}_\sigma[i] \tag{14}$$
$$w_R(i \to j\ k) = \boldsymbol{A}[i, j, k] \tag{15}$$
$$\bar{\beta}_{\bar{G}}(i \overset{\star}{\Rightarrow} x) = \beta_G(x)[i] \tag{16}$$
$$\bar{\alpha}_{\bar{G}}(x; i; z) = \alpha_G(x; z)[i] \tag{17}$$

See Section A.1 for a proof of Eq. 16 and 17.

3 WCFG and Hankel Matrices

In this section we describe Hankel matrices for WCFG. These matrices explicitly capture inside-outside recursions employed by WCFG functions, and are key to a derivation of a spectral learning algorithm that learns a grammar G using statistics of a training sample.

Let us define some sets. We say that $\mathcal{I}^1 = \Sigma^+$ is the set of *inside strings*. The set of *composed inside strings* $\mathcal{I}^2$ is the set of elements (x, x'), where $x, x' \in \Sigma^+$. Intuitively (x, x') represents two adjacent spans with an operation, i.e., it keeps the trace of the operation that composes x with x' and yields xx'. We will use the set $\mathcal{I} = \mathcal{I}^1 \cup \mathcal{I}^2$.

The set of *outside contexts* $\mathcal{O}$ is the set containing elements $\langle x; z \rangle$, where $x, z \in \Sigma^\star$. Intuitively, $\langle x; z \rangle$ represents a context where we can insert an inside element y in between x and z, yielding xyz.

Consider a function $f : \mathcal{O} \times \mathcal{I} \to \mathbb{R}$. The Hankel matrix of f is the bi-infinite matrix $\boldsymbol{H}_f \in \mathbb{R}^{\mathcal{O} \times \mathcal{I}}$ such that $\boldsymbol{H}_f(o, i) = f(o, i)$.

In practice we will work with finite sub-blocks of $\boldsymbol{H}_f$. To this end we will employ the notion of basis $\mathcal{B} = (\mathcal{P}, \mathcal{S})$, where $\{\langle \lambda, \lambda \rangle\} \subseteq \mathcal{P} \subseteq \mathcal{O}$ is a set of outside contexts and $\Sigma \subseteq \mathcal{S} \subseteq \mathcal{I}^1$ is a set of inside strings. We will use $p = |\mathcal{P}|$ and $s = |\mathcal{S}|$. Furthermore, we define the *inside completion* of $\mathcal{S}$ as the set $\mathcal{S}^\dagger = \{(x, x') \mid x, x' \in \mathcal{S}\}$. Note that $\mathcal{S}^\dagger \subseteq \mathcal{I}^2$. We say that $\mathcal{B}^\dagger = (\mathcal{P}, \mathcal{S}^\dagger)$ is the inside completion of $\mathcal{B}$.

The sub-block of $\boldsymbol{H}_f$ defined by $\mathcal{B}$ is the $p \times s$ matrix $\boldsymbol{H}_\mathcal{B} \in \mathbb{R}^{\mathcal{P} \times \mathcal{S}}$ with $\boldsymbol{H}_\mathcal{B}(o, i) = \boldsymbol{H}_f(o, i) = f(o, i)$. In addition to $\boldsymbol{H}_\mathcal{B}$, we are interested in these additional finite vectors and matrices:

- $\boldsymbol{h}_\star \in \mathbb{R}^\mathcal{S}$ is the s-dimensional vector with coordinates $\boldsymbol{h}_\star(x) = f(\langle \lambda, \lambda \rangle, x)$.
- $\boldsymbol{h}_\sigma \in \mathbb{R}^\mathcal{P}$ is the p-dimensional vector with coordinates $\boldsymbol{h}_\sigma(o) = f(o, \sigma)$.
- $\boldsymbol{H}_A \in \mathbb{R}^{\mathcal{P} \times \mathcal{S}^\dagger}$ with $\boldsymbol{H}_A(o, (x_1, x_2)) = f(o, (x_1, x_2))$.

3.1 Hankel Factorizations

If f is computed by a WCFG G, then $\boldsymbol{H}_f$ has rank n factorization. To see this, consider the following matrices. First a matrix $\boldsymbol{S} \in \mathbb{R}^{n \times \mathcal{I}^1}$ of *inside* vectors for all strings, with column x taking value $\boldsymbol{S}_x = \beta_G(x)$. Then a matrix $\boldsymbol{P} \in \mathbb{R}^{\mathcal{O} \times n}$ of outside vectors for all contexts, with row $\langle x; z \rangle$ taking value $\boldsymbol{P}_{\langle x; z \rangle} = \alpha_G(x; z)$. It is easy to see that $\boldsymbol{H}_f = \boldsymbol{P}\boldsymbol{S}$, since $\boldsymbol{H}_f(\langle x; z \rangle, y) = \boldsymbol{P}_{\langle x; z \rangle}\boldsymbol{S}_y = \alpha_G(x; z)^\top \beta_G(y)$. Therefore $\boldsymbol{H}_f$ has rank n.

The same happens for sub-blocks. If $\boldsymbol{H}_\mathcal{B}$ is the sub-block associated with basis $\mathcal{B} = (\mathcal{P}, \mathcal{S})$, then the sub-blocks $\boldsymbol{P}_\mathcal{B} \in \mathbb{R}^{\mathcal{P} \times n}$ and $\boldsymbol{S}_\mathcal{B} \in \mathbb{R}^{n \times \mathcal{S}}$ of $\boldsymbol{P}$ and $\boldsymbol{S}$ also accomplish that $\boldsymbol{H}_\mathcal{B} = \boldsymbol{P}_\mathcal{B}\boldsymbol{S}_B$. It also happens that

$$\boldsymbol{h}_\star^\top = \boldsymbol{\alpha}_\star^\top \boldsymbol{S}_\mathcal{B} \tag{18}$$
$$\boldsymbol{h}_\sigma = \boldsymbol{P}_\mathcal{B}\boldsymbol{\beta}_\sigma \tag{19}$$
$$\boldsymbol{H}_A = \boldsymbol{P}_\mathcal{B}\boldsymbol{A}(\boldsymbol{S}_\mathcal{B} \otimes \boldsymbol{S}_\mathcal{B}) \quad . \tag{20}$$

We say that a basis $\mathcal{B}$ is complete for f if $\text{rank}(\boldsymbol{H}_\mathcal{B}) = \text{rank}(\boldsymbol{H}_f)$. The following is a key result for spectral methods.

Lemma 1. *Let $\mathcal{B} = (\mathcal{P}, \mathcal{S})$ be a complete basis of dimension n for a function f and let $\boldsymbol{H}_\mathcal{B} \in \mathbb{R}^{\mathcal{P} \times \mathcal{S}}$ be the Hankel sub-block of f for $\mathcal{B}$. Let $\boldsymbol{h}_\star$, $\boldsymbol{h}_\sigma$ and $\boldsymbol{H}_A$ be the additional matrices for $\mathcal{B}$. If $\boldsymbol{H}_\mathcal{B} = \boldsymbol{P}\boldsymbol{S}$ is a rank n factorization, then the WCFG $G = \langle \boldsymbol{\alpha}_\star, \{\boldsymbol{\beta}_\sigma\}, \boldsymbol{A} \rangle$ with*

$$\boldsymbol{\alpha}_\star^\top = \boldsymbol{h}_\star^\top \boldsymbol{S}^+ \tag{21}$$
$$\boldsymbol{\beta}_\sigma = \boldsymbol{P}^+ \boldsymbol{h}_\sigma \tag{22}$$
$$\boldsymbol{A} = \boldsymbol{P}^+ \boldsymbol{H}_A(\boldsymbol{S} \otimes \boldsymbol{S})^+ \tag{23}$$

computes f.

See proof in Section A.2.

3.2 Supervised Spectral Learning of WCFG

The spectral learning method directly exploits Lemma 1. In a nutshell, the spectral method is:

1. Choose a complete basis $\mathcal{B} = (\mathcal{P}, \mathcal{S})$ and a dimension n.
2. Use training data to compute estimates of the necessary Hankel matrices: $\boldsymbol{H}_{\mathcal{B}}$, $\boldsymbol{h}_{\star}$, $\boldsymbol{h}_{\sigma}$, $\boldsymbol{H}_{A}$.
3. Compute the SVD of $\boldsymbol{H}_{\mathcal{B}}$, $\boldsymbol{H}_{\mathcal{B}} = \boldsymbol{U}\boldsymbol{\Lambda}\boldsymbol{V}^{\top}$.
4. Create a truncated rank n factorization of $\boldsymbol{H}_{\mathcal{B}}$ as $\boldsymbol{P}_n\boldsymbol{S}_n$, having $\boldsymbol{P}_n = \boldsymbol{U}_n\boldsymbol{\Lambda}_n$ and $\boldsymbol{S}_n = \boldsymbol{V}_n^{\top}$, where we only consider the top n singular values/vectors of $\boldsymbol{\Lambda}, \boldsymbol{U}, \boldsymbol{V}$.
5. Use Lemma 1 to compute G, using $\boldsymbol{P}_n$ and $\boldsymbol{S}_n$.

Because of Lemma 1, if $\mathcal{B}$ is complete and we have access to the true $\boldsymbol{H}_{\mathcal{B}}$, $\boldsymbol{h}_{\star}$, $\boldsymbol{h}_{\sigma}$, $\boldsymbol{H}_{A}$ of a WCFG target function g^*, then the algorithm will compute a G that exactly computes g^*. In practice, we only have access to empirical estimates of the Hankel matrices. In this case, there exist PAC-style sample complexity bounds that state that g_G will be a close approximation to g^* (Hsu et al., 2009; Bailly et al., 2009; Bailly et al., 2010).

The parameters of the algorithm are the basis and the dimension of the grammar n. One typically employs some validation strategy using held-out data. Empirically, the performance of these methods has been shown to be good, and similar to that of EM (Luque et al., 2012; Cohen et al., 2013). It is also important to mention that in the case that the target g^* is a probability distribution, the function g_G will be close to g^*, but it will only define a distribution *in the limit*: in practice it will not sum to one, and for some inputs it might return negative values. This is a practical difficulty of spectral methods, for example to apply evaluation metrics like perplexity which are only defined for distributions.

4 Unsupervised Learning of WCFG

In the previous section we have exposed that if we have access to estimates of a Hankel matrix of a WCFG G, we can recover G. However, the statistics in the Hankel require access to strings that have information about context-free cuts. We will assume that we only have access to statistics about plain strings of a distribution, i.e. $p(x)$, which we call *observations*. In this scenario, one natural idea is to search for a Hankel matrix that agrees with the observations. The method we present in this section frames this problem as a low-rank matrix optimization problem. We first characterize the space of solutions to our problem, i.e. Hankel matrices associated with WCFG that agree with observable statistics. Then we present the method.

4.1 Characterization of a WCFG Hankel

In this section we describe valid WCFG Hankel matrices using linear constraints.

We first describe an inside-outside basis that is an extension of the one in the previous section. Inside elements are the same, namely $\mathcal{I} = \mathcal{I}^1 \cup \mathcal{I}^2$, where $\mathcal{I}^1$ are strings (x) and $\mathcal{I}^2$ are composed strings (x, x'). The set of *outside contexts* $\mathcal{O}^1$ is the set containing elements $\langle x; z\rangle$, defined as before. The set of *composed outside contexts* has elements $\langle x, x'; z\rangle$, and $\langle x; z', z\rangle$, where $x, z \in \Sigma^{\star}$ and $x', z' \in \Sigma^{+}$. These outside contexts keep an operation open in one of the sides. For example, if we consider $\langle x; z', z\rangle$ and insert a string y, we obtain $x(y, z')z$, where we use (y, z') to explicitly denote a composed inside string. We will use $\mathcal{O} = \mathcal{O}^1 \cup \mathcal{O}^2$.

In this section, we will assume that $\mathcal{I}$ and $\mathcal{O}$ are finite and closed. By closed, we mean that:

- $(x) \in \mathcal{I} \Rightarrow (x_1, x_2) \in \mathcal{I}$ for $x = x_1x_2$
- $(x_1, x_2) \in \mathcal{I} \Rightarrow x_1 \in \mathcal{I}, x_2 \in \mathcal{I}$
- $\langle x; z\rangle \in \mathcal{O} \Rightarrow \langle x_1, x_2; z\rangle \in \mathcal{O}$ for $x = x_1x_2$
- $\langle x; z\rangle \in \mathcal{O} \Rightarrow \langle x; z_1, z_2\rangle \in \mathcal{O}$ for $z = z_1z_2$
- $\langle x_1, x_2; z\rangle \in \mathcal{O} \Rightarrow (x_2) \in \mathcal{I}$
- $\langle x; z_1, z_2\rangle \in \mathcal{O} \Rightarrow (z_1) \in \mathcal{I}$

We will consider a Hankel matrix $\boldsymbol{H} \in \mathbb{R}^{\mathcal{O}\times\mathcal{I}}$. Some entries of this matrix will correspond to *observable* quantities. Specifically, for any string $x \in \mathcal{I}^1$ for which we know $p(x)$ we can define the following *observable constraint*:

$$p(x) = \boldsymbol{H}(\langle\lambda;\lambda\rangle, (x)) \tag{24}$$

The rest of entries of $\boldsymbol{H}$ correspond to a string with an inside-outside cut, and these are not observable. Our method will infer the values of these entries. The following constraints will ensure that the matrix $\boldsymbol{H}$ is a well defined Hankel matrix for WCFG:

- Hankel constraints: $\forall \langle x; z\rangle \in \mathcal{O}, (y_1, y_2) \in \mathcal{I}$

$$\begin{aligned}\boldsymbol{H}(\langle x; z\rangle, (y_1, y_2)) &= \boldsymbol{H}(\langle x, y_1; z\rangle, (y_2)) \\ &= \boldsymbol{H}(\langle x; y_2, z\rangle, (y_1)) \quad (25)\end{aligned}$$

- Inside constraints: $\forall\, o \in \mathcal{O}, (x) \in \mathcal{I}$

$$\boldsymbol{H}(o, (x)) = \sum_{x=x_1x_2} \boldsymbol{H}(o, (x_1, x_2)) \quad (26)$$

- Outside constraints: $\forall \langle x; z\rangle \in \mathcal{O}, i \in \mathcal{I}$

$$\begin{aligned}\boldsymbol{H}(\langle x; z\rangle, i) &= \sum_{x=x_1x_2} \boldsymbol{H}(\langle x_1, x_2; z\rangle, i) \\ &+ \sum_{z=z_1z_2} \boldsymbol{H}(\langle x; z_1, z_2\rangle, i) \quad (27)\end{aligned}$$

Constraint (25) states that composition operations that result in the same structure should have the same value. Constraints (26) and (27) ensure that the values in the Hankel follow the inside-outside recursions that define the computations of a WCFG function. The following lemma formalizes this concept. Let $\boldsymbol{H}_\varepsilon$ be the sub-block of $\boldsymbol{H}$ restricted to $\mathcal{O}^1 \times \mathcal{I}^1$, i.e. without compositions.

Lemma 2. *If $\boldsymbol{H}$ satisfies constraints (25),(26) and (27), and if $\mathrm{rank}(\boldsymbol{H}) = \mathrm{rank}(\boldsymbol{H}_\varepsilon)$ then there exists a WCFG that generates $\boldsymbol{H}_\varepsilon$.*

See proof in Section A.3.

4.2 Convex Optimization

We now present the core optimization program behind our method. Let $\mathbf{vec}(\boldsymbol{H})$ be a vector in $\mathbb{R}^{|\mathcal{O}|\cdot|\mathcal{I}|}$ corresponding to all coefficients of $\boldsymbol{H}$ in column vector form. Let $\boldsymbol{O}$ be a matrix such that $\boldsymbol{O} \cdot \mathbf{vec}(\boldsymbol{H}) = \boldsymbol{z}$ represents the observation constraints. For example, if i-th row of $\boldsymbol{O}$ corresponds to the Hankel coefficient $\boldsymbol{H}(\langle\lambda;\lambda\rangle, (x))$ then $\boldsymbol{z}(i) = p(x)$. Let $\boldsymbol{K}$ be a matrix such that $\boldsymbol{K} \cdot \mathbf{vec}(\boldsymbol{H}) = \mathbf{0}$ represents the constraints (25), (26) and (27).

The optimization problem is:

$$\begin{aligned}\underset{\boldsymbol{H}}{\text{minimize}} \quad & \mathrm{rank}(\boldsymbol{H}) \\ \text{subject to} \quad & \|\boldsymbol{O} \cdot \mathbf{vec}(\boldsymbol{H}) - \boldsymbol{z}\|_2 \leq \mu \\ & \boldsymbol{K} \cdot \mathbf{vec}(\boldsymbol{H}) = \mathbf{0} \\ & \|\boldsymbol{H}\|_2 \leq 1.\end{aligned} \quad (28)$$

Intuitively, we look for $\boldsymbol{H}$ that agrees with the observable statistics and satisfies the inside-outside constraints. μ is a parameter of the method that controls the degree of error in fitting the observables $\boldsymbol{z}$. The $\|\boldsymbol{H}\|_2 \leq 1$ is satisfied by any Hankel matrix derived from a true distribution, and is used to avoid incoherent solutions.

The above optimization problem, however, is computationally hard because of the rank objective. We employ a common relaxation of the rank objective, based on the nuclear norm as in (Balle et al., 2012). The optimization is:

$$\begin{aligned}\underset{\boldsymbol{H}}{\text{minimize}} \quad & \|\boldsymbol{H}\|_* \\ \text{subject to} \quad & \|\boldsymbol{O} \cdot \mathbf{vec}(\boldsymbol{H}) - \boldsymbol{z}\|_2 \leq \mu \\ & \boldsymbol{K} \cdot \mathbf{vec}(\boldsymbol{H}) = \mathbf{0} \\ & \|\boldsymbol{H}\|_2 \leq 1.\end{aligned} \quad (29)$$

To optimize (29) we employ a projected gradient strategy, similar to the FISTA scheme proposed by Beck and Teboulle (2009). The method alternates between separate projections for the observable constraints, the ℓ_2 norm, the inside-outside constraints, and the nuclear norm. Of these, the latter two are the most expensive.

Elsewhere, we develop theoretical properties of the optimization (28) applied to finite-state transductions (Bailly et al., 2013). One can prove that there is theoretical identifiability of the rank and the parameters of an FST distribution, using a rank minimization formulation. However, this problem is NP-hard, and it remains open whether there exists a polynomial method with identifiability results. These results should generalize to WCFG.

5 Experiments

In this section we describe some experiments with the learning algorithms for WCFG. Our goal is to verify that the algorithms can learn some basic context-free languages, and to study the possibility of using them on real data.

5.1 Synthetic Experiments

We performed experiments on synthetic data, obtained by choosing a PCFG with random parameters ($\in [0, 1]$), with a normalization step in order to get a probability distribution. We built the Hankel matrix from the inside basis $\{(x)\}_{x\in\Sigma}$ and outside basis

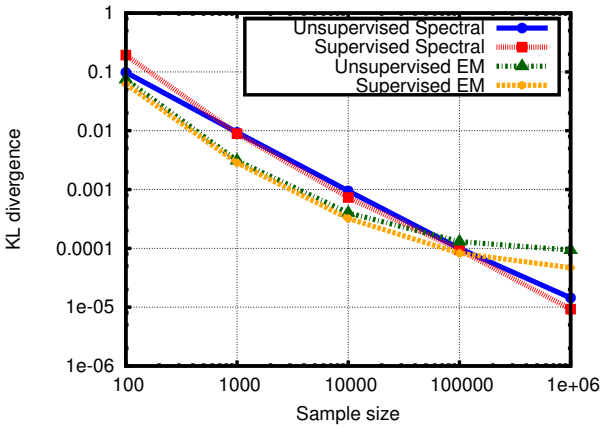

Figure 1: KL divergence for spectral and EM methods, unsupervised and supervised, for different sizes of learning sample, on log-log scales. Results are averages over 50 random target PCFG with 2 states and 2 symbols.

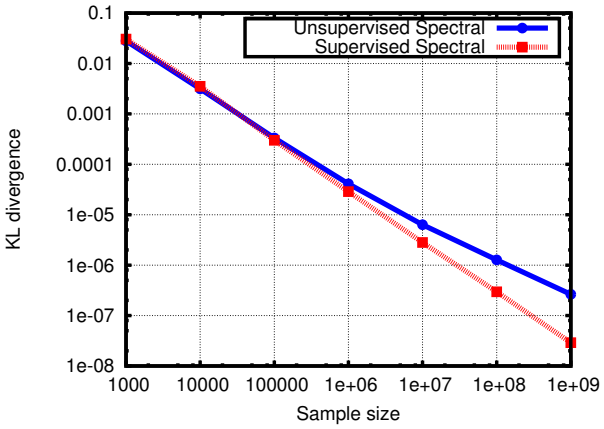

Figure 2: KL divergence for unsupervised and supervised spectral methods, for different sizes of learning sample, on log-log scales. Results are averages over 50 random target PCFG with 3 states and 6 symbols.

$\{\langle\lambda;\lambda\rangle\} \cup \{\langle x;\lambda\rangle, \langle\lambda;x\rangle\}_{x\in\Sigma}$. The composed insides for the operator matrix are thus $\{(x,y)\}_{x,y\in\Sigma}$. The matrix in the optimizer has the following structure

$$H = \begin{array}{c} \\ \langle\lambda;\lambda\rangle \\ \langle x;\lambda\rangle \\ \langle\lambda;x\rangle \\ \vdots \end{array} \begin{array}{c} \begin{array}{ccc} (y) & \cdots & (y,z) \end{array} \\ \begin{pmatrix} (\lambda;y;\lambda) & \cdots & (\lambda;y,z;\lambda) \\ (x;y;\lambda) & \cdots & (x;y,z;\lambda) \\ (\lambda;y;x) & \cdots & (\lambda;y,z;x) \\ \cdots & \cdots & \cdots \end{pmatrix} \end{array}$$

The constraints we use are:

$$\begin{aligned} K = &\{\boldsymbol{H}((x;y;\lambda)) = \boldsymbol{H}((\lambda;x;y))\}_{x,y\in\Sigma} \cup \\ &\{\boldsymbol{H}((\lambda;x;y)) = \boldsymbol{H}((\lambda;x,y;\lambda))\}_{x,y\in\Sigma} \cup \\ &\{\boldsymbol{H}((x;y;\lambda)) = \boldsymbol{H}((\lambda;x,y;\lambda))\}_{x,y\in\Sigma} \end{aligned}$$

and

$$\begin{aligned} O = &\{\boldsymbol{H}((\lambda;x;\lambda)) = p_S(x)\}_{x\in\Sigma} \cup \\ &\{\boldsymbol{H}((\lambda;x;y)) = p_S(xy)\}_{x,y\in\Sigma} \cup \\ &\{\boldsymbol{H}((x;y,z;\lambda)) + \boldsymbol{H}((\lambda;x,y;z)) = p_S(xyz)\}_{x,y,z\in\Sigma} \end{aligned}$$

We use p_S to denote the empirical distribution. Those are simplified versions of the Hankel, inside, outside and observation constraints. The set O is built from the following remarks: (1) $(xy) = (x,y)$ and (2) $(xyz) = (xy,z)+(x,yz)$. The method uses statistics for sequences up to length 3.

The algorithm we use for the unsupervised spectral method is a simplified version: we use alternatively a hard projection on the constraints (by projecting iteratively on each constraint), and a thresholding-shrinkage operation for the target dimension. We use the same trick as FISTA for the update. We finally use the regular spectral method on this matrix to get our model.

We compare this method with an unsupervised EM, and also with supervised versions of spectral method and EM. We compare the accuracy of the different models in terms of KL-divergence for sequences up to length 10. We run 50 optimization steps for the unsupervised spectral method, and 200 iterations for the EM methods. Figure 1 shows the results, corresponding the the geometric mean over 50 experiments on random targets of 2 symbols and 2 states.

For sample size greater than 10^5, the unsupervised spectral method seems to provide better solutions than both EM and supervised EM. The solution, in terms of KL-divergence, is comparable to the one obtained with the supervised spectral method. The computation time of unsupervised spectral method is almost constant w.r.t. the sample size, around $1.67s$, while computation time of unsupervised EM (resp. supervised EM) is $6.10^3 s$ (resp. $2.10^4 s$) for sample size 10^6.

Figure 2 presents learnings curve for random targets with 3 states and 6 symbols. One can see that, for big sample sizes (10^9), the unsupervised spectral method is losing accuracy compared to the supervised method. This is due to a lack of information,

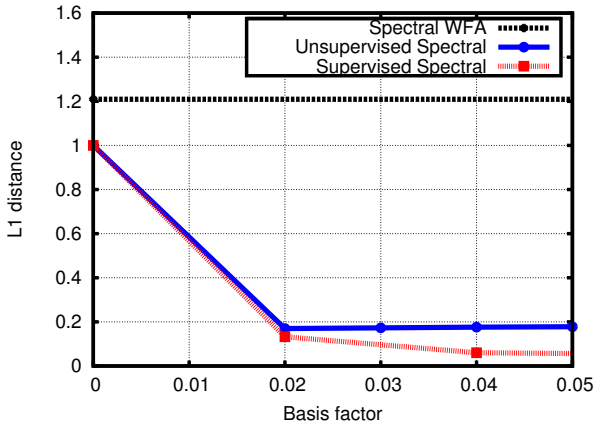

Figure 3: Learning errors for different models in terms of the size of the basis.

and could be overcome by considering a greater basis (e.g. inside sequences up to length 2 or 3).

5.2 Dyck Languages

We now present experiments using the following PCFG:

$$S \rightarrow \; S\,S\;(0.2) \mid a\,S\,b\;(0.4) \mid a\,b\;(0.4)$$

This PCFG generates a probabilistic version of the well-known Dyck language or balanced parenthesis language, an archetypical context-free language.

We do experiments with the following models and algorithms:

- WFA: a Weighted Finite Automata learned using spectral methods as described in (Luque et al., 2012). Parameters: number of states and size of basis.

- Supervised Spectral: a WCFG learned from structured strings using the algorithm of section 3.2. We choose as basis the most frequent insides and outsides observed in the training data. The size of the basis is determined by a parameter f called the basis factor, that determines the proportion of total insides and outsides that will be in the basis.

- Unsupervised Spectral: a WCFG learned from strings using the algorithm of Section 4. The basis is like in the supervised case, but since context-free cuts in the strings are not observed, all possible inside and outsides of the sample (i.e. all possible substrings and contexts) are considered.

basis	size of $\boldsymbol{H}$	obs.	i/o ctr.
1×11	39×159	34	162
6×14	$1{,}163 \times 764$	146	6,360
12×18	$4{,}462 \times 2{,}239$	322	25,374
18×22	$9{,}124 \times 4{,}149$	479	52,524
24×26	$15{,}755 \times 6{,}858$	657	89,718
30×29	$19{,}801 \times 8{,}545$	769	112,374
36×34	$27{,}989 \times 11{,}682$	916	156,690
42×37	$3{,}638 \times 15{,}026$	1,035	200,346
48×41	$45{,}192 \times 18{,}235$	1,157	244,398
54×45	$53{,}741 \times 21{,}196$	1,281	284,466
60×48	$60{,}844 \times 23{,}890$	1,382	318,354

Table 1: Problem sizes for the WSJ10 training corpus.

basis / n	5	10	15	20
1×11	$1.265\,10^{-3}$			
6×14	$7.06\,10^{-4}$	$6.92\,10^{-4}$		
12×18	$7.30\,10^{-4}$	$6.28\,10^{-4}$	$6.01\,10^{-4}$	
18×22	$7.31\,10^{-4}$	$6.29\,10^{-4}$	$5.84\,10^{-4}$	$5.59\,10^{-4}$
24×26	$7.35\,10^{-4}$	$6.39\,10^{-4}$	$5.88\,10^{-4}$	$5.31\,10^{-4}$
30×29	$7.34\,10^{-4}$	$6.41\,10^{-4}$	$5.86\,10^{-4}$	$5.30\,10^{-4}$

Table 2: Experiments with the unsupervised spectral method on the WSJ10 corpus. Results are in terms of expected L_1 on the training set, for different basis and numbers of states.

We generate a training set by sampling 4,000 strings from the target PCFG and counting the relative frequency of each. For the supervised model, we generate strings paired with their context-free derivation. To measure the quality of the learned models, we use the L_1 distance to the target distribution over a fixed set of strings $\Sigma^{\leq n}$, for $n = 7$.[1]

Figure 3 shows the results for the different models and for different basis sizes (in terms of the basis factor f). Here we can clearly see that the WCFG models, even the unsupervised one, outperform the WFA in reproducing the target distribution.

5.3 Natural Language Experiments

Now we present some preliminar tests using natural language data. For these tests, we used the WSJ10 subset of the Penn Treebank, as Klein and Manning (2002). This dataset consists of the sentences of length ≤ 10 after filtering punctuation and currency. We removed lexical items and mapped the POS tags

[1] Given two functions f_1 and f_2 over strings, the L_1 distance is the sum of the absolute difference over all strings in a set: $\sum_x |f_1(x) - f_2(x)|$.

to the Universal Part-of-Speech Tagset (Petrov et al., 2012), reducing the alphabet to a set of 11 symbols.

Table 1 shows the size of the problem for different basis sizes. As described in the previous subsection for the unsupervised case, we obtain the basis by taking the most frequent observed substrings and contexts. We then compute all yields that can be generated with this basis, and close the basis to include all possible insides and outsides with operations completions, such that we create a Hankel as described in Section 4.1. Table 1 shows, for each base, the size of $\boldsymbol{H}$ we induce, the number of observable constraints (i.e. sentences we train from), and the number of inside-outside constraints.

With the current implementation of the optimizer we were only able to run the unsupervised learning for small basis sizes. Table 2 shows the expected L_1 on training data. For a fixed basis, as we increase the number of states we see that the error decreases, showing that the method is inducing a Hankel matrix that explains the observable statistics.

6 Conclusions

We have presented a novel approach for unsupervised learning of WCFG. Our method combines ingredients of spectral learning with low-rank convex optimization methods.

Our method optimizes over a matrix that, even if it grows polynomially with respect to the size of training, results in a large problem. To scale the method to learn languages of the complexity of natural languages we would need to identify optimization algorithms specially suited for this problem.

A Proofs

A.1 Proof of Inside-Outside Eq. 16 and 17

For the inside function, the base case is trivial. By induction:

$$\begin{aligned}
\beta_G(x)[i] &= \sum_{x=x_1x_2} \boldsymbol{A}(\beta_G(x_1) \otimes \beta_G(x_2))[i] \\
&= \sum_{\substack{j,k\in V \\ x=x_1x_2}} \boldsymbol{A}[i,j,k] \cdot \beta_G(x_1)[j] \cdot \beta_G(x_2)[k] \\
&= \sum_{\substack{j,k\in V \\ x=x_1x_2}} w_R(i \to j\ k) \cdot \bar{\beta}_{\bar{G}}(j \overset{\star}{\Rightarrow} x_1) \cdot \bar{\beta}_{\bar{G}}(k \overset{\star}{\Rightarrow} x_2) \\
&= \bar{\beta}_{\bar{G}}(i \overset{\star}{\Rightarrow} x)
\end{aligned}$$

For the outside function, let $\boldsymbol{e}_i$ be an n-dimensional vector with coordinate i to 1 and the rest to 0. We reformulate the mapping as:

$$\alpha_G(x;z)^\top \boldsymbol{e}_i = \bar{\alpha}_{\bar{G}}(x;i;z) \tag{30}$$

The base case is trivial by definitions. We use the property of Kronecker products that $(\boldsymbol{v} \otimes \boldsymbol{I}_n)\boldsymbol{v}' = (\boldsymbol{v} \otimes \boldsymbol{v}')$ and $(\boldsymbol{I}_n \otimes \boldsymbol{v})\boldsymbol{v}' = (\boldsymbol{v}' \otimes \boldsymbol{v})$ for $\boldsymbol{v}, \boldsymbol{v}' \in \mathbb{R}^n$. We first look at one of the terms of $\alpha_G(x;z)^\top \boldsymbol{e}_i$:

$$\begin{aligned}
&\alpha_G(x_1;z)^\top \boldsymbol{A}(\beta_G(x_2) \otimes \boldsymbol{I}_n)\boldsymbol{e}_i \\
&= \alpha_G(x_1;z)^\top \boldsymbol{A}(\beta_G(x_2) \otimes \boldsymbol{e}_i) \\
&= \sum_{j,k\in V} (\alpha_G(x_1;z)^\top \boldsymbol{e}_j) \cdot \boldsymbol{A}[j,k,i] \cdot \beta_G(x_2)[k] \\
&= \sum_{j,k\in V} \bar{\alpha}_{\bar{G}}(x_1;j;z) \cdot w_R(j \to k\ i) \cdot \bar{\beta}_{\bar{G}}(k \overset{\star}{\Rightarrow} x_2)
\end{aligned}$$

Applying the distributive property in $\alpha_G(x;z)^\top \boldsymbol{e}_i$ it is easy to see that all terms are mapped to the corresponding term in $\bar{\alpha}_{\bar{G}}(x;i;z)$.

A.2 Proof of Lemma 1

Let $G' = \langle \boldsymbol{\alpha}'_\star, \{\boldsymbol{\beta}'_\sigma\}, \boldsymbol{A}' \rangle$ be a WCFG for f that induces a rank factorization $\boldsymbol{H} = \boldsymbol{P}'\boldsymbol{S}'$. We first show that there exists an invertible matrix $\boldsymbol{M}$ that changes the basis of the operators of G into those of G'. Define $\boldsymbol{M} = \boldsymbol{S}'\boldsymbol{S}^+$ and note that $\boldsymbol{P}^+\boldsymbol{P}'\boldsymbol{S}'\boldsymbol{S}^+ = \boldsymbol{P}^+\boldsymbol{H}\boldsymbol{S}^+ = \boldsymbol{I}$ implies that $\boldsymbol{M}$ is invertible with $\boldsymbol{M}^{-1} = \boldsymbol{P}^+\boldsymbol{P}'$. We now check that the operators of G correspond to the operators of G' under this change of basis. First we see that

$$\begin{aligned}
\boldsymbol{A} &= \boldsymbol{P}^+\boldsymbol{H}_A(\boldsymbol{S} \otimes \boldsymbol{S})^+ \\
&= \boldsymbol{P}^+\boldsymbol{P}'\boldsymbol{A}'(\boldsymbol{S}' \otimes \boldsymbol{S}')(\boldsymbol{S} \otimes \boldsymbol{S})^+ \\
&= \boldsymbol{M}^{-1}\boldsymbol{A}'(\boldsymbol{S}'\boldsymbol{S}^+ \otimes \boldsymbol{S}'\boldsymbol{S}^+) \\
&= \boldsymbol{M}^{-1}\boldsymbol{A}'(\boldsymbol{M} \otimes \boldsymbol{M}) \quad .
\end{aligned}$$

Now, since $\boldsymbol{h}_\star = \boldsymbol{\alpha}'^\top_\star \boldsymbol{S}'$ and $\boldsymbol{h}_\sigma = \boldsymbol{P}'\boldsymbol{\beta}'_\sigma$, it follows that $\boldsymbol{\alpha}^\top_\star = \boldsymbol{\alpha}'^\top_\star \boldsymbol{M}$ and $\boldsymbol{\beta}_\sigma = \boldsymbol{M}^{-1}\boldsymbol{\beta}'_\sigma$.

Finally we check that G and G' compute the same function, namely $f(o,i) = \alpha_G(o)^\top \beta_G(i) = \alpha_{G'}(o)^\top \beta_{G'}(i)$. We first see that $\beta_G(x) =$

$\boldsymbol{M}^{-1}\beta_{G'}(x)$:

$$\beta_G(\sigma) = \boldsymbol{\beta}_\sigma = \boldsymbol{M}^{-1}\boldsymbol{\beta}'_\sigma \tag{31}$$

$$\beta_G(x) = \sum_{x=x_1x_2} \boldsymbol{A}(\beta_G(x_1) \otimes \beta_G(x_2)) \tag{32}$$

$$= \sum_{x=x_1x_2} \boldsymbol{M}^{-1}\boldsymbol{A}'(\boldsymbol{M} \otimes \boldsymbol{M})(\beta_G(x_1) \otimes \beta_G(x_2))$$

$$= \boldsymbol{M}^{-1} \sum_{x=x_1x_2} \boldsymbol{A}'(\boldsymbol{M}\beta_G(x_1) \otimes \boldsymbol{M}\beta_G(x_2))$$

$$= \boldsymbol{M}^{-1} \sum_{x=x_1x_2} \boldsymbol{A}'(\beta_{G'}(x_1) \otimes \beta_{G'}(x_2))$$

It can also be shown that $\alpha_G(x;z)^\top = \alpha_{G'}(x;z)^\top \boldsymbol{M}$. One must see that in any term:

$$\alpha_G(x_1;z)^\top \boldsymbol{A}(\beta_G(x_2) \otimes \boldsymbol{I}_n) \tag{33}$$
$$= \alpha_G(x_1;z)^\top \boldsymbol{M}^{-1}\boldsymbol{A}'(\boldsymbol{M} \otimes \boldsymbol{M})(\beta_G(x_2) \otimes \boldsymbol{I}_n)$$
$$= \alpha_{G'}(x_1;z)^\top \boldsymbol{A}'(\boldsymbol{M}\beta_G(x_2) \otimes \boldsymbol{M}\boldsymbol{I}_n)$$
$$= \alpha_{G'}(x_1;z)^\top \boldsymbol{A}'(\beta_{G'}(x_2) \otimes \boldsymbol{I}_n)\boldsymbol{M}$$

and the relation follows. Finally:

$$\alpha_G(x;z)^\top \beta_G(y) \tag{34}$$
$$= \alpha_{G'}(x;z)^\top \boldsymbol{M}\boldsymbol{M}^{-1}\beta_{G'}(y)$$
$$= \alpha_{G'}(x;z)^\top \beta_{G'}(y)$$

□

A.3 Proof of Lemma 2

We will use the following sub-blocks of $\boldsymbol{H}$:

- $\boldsymbol{H}_\varepsilon$ is the sub-block restricted to $\mathcal{O}^1 \times \mathcal{I}^1$, i.e. without compositions.
- $\boldsymbol{H}_A$ is the sub-block restricted to $\mathcal{O}^1 \times \mathcal{I}^2$, i.e. inside compositions.
- $\boldsymbol{H}'_A$ is the sub-block restricted to $\mathcal{O}^2 \times \mathcal{I}^1$, i.e. outside compositions.
- $\boldsymbol{h}_\star^\top \in \mathbb{R}^{\mathcal{I}^1}$ is the row of $\boldsymbol{H}_\varepsilon$ for $\langle\lambda;\lambda\rangle$.
- $\boldsymbol{h}_{(x)} \in \mathbb{R}^{\mathcal{O}^1}$ is the column of $\boldsymbol{H}_\varepsilon$ for (x).
- $\boldsymbol{h}_{(x_1,x_2)} \in \mathbb{R}^{\mathcal{O}^1}$ is the column of $\boldsymbol{H}_A$ for (x_1,x_2).
- $\boldsymbol{h}'_{\langle x;z\rangle} \in \mathbb{R}^{\mathcal{I}^1}$ is the row of $\boldsymbol{h}_\varepsilon$ for $\langle x;z\rangle$.
- $\boldsymbol{h}'_{\langle x_1,x_2;z\rangle}$ and $\boldsymbol{h}'_{\langle x;z_1,z_2\rangle}$ be the rows in $\mathbb{R}^{\mathcal{I}^1}$ of $\boldsymbol{h}'{}_A$ for $\langle x_1,x_2;z\rangle$ and $\langle x;z_1,z_2\rangle$).

One supposes that $\mathrm{rank}(\boldsymbol{H}_\varepsilon) = \mathrm{rank}(\boldsymbol{H})$. We define G as

$$\alpha_\star^\top = \boldsymbol{h}_\star^\top \boldsymbol{H}_\varepsilon^+, \beta_a = \boldsymbol{h}_{(a)}, \boldsymbol{A} = \boldsymbol{H}_A(\boldsymbol{H}_\varepsilon^+ \otimes \boldsymbol{H}_\varepsilon^+)$$

Lemma 3. *One has that* $\beta_G(x) = \boldsymbol{h}_{(x)}$, *and* $\beta_G(x_1,x_2) = \boldsymbol{h}_{(x_1,x_2)}$.

Proof. By induction. For sequences of size 1, one has $\beta_G(x) = \beta_x = \boldsymbol{h}_{(x)}$. For the recursive case, let $\boldsymbol{e}_{(x)}$ be a vector in $\mathbb{R}^{\mathcal{I}^1}$ with 1 in the coordinate of (x) in $\boldsymbol{H}_\varepsilon$. Let $\boldsymbol{e}_{(x,y)}$ be a vector in $\mathbb{R}^{\mathcal{I}^2}$ with 1 in the coordinate of (x,y) in $\boldsymbol{H}_A$. For $\beta_G(x,y)$, one has $\boldsymbol{H}_\varepsilon^+\beta_G(x) = \boldsymbol{e}_{(x)}$, and $\boldsymbol{H}_\varepsilon^+\beta_G(y) = \boldsymbol{e}_{(y)}$, thus $\boldsymbol{H}_\varepsilon^+\beta_G(x) \otimes \boldsymbol{H}_\varepsilon^+\beta_G(y) = \boldsymbol{e}_{(x,y)}$ and $\boldsymbol{H}_A(\boldsymbol{H}_\varepsilon^+\beta_G(x) \otimes \boldsymbol{H}_\varepsilon^+\beta_G(y)) = \boldsymbol{h}_{(x,y)}$. Finally, one has that $\beta_G(x) = \sum_{x=x_1x_2}\beta_G(x_1,x_2) = \sum_{x=x_1x_2}\boldsymbol{h}_{(x_1,x_2)} = \boldsymbol{h}_{(x_1x_2x_3)}$ by the equation (26). □

One has a symmetric result for outside vectors. We define G' as

$$\alpha_\star^\top = \boldsymbol{h}_\star^\top, \beta_a = \boldsymbol{H}_\varepsilon^+\boldsymbol{h}_{(a)}, \boldsymbol{A} = \boldsymbol{H}_\varepsilon^+\boldsymbol{H}_A$$

Lemma 4. *One has that* $\alpha_{G'}(\langle x;z\rangle)^\top = \boldsymbol{h}'_{\langle x;z\rangle}$, $\alpha_{G'}(\langle x_1,x_2;z\rangle)^\top = \boldsymbol{h}'_{\langle x_1,x_2;z\rangle}$ *and* $\alpha_{G'}(\langle x;z_1,z_2\rangle)^\top = \boldsymbol{h}'_{\langle x;z_1,z_2\rangle}$.

Proof. (Sketch) Equation (31) is used in the same way than (27) before. Equation (25) is used to ensure a link between $\boldsymbol{H}'_A$ and $\boldsymbol{H}_A$. □

Let g be the mapping computed by G and G'. One has that $g(o,i) = \alpha_{G'}(o)^\top\beta_{G'}(i) = \alpha_G(o)^\top\beta_G(i) = \alpha_{G'}(o)^\top\boldsymbol{H}_\varepsilon^+\beta_G(i) = \boldsymbol{H}_\varepsilon(o,i)$.

Identifying Phrasal Verbs Using Many Bilingual Corpora

Abstract

We address the problem of identifying multiword expressions in a language, focusing on English phrasal verbs. Our *polyglot ranking* approach integrates frequency statistics from translated corpora in 50 different languages. Our experimental evaluation demonstrates that combining statistical evidence from many parallel corpora using a novel ranking-oriented boosting algorithm produces a comprehensive set of English phrasal verbs, achieving performance comparable to a human-curated set.

1 Introduction

A *multiword expression* (MWE), or *noncompositional compound*, is a sequence of words whose meaning cannot be composed directly from the meanings of its constituent words. These idiosyncratic phrases are prevalent in the lexicon of a language; Jackendoff (1993) estimates that their number is on the same order of magnitude as that of single words, and Sag et al. (2002) suggest that they are much more common, though quantifying them is challenging (Church, 2011). The task of identifying MWEs is relevant not only to lexical semantics applications, but also machine translation (Koehn et al., 2003; Ren et al., 2009; Pal et al., 2010), information retrieval (Xu et al., 2010; Acosta et al., 2011), and syntactic parsing (Sag et al., 2002). Awareness of MWEs has empirically proven useful in a number of domains: Finlayson and Kulkarni (2011), for example, use MWEs to attain a significant performance improvement in word sense disambiguation; Venkatapathy and Joshi (2006) use features associated with MWEs to improve word alignment.

We focus on a particular subset of MWEs, English *phrasal verbs*. A phrasal verb consists of a head verb followed by one or more particles, such that the meaning of the phrase cannot be determined by combining the simplex meanings of its constituent words (Baldwin and Villavicencio, 2002; Dixon, 1982; Bannard et al., 2003).[1] Examples of phrasal verbs include *count on* [*rely*], *look after* [*tend*], or *take off* [*remove*], the meanings of which do not involve counting, looking, or taking. In contrast, there are verbs followed by particles that are not phrasal verbs, because their meaning is compositional, such as *walk towards*, *sit behind*, or *paint on*.

We identify phrasal verbs by using frequency statistics calculated from parallel corpora, consisting of bilingual pairs of documents such that one is a translation of the other, with one document in English. We leverage the observation that a verb will translate in an atypical way when occurring as the head of a phrasal verb. For example, the word *look* in the context of *look after* will tend to translate differently from how *look* translates generally. In order to characterize this difference, we calculate a frequency distribution over translations of *look*, then compare it to the distribution of translations of *look* when followed by the word *after*. We expect that idiomatic phrasal verbs will tend to have unexpected translation of their head verbs, measured by the Kullback-Leibler divergence between those distributions.

Our *polyglot ranking* approach is motivated by the hypothesis that using many parallel corpora of different languages will help determine the degree of semantic idiomaticity of a phrase. In order to com-

*Research conducted during an internship at Google.

[1] Nomenclature varies: the term *verb-particle construction* is also used to denote what we call phrasal verbs; further, the term *phrasal verb* is sometimes used to denote a broader class of constructions.

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 636–646,
Seattle, Washington, USA, 18-21 October 2013.

bine evidence from multiple languages, we develop a novel boosting algorithm tailored to the task of ranking multiword expressions by their degree of idiomaticity. We train and evaluate on disjoint subsets of the phrasal verbs in English Wiktionary[2]. In our experiments, the set of phrasal verbs identified automatically by our method achieves held-out recall that nears the performance of the phrasal verbs in WordNet 3.0, a human-curated set. Our approach strongly outperforms a monolingual system, and continues to improve when incrementally adding translation statistics for 50 different languages.

2 Identifying Phrasal Verbs

The task of identifying phrasal verbs using corpus information raises several issues of experimental design. We consider four central issues below in motivating our approach.

Types vs. Tokens. When a phrase is used in context, it takes a particular meaning among its possible senses. Many phrasal verbs admit compositional senses in addition to idiomatic ones—contrast idiomatic "*look down on him for his politics*" with compositional "*look down on him from the balcony*." In this paper, we focus on the task of determining whether a phrase type is a phrasal verb, meaning that it frequently expresses an idiomatic meaning across its many token usages in a corpus. We do not attempt to distinguish which individual phrase tokens in the corpus have idiomatic senses.

Ranking vs. Classification. Identifying phrasal verbs involves relative, rather than categorical, judgments: some phrasal verbs are more compositional than others, but retain a degree of noncompositionality (McCarthy et al., 2003). Moreover, a polysemous phrasal verb may express an idiosyncratic sense more or less often than a compositional sense in a particular corpus. Therefore, we should expect a corpus-driven system not to classify phrases as strictly idiomatic or compositional, but instead assign a ranking or relative scoring to a set of candidates.

Candidate Phrases. We distinguish between the task of identifying candidate multiword expressions and the task of ranking those candidates by their semantic idiosyncracy. With English phrasal verbs, it is straightforward to enumerate all desired verbs followed by one or more particles, and rank the entire set.

Feature	*Description*
φ_L ($\times 50$)	KL Divergence for each language L
μ_1	frequency of phrase given verb
μ_2	PMI of verb and particles
μ_3	μ_1 with interposed pronouns

Table 1: Features used by the polyglot ranking system.

Using Parallel Corpora. There have been a number of approaches proposed for the use of multilingual resources for MWE identification (Melamed, 1997; Villada Moirón and Tiedemann, 2006; Caseli et al., 2010; Tsvetkov and Wintner, 2012; Salehi and Cook, 2013). Our approach differs from previous work in that we identify MWEs using translation distributions of verbs, as opposed to 1–1, 1–m, or m–n word alignments, most-likely translations, bilingual dictionaries, or distributional entropy. To the best of our knowledge, ours is the first approach to use translational distributions to leverage the observation that a verb typically translates differently when it heads a phrasal verb.

3 The Polyglot Ranking Approach

Our approach uses bilingual and monolingual statistics as features, computed over unlabeled corpora. Each statistic characterizes the degree of idiosyncrasy of a candidate phrasal verb, using a single monolingual or bilingual corpus. We combine features for many language pairs using a boosting algorithm that optimizes a ranking objective using a supervised training set of English phrasal verbs. Each of these aspects of our approach is described in detail below; for reference, Table 1 provides a list of the features used.

3.1 Bilingual Statistics

One of the intuitive properties of an MWE is that its individual words likely do not translate literally when the whole expression is translated into another language (Melamed, 1997). We capture this effect

by measuring the divergence between how a verb translates generally and how it translates when heading a candidate phrasal verb.

A *parallel corpus* is a collection of document pairs $\langle D_E, D_F \rangle$, where D_E is in English, D_F is in another language, one document is a translation of the other, and all documents D_F are in the same language. A *phrase-aligned parallel corpus* aligns those documents at a sentence, phrase, and word level. A phrase e aligns to another phrase f if some word in e aligns to some word in f and no word in e or f aligns outside of f or e, respectively. As a result of this definition, the words within an aligned phrase pair are themselves connected by word-level alignments.

Given an English phrase e, define $F(e)$ to be the set of all foreign phrases observed aligned to e in a parallel corpus. For any $f \in F(e)$, let $P(f|e)$ be the conditional probability of the phrase e translating to the phrase f. This probability is estimated as the relative frequency of observing f and e as an aligned phrase pair, conditioned on observing e aligned to any phrase in the corpus:

$$P(f|e) = \frac{N(e,f)}{\sum_{f'} N(e,f')}$$

with $N(e,f)$ the number of times e and f are observed occurring as an aligned phrase pair.

Next, we assign statistics to individual verbs within phrases. The first word of a candidate phrasal verb e is a verb. For a candidate phrasal verb e and a foreign phrase f, let $\pi_1(e,f)$ be the subphrase of f that is most commonly word-aligned to the first word of e. As an example, consider the phrase pair $e =$ *talk down to* and $f =$ *hablar con menosprecio*. Suppose that when e is aligned to f, the word *talk* is most frequently aligned to *hablar*. Then $\pi_1(e,f) =$ *hablar*.

For a phrase e and its set $F(e)$ of aligned translations, we define the *constituent translation probability* of a foreign subphrase x as:

$$P_e(x) = \sum_{f \in F(e)} P(f|e) \cdot \delta\left(\pi_1(e,f), x\right) \quad (1)$$

where δ is the Kronecker delta function, taking value 1 if its arguments are equal and 0 otherwise. Intuitively, P_e assigns the probability mass for every f to its subphrase most commonly aligned to the verb in e. It expresses how this verb is translated in the context of a phrasal verb construction.[3] Equation (1) defines a distribution over all phrases x of a foreign language.

We also assign statistics to verbs as they are translated outside of the context of a phrase. Let $v(e)$ be the verb of a phrasal verb candidate e, which is always its first word. For a single-word verb phrase $v(e)$, we can compute the constituent translation probability $P_{v(e)}(x)$, again using Equation (1). The difference between $P_e(x)$ and $P_{v(e)}(x)$ is that the latter sums over all translations of the verb $v(e)$, regardless of whether it appears in the context of e:

$$P_{v(e)}(x) = \sum_{f \in F(v(e))} P(f|v(e)) \cdot \delta\left(\pi_1(v(e),f), x\right)$$

For a one-word phrase such as $v(e)$, $\pi_1(v(e),f)$ is the subphrase of f that most commonly directly word-aligns to the one word of $v(e)$.

Finally, for a phrase e and its verb $v(e)$, we calculate the Kullback-Leibler (KL) divergence between the translation distribution of $v(e)$ and e:

$$D_{KL}\left(P_{v(e)} \| P_e\right) = \sum_x P_{v(e)}(x) \ln \frac{P_{v(e)}(x)}{P_e(x)} \quad (2)$$

where the sum ranges over all x such that $P_{v(e)}(x) > 0$. This quantifies the difference between the translations of e's verb when it occurs in e, and when it occurs in general. Figure 1 illustrates this computation on a toy corpus.

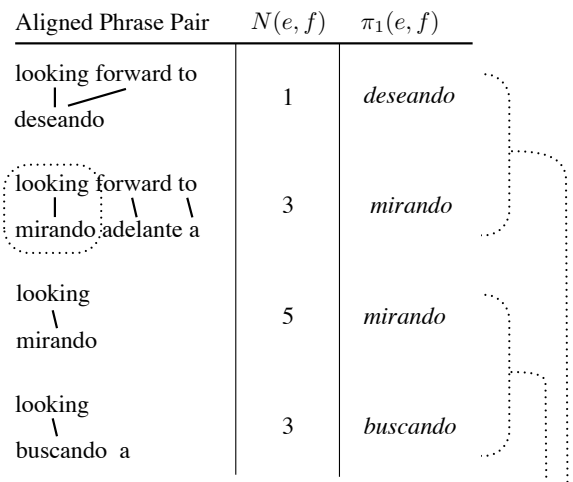
Smoothing. Equation (2) is defined only if, for every x such that $P_{v(e)}(x) > 0$, it is also the case that $P_e(x) > 0$. In order to ensure that this condition holds, we smooth the translation distributions toward uniform. Let D be the set of phrases with non-zero probability under either distribution:

$$D = \{x : P_{v(e)}(x) > 0 \text{ or } P_e(x) > 0\}$$

Then, let U_D be the uniform distribution over D:

$$U_D(x) = \begin{cases} 1/|D| & \text{if } x \in D \\ 0 & \text{if } x \notin D \end{cases}$$

[3] To extend this statistic to other types of multiword expressions, one could compute a similar distribution for other content words in the phrase.



Aligned Phrase Pair	$N(e,f)$	$\pi_1(e,f)$
looking forward to / deseando	1	*deseando*
looking forward to / mirando adelante a	3	*mirando*
looking / mirando	5	*mirando*
looking / buscando a	3	*buscando*

	mirando	*deseando*	*buscando*
$P_{v(e)}(x)$	$\frac{5}{8} = 0.625$	0	$\frac{3}{8} = 0.375$
$P'_{v(e)}(x)$	0.610	0.02	0.373
$P_e(x)$	$\frac{3}{4} = 0.75$	$\frac{1}{4} = 0.25$	0
$P'_e(x)$	0.729	0.254	0.02

$$D_{KL}(P'_{v(e_i)} \| P'_{e_i}) = -0.109 + -0.045 + 1.159 = 1.005$$

Figure 1: The computation of $D_{KL}(P'_{v(e_i)} \| P'_{e_i})$ using a toy corpus, for $e =$ *looking forward to*. Note that the second aligned phrase pair contains the third, so the second's count of 3 must be included in the third's count of 5.

When computing divergence in Equation (2), we use the smoothed distributions P'_e and $P'_{v(e)}$:

$$P'_e(x) = \alpha P_e(x) + (1-\alpha)U_D(x)$$
$$P'_{v(e)}(x) = \alpha P_{v(e)}(x) + (1-\alpha)U_D(x).$$

We use $\alpha = 0.95$, which distributes 5% of the total probability mass evenly among all events in D.

Morphology. We calculate statistics for morphological variants of an English phrase. For a candidate English phrasal verb e (for example, *look up*), let E denote the set of inflections of that phrasal verb (for *look up*, this will be [*look*|*looks*|*looked*|*looking*] *up*). We extract the variants in E from the verb entries in English Wiktionary. The final score computed from a phrase-aligned parallel corpus translating English sentences into a language L is the average KL divergence of smoothed constituent translation distributions for any inflected form $e_i \in E$:

$$\varphi_L(e) = \frac{1}{|E|} \sum_{e_i \in E} D_{KL}\left(P'_{v(e_i)} \| P'_{e_i}\right)$$

3.2 Monolingual Statistics

We also collect a number of monolingual statistics for each phrasal verb candidate, motivated by the considerable body of previous work on the topic (Church and Hanks, 1990; Lin, 1999; McCarthy et al., 2003). The monolingual statistics are designed to identify frequent collocations in a language. This set of monolingual features is not comprehensive, as we focus our attention primarily on bilingual features in this paper.

As above, define E to be the set of morphologically inflected variants of a candidate e, and let V be the set of inflected variants of the head verb $v(e)$ of e. We define three statistics calculated from the phrase counts of a monolingual English corpus. First, we define $\mu_1(e)$ to be the relative frequency of the candidate e, given e's head verb, summed over morphological variants:

$$\begin{aligned}\mu_1(e) &= \ln P(E|V) \\ &= \ln \frac{\sum_{e_i \in E} N(e_i)}{\sum_{v_i \in V} N(v_i)}\end{aligned}$$

where $N(x)$ is the number of times phrase x was observed in the monolingual corpus.

Second, define $\mu_2(e)$ to be the pointwise mutual information (PMI) between V (the event that one of the inflections of the verb in e is observed) and R, the event of observing the rest of the phrase:

$$\begin{aligned}&\mu_2(e) \\ &= \text{PMI}(V, R) \\ &= \lg P(V,R) - \lg\left(P(V)P(R)\right) \\ &= \lg P(E) - \lg\left(P(V)P(R)\right) \\ &= \lg \sum_{e_i \in E} N(e_i) - \lg \sum_{v_i \in V} N(v_i) - \lg N(r) + \lg N\end{aligned}$$

where N is the total number of tokens in the corpus, and logarithms are base-2. This statistic characterizes the degree of association between a verb and its phrasal extension. We only calculate μ_2 for two-word phrases, as it did not prove helpful for longer phrases.

Finally, define $\mu_3(e)$ to be the relative frequency of the phrasal verb e augmented by an accusative pronoun, conditioned on the verb. Let A be the set of phrases in E with an accusative pronoun (*it, them, him, her, me, you*) optionally inserted either at the end of the phrase or directly after the verb. For $e =$ *look up*, $A = \{$*look up, look X up, look up X, looks up, looks X up, looks up X,* $\dots\}$, with X an accusative pronoun. The μ_3 statistic is similar to μ_1, but allows for an intervening or following pronoun:

$$\begin{aligned}\mu_3(e) &= \ln P(A|V) \\ &= \ln \frac{\sum_{e_i \in A} N(e_i)}{\sum_{v_i \in V} N(v_i)}.\end{aligned}$$

This statistic is designed to exploit the intuition that phrasal verbs frequently have accusative pronouns either inserted into the middle (e.g. *look it up*) or at the end (e.g. *look down on him*).

3.3 Ranking Phrasal Verb Candidates

Our goal is to assign a single real-valued score to each candidate e, by which we can rank candidates according to semantic idiosyncrasy. For each language L for which we have a parallel corpus, we defined, in section 3.1, a function $\varphi_L(e)$ assigning real values to candidate phrasal verbs e, which we hypothesize is higher on average for more idiomatic compounds. Further, in section 3.2, we defined real-valued monolingual functions μ_1, μ_2, and μ_3 for which we hypothesize the same trend holds. Because each score individually ranks all candidates, it is natural to view each φ_L and μ_i as a weak ranking function that we can combine with a supervised boosting objective. We use a modified version of AdaBoost (Freund and Schapire, 1995) that optimizes for recall.

For each φ_L and μ_i, we compute a ranked list of candidate phrasal verbs, ordered from highest to lowest value. To simplify learning, we consider only the top 5000 candidate phrasal verbs according to μ_1, μ_2, and μ_3. This pruning procedure excludes candidates that do not appear in our monolingual corpus.

We optimize the ranker using an unranked, incomplete training set of phrasal verbs. We can evaluate the quality of the ranker by outputting the top N ranked candidates and measuring recall relative to this gold-standard training set. We choose this recall-at-N metric so as to not directly penalize precision errors, as our training set is incomplete.

Algorithm 1 Recall-Oriented Ranking AdaBoost

for $i = 1 : |X|$ **do**
  $w[i] \leftarrow 1/|X|$
end for
for $t = 1 : T$ **do**
  for all $h \in \mathcal{H}$ **do**
    $\epsilon_h \leftarrow 0$
    for $i = 1 : |X|$ **do**
      if $x_i \notin h$ **then**
        $\epsilon_h \leftarrow \epsilon_h + w[i]$
      end if
    end for
  end for
  $h_t \leftarrow \text{argmax}_{h \in \mathcal{H}} |\epsilon_B - \epsilon_h|$
  $\alpha_t \leftarrow \ln(\epsilon_B / \epsilon_{h_t})$
  for $i = 1 : |X|$ **do**
    if $x_i \in h_t$ **then**
      $w[i] \leftarrow \frac{1}{Z} w[i] \exp(-\alpha_t)$
    else
      $w[i] \leftarrow \frac{1}{Z} w[i] \exp(\alpha_t)$
    end if
  end for
end for

Define $\mathcal{H}$ to be the set of N-element sets containing the top proposals for each weak ranker (we use $N = 2000$). That is, each element of $\mathcal{H}$ is a set containing the 2000 highest values for some φ_L or μ_i. We define the baseline error ϵ_B to be $1 - \mathbb{E}[R]$, with R the recall-at-N of a ranker ordering the candidate phrases in the set $\cup\mathcal{H}$ at random. The value $\mathbb{E}[R]$ is estimated by averaging the recall-at-N of 1000 random orderings of $\cup\mathcal{H}$.

Algorithm 1 gives the formulation of the AdaBoost training algorithm that we use to combine weak rankers. The algorithm maintains a weight vector w (summing to 1) which contains a positive real number for each gold standard phrasal verb in the training set X. Initially, w is uniformly set to $1/|X|$. At each iteration of the algorithm, w is modified to take higher values for recently misclassified examples. We repeatedly choose weak rankers $h_t \in \mathcal{H}$ (and corresponding real-valued coefficients α_t) that correctly rank examples with high w values.

Lines 5–12 of Algorithm 1 calculate the weighted error values ϵ_h for every weak ranker set $h \in \mathcal{H}$. The error ϵ_h will be 1 if h contains none of X and 0 if h contains all of X, as w always sums to 1. Line 13 picks the ranker $h_t \in \mathcal{H}$ whose weighted error is as far as possible from the random baseline error ϵ_B. Line 14 calculates a coefficient α_t for h_t, which will be positive if $\epsilon_{h_t} < \epsilon_B$ and negative if $\epsilon_{h_t} > \epsilon_B$. Intuitively, α_t encodes the importance of h_t—it will be high if h_t performs well, and low if it performs poorly. The Z in lines 17 and 19 is the normalizing constant ensuring the vector w sums to 1.

After termination of Algorithm 1, we have weights $\alpha_1, \ldots, \alpha_T$ and lists $h_1, \ldots, h_T$. Define f_t as the function that generated the list h_t (each f_t will be some φ_L or μ_i). Now, we define a final combined function φ, taking a phrase e and returning a real number:

$$\varphi(e) = \sum_{t=1}^{T} \alpha_t f_t(e).$$

We standardize the scores of individual weak rankers to have mean 0 and variance 1, so that their scores are comparable.

The final learned ranker outputs a real value, instead of the class labels frequently found in AdaBoost. This follows previous work using boosting for learning to rank (Freund et al., 2003; Xu and Li, 2007). Our algorithm differs from previous methods because we are seeking to optimize for Recall-at-N, rather than a ranking loss.

4 Experimental Evaluation

4.1 Training and Test Set

In order to train and evaluate our system, we construct a gold-standard list of phrasal verbs from the freely available English Wiktionary. We gather phrasal verbs from three sources within Wiktionary:

1. Entries labeled as *English phrasal verbs*[4],
2. Entries labeled as *English idioms*[5], and
3. The *derived terms*[6] of English verb entries.

[4] http://en.wiktionary.org/wiki/Category:English_phrasal_verbs

[5] http://en.wiktionary.org/wiki/Category:English_idioms

[6] For example, see http://en.wiktionary.org/wiki/take#Derived_terms

about	*across*	*after*	*against*	*along*
among	*around*	*at*	*before*	*behind*
between	*beyond*	*by*	*down*	*for*
from	*in*	*into*	*like*	*off*
on	*onto*	*outside*	*over*	*past*
round	*through*	*to*	*towards*	*under*
up	*upon*	*with*	*within*	*without*

Table 2: Particles and prepositions allowed in phrasal verbs gathered from Wiktionary.

Many of the idioms and derived terms are not phrasal verbs (e.g. *kick the bucket*, *make-or-break*). We filter out any phrases not of the form VP^+, with V a verb, and P^+ denoting one or more occurrences of particles and prepositions from the list in Table 2. We omit prepositions that do not productively form English phrasal verbs, such as *amid* and *as*. This process also omits some compounds that are sometimes called phrasal verbs, such as light verb constructions, e.g. *have a go* (Butt, 2003), and noncompositional verb-adverb collocations, e.g. *look forward*.

There are a number of extant phrasal verb corpora. For example, McCarthy et al. (2003) present graded human compositionality judgments for 116 phrasal verbs, and Baldwin (2008) presents a large set of candidates produced by an automated system, with false positives manually removed. We use Wiktionary instead, in an attempt to construct a maximally comprehensive data set that is free from any possible biases introduced by automatic extraction processes.

4.2 Filtering and Data Partition

The merged list of phrasal verbs extracted from Wiktionary included some common collocations that have compositional semantics (e.g. *know about*), as well as some very rare constructions (e.g. *cheese down*). We removed these spurious results systematically by filtering out very frequent and very infrequent entries. First, we calculated the log probability of each phrase, according to a language model built from a large monolingual corpus of news documents and web documents, smoothed with stupid backoff (Brants et al., 2007). We sorted all Wiktionary phrasal verbs according to this value. Then, we selected the contiguous 75% of the sorted phrases that minimize the variance of this statistic. This method

		Recall-at-1220	
		Dev	Test
Baseline	Frequent Candidates	17.0	19.3
	WordNet 3.0 Frequent	41.6	43.7
	WordNet 3.0 Filtered	49.4	**48.8**
Boosted	Monolingual Only	30.1	30.2
	Bilingual Only	47.1	43.9
	Monolingual+Bilingual	**50.8**	47.9

Table 3: Our boosted ranker combining monolingual and bilingual features (bottom) compared to three baselines (top) gives comparable performance to the human-curated upper bound.

removed a few very frequent phrases and a large number of rare phrases. The remaining phrases were split randomly into a development set of 694 items and a held-out test set of 695 items.

4.3 Corpora

Our monolingual English corpus consists of news articles and documents collected from the web. Our parallel corpora from English to each of 50 languages also consist of documents collected from the web via distributed data mining of parallel documents based on the text content of web pages (Uszkoreit et al., 2010).

The parallel corpora were segmented into aligned sentence pairs and word-aligned using two iterations of IBM Model 1 (Brown et al., 1993) and two iterations of the HMM-based alignment model (Vogel et al., 1996) with posterior symmetrization (Liang et al., 2006). This training recipe is common in large-scale machine translation systems.

4.4 Generating Candidates

To generate the set of candidate phrasal verbs considered during evaluation, we exhaustively enumerated the Cartesian product of all verbs present in the previously described Wiktionary set ($\mathcal{V}$), all particles in Table 2 ($\mathcal{P}$) and a small set of second particles $\mathcal{T} = \{$*with, to, on,* $\epsilon\}$, with ϵ the empty string. The set of candidate phrasal verbs we consider during evaluation is the product $\mathcal{V} \times \mathcal{P} \times \mathcal{T}$, which contains 96,880 items.

4.5 Results

We optimize a ranker using the boosting algorithm described in section 3.3, using the features from Table 1, optimizing performance on the Wiktionary development set described in section 4.2. Monolingual and bilingual statistics are calculated using the corpora described in section 4.3, with candidate phrasal verbs being drawn from the set described in section 4.4.

We evaluate our method of identifying phrasal verbs by computing *recall-at-*N. This statistic is the fraction of the Wiktionary test set that appears in the top N proposed phrasal verbs by the method, where N is an arbitrary number of top-ranked candidates held constant when comparing different approaches (we use $N = 1220$). We do not compute precision, because the test set to which we compare is not an exhaustive list of phrasal verbs, due to the development/test split, frequency filtering, and omissions in the original lexical resource. Proposing a phrasal verb not in the test set is not necessarily an error, but identifying many phrasal verbs from the test set is an indication of an effective method. Recall-at-N is a natural way to evaluate a ranking system where the gold-standard data is an incomplete, unranked set.

Table 3 compares our approach to three baselines using the Recall-at-1220 metric evaluated on both the development and test sets. As a lower bound, we evaluated the 1220 most frequent candidates in our Monolingual corpus (*Frequent Candidates*).

As a competitive baseline, we evaluated the set of phrasal verbs in WordNet 3.0 (Fellbaum, 1998). We selected the most frequent 1220 out of 1781 verb-particle constructions in WordNet (*WordNet 3.0 Frequent*). A stronger baseline resulted from applying the same filtering procedure to WordNet that we did to Wiktionary: sorting all verb-particle entries by their language model score and retaining the 1220 consecutive entries that minimized language model variance (*WordNet 3.0 Filtered*). WordNet is a human-curated resource, and yet its recall-at-N compared to our Wiktionary test set is only 48.8%, indicating substantial divergence between the two resources. Such divergence is typical: lexical resources often disagree about what multiword expressions to include (Lin, 1999).

The three final lines in Table 3 evaluate our

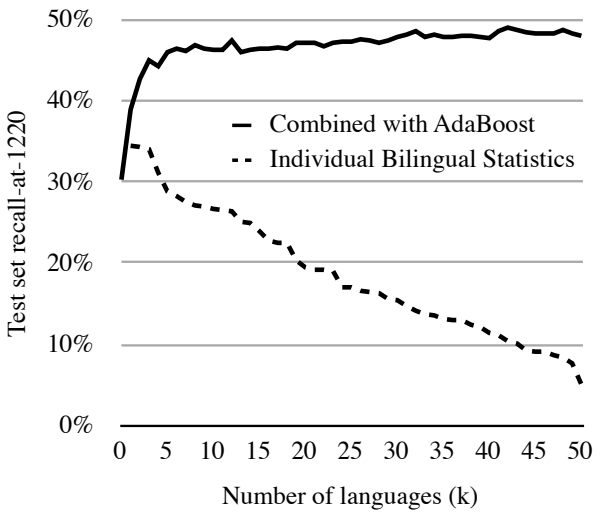


Figure 2: The solid line shows recall-at-1220 when combining the k best-performing bilingual statistics and three monolingual statistics. The dotted line shows the individual performance of the kth best-performing bilingual statistic, when applied in isolation to rank candidates.

boosted ranker. Automatically detecting phrasal verbs using monolingual features alone strongly outperformed the frequency-based lower bound, but underperformed the WordNet baseline. Bilingual features, using features from 50 languages, proved substantially more effective. The combination of both types of features yielded the best performance, outperforming the human-curated WordNet baseline on the development set (on which our ranker was optimized) and approaching its performance on the held-out test set.

4.6 Feature Analysis

The solid line in Figure 2 shows the recall-at-1220 for a boosted ranker using all monolingual statistics and k bilingual statistics, for increasing k. Bilingual statistics are added according to their individual recall, from best-performing to worst. That is, the point at $k = 0$ uses only μ_1, μ_2, and μ_3, the point at $k = 1$ adds the best individually-performing bilingual statistic (Spanish) as a weak ranker, the next point adds the second-best bilingual statistic (German), etc. Boosting maximizes performance on the development set, and evaluation is performed on the test set. We use $T = 53$ (equal to the total number of weak rankers).

	Recall-at-1220	
	Dev	Test
Bilingual only	47.1	43.9
Bilingual+μ_1	48.1	46.9
Bilingual+μ_2	50.1	48.3
Bilingual+μ_3	48.4	46.3
Bilingual+$\mu_1 + \mu_2$	50.2	47.9
Bilingual+$\mu_1 + \mu_3$	49.0	47.4
Bilingual+$\mu_2 + \mu_3$	50.4	**49.4**
Bilingual+$\mu_1 + \mu_2 + \mu_3$	**50.8**	47.9

Table 4: An ablation of monolingual statistics shows that they are useful in addition to the 50 bilingual statistics combined, and no single statistic provides maximal performance.

The dotted line in Figure 2 shows that individual bilingual statistics have recall-at-1220 ranging from 34.4% to 5.0%. This difference reflects the different sizes of parallel corpora and usefulness of different languages in identifying English semantic idiosyncrasy. Combining together the signal of multiple languages is clearly beneficial, and including many low-performing languages still offers overall improvements.

Table 4 shows the effect of adding different subsets of the monolingual statistics to the set of all 50 bilingual statistics. Monolingual statistics give a performance improvement of up to 5.5% recall on the test set, but the comparative behavior of the various combinations of the μ_i is somewhat unpredictable when training on the development set and evaluating on the test set. The pointwise mutual information of a verb and its particles (μ_2) appears to be the most useful feature. In fact, the test set performance of using μ_2 alone outperforms the combination of all three. The best combination even outperforms the WordNet 3.0 baseline on the test set, though optimizing on the development set would not select this model.

4.7 Error Analysis

Table 5 shows the 100 highest ranked phrasal verb candidates by our system that do not appear in either the development or test sets. Most of these candidates are in fact English phrasal verbs that happened to be missing from Wiktionary; some are present in Wiktionary but were removed from the reference

pick up	*pat on*	*tap into*	*fit for*	*charge with*	*suit against*

Table 5: The highest ranked phrasal verb candidates from our full system that do not appear in either Wiktionary set. Candidates are presented in decreasing rank; "pat on" is the second highest ranked candidate.

sets during filtering, and the remainder are in fact not phrasal verbs (true precision errors).

These errors fall largely into two categories. Some candidates are compositional, but contain polysemous verbs, such as *hit by*, *drive along*, and *head towards*. In these cases, prepositions disambiguate the verb, which naturally affects translation distributions. Other candidates are not phrasal verbs, but instead phrases that tend to have a different syntactic role, such as *suit against*, *instance through*, *fit for*, and *lie over* (conjugated as *lay over*). A careful treatment of part-of-speech tags when computing corpus statistics might address this issue.

5 Related Work

The idea of using word-aligned parallel corpora to identify idiomatic expressions has been pursued in a number of different ways. Melamed (1997) tests candidate MWEs by collapsing them into single tokens, training a new translation model with these tokens, and using the performance of the new model to judge candidates' noncompositionality. Villada Moirón and Tiedemann (2006) use word-aligned parallel corpora to identify Dutch MWEs, testing the assumption that the distributions of alignments of MWEs will generally have higher entropies than those of fully compositional compounds. Caseli et al. (2010) generate candidate multiword expressions by picking out sufficiently common phrases that align to single target-side tokens. Tsvetkov and Wintner (2012) generate candidate MWEs by finding one-to-one alignments in parallel corpora which are not in a bilingual dictionary, and ranking them based on monolingual statistics. The system of Salehi and Cook (2013) is perhaps the closest to the current work, judging noncompositionality using string edit distance between a candidate phrase's automatic translation and its components' individual translations. Unlike the current work, their method does not use distributions over translations or combine individual bilingual values with boosting; however, they find, as we do, that incorporating many languages is beneficial to MWE identification.

A large body of work has investigated the identification of noncompositional compounds from monolingual sources (Lin, 1999; Schone and Jurafsky, 2001; Fazly and Stevenson, 2006; McCarthy et al., 2003; Baldwin et al., 2003; Villavicencio, 2003). Many of these monolingual statistics could be viewed as weak rankers and fruitfully incorporated into our framework.

There has also been a substantial amount of work addressing the problem of differentiating between literal and idiomatic instances of phrases in context (Katz and Giesbrecht, 2006; Li et al., 2010;

Sporleder and Li, 2009; Birke and Sarkar, 2006; Diab and Bhutada, 2009). We do not attempt this task; however, techniques for token identification could be used to improve type identification (Baldwin, 2005).

6 Conclusion

We have presented the polyglot ranking approach to phrasal verb identification, using parallel corpora from many languages to identify phrasal verbs. We proposed an evaluation metric that acknowledges the inherent incompleteness of reference sets, but distinguishes among competing systems in a manner aligned to the goals of the task. We developed a recall-oriented learning method that integrates multiple weak ranking signals, and demonstrated experimentally that combining statistical evidence from a large number of bilingual corpora, as well as from monolingual corpora, produces the most effective system overall. We look forward to generalizing our approach to other types of noncompositional phrases.

Abstract

This study explores the feasibility of performing Chinese word segmentation (CWS) and POS tagging by deep learning. We try to avoid task-specific feature engineering, and use deep layers of neural networks to discover relevant features to the tasks. We leverage large-scale unlabeled data to improve internal representation of Chinese characters, and use these improved representations to enhance supervised word segmentation and POS tagging models. Our networks achieved close to state-of-the-art performance with minimal computational cost. We also describe a perceptron-style algorithm for training the neural networks, as an alternative to maximum-likelihood method, to speed up the training process and make the learning algorithm easier to be implemented.

1 Introduction

Word segmentation has been a long-standing challenge for the Chinese NLP community. It has received steady attention over the past two decades. Previous studies show that joint solutions usually lead to the improvement in accuracy over pipelined systems by exploiting POS information to help word segmentation and avoiding error propagation. However, traditional joint approaches usually involve a great number of features, which arises four limitations. First, the size of the result models is too large for practical use due to the storage and computing constraints of certain real-world applications. Second, the number of parameters is so large that the trained model is apt to overfit on training corpus. Third, a longer training time is required. Last but not the least, the decoding by dynamic programming technique might be intractable since a large search space is faced by the decoder.

The choice of features, therefore, is a critical success factor for these systems. Most of the state-of-the-art systems address their tasks by applying linear statistical models to the features carefully optimized for the tasks. This approach is effective because researchers can incorporate a large body of linguistic knowledge into the models. However, the approach does not scale well when it is used to perform more complex joint tasks, for example, the task of joint word segmentation, POS tagging, parsing, and semantic role labeling. A challenge for such a joint model is the large combined search space, which makes engineering effective task-specific features and structured learning of parameters very hard. Instead, we use multilayer neural networks to discover the useful features from the input sentences.

There are two main contributions in this paper. (1) We describe a perceptron-style algorithm for training the neural networks, which not only speeds up the training of the networks with negligible loss in performance, but also can be implemented more easily; (2) We show that the tasks of Chinese word segmentation and POS tagging can be effectively performed by the deep learning. Our networks achieved close to state-of-the-art performance by transferring the unsupervised internal representations of Chinese characters into the supervised models.

Section 2 presents the general architecture of neural networks, and our perceptron-style training algorithm for tagging. Section 3 describes how to

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 647–657,
Seattle, Washington, USA, 18-21 October 2013.

leverage large unlabeled data to obtain more useful character embeddings, and reports the experimental results of our systems. Section 4 presents a brief overview of related work. The conclusions are given in section 5.

2 The Neural Network Architecture

Chinese word segmentation and part-of-speech tagging tasks can be formulated as assigning labels to characters of an input sentence. The performance of the traditional tagging approaches is heavily dependent on the choice of features, for example, conditional random fields (CRFs), often with a set of feature templates. For that reason, much of the effort in designing such systems goes into the feature engineering, which is important but labor-intensive, mainly based on human ingenuity and linguistic intuition.

In order to make learning algorithms less dependent on the feature engineering, we chose to use a variant of the neural network architecture first proposed by (Bengio et al., 2003) for probabilistic language model, and reintroduced later by (Collobert et al., 2011) for multiple NLP tasks. The network takes the input sentence and discovers multiple levels of feature extraction from the inputs, with higher levels representing more abstract aspects of the inputs. The architecture is shown in Figure 1. The first layer extracts features for each Chinese character. The next layer extracts features from a window of characters. The following layers are classical neural network layers. The output of the network is a graph over which tag inference is achieved with a Viterbi algorithm.

2.1 Mapping Characters into Feature Vectors

The characters are fed into the network as indices that are used by a lookup operation to transform characters into their feature vectors. We consider a fixed-sized character dictionary $\mathcal{D}$[1]. The vector representations are stored in a character embedding matrix $\mathcal{M} \in \mathbb{R}^{d \times |\mathcal{D}|}$, where d is the dimensionality of the vector space (a hyper-parameter to be chosen) and $|\mathcal{D}|$ is the size of the dictionary.

[1]Unless otherwise specified, the character dictionary is extracted from the training set. Unknown characters are mapped to a special symbol that is not used elsewhere.

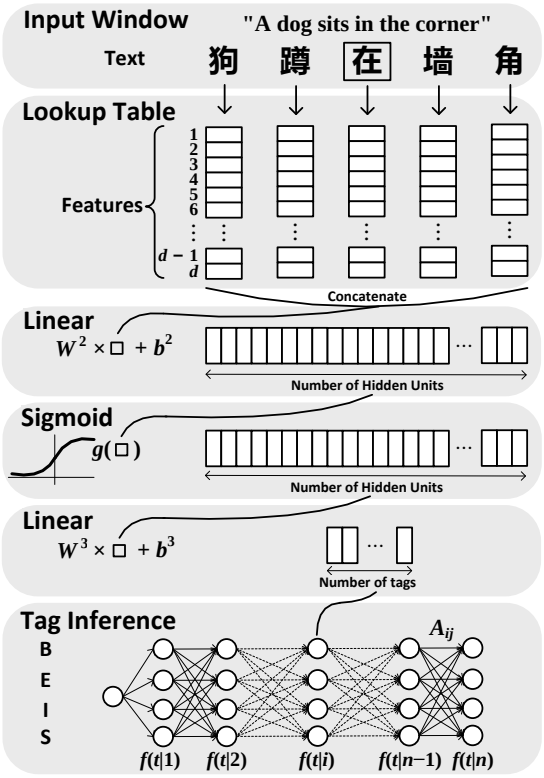

Figure 1: The neural network architecture.

Formally, assume we are given a Chinese sentence $c_{[1:n]}$ that is a sequence of n characters $c_i, 1 \leq i \leq n$. For each character $c_i \in \mathcal{D}$ that has an associated index k_i into the column of the embedding matrix, an d-dimensional feature vector representation is retrieved by the lookup table layer $\mathcal{Z}_{\mathcal{D}}(\cdot) \in \mathbb{R}^d$:

$$\mathcal{Z}_{\mathcal{D}}(c_i) = \mathcal{M} e_{k_i} \quad (1)$$

where we use a binary vector $e_{k_i} \in \mathbb{R}^{|\mathcal{D}| \times 1}$ which is zero in all positions except at the k_i-th index. The lookup operation can be seen as a simple projection layer. The feature vector of each character, starting from a random initialization, can be automatically trained by back propagation to be relevant to the task of interest.

In practice, it is common that one might want to provide other additional features that is thought to be helpful for the task. For example, for the name entity recognition task, one could provide a feature which says if a character is in a list of the common Chinese surnames or not. Another common practice is to introduce some statistics-based measures, such

as *boundary entropy* (Jin and Tanaka-Ishii, 2006) and *accessor variety* (Feng et al., 2004), which are commonly used in unsupervised CWS models. We associate a lookup table to each additional feature, and the character feature vector becomes the concatenation of the outputs of all these lookup tables.

2.2 Tag scoring

A neural network can be considered as a function $f_\theta(\cdot)$ with parameters θ. Any feed-forward neural network with L layers can be seen as a composition of functions $f_\theta^l(\cdot)$ defined for each layer l:

$$f_\theta(\cdot) = f_\theta^L(f_\theta^{L-1}(\dots f_\theta^1(\cdot)\dots)) \tag{2}$$

For each character in a sentence, a score is produced for every tag by applying several layers of the neural network over the feature vectors produced by the lookup table layer. We use a window approach to handle the sequences of variable sentence length. The window approach assumes that the tag of a character depends mainly on its neighboring characters. More precisely, given an input sentence $c_{[1:n]}$, we consider all successive windows of size w (a hyper-parameter), siding over the sentence, from character c_1 to c_n. At position c_i, the character feature window produced by the first lookup table layer can be written as:

$$f_\theta^1(c_i) = \begin{pmatrix} \mathcal{Z}_\mathcal{D}(c_{i-w/2}) \\ \vdots \\ \mathcal{Z}_\mathcal{D}(c_i) \\ \vdots \\ \mathcal{Z}_\mathcal{D}(c_{i+w/2}) \end{pmatrix} \tag{3}$$

The characters with indices exceeding the sentence boundaries are mapped to one of two special symbols, namely *"start"* and *"stop"* symbols.

The fixed-sized vector f_θ^1 is fed to two standard *Linear Layers* that successively perform affine transformations over f_θ^1, interleaved with some non-linearity function $g(\cdot)$, to extract highly non-linear features. Given a set of tags $\mathcal{T}$ for the task of interest, the network outputs a vector of size $|\mathcal{T}|$ for each character at position i, interpreted as a score for each tag in $\mathcal{T}$ and each character c_i in the sentence:

$$\begin{aligned} f_\theta(c_i) &= f_\theta^3(g(f_\theta^2(f_\theta^1(c_i)))) \\ &= W^3 g(W^2 f_\theta^1(c_i) + b^2) + b^3 \end{aligned} \tag{4}$$

where the matrices $W^2 \in \mathbb{R}^{H\times(wd)}, b^2 \in \mathbb{R}^H$, $W^3 \in \mathbb{R}^{|\mathcal{T}|\times H}$ and $b^3 \in \mathbb{R}^{|\mathcal{T}|}$ are the parameters to be trained. The hyper-parameter H is usually called the *number of hidden units*. As non-linear function, we chose a sigmoidal function[2]:

$$g(x) = 1/(1+e^{-x}) \tag{5}$$

2.3 Tag Inference

There are strong dependencies between character tags in a sentence for the tasks like word segmentation and POS tagging. The tags are organized in chunks, and it is impossible for some tags to follow other tags. We introduce a transition score A_{ij} for jumping from $i \in \mathcal{T}$ to $j \in \mathcal{T}$ tags in successive characters, and an initial scores A_{0i} for starting from the i-th tag for taking into account the sentence structure. We want the valid paths of tags to be encouraged, while discouraging all other paths.

Given an input sentence $c_{[1:n]}$, the network outputs the matrix of scores $f_\theta(c_{[1:n]})$. We use a notation $f_\theta(t|i)$ to indicate the score output by the network with parameters θ, for the sentence $c_{[1:n]}$ and for the t-th tag, at the i-th character. The score of a sentence $c_{[1:n]}$ along a path of tags $t_{[1:n]}$ is then given by the sum of transition and network scores:

$$s(c_{[1:n]}, t_{[1:n]}, \theta) = \sum_{i=1}^{n} (A_{t_{i-1}t_i} + f_\theta(t_i|i)) \tag{6}$$

Given a sentence $c_{[1:n]}$, we can find the best tag path $t^*_{[1:n]}$ by maximizing the sentence score:

$$t^*_{[1:n]} = \arg\max_{\forall t'_{[1:n]}} s(c_{[1:n]}, t'_{[1:n]}, \theta) \tag{7}$$

The Viterbi algorithm can be used for this inference. Now we are prepared to show how to train the parameters of the network in an end-to-end fashion.

2.4 Training

The training problem is to determine all the parameters of the network $\theta = (\mathcal{M}, W^2, b^2, W^3, b^3, A)$ from training data. The network generally is trained

[2]In our experiments, the sigmoidal function performs slightly better than the "hard" version of the hyperbolic tangent used by (Collobert, 2011).

by maximizing a likelihood over all the sentences in the training set $\mathcal{R}$ with respect to θ:

$$\theta \mapsto \sum_{\forall (c,t) \in \mathcal{R}} \log p(t|c,\theta) \tag{8}$$

where c represents a sentence and its associated features, and t denotes the corresponding tag sequence. We drop the subscript $[1:n]$ from now for notation simplification. The probability $p(\cdot)$ is calculated from the outputs of the neural network. We will present in the following section how to interpret neural network outputs as probabilities.

Maximizing the log-likelihood (8) with the gradient ascent algorithm[3] is achieved by iteratively selecting a example (c,t) and applying the following gradient update rule:

$$\theta \leftarrow \theta + \lambda \frac{\partial \log p(t|c,\theta)}{\partial \theta} \tag{9}$$

where λ is the learning rate (a hyper-parameter). The gradient in (9) can be computed by a classical back propagation: the differentiation chain rule is applied through the network, until the character embedding layer.

2.4.1 Sentence-Level Log-Likelihood

The score of a sentence (6) is interpreted as a conditional tag path probability by taking it to the exponential (making the score positive) and normalizing it over all possible tag paths (summing to 1 over all paths). Taking the log, the conditional probability of the true path t is given by[4]:

$$\log p(t|c,\theta) = s(c,t,\theta) - \log \sum_{\forall t'} \exp\{s(c,t',\theta)\} \tag{10}$$

[3]We did not use the stochastic gradient ascent algorithm (Bottou, 1991) to train the network as (Collobert et al., 2011). The gradient ascent algorithm was used instead for fairly comparing our algorithm with the sentence-level maximum-likelihood method (see Section 2.4.1). The gradient ascent algorithm requires a loop over all the examples to compute the gradient of the cost function, which will not cause a problem since all the training sets used in this article are finite.

[4]The cost functions are differentiable everywhere thanks to the differentiability of sigmoidal function chosen as non-linearity instead of a "hard" version of the hyperbolic tangent. For details about gradient computations, see Appendix A of (Collobert et al., 2011).

The number of terms in (10) grows exponentially with the length of the input sentence. Although one can compute it in linear time with the Viterbi algorithm, it is quite computationally expensive to compute the conditional probability of the true path, and its derivatives with respect to $f_\theta(t|i)$ and A_{ij}. The gradients with respect to the trainable parameters other than $f_\theta(t|i)$ and A_{ij} can all be computed using the derivatives with respect to $f_\theta(t|i)$ by applying the differentiation chain rule. We will see in the next section our training algorithm that has the advantage of being much cheaper to compute the gradients.

2.5 A New Training Method

The log-likelihood (10) can be seen as the difference between the forward score constrained over the valid path and the sum of the scores of all possible paths. While this training criterion is used, the neural networks are trained by maximizing the likelihood of training data. In fact, a CRF maximizes the same log-likelihood (Lafferty et al., 2001) by using a linear model in stead of a nonlinear neural network.

As an alternative to maximum-likelihood method, we propose the following training algorithm inspired by the work of (Collins, 2002). Given a training example (c,t), the network outputs the matrix of scores $f_\theta(c)$ under the current parameter settings. The highest scoring sequence of tags for the input sentence c then can be found using the Viterbi algorithm: this tagged sequence is denoted by t'. For every character c_i where $t_i \neq t'_i$, we simply set

$$\frac{\partial L_\theta(t,t'|c)}{\partial f_\theta(t_i|i)} {+}{+}, \ \frac{\partial L_\theta(t,t'|c)}{\partial f_\theta(t'_i|i)} {-}{-} \tag{11}$$

and for every transition where $t_{i-1} \neq t'_{i-1}$ or $t_i \neq t'_i$, we set

$$\frac{\partial L_\theta(t,t'|c)}{\partial A_{t_{i-1}t_i}} {+}{+}, \ \frac{\partial L_\theta(t,t'|c)}{\partial A_{t'_{i-1}t'_i}} {-}{-} \tag{12}$$

where "$+\,+$" (which increases a value by one) and "$-\,-$" (which decreases a value by one) are two unary operators, and $L_\theta(t,t'|c)$ is a new function which we now want to maximize over all the training pairs (c,t). The function $L_\theta(t,t'|c)$ can be viewed as the difference between the score of the correct path and that of the incorrect one (which is the highest scoring sequence produced by the network under the current parameters θ).

As an example, say the correct tag sequence of the sentence 狗蹲在墙角 'A dog sits in the corner' is

狗/S 蹲/S 在/S 墙/B 角/E

and under the current parameter settings the highest scoring tag sequence is

狗/S 蹲/B 在/E 墙/B 角/E

Then the derivatives with respect to $f_\theta(S|蹲)$, and $f_\theta(S|在)$ will be set to 1, that with respect to A_{SB}, A_{BE}, A_{EB}, $f_\theta(B|蹲)$, and $f_\theta(E|在)$ to -1, and that with respect to A_{SS} to 2 respectively[5]. Intuitively these assignments have the effect of updating the parameter values in a way that increases the score of the correct tag sequence and decreases the score of the incorrect one output by the network with the current parameter settings. If the tag sequence produced by the network is correct, no changes are made to the values of parameters.

Inputs:
$\mathcal{R}$: a training set.
N: a specified maximum number of iterations.
E: a desired tagging precision.

Initialization: set the initial parameters of the network with small random values.

Output: the trained parameters $\tilde{\theta}$

Algorithm:

do
  for each example $(c, t) \in \mathcal{R}$
    get the matrix $f_\theta(c)$ by the neural network under the current parameters θ
    find the highest scoring sequence of tags t' for c with $f_\theta(c)$ and A_{ij} by using the Viterbi algorithm
    if $(t \neq t')$
      compute the gradients with respect to $f_\theta(c)$ and A_{ij} as (11) and (12)
      compute the gradients with respect to the weights from output layer to character embedding layer
      update the parameters of the network by (9)
until the desired precision E achieved or maximum number of iterations N reached
return $\tilde{\theta}$

Figure 2: The training algorithm for tagging.

We propose the training algorithm in Figure 2. Note that the perceptron algorithm of (Collins, 2002) was designed for discriminatively training an HMM-style tagger, while our algorithm is used to calculate the "direction" in which the parameters are updated (i.e. the gradient of the function we want to maximize). Due to space limitations, we do not give convergence theorems justifying the training algorithm in this paper. Intuitively it can be achieved by combining the theorems of convergence for the perceptron applied to tagging problem from (Collins, 2002) with the convergence results of backpropagation algorithm from (Rumelhart et al., 1986).

3 Experiments

We conducted three sets of experiments. The goal of the first one is to test several variants for each training algorithm on the development set, to gain some understanding of how the choice of hyperparameters impacts upon the performance. We applied the network both with the sentence-level log-likelihood (SLL) and our perceptron-style training algorithm (PSA) to the two Chinese NLP problems: word segmentation, and joint CWS and POS tagging. We ran this set of experiments on the part of Chinese Treebank 4 (CTB-4)[6]. Ninety percent of the sentences (1529) were randomly chosen for training and the rest (168) were used as development set.

The second set of experiments was run on the Chinese Treebank (CTB) data sets from Bakeoff-3 (Levow, 2006), which contains a training and a test corpus for supervised word segmentation and POS tagging tasks. The results were obtained without using any extra knowledge (i.e. the closed test), and are comparable with other models in the literature.

In the third experiment, we study to see how well large unlabeled texts can be used to enhance the supervised learning. Following (Collobert et al., 2011), we first use large unlabeled data set to obtain character embeddings carrying more syntactic and semantic information, and then use these improved embeddings to initialize the character lookup tables of the networks instead of previous random values. Our corpus is the Sina news[7] that contains about 325MB data.

[5]The derivatives with respect to A_{SB} will be set to 0, because it is increased first and decreased afterwards.

[6]The data set was sections 1–43, 144–169, and 900–931 of the treebank, containing 78,023 characters, 45,135 words and 1,697 sentences. These files are double-annotated and can be regarded as golden standard files.

[7]Available at http://www.sina.com.cn/

We implemented two versions of the network: one for the sentence-level log-likelihood and one for our perceptron-style training algorithm. Both are written in Java language. All experiments were run on a computer equipped with an Intel Core i3 processor working at 2.13GHz, with 2GB RAM, running Linux and Java Development Kit 1.6. The standard F-score was used to evaluate the performance of both word segmentation and joint word segmentation and POS tagging tasks. F-score is the harmonic mean of precision p and recall r, which is defined as $2pr/(p+r)$.

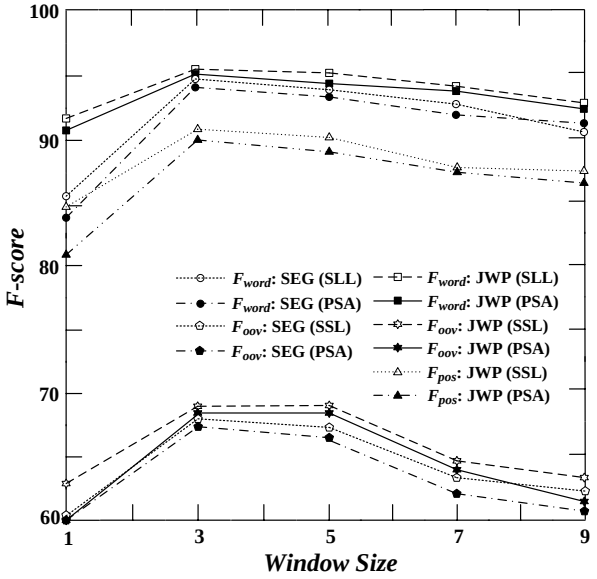

Figure 3: Average F-score versus window size.

3.1 Tagging Schemes

The network will output the scores for all the possible tags for the task of interest. For word segmentation, each character will be assigned one of four possible boundary tags: "*B*" for a character located at the beginning of a word, "*I*" for that inside of a word, "*E*" for that at the end of a word, and "*S*" for a character that is a word by itself.

Following Ng and Lou (2004) we perform joint word segmentation and POS tagging task in a labeling fashion by expanding boundary labels to include POS tags. For instance, we describe verb phases using four different tags. Tag "*S_VP*" is used to mark a verb phase containing a single character. Other tags "*B_VP*", "*I_VP*", and "*E_VP*" are used to mark the first, in-between and last characters of the verb phrase. In fact, we used the "*IOBES*" tagging scheme, and tag "*O*" is not applicable to Chinese word segmentation and POS tagging tasks.

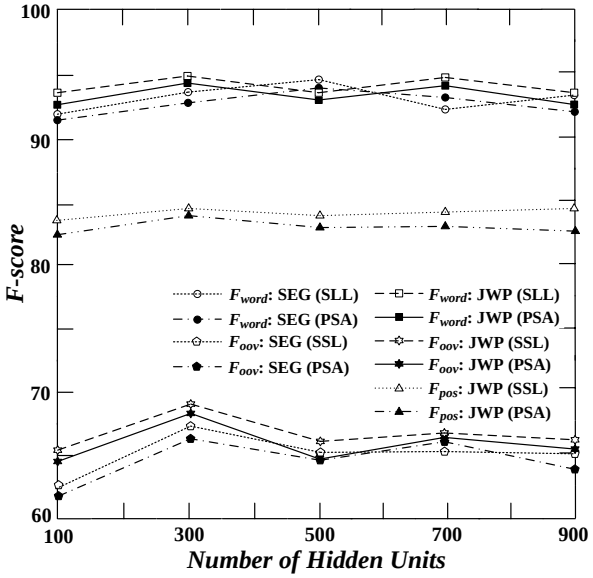

Figure 4: Average F-score versus number of hidden units.

3.2 The Choice of Hyper-parameters

We tuned the hyper-parameters by trying only a few different networks. We report in Figure 3 the F-scores on the development set versus window size for word segmentation (SEG) and joint word segmentation and POS tagging (JWP) tasks with the sentence-level log-likelihood (SLL) and our perceptron-style training algorithm (PSA), and report in Figure 4 the F-scores on the same data set versus number of hidden units. The average F-scores were obtained over 5 runs with different random initialization for each setting of the network. The F-scores of the word segmentation, out-of-vocabulary, and POS tagging are denoted by F_{word}, F_{oov} and F_{pos} respectively.

Generally, the number of hidden units has a limited impact on the performance if it is large enough, which is consistent with the findings of (Collobert et al., 2011) for English. It can be seen from Figure 3 that the performance drops smoothly when the window size is larger than 3. In particularly, the F-score of out-of-vocabulary identification decreases relatively fast beyond window size 5, which shows

that the size of window (and the number of parameters) is too large that the trained network has overfitted on training data. An explanation for this result is that most Chinese words are less than 3 characters, and the neighboring characters outside of the window (size 5) become "noise" when we perform word segmentation.

The hyper-parameters of the network used in all the following experiments are shown in Table 1. Although the top performance was obtained by the network with window size 3, we chose the architecture with window size 5 because a larger training corpus will be used in the following experiments, and the sparseness problem would be alleviated. Furthermore, in order to obtain character embeddings by using large unlabeled data, we prefer to "observe" a character within a slightly larger window to better discover its syntactic and semantic information.

Hyper-parameter	Value
Window size	5
Number of hidden units	300
Character feature dimension	50
Learning rate	0.02

Table 1: Hyper-parameters of the network.

We report in Table 2 the F-score of the first five iterations on the development set for word segmentation with SLL and PSA. The data in the fourth and fifth rows of the table shows the convergence of PSA. The difference of the F-scores between the networks with SLL and PSA can be negligible after the number of iteration is greater than 5. In our implementation, for each iteration the training time is reduced at least 10% by using PSA, compared with SLL. The training time can be reduced further for more complex tasks like POS tagging and semantic role labeling in which a larger tag set is used.

Iteration		1	2	3	4	5
SSL	F_{word}	49.89	69.56	88.91	90.19	91.24
	F_{oov}	15.92	27.54	54.37	55.89	59.74
	Time (s)	209	398	586	737	886
PSA	F_{word}	49.04	68.54	87.79	89.07	91.19
	F_{oov}	13.61	25.79	52.30	55.15	60.49
	Time (s)	184	343	497	610	754

Table 2: Word segmentation results with SLL and PSA for the first five iterations.

Many exponential sums ($\sum_i \exp(x_i)$) are required for training the networks with SLL, and in most cases the values of exponential sums will exceed the range of double-precision floating-point arithmetic defined in popular programming languages. These sums need to be estimated by analytic number theory. In comparison, a lot of the computation-intensive exponential sums are avoided in our training algorithm, which not only speed up the training of the networks but also make it easier to be implemented.

3.3 Closed Test on the SIGHAN Bakeoff

We trained the networks with PSA on the Chinese Treebank (CTB) data set from Bakeoff-3 for both SEG and JWP tasks. The results are reported in Table 3. The hyper-parameters of our networks are reported in Table 1. Although results show that our networks with PSA are behind the state-of-the-art systems, the networks perform comparatively well, considering we did not use any extra information. Many other systems used some extra heuristics or resources to improve their performance. For example, a key parameter in the system of (Wang et al., 2006) was optimized in advance by using an external segmented corpus, and a manually prepared list of characters as well as their types was used in (Zhao et al., 2006; Zhu et al., 2006; Kruengkrai et al., 2009).

It is worth noting that the comparison for joint word segmentation and POS tagging task is indirect because the different versions of CTB were used. We reported the results on CTB-3 from SIGHAN Bakeoff-3, while both (Jiang et al., 2008) and (Kruengkrai et al., 2009) used CTB-5. Both (Ng and Lou, 2004) and (Zhang and Clark, 2008) evenly partitioned the sentences in CTB3 into ten groups, and used nine groups for training and the rest for testing.

Following (Bengio et al., 2003; Collobert et al., 2011), we want semantically and syntactically similar characters to be close in the embedding space. If we knew that 狗 'dog' and 猫 'cat' were similar semantically, and similarly for 蹲 'sit' and 躺 'lie', we could generalize from 狗蹲在墙角 'A dog sits in the corner' to 猫蹲在墙角 'A cat sits in the corner', and to 猫躺在墙角 'A cat lies in the corner' in the same way. We describe the way to obtain these character embeddings by using large unlabeled data in the next section.

Approach		F_{word}	R_{oov}	F_{pos}
SEG	(Zhao et al., 2006)	93.30	70.70	–
	(Wang et al., 2006)	93.00	68.30	–
	(Zhu et al., 2006)	92.70	63.40	–
	(Zhang et al., 2006)	92.60	61.70	–
	(Feng et al., 2006)	91.70	68.00	–
	PSA	92.59	64.24	–
	PSA + LM	94.57	70.12	–
JWP	(Ng and Lou, 2004)	95.20	–	–
	(Zhang and Clark, 2008)	95.90	–	91.34
	(Jiang et al., 2008)	97.30	–	92.50
	(Kruengkrai et al., 2009)	96.11	–	90.85
	PSA	93.83	68.21	90.79
	PSA + LM	95.23	72.38	91.82

Table 3: Comparison of the F-scores on the Penn Chinese Treebank

3.4 Combined Approach

We used the corpus of Sina news to obtain character embeddings carrying more semantic and syntactic information by training a language model that evaluates the acceptability of a piece of text. This language model is again the neural network, and we also use PSA to train the language model. Following (Collobert et al., 2011), we minimize the following criterion with respect to the parameters θ:

$$\theta \mapsto \sum_{\forall h \in \mathcal{H}} \sum_{\forall c' \in \mathcal{D}} \max\{0, 1 - f_\theta(c|h) + f_\theta(c'|h)\} \tag{13}$$

where the score $f_\theta(c|h)$ is the output of the network with parameters θ for a character c at the center of a window h, $\mathcal{D}$ is the dictionary of characters, $\mathcal{H}$ is the set of all possible text windows (i.e. character sequences) from the training data, and $c'|h$ denotes the window obtained by replacing the central character of the window h by the character c'.

We used a dictionary consisting of the characters extracted from all the data sets in Bakeoff-3, which contains about eight thousand characters. The total unsupervised training time was about two weeks. Our combined approach works as initializing the lookup tables of the supervised networks with the character embeddings obtained by unsupervised learning, and then performing supervised training on CTB-3. The lookup tables will not be modified at the supervised training stage.

We reported the results in Table 3, in which our combined approach is indicated by "PSA + LM". It can be seen from Table 3 that this approach results in a performance boost for both SEG and JWP tasks. The POS tagging F-score of our approach was comparable to but still less than the model of (Jiang et al., 2008). They achieved the best score by first separately training multiple word-, character-, and POS n-gram based models, and then integrating them by cascading method. In comparison, our networks achieve the performance by automatically discovering useful features by itself and avoiding the task-specific engineering.

Table 4 compares the decoding speeds on the test data from CTB-3 for our system and for two CRFs-based word segmentation systems. Regardless of the differences in implementation, the neural networks clearly run considerably faster than the systems based on the CRFs model. They also require much more memory than our neural networks.

System	Number of parameters	Time (s)
(Tsai et al., 2006)	3.1×10^6	1669
(Zhao et al., 2006)	3.8×10^6	2382
Neural network	4.7×10^5	138

Table 4: Comparison of computational cost.

4 Related Work

Word segmentation has been pursued with considerable efforts in the Chinese NLP community, and statistical approaches are clearly dominant in the last decade. A popular statistical approach is the character-based tagging solution that treats word segmentation as a sequence tagging problem, assigning labels to the characters indicating whether a character locates at the beginning of, inside, or at the end of a word. The character-based tagging solution was first proposed in (Xue, 2003). This work caused quite a number of character position tagging based CWS studies because known and unknown words can be treated in the same way. Peng, Feng and McCallum (2004) first introduced a linear-chain CRFs model to the character tagging based word segmentation. Zhang and Clark (2007) proposed a word-based CWS approach using a discriminative perceptron learning algorithm, which allows word-level information to be added as features.

Recent years have seen a rise of joint word segmentation and POS tagging approach that improves

the accuracies of both tasks and does not suffer from the error propagation. Ng and Lou (2004) perform such joint task in a labeling fashion by expanding boundary labels to include POS tags. Zhang and Clark (2008) proposed a linear model for the same joint task, which overcomed the disadvantage of (Ng and Lou, 2004), in which it was unable to incorporate "whole word + POS tag" features. Sun (2011) described a sub-word model using stacked learning technique for the joint task, which explored the complementary strength of different character- and word-based segmenters with different views.

The majority of the state-of-the-art systems address their tasks by applying linear statistical models to ad-hoc features. The researchers first chose task-specific features which are then fed to a classification algorithm. The selected features may vary greatly because they are usually chosen in a empirical process, mainly based first on linguistic intuition, and then trial and error. It seems reasonable to assume that the number and effectiveness of features constitutes a major factor in the performance of the various systems, and might even more important than the particular statistical models they used. In comparison, we try to avoid task-specific feature engineering, and use the neural network to learn several layers of feature extraction from the inputs. To the best of our knowledge, this study is among the first ones to perform Chinese word segmentation and POS tagging by deep learning.

It was reported that supervised and unsupervised approaches can be integrated to improve on the overall performance of word segmentation by combining the strengths of both. Zhao and Kit (2011) explored the feasibility of enhancing supervised segmentation by informing the supervised learner of goodness scores obtained from large unlabeled corpus. Sun and Xu (2011) investigated how to improve on the accuracy of supervised word segmentation by leveraging the statistics-based features derived from large unlabeled in-domain corpus and the document to be segmented. The basic idea of these integration solutions is to incorporate a set of statistics-based measures into a CRFs model after these measures are derived from unlabeled data and discretized into feature values. In comparison, we use large unlabeled data to obtain the character embeddings with more syntactic and semantic information.

Several works have investigated how to use deep learning for NLP applications (Bengio et al., 2003; Collobert et al., 2011; Collobert, 2011; Socher et al., 2011). In most cases, words are fed to the neural networks as inputs, and the lookup tables map each word to a vector representation. Our network is different in that the inputs to the network are characters, more raw units than words. In many Asian languages, such as Chinese and Japanese, they are written without using whitespace to delimit words. For these languages, the character becomes a more natural form of input. Furthermore, a perceptron-style algorithm for tagging is proposed for training the networks.

5 Conclusion

We have described a perceptron-style algorithm for training the neural networks, which is much easier to be implemented, and has speed advantage over the maximum-likelihood scheme, while the loss in performance is negligible. The neural networks trained with PSA have been applied to Chinese word segmentation and POS tagging tasks, and the networks achieved close to state-of-the-art performance by using the character representations learned from large unlabeled corpus.

Although we focus on the question of how far we can go for Chinese word segmentation and POS tagging without using the extra task-specific features in this study, there are at least three ways to further improve the performance of the networks, which are worthy to be explored in the future: (1) introduce specific linguistic features (e.g. gazetteer features) that are helpful for the tasks; (2) incorporate some common techniques, such as cascading, voting, and ensemble; and (3) use the special network architecture tailored for the tasks of interest.

Abstract

Chinese word segmentation and part-of-speech tagging (S&T) are fundamental steps for more advanced Chinese language processing tasks. Recently, it has attracted more and more research interests to exploit heterogeneous annotation corpora for Chinese S&T. In this paper, we propose a unified model for Chinese S&T with heterogeneous annotation corpora. We first automatically construct a loose and uncertain mapping between two representative heterogeneous corpora, Penn Chinese Treebank (CTB) and PKU's People's Daily (PPD). Then we regard the Chinese S&T with heterogeneous corpora as two "related" tasks and train our model on two heterogeneous corpora simultaneously. Experiments show that our method can boost the performances of both of the heterogeneous corpora by using the shared information, and achieves significant improvements over the state-of-the-art methods.

1 Introduction

Currently, most of statistical natural language processing (NLP) systems rely heavily on manually annotated resources to train their statistical models. The more of the data scale, the better the performance will be. However, the costs are extremely expensive to build the large scale resources for some NLP tasks. Even worse, the existing resources are often incompatible even for a same task and the annotation guidelines are usually different for different projects, since there are many underlying linguistic theories which explain the same language with different perspectives. As a result, there often exist multiple heterogeneous annotated corpora for a same task with vastly different and incompatible annotation philosophies. These heterogeneous resources are waste on some level if we cannot fully exploit them.

However, though most of statistical NLP methods are not bound to specific annotation standards, almost all of them cannot deal simultaneously with the training data with different and incompatible annotation. The co-existence of heterogeneous annotation data therefore presents a new challenge to utilize these resources.

The problem of incompatible annotation standards is very serious for many tasks in NLP, especially for Chinese word segmentation and part-of-speech (POS) tagging (Chinese S&T). In Chinese S&T, the annotation standards are often incompatible for two main reasons. One is that there is no widely accepted segmentation standard due to the lack of a clear definition of Chinese words. Another is that there are no morphology for Chinese word so that there are many ambiguities to tag the parts-of-speech for Chinese word. For example, the two commonly-used corpora, PKU's People's Daily (PPD) (Yu et al., 2001) and Penn Chinese Treebank (CTB) (Xia, 2000), use very different segmentation and POS tagging standards.

For example, in Table 1, it is very different to annotate the sentence "刘翔进入中国区总决赛 (Liu Xiang reaches the national final in China)" with guidelines of CTB and PDD. PDD breaks some phrases, which are single words in

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 658–668,

	Liu	Xiang	reachs	China		final	
CTB	刘翔/NR		进入/VV	中国区/NN		总决赛/NN	
PDD	刘/nrf	翔/nrg	进入/v	中国/ns	区/n	总/b	决赛/vn

Table 1: Incompatible word segmentation and POS tagging standards between CTB and PDD

CTB, into two words. The POS tagsets are also significantly different. For example, PDD gives diverse tags "n" and "vn" for the noun, while CTB just gives "NN". For proper names, they may be tagged as "nr", "ns", etc in PDD, while they are just tagged as "NR" in CTB.

Recently, it has attracted more and more research interests to exploit heterogeneous annotation data for Chinese word segmentation and POS tagging. (Jiang et al., 2009) presented a preliminary study for the annotation adaptation topic. (Sun and Wan, 2012) proposed a structure-based stacking model to fully utilize heterogeneous word structures. They also reported that there is no one-to-one mapping between the heterogeneous word classification and the mapping between heterogeneous tags is very uncertain.

These methods usually have a two-step process. The first step is to train the preliminary taggers on heterogeneous annotations. The second step is to train the final taggers by using the outputs of the preliminary taggers as features. We call these methods as "**pipeline-based**" methods.

In this paper, we propose a method for joint Chinese word segmentation and POS tagging with heterogeneous annotation corpora. We regard the Chinese S&T with heterogeneous corpora as two "related" tasks which can improve the performance of each other. Since it is impossible to establish an exact mapping between two annotations, we first automatically construct a loose and uncertain mapping the heterogeneous tagsets of CTB and PPD. Thus we can tag a sentence in one style with the help of the "related" information in another heterogeneous style. The proposed method can improve the performances of joint Chinese S&T on both corpora by using the shared information of each other, which is proven effective by experiments.

There are three main contributions of our model:

- First, we regard these two joint S&T tasks on different corpora as two related tasks which have interdependent and peer relationship.
- Second, different to the pipeline-based methods, our model can be trained simultaneously on the heterogeneous corpora. Thus, it can also produce two different styles of POS tags.
- Third, our model do not depend on the exactly correct mappings between the two heterogeneous tagsets. The correct mapping relations can be automatically built in training phase.

The rest of the paper is organized as follows: We first introduce the related works in section 2 and describe the background of character-based method for joint Chinese S&T in section 3. Section 4 presents an automatic method to build the loose mapping function. Then we propose our method on heterogeneous corpora in 5 and 6. The experimental results are given in section 7. Finally, we conclude our work in section 8.

2 Related Works

There are some works to exploit heterogeneous annotation data for Chinese S&T.

(Gao et al., 2004) described a transformation-based converter to transfer a certain annotation-style word segmentation result to another style. However, this converter need human designed transformation templates, and is hard to be generalized to POS tagging.

(Jiang et al., 2009) proposed an automatic adaptation method of heterogeneous annotation standards, which depicts a general pipeline to integrate the knowledge of corpora with different

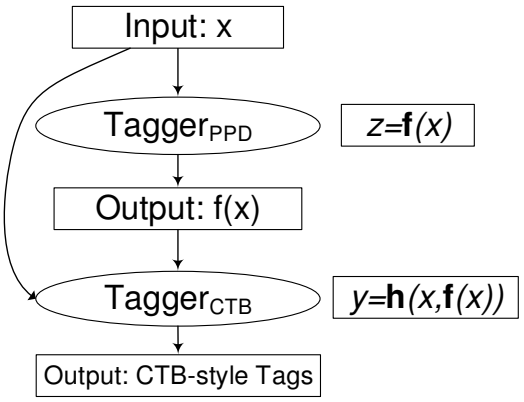

Figure 1: Traditional Pipeline-based Strategy for Heterogeneous POS Tagging

underling annotation guidelines. They further proposed two optimization strategies, iterative training and predict-self re-estimation, to further improve the accuracy of annotation guideline transformation (Jiang et al., 2012).

(Sun and Wan, 2012) proposed a structure-based stacking model to fully utilize heterogeneous word structures.

These methods regard one annotation as the main target and another annotation as the complementary/auxiliary purposes. For example, in their solution, an auxiliary tagger $\mathbf{Tagger_{PPD}}$ is trained on a complementary corpus PPD, to assist the target CTB-style $\mathbf{Tagger_{CTB}}$. To refine the character-based tagger, PPD-style character labels are directly incorporated as new features. The brief sketch of these methods is shown in Figure 1.

The related work in machine learning literature is multiple task learning (Ben-David and Schuller, 2003), which learns a problem together with other related problems at the same time, using a shared representation. This often leads to a better model for the main task, because it allows the learner to use the commonality among the tasks. Multiple task learning has been proven quite successful in practice and has been also applied to NLP (Ando and Zhang, 2005). We also preliminarily verified that multiple task learning can improve the performance on this problem in our previous work (Zhao et al., 2013), which is a simplified case of the work in this paper and has a relative low complexity.

Different with the multiple task learning, whose tasks are actually different labels in the same classification task, our model utilizes the shared information between the real different tasks and can produce the corresponding different styles of outputs.

3 Joint Chinese Word Segmentation and POS Tagging

Currently, the mainstream method of Chinese POS tagging is joint segmentation & tagging with character-based sequence labeling models(Lafferty et al., 2001), which can avoid the problem of segmentation error propagation and achieve higher performance on both subtasks(Ng and Low, 2004; Jiang et al., 2008; Sun, 2011; Qiu et al., 2012).

The label of each character is the cross-product of a segmentation label and a tagging label. If we employ the commonly used label set {B, I, E, S} for the segmentation part of cross-labels ({B, I, E} represent *Begin*, *Inside*, *End* of a multi-node segmentation respectively, and S represents a *Single* node segmentation), the label of character can be in the form of {B-T}(T represents POS tag). For example, *B-NN* indicates that the character is the begin of a noun.

4 Automatically Establishing the Loose Mapping Function for the Labels of Characters

To combine two human-annotated corpora, the relationship of their guidelines should be found. A **mapping function** should be established to represent the relationship between two different annotation guidelines. However, the exact mapping relations are hard to establish. As reported in (Sun and Wan, 2012), there is no one-to-one mapping between their heterogeneous word classification, and the mapping between heterogeneous tags is very uncertain.

Fortunately, there is a loose mapping can be found in CTB annotation guideline[1] (Xia, 2000). Table 2 shows some

[1]Available at http://www.cis.upenn.edu/ ~chi-

	CTB's Tag	PDD' Tag[1]
Total tags	33	26
verbal noun	NN	v[+nom]
proper noun	NR	n
是 (shi4)	VC	v
有 (you3)	VE, VV	v
conjunctions	CC, CS	c
other verb	VV, VA	v, a, z
number	CD, OD	m

[1] The tag set of PDD just includes the 26 broad categories in the mapping table. The whole tag set of PDD has 103 sub categories.

Table 2: Examples of mapping between CTB and PDD's tagset

mapping relations in CTB annotation guideline. These loose mapping relations are many-to-many mapping. For example, the mapping may be "NN/CTB↔{n,nt,nz}/PDD", "NR/CTB↔{nr,ns}/PDD", "v/PDD↔{VV, VA}/CTB" and so on.

We define $\mathcal{T}_1$ and $\mathcal{T}_2$ as the tag sets for two different annotations, and $t_1 \in \mathcal{T}_1$ and $t_2 \in \mathcal{T}_2$ are the corresponding tags in two tag sets respectively.

We first establish a loose mapping function $\mathbf{m} : \mathcal{T}_1 \times \mathcal{T}_2 \rightarrow \{0, 1\}$ between the tags of CTB and PDD.

$$\mathbf{m}(t_1, t_2) = \begin{cases} 1 & \text{if } t_1 \text{ and } t_2 \text{ have mapping relation} \\ 0 & \text{else} \end{cases} \quad (1)$$

The mapping relations are automatically build from the CTB guideline (Xia, 2000). Due to the fact that the tag set of PPD used in the CTB guideline is just broad categories, we expand the mapping relations to include the sub categories. If a PPD's tag is involved in the mapping, all its sub categories should be involved. For example, for the mapping "NR/CTB↔nr/PDD", the relation of *NR* and *nrf/nrg* should be added in the mapping relations too (*nrf/nrg* belong to *nr*).

Since we use the character-based joint S&T model, we also need to find the mapping function between the labels of characters.

nese/posguide.3rd.ch.pdf

In this paper, we employ the commonly used label set {B, I, E, S} for the segmentation part of cross-labels and the label of character can be in the form of {B-T}(T represents POS tag). Thus, each mapping relation $t_1 \leftrightarrow t_2$ can be automatically transformed to four forms: B-t_1 ↔B-t_2, I-t_1 ↔I-t_2, E-t_1 ↔E-t_2 and S-t_1 ↔S-t_2. ("B-NR/CTB↔{B-nr,B-ns}/PPD" for example).

Beside the above transformation, we also give a slight modification to adapt the different segmentation guidelines. For instance, the person name "莫言 (Mo Yan)" is tagged as "B-NR, E-NR" in CTB but "S-nrf, S-nrg" in PPD. So, some special mappings may need to be added like "B-NR/CTB↔S-nrf/PPD", "E-NR/CTB↔{S-nrg, E-nrg}/PPD", "M-NR/CTB↔{B-nrg, M-nrg}/PPD" and so on. Although these special mappings are also established automatically with an exhaustive solution. In fact, we give segmentation alignment only to proper names due to the limitation of computing ability.

Thus, we can easily build the **loose bidirectional mapping function $\tilde{\mathbf{m}}$** for the labels of characters. An illustration of our construction flowchart is shown in Figure 2.

Finally, total 524 mappings relationships are established.

5 Joint Chinese S&T with Heterogeneous Data with Multiple Task Learning

Inspired by the multiple task learning (Ben-David and Schuller, 2003), we can regard the joint Chinese S&T with heterogeneous data as two "related" tasks, which can improve the performance of each other simultaneously with shared information.

5.1 Sequence Labeling Model

We first introduce the commonly used sequence labeling model in character-based joint Chinese S&T.

Sequence labeling is the task of assigning labels $\mathbf{y} = y_1, \ldots, y_n (y_i \in \mathcal{Y})$ to an input sequence $\mathbf{x} = x_1, \ldots, x_n$. $\mathcal{Y}$ is the set of labels.

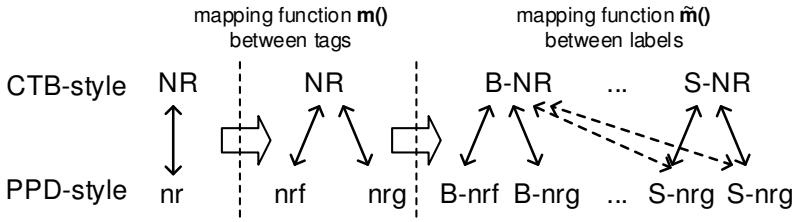

Figure 2: An Illustration of Automatically Establishing the Loose Mapping Function

Given a sample $\mathbf{x}$, we define the feature $\Phi(\mathbf{x}, \mathbf{y})$. Thus, we can label $\mathbf{x}$ with a score function,

$$\hat{\mathbf{y}} = \arg\max_{\mathbf{y}} S(\mathbf{w}, \Phi(\mathbf{x}, \mathbf{y})), \tag{2}$$

where $\mathbf{w}$ is the parameter of score function $S(\cdot)$. The feature vector $\Phi(\mathbf{x}, \mathbf{y})$ consists of lots of overlapping features, which is the chief benefit of discriminative model. Different algorithms vary in the definition of $S(\cdot)$ and the corresponding objective function. $S(\cdot)$ is usually defined as linear or exponential family function.

For first-order sequence labeling, the feature can be denoted as $\phi_k(\mathbf{x}, y_{i-1:i})$, where i stands for the position in the sequence and k stands for the number of feature templates. For the linear classifier, the score function can be rewritten in detail as

$$\hat{\mathbf{y}} = \arg\max_{\mathbf{y}} \sum_{i=1}^{L} \left(\langle \mathbf{u}, \mathbf{f}(\mathbf{x}, y_i) \rangle + \langle \mathbf{v}, \mathbf{g}(\mathbf{x}, y_{i-1:i}) \rangle \right), \tag{3}$$

where $y_{i:j}$ denotes label subsequence $y_i y_{i+1} \cdots y_j$; $\mathbf{f}$ and $\mathbf{g}$ denote the state and transition feature vectors respectively, $\mathbf{u}$ and $\mathbf{v}$ are their corresponding weight vectors; L is the length of $\mathbf{x}$.

5.2 The Proposed Model

Different to the single task learning, the heterogeneous data have two sets of labels $\mathcal{Y}$ and $\mathcal{Z}$.

The heterogeneous datasets $\mathbb{D}_s$ and $\mathbb{D}_s$ consist of $\{\mathbf{x}_i, \mathbf{y}_i\}(i = 0, \cdots, m)$ and $\{\mathbf{x}_i, \mathbf{z}_i\}(i = 0, \cdots, n)$ respectively.

For a sequence $\mathbf{x} = x_1, \ldots, x_L$ with length L. , there may have two output sequence labels $\mathbf{y} = y_1, \ldots, y_L$ and $\mathbf{z} = z_1, \ldots, z_L$, where $y_i \in \mathcal{Y}$ and $z_i \in \mathcal{Z}$.

We rewrite the loose mapping function $\tilde{\mathbf{m}}$ between two label sets into the following forms,

$$\varphi(y) = \{z | \tilde{\mathbf{m}}(y, z) = 1\}, \tag{4}$$
$$\varphi(z) = \{y | \tilde{\mathbf{m}}(y, z) = 1\}, \tag{5}$$

where $\varphi(z) \subset \mathcal{Y}$ and $\varphi(y) \subset \mathcal{Z}$ are the subsets of $\mathcal{Y}$ and $\mathcal{Z}$. Give a label y(or z) in an annotation, the loose mapping function φ returns the corresponding mapping label set in another heterogeneous annotation.

Our model for heterogeneous sequence labeling can be write as

$$\begin{aligned}\hat{\mathbf{y}} = \arg\max_{\mathbf{y}, y_i \in \mathcal{Y}} \sum_{i=1}^{L} \Big(& \langle \mathbf{u}, \mathbf{f}(\mathbf{x}, y_i) \rangle \\ & + \langle \mathbf{s}, \sum_{z \in \varphi(y_i)} \mathbf{h}(\mathbf{x}, z) \rangle \\ & + \langle \mathbf{v}_1, \mathbf{g}_1(\mathbf{x}, y_{i-1:i}) \rangle \\ & + \langle \mathbf{v}_2, \sum_{\substack{z_{i-1} \in \varphi(y_{i-1}) \\ z_i \in \varphi(y_i)}} \mathbf{g}_2(\mathbf{x}, z_{i-1:i}) \rangle \Big),\end{aligned} \tag{6}$$

and

$$\begin{aligned}\hat{\mathbf{z}} = \arg\max_{\mathbf{z}, z_i \in \mathcal{Z}} \sum_{i=1}^{L} \Big(& \langle \mathbf{u}, \sum_{y \in \varphi(z_i)} \mathbf{f}(\mathbf{x}, y) \rangle + \\ & \langle \mathbf{s}, \mathbf{h}(\mathbf{x}, z_i) \rangle \\ & + \langle \mathbf{v}_1, \sum_{\substack{y_{i-1} \in \varphi(z_{i-1}) \\ y_i \in \varphi(z_i)}} \mathbf{g}_1(\mathbf{x}, y_{i-1:i}) \rangle \\ & + \langle \mathbf{v}_2, \mathbf{g}_2(\mathbf{x}, z_{i-1:i}) \rangle \Big),\end{aligned} \tag{7}$$

where $\mathbf{f}$ and $\mathbf{h}$ represent the state feature vectors on two label sets $\mathcal{Y}$ and $\mathcal{Z}$ respectively.

In Eq.(6) and (7), the score of the label of every character is decided by the weights of the corresponding mapping labels and itself.

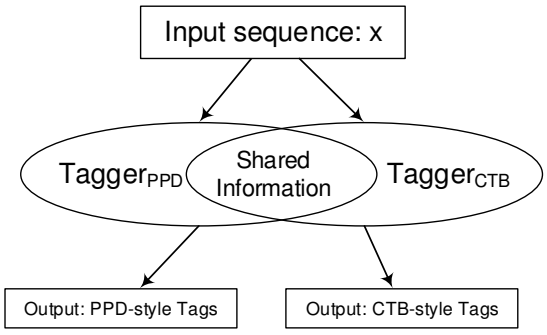

Figure 3: Our model for Heterogeneous POS Tagging

The main challenge of our model is the efficiency of decoding algorithm, which is similar to structured learning with latent variables(Liang et al., 2006) (Yu and Joachims, 2009). Most methods for structured learning with latent variables have not expand all possible mappings. In this paper, we also only expand the mapping that with highest according to the current model.

Our model is shown in Figure 3 and the flowchart is shown in Algorithm 1. If given the output type of label T, we only consider the labels in T to initialize the Viterbi matrix, and the score of each node is determined by all the involved heterogeneous labels according to the loose mapping function.

input : character sequence $x_{1:L}$
loose mapping function φ
output type: $T(T \in \{T_y, T_z\})$
output: label sequence **ls**
if $T == T_y$ **then**
  calculate **ls** using Eq. (6);
else if $T == T_z$ **then**
  calculate **ls** using Eq. (7) ;
else
  return null;
end
return ls

Algorithm 1: Flowchart of the Tagging process of the proposed model

6 Training

We use online Passive-Aggressive (PA) algorithm (Crammer and Singer, 2003; Crammer et al., 2006) to train the model parameters. Following (Collins, 2002), the average strategy is used to avoid the overfitting problem.

For the sake of simplicity, we merge the Eq.(6) and (7) into a unified formula.

Given a sequence $\mathbf{x}$ and the expect type of tags T, the merged model is

$$\hat{\mathbf{y}} = \arg\max_{\substack{\mathbf{y} \\ t(\mathbf{y})=T}} \langle \mathbf{w}, \sum_{\mathbf{z} \in \psi(\mathbf{y})} \Phi(\mathbf{x}, \mathbf{z}) \rangle, \quad (8)$$

where $t(\mathbf{y})$ is a function to judge the type of output tags; $\psi(\mathbf{y})$ represents the set $\{\varphi(y_1) \otimes \varphi(y_2) \otimes \cdots \otimes \varphi(y_L)\} \cup \{\mathbf{y}\}$, where $\otimes$ means Cartesian product; $\mathbf{w} = (\mathbf{u}^T, \mathbf{s}^T, \mathbf{v}_1^T, \mathbf{v}_2^T)^T$ and $\Phi = (\mathbf{f}^T, \mathbf{h}^T, \mathbf{g}_1^T, \mathbf{g}_2^T)^T$.

We redefine the score function as

$$S(\mathbf{w}, \mathbf{x}, \mathbf{y}) = \langle \mathbf{w}, \sum_{\mathbf{z} \in \psi(\mathbf{y})} \Phi(\mathbf{x}, \mathbf{z}) \rangle. \quad (9)$$

Thus, we rewrite the model into a unified formula

$$\hat{\mathbf{y}} = \arg\max_{\substack{\mathbf{y} \\ t(\mathbf{y})=T}} S(\mathbf{w}, \mathbf{x}, \mathbf{y}). \quad (10)$$

Given an example $(\mathbf{x}, \mathbf{y})$, $\hat{\mathbf{y}}$ is denoted as the incorrect label sequence with the highest score

$$\hat{\mathbf{y}} = \arg\max_{\substack{\bar{\mathbf{y}} \neq \mathbf{y} \\ t(\bar{\mathbf{y}})=t(\mathbf{y})}} S(\mathbf{w}, \mathbf{x}, \bar{\mathbf{y}}). \quad (11)$$

The **margin** $\gamma(\mathbf{w}; (\mathbf{x}, \mathbf{y}))$ is defined as

$$\gamma(\mathbf{w}; (\mathbf{x}, \mathbf{y})) = S(\mathbf{w}, \mathbf{x}, \mathbf{y}) - S(\mathbf{w}, \mathbf{x}, \hat{\mathbf{y}}). \quad (12)$$

Thus, we calculate the **hinge loss** $\ell(\mathbf{w}; (\mathbf{x}, \mathbf{y}))$, (abbreviated as ℓ_w) by

$$\ell_w = \begin{cases} 0, & \gamma(\mathbf{w}; (\mathbf{x}, \mathbf{y})) > 1 \\ 1 - \gamma(\mathbf{w}; (\mathbf{x}, \mathbf{y})), & \text{otherwise} \end{cases} \quad (13)$$

In round k, the new weight vector $\mathbf{w}_{k+1}$ is calculated by

$$\mathbf{w}_{k+1} = \arg\min_{\mathbf{w}} \frac{1}{2} ||\mathbf{w} - \mathbf{w}_k||^2 + \mathcal{C} \cdot \xi,$$
$$\textbf{s.t. } \ell(\mathbf{w}; (\mathbf{x}_k, \mathbf{y}_k)) <= \xi \textbf{ and } \xi >= 0 \quad (14)$$

where ξ is a non-negative slack variable, and $\mathcal{C}$ is a positive parameter which controls the influence of the slack term on the objective function.

Following the derivation in PA (Crammer et al., 2006), we can get the update rule,

$$\mathbf{w}_{k+1} = \mathbf{w}_k + \tau_k \mathbf{e}_k, \tag{15}$$

where

$$\begin{aligned} \mathbf{e}_k &= \sum_{\mathbf{z} \in \psi(\mathbf{y}_k)} \Phi(\mathbf{x}_k, \mathbf{z}) - \sum_{\mathbf{z} \in \psi(\hat{\mathbf{y}_k})} \Phi(\mathbf{x}_k, \mathbf{z}), \\ \tau_k &= \min(\mathcal{C}, \frac{\ell_{w_k}}{\|\mathbf{e}_k\|^2}). \end{aligned}$$

As we can see from the Eq. (15), when we update the weight vector, the update information includes not only the features extracted from current input, but also that extracted from the loose mapping sequence of input. For each feature, the weights of its corresponding related features derived from the loose mapping function will be updated with the same magnitude as well as itself.

Our method regards two annotations to be interdependence and peer relationship. Therefore, the two heterogeneous annotated corpora can be simultaneously used as the input of our training algorithm. Because of the tagging and training algorithm, the weights and tags of two corpora can be used separately with the only dependent part built by the loose mapping function.

Our training algorithm based on PA is shown in Algorithm 2.

input : mixed heterogeneous datasets: $(\mathbf{x}_i, \mathbf{y}_i), i = 1, \cdots, N$;
parameters: $\mathcal{C}, K$;
loose mapping function: φ ;
output: $\mathbf{w}_K$

Initialize: $\mathbf{wTemp} \leftarrow 0, \mathbf{w} \leftarrow 0$;
for $k = 0 \cdots K-1$ **do**
  for $i = 1 \cdots N$ **do**
    receive an example $(\mathbf{x}_i, \mathbf{y}_i)$;
    predict: $\hat{\mathbf{y}}_i$ with Eq.(11);
    if ***hinge loss*** $\ell_w > 0$ **then**
      update $\mathbf{w}$ with Eq. (15);
    end
  end
  $\mathbf{wTemp} = \mathbf{wTemp} + \mathbf{w}$;
end
$\mathbf{w}_K = \mathbf{wTemp}/K$;

Algorithm 2: Training Algorithm

6.1 Analysis

Although our mapping function between two heterogeneous annotations is loose and uncertain, our online training method can automatically increase the relative weights of features from the beneficial mapping relations and decrease the relative weights of features from the unprofitable mapping relations.

Consider an illustrative loose mapping relation "NN/CTB↔n,nt,nz/PDD". For an input sequence $\mathbf{x}$ and PDD-style output is expected. If the algorithm tagging a character as "n/PDD"(with help of the weight of "NN/CTB") and the right tag isn't one of "n,nt,nz/PDD", the weight of "NN/CTB" will also be decreased, which is reasonable since it is beneficial to distinguish the right tag. And if the right tag is one of "n,nt,nz/PDD" but not "n/PDD" (for example, "nt/PDD"), which means it is a "NN/CTB", the weight of "NN/CTB" will remain unchanged according to the algorithm (updating "n/PDD" changes the "NN/CTB", but updating "nt/PDD" changes it back).

Therefore, after multiple iterations, useful features derived from the mapping function are typically receive more updates, which take relatively more responsibility for correct prediction. The final model has good parameter estimates for the shared information.

We implement our method based on FudanNLP(Qiu et al., 2013).

7 Experiments

7.1 Datasets

We use the two representative corpora mentioned above, Penn Chinese Treebank (CTB) and PKU's People's Daily (PPD) in our experiments.

Dataset	Partition	Sections	Words
CTB-5	Training	1−270 400−931 1001−1151	0.47M
	Develop	301−325	6.66K
	Test	271−300	7.82K
CTB-S	Training		0.64M
	Test	-	59.96K
PPD	Training	-	1.11M
	Test	-	0.16M

Table 3: Data partitioning for CTB and PD

7.1.1 CTB Dataset

To better comparison with the previous works, we use two commonly used criterions to partition CTB dataset into the train and test sets.

- One is the partition criterion used in (Jin and Chen, 2008; Jiang et al., 2009; Sun and Wan, 2012) for CTB 5.0.
- Another is the CTB dataset from the POS tagging task of the Fourth International Chinese Language Processing Bakeoff (SIGHAN Bakeoff 2008)(Jin and Chen, 2008).

7.1.2 PPD Dataset

For the PPD dataset, we use the PKU dataset from SIGHAN Bakeoff 2008.

The details of all datasets are shown in Table 3. Our experiment on these datasets may lead to a fair comparison of our system and the related works.

7.2 Setting

We conduct two experiments on **CTB-5 + PPD** and **CTB-S + PPD** respectively.

The form of feature templates we used is shown in Table 7.2, where C represents a Chinese character, and T represents the character-based tag. The subscript i indicates its position related to the current character.

Our method can be easily combined with some other complicated models, but we only use the simple one for the purpose of observing the sole influence of our unified model. The parameter C is tested on develop dataset, and we found that it just impact the speed of convergence and have no effect on the accuracy. Moreover, since we use the averaged strategy, we wish more iterations to avoid overfitting and set a small value 0.01 to it. The maximum number of iterations K is 50.

$C_i, T_0 (i = -2, -1, 0, 1, 2)$
$C_i, C_{i+1}, T_0 (i = -1, 0)$
T_{-1}, T_0

Table 4: Feature Templates

The $F1$ score is used for evaluation, which is the harmonic mean of precision P (percentage of predict phrases that exactly match the reference phrases) and recall R (percentage of reference phrases that returned by system).

7.3 Evaluation on CTB-5 + PPD

The experiment results on the heterogeneous corpora CTB-5 + PPD are shown in Table 5. Our method obtains an error reductions of 24.08% and 90.8% over the baseline on CTB-5 and PDD respectively.

Our method also gives better performance than the pipeline-based methods on heterogeneous corpora, such as (Jiang et al., 2009) and (Sun and Wan, 2012).

The reason is that our model can utilize the information of both corpora effectively, which can boost the performance of each other.

Although the loose mapping function are bidirectional between two annotation tagsets, we may also use unidirectional mapping. Therefore, we also evaluate the performance when we use unidirectional mapping. We just use the mapping function $\psi_{\mathbf{PDD}\rightarrow\mathbf{CTB}}$, which means we obtain the PDD-style output without the information from CTB in tagging stage. Thus, in training stage, there are no updates for the weights of CTB-features for the instances from PDD corpus, while instances from CTB corpus can result to updates for PDD-features.

Surprisedly, we find that the one-way mapping can also improve the performances of both corpora. The results are shown in Table 7. The

Method	Training Dataset	Test Dataset	P	R	F1
(Jiang et al., 2009)	CTB-5, PDD	CTB-5	-	-	94.02
(Sun and Wan, 2012)	CTB-5, PDD	CTB-5	94.42	94.93	94.68
Our Model	CTB-5	CTB-5	93.28	93.35	93.31
Our Model	PDD	PDD	89.41	88.58	88.99
Our Model	CTB-5, PDD	CTB-5	**94.74**	**95.11**	**94.92**
Our Model	CTB-5, PDD	PDD	**90.25**	**89.73**	**89.99**

Table 5: Performances of different systems on CTB-5 and PPD.

Method	Training Dataset	Test Dataset	P	R	F1
Our Model	CTB-S	CTB-S	89.11	89.16	89.13
Our Model	PDD	PDD	89.41	88.58	88.99
Our Model	CTB-S, PDD	CTB-S	**89.86**	**90.02**	**89.94**
Our Model	CTB-S, PDD	PDD	**90.5**	**89.82**	**90.16**

Table 6: Performances of different systems on CTB-S and PPD.

model$_{PPD \rightarrow CTB}$ obtains an error reductions of 14.63% and 6.12% over the baseline on CTB-5 and PDD respectively.

Method	P	R	F1
Model$_S$ on CTB-5	93.86	94.73	94.29
Model$_S$ on PDD	90.05	89.28	89.66

"Model$_S$" is the model which is trained on both CTB-5 and PDD training datasets with just just using the unidirectional mapping function $\psi_{\mathbf{PDD \rightarrow CTB}}$.

Table 7: Performances of unidirectional PPD→CTB mapping on CTB-5 and PPD.

7.4 Evaluation on CTB-S + PPD

Table 6 shows the experiment results on the heterogeneous corpora CTB-S + PPD. Our method obtains an error reductions of 7.41% and 10.59% over the baseline on CTB-S and PDD respectively.

7.5 Analysis

As we can see from the above experiments, our proposed unified model can improve the performances of the two heterogeneous corpora with unidirectional or bidirectional loose mapping functions. Different to the pipeline-based methods, our model can use the shared information between two heterogeneous POS taggers. Although the mapping function is loose and uncertain, it is still can boost the performances. The features derived from the wrong mapping function take relatively less responsibility for prediction after multiple updates of their weights in training stage. The final model has good parameter estimates for the shared information.

Another phenomenon is that the performance of one corpus can gains when the data size of another corpus increases. In our two experiments, the training set's size of CTB-S is larger than CTB-5, so the performance of PDD is higher in latter experiment.

8 Conclusion

We proposed a method for joint Chinese word segmentation and POS tagging with heterogeneous annotation data. Different to the previous pipeline-based works, our model is learned on heterogeneous annotation data simultaneously. Our method also does not require the exact corresponding relation between the standards of heterogeneous annotations. The experimental results show our method leads to a significant improvement with heterogeneous annotations over the best performance for this task. Although our work is for a specific task on joint Chinese word segmentation and POS, the key idea to leverage heterogeneous annotations is very general and applicable to other NLP tasks.

In the future, we will continue to refine the proposed model in two ways: (1) We wish to use the unsupervised method to extract the loose mapping relation between the different annotation standards, which is useful to the corpora without loose mapping guideline. (2) We will analyze the shared information (weights of the features derived from the tags which have the mapping relation) in detail and propose a more effective model. Besides, we would also like to investigate for other NLP tasks which have different annotation-style corpora.

Abstract

Studies of the graph of dictionary definitions (DD) (Picard et al., 2009; Levary et al., 2012) have revealed strong semantic coherence of local topological structures. The techniques used in these papers are simple and the main results are found by understanding the structure of cycles in the directed graph (where words point to definitions). Based on our earlier work (Levary et al., 2012), we study a different class of word definitions, namely those of the Free Association (FA) dataset (Nelson et al., 2004). These are responses by subjects to a cue word, which are then summarized by a directed, free association graph.

We find that the structure of this network is quite different from both the Wordnet and the dictionary networks. This difference can be explained by the very nature of free association as compared to the more "logical" construction of dictionaries. It thus sheds some (quantitative) light on the psychology of free association.

In NLP, semantic groups or clusters are interesting for various applications such as word sense disambiguation. The FA graph is tighter than the DD graph, because of the large number of triangles. This also makes drift of meaning quite measurable so that FA graphs provide a quantitative measure of the semantic coherence of small groups of words.

1 Introduction

The computer study of semantic networks has been around since the advent of computers (Brunet, 1974) and has been used to study semantic relations between concepts and for analyzing semantic data. Traditionally, a popular lexical database of English is Wordnet (Miller, 1995; Miller and Fellbaum, 1998), which organizes the semantic network in terms of graph theory. In contrast to manual approaches, the automatic analysis of semantically interesting graph structures of language has received increasing attention. For example, it has become clear more recently that cycles and triangles play an important role in semantic networks, see *e.g.*, (Dorow et al., 2005). These results suggest that the underlying semantic structure of language may be discovered through graph-theoretical methods. This is in line with similar findings in much wider realms than NLP (Eckmann and Moses, 2002).

In this paper, we compare two different types of association networks. The first network is constructed from an English dictionary (DD), the second from a free association (FA) database (Nelson et al., 2004). We represent both datasets through directed graphs. For DD, the nodes are words and the directed edges point from a word to its definition(s). For FA, the nodes are again words, and each cue word has a directed edge to each association it elicits.

Although the links in these graphs were not constructed by following a rational centralized process, their graph exhibits very specific features and we concentrate on the study of its topological properties. We will show that these graphs are quite different in global and local structure, and we interpret this as a reflection of the different nature of DD vs. FA. The first is an *objective* set of rela-

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 669–680,
Seattle, Washington, USA, 18-21 October 2013.

tions between words and their meaning, as explained by other words, while the second reveals the nature of *subjective* reactions to cue words by individuals. This matter of fact is reflected by several quantitative differences in the structure of the corresponding graphs.

The main contribution of this paper is an empirical analysis of the way semantic knowledge is structured, comparing two different types of association networks (DD and FA). We conduct a mathematical analysis of the structure of the graphs to show that the way humans express their thoughts exhibits structural properties in which one can find semantic patterns. We show that a simple graph-based approach can leverage the information encoded in free association to narrow down the ambiguity of meaning, resulting in precise semantic groups. In particular, we find that the main strongly connected component of the FA graph (the so-called **core**) is very cyclic in nature and contains a large predominance of short cycles (*i.e.*, co-links and triangles). In contrast to the DD graph, bunches of triangles form well-delimited lexical fields of collective semantic knowledge. This property may be promising for downstream tasks. Further, the methods developed in this paper may be applicable to graph representations that occur in other problems such as word sense disambiguation (*e.g.*, (Heylighen, 2001; Agirre and Soroa, 2009)) or sentiment polarity induction (Hassan and Radev, 2010; Scheible, 2010).

To show the semantic coherence of these lexical fields of the FA graph, we perform an experiment with human raters and find that cycles are strongly semantically connected even when compared to close neighbors in the graph.

The reader might wonder why sets of pairwise associations can lead to any interesting structure. One of the deep results in graph theory, (Bollobás, 2001), is that in sparse graphs, *i.e.*, in graphs with few links per node, the number of triangles is extremely rare. Therefore, if one does find many triangles in a graph, they must be not only a signal of non-randomness, but carry relevant information about the domain of research as shown earlier (Eckmann and Moses, 2002).

2 The USF FA dataset

This dataset is one of the largest existing databases of free associations (FA) and has been collected at the University of South Florida since 1973 by researchers in psychology (Nelson et al., 2004). Over the years, more than 6'000 participants produced about 750'000 responses to 5'019 stimulus words.

The procedure for collecting the data is called discrete association task and consists in asking participants to give the first word that comes to mind (**target**) when presented a stimulus word (**cue**).

For creating the initial set of stimulus words, the Jenkins and Palermo word association norms (Palermo and Jenkins, 1964) proved useful but too limited as they consist of only 200 words. For this reason, additional words have been regularly added to the pool of normed words, unfortunately without well established rules being followed. For instance, some were selected as potentially interesting cues, some were added as responses to the first sets of cues and, some others were collected for supporting new studies on verbs. We still work with this database, because of its breadth.

The final pool of stimuli comprises 5'019 words of which 76% are nouns, 13% adjectives, and 7% verbs. A word association is said to be **normed** when the target is also part of the set of norms, *i.e.*, a cue. The USF dataset of free associations contains 72'176 cue-target pairs, 63'619 of which are normed. As an example, the association *puberty-sex* is normed whereas the association *puberty-thirteen* is not, because *thirteen* is not a cue.

3 Mathematical definitions

We collect here those notions we need for the analysis of the data.

A **directed graph** is a pair $G = (V, E)$ of a set V of **vertices** and, a set E of ordered pairs of vertices also called **directed edges**. For a directed edge $(u, v) \in E$, u is called the **tail** and v the **head** of the edge. The number of edges incident to a vertex $v \in V$ is called the **degree** of v. The **in-degree** (resp. **out-degree**) of a vertex v is the number of edge heads (resp. edge tails) adjacent to it. A vertex with null in-degree is called a **source** and a vertex with null out-degree is called a **sink**.

A **directed path** is a sequence of vertices such

that a directed edge exists between each consecutive pair of vertices of the graph. A directed graph is said to be **strongly connected**, (resp. **weakly connected**) if for every pair of vertices in the graph, there exists a directed path (resp. undirected path) between them. A **strongly connected component**, SCC, (resp. **weakly connected component**, WCC) of a directed graph G is a maximal strongly connected (resp. weakly connected) subgraph of G.

A **directed cycle** is a directed path such that its **start vertex** is the same as its **end vertex**. A **colink** is a directed cycle of length 2 and a **triangle** a directed cycle of length 3.

The **distance** between two vertices in a graph is the number of edges in the shortest path connecting them. The **diameter** of a graph G is the greatest distance between any pair of vertices. The **characteristic path length** is the average distance between any two vertices of G.

The **density** of a directed graph $G(V, E)$ is the proportion of existing edges over the total number of possible edges and is defined as:

$$d = |E|/(|V|(|V| - 1))$$

The **neighborhood** N_i of a vertex v_i is $N_i = \{v_j : e_{ij} \in E \text{ or } e_{ji} \in E\}$.

The **local clustering coefficient** C_i for a vertex v_i corresponds to the density of its neighborhood subgraph. For a directed graph, it is thus given by:

$$C_i = \frac{|\{e_{jk} : v_j, v_k \in N_i, e_{jk} \in E\}|}{|N_i|(|N_i| - 1)}$$

The **clustering coefficient** of a graph G is the average of the local clustering coefficients of all its vertices.

The **efficiency** Eff of a directed graph G is an indicator of the traffic capacity of a network. It is the harmonic mean of the distance between any two vertices of G. It is defined as:

$$\text{Eff} = \frac{1}{|V|(|V| - 1)} \sum_{i \neq j \in V} \frac{1}{d_{ij}}$$

The linear correlation coefficient between two random variables X and Y is defined as:

$$\rho(X, Y) = (E[XY] - \mu_X \mu_Y)/(\sigma_X \sigma_Y)$$

where μ_X and σ_X are respectively the mean and standard deviation of the random variable X.

The linear degree correlation coefficient of a graph is called **assortativity** and is expressed as:

$$\rho_D = \sum_{xy} xy(e_{xy} - a_x b_y)/(\sigma_a \sigma_b)$$

where e_{xy} is the fraction of all links that connect nodes of degree x and y and where a_x and b_y are respectively the fraction of links whose tail is adjacent to nodes with degree x and whose head is adjacent to nodes with degree y, satisfying the following three conditions:

$$\sum_{xy} e_{xy} = 1, a_x = \sum_{y} e_{xy}, b_y = \sum_{x} e_{xy}$$

When ρ_D is positive, the graph possesses **assortative mixing** and high-degree nodes tend to connect to other high-degree nodes. On the other hand, when ρ_D is negative, the graph features **disassortative mixing** and high-degree nodes tend to connect to low degree nodes.

The **intersection graph** of sets A_i, $i = 1, \ldots, m$, is constructed by representing each set A_i as a vertex $v_i \in V$ and adding an edge for each pair of sets with a non-empty intersection:

$$E = \{(v_i, v_j) : A_i \cap A_j \neq \varnothing\}$$

4 Graph topology analysis

4.1 Graph generation

Our goal being to study the FA network topology, we first concentrate on the generation of an unweighted directed graph. We generate the corresponding graph by adding a directed edge for each cue-target pair of the dataset. We only consider pairs whose target was normed in order to avoid overloading the graph with noisy data (*e.g.*, a response meaningful only to a specific participant). The graph has 5'019 vertices and 63'619 edges. It is composed of a single WCC and 166 SCCs.

For comparison with dictionary definitions (DD), we construct a graph from the Wordnet2 dictionary (nouns only), following (Levary et al., 2012). This graph contains 54'453 vertices and 179'848 edges.

4.2 Core extraction

The so-called **core** was defined previously in (Picard et al., 2009; Levary et al., 2012) as that subset of nodes in which a random walker gets trapped after only a few steps.

The shave algorithm was used in (Levary et al., 2012) to isolate this subset. It consists in recursively removing the source and sink nodes from a weakly connected directed graph and permits to get the subgraph induced by the union of its strongly connected components. Note that the dictionary graph (DD) has no sinks (*i.e.*, words that never get defined) and that it contains a giant SCC whose size is comparable to the one of the initial graph.

It turns out that the FA graph also contains a giant SCC, therefore getting the core consists more simply in extracting the main SCC of the initial graph. We use Tarjan's algorithm (Tarjan, 1972) for isolating the FA core.

4.3 Vertex degree analysis

The FA core has a maximum in-degree of 313, a maximum out-degree of 33 and an average degree of 25.42. The in-degree distribution follows a power law ($\gamma = 1.93$) and the out-degrees are Poisson-like distributed with a peak at 14 (Steyvers and Tenenbaum, 2005; Gravino et al., 2012).

Words having a high in-degree are **targets** that tend to be cited more frequently. On the other hand, words having a high out-degree are **cues** that evoke many different targets.

The most evocative cues are, in decreasing order of out-degree: *field* (33), *body* (31), *condemn* (29), *farmer* (29), *crisis* (28), *plan* (28), *attention* (27), *animal* (27), and *hang* (27). Interestingly, the most cited targets (*i.e.*, targets with highest in-degree) are in decreasing order: *food* (313), *money* (295), *water* (271), *car* (251), *good* (246), *bad* (221), *work* (187), *house* (183), *school* (182), *love* (179).

4.4 Cycle decomposition of the core

We define the **vertex k-cycle multiplicity** (resp. **edge k-cycle multiplicity**) as the number of k-cycles a given vertex (resp. edge) belongs to. We call **core-ER** the set of Erdös-Rényi (ER) random graphs $G(n, M)$ having the same number of nodes and the same number of edges as the FA core. We start by extracting the 2- and 3-cycles by using a customized version of Johnson's algorithm (Johnson, 1975). The first thing we observe is that the core has a very high density of short cycles: the subset of nodes belonging to 2-cycles (*i.e.*, nodes with 2-cycle multiplicities > 0) cover 95% of the core vertices and the 3-cycles cover 88% of the core vertices. The corresponding core-ER graphs have on average about 100 times fewer 2-cycles and almost 20 times fewer 3-cycles.

This shows that the core is very cyclic in nature and that it remains very well connected for short-length cycles: most vertices of the core indeed belong to at least one co-link or triangle.

In order to limit computation times, we only considered shortest cycles for lengths ≥ 3 and analyzed the distribution of the number of shortest cycles in the core compared to equivalent random graphs. Whereas there are many more short cycles in the core, we observe a predominance of 4, 5 and 6-cycles in core-ER graphs. However, we find again a slight predominance of long cycles (length between 7 and 15) in the core (see Fig. 1). See (Levary et al., 2012), Fig. 3, where the cycle distribution is very different, with a minimum at length 5.

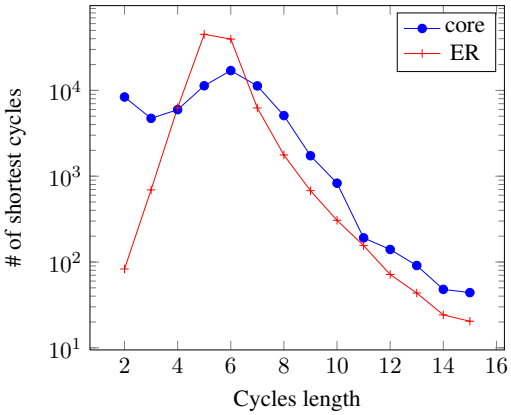

Figure 1: Distribution of shortest cycles lengths in the core compared to equivalent ER models

One should bear in mind that we only consider the set of *shortest* cycles. Thus, a k-cycle is not counted if each of its nodes belongs to a cycle whose length is $< k$. Although the number of 4-shortest cycles is comparable in the core and core-ER graphs for example, there are in reality far more 4-cycles in the core (*i.e.*, 42'738 versus 6'517). We see that when considering shortest cycles, short cycles tend to hide long ones, and, as a large proportion of nodes in the core belong to 2- and 3-cycles, many longer cycles do not get counted at all.

4.5 Interpretation of cycles

2-cycles are composed of concretely related words (*e.g.*, *drug-coke*, *destiny-fate*, *einstein-genius*, ...). The vertex with highest 2-cycle multiplicity is *music* (22).

Words in 3- and 4-cycles often belong to the same lexical field. Examples of 3-cycles: *protect-guard-defend* or *space-universe-star*. The vertex (resp. edge) with highest 3-cycle multiplicity is *car* (86) (resp. *bad-crime* (11)). Examples of 4-cycles: *monster-dracula-vampire-ghost* or *flu-virus-infection-sick*.

Longer cycles are more difficult to describe: Relations linking words of a given cycle exhibit semantic drift with increasing length (cf. (Levary et al., 2012)). Examples of 5-cycles: *yellow-coward-chicken-soup-noodles* and *sleep-relax-music-art-beauty*.

The cumulated set of free associations reflects the way in which a group of people retrieved its semantic knowledge. As the associated graph is highly circular, this suggests that this knowledge is not stored in a hierarchical way (Steyvers and Tenenbaum, 2005). The large predominance of short cycles in the core may indeed be a natural consequence of the semantic information being acquired by means of associative learning (Ashcraft and Radvansky, 2009; Shanks, 1995).

4.6 FA core clustering

4.6.1 The walktrap community algorithm

Complex networks are globally sparse but contain locally dense subgraphs. These groups of highly interconnected vertices are called **communities** and convey important properties of the network.

Although the notion of community is difficult to define formally, the current consensus establishes that a partition $P = \{C_1, C_2, \ldots, C_k\}$ of the vertex set of a graph G represents a good community structure if the proportion of edges inside the C_i is higher than the proportion of edges between them (Fortunato, 2010).

Computing such communities in a large graph is generally computationally expensive (Lancichinetti and Fortunato, 2009). We use the so-called 'Walktrap' community detection algorithm (Pons and Latapy, 2006) for extracting communities from the FA networks. The idea lying behind this algorithm is that random walks on a graph will tend to get trapped in the densely connected subgraphs.

Let P_{ij}^t be the probability of going from vertex i to vertex j through a random walk of length t. The distance between two vertices i and j of the graph is defined as:

$$r_{ij}(t) = \sqrt{\sum_{k=1}^{n} \frac{(P_{ik}^t - P_{jk}^t)^2}{d(k)}}$$

where $d(k)$ is the degree of vertex k.

One defines the probability $P_{C,j}^t$ to go from community C to vertex j in t steps: $P_{C,j}^t = \sum_{i \in C} P_{ij}^t / |C|$, and then the distance is easily generalized for two communities C_1, C_2.

The algorithm starts with a partition $P_1 = \{\{v\} \in V\}$ of the initial graph into n communities each of which is a single vertex. At each step, two communities are chosen and merged according to the criterion described below and the distances between communities are updated. The process goes on until we obtain the partition $P_n = \{V\}$.

In order to reduce complexity, only adjacent communities are considered for merging. The decision is then made according to Ward's method (Everitt et al., 2001): at each step k, the two communities that minimize the mean σ_k of the squared distances between each vertex and its community are merged:

$$\sigma_k = \frac{1}{n} \sum_{C \in P_k} \sum_{i \in C} r_{iC}^2$$

4.6.2 Clustering of the core

We first identify the communities of the FA core using the Walktrap algorithm. We immediately observe that when the path length parameter increases, the number of identified communities decreases (*i.e.*, for a length of 2, we find 35 communities whereas for a length of 9, we only find 8 communities).

For a path length of 2, the algorithm extracts 35 communities, 7 of which contain more than 100 vertices, 3 of which contain between 100 and 50 vertices and 25 of which contain less than 50 vertices.

We observe that for most small communities (*i.e.*, the ones containing less than 50 vertices), there exists a clear relation between the labels of their ver-

tices. Typically, the labels are part of the same lexical field (*e.g.*, all the planets (except *earth*) or related by a common grammatical function (such as *why*, *where*, *what*, ...).

4.6.3 Clustering of the core co-links

We define the **k-cycle induced subgraph** of a graph G as the subgraph of G induced by the set of its vertices with k-cycle multiplicity > 0.

The **co-link graph** of a graph $G(V, E)$ is the undirected graph obtained by replacing each co-link (*i.e.*, 2-cycle) of the 2-cycle induced subgraph of G by a single undirected edge and removing all other edges.

The co-link graph of the FA core has 4'508 vertices and 8'309 edges for a density of 8×10^{-4}. It is composed of a single weakly connected component that can be seen as a projection of the strongest semantic links from the original graph. Extracting the co-link graph is thus an efficient way of selecting the set of most important semantic links (*i.e.*, the set of 2-cycles that appear in large predominance in the core compared to what is found in an equivalent random graph) while filtering out the noisy or negligible ones.

The sets of communities extracted by the Walktrap algorithm exhibit different degrees of granularity depending on the length parameter. For short paths, a large number of very small communities are returned (*e.g.*, 923 communities when length equals 2) whereas for longer paths the average size of the communities increases more and more.

The community detection exhibits thus a far finer degree of granularity for the core co-links graph than for the core itself. The size of the communities being much smaller in average, it is striking to notice to which extent the words of a given community are semantically related.

Examples of communities found in the core co-links graph include (*standards*, *values*, *morals*, *ethics*), (*hopeless*, *romantic*, *worthless*, *useless*), (*thesaurus*, *dictionary*, *vocabulary*, *encyclopedia*) or (*molecule*, *atom*, *electron*, *nucleus*, *proton*, *neutron*).

4.6.4 DD core clustering vs FA core clustering

The clustering of both cores has very different characteristics: We illustrate the neighborhoods of *conflict* for both cases in Fig. 2 and 3.

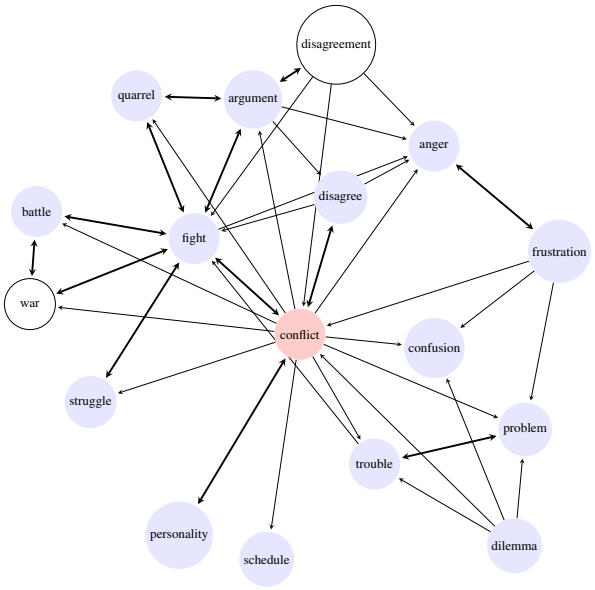

Figure 2: Neighborhood of *conflict* in the FA core
The set of words belonging to the neighborhood of *conflict* are clearly part of the same lexical field. The high density of co-links leads to cyclicity and we see that many directed triangles are present in the local subgraph (*e.g.*, *conflict-trouble-fight, conflict-argument-disagree*). We can even find triangles of co-links that link together words semantically strongly related (*e.g.*, *fight-war-battle, fight-quarrel-argument*). Nodes that are part of the neighborhood of *conflict* in both FA and DD are in empty circles.

On one hand, the words in communities of the DD core are in most cases either synonyms, *e.g.*, *(declaration, assertion, claim)* or an instance-of kind of relation, *e.g.*, *(signal, gesture, motion)* or *(zero, integer)*.

On the other hand, communities of the FA core are generally composed of words belonging to the same lexical field and sharing the same level of abstraction.

Moreover, we notice that it is often difficult to establish the semantic relation existing between words of many small communities (*i.e.*, containing less than 10 words) of the DD core. Two such examples are: (*choice*, *probate*, *executor*, *chosen*, *certificate*, *testator*, *will*) and (*numeral*, *monarchy*, *monarch*, *crown*, *significance*, *autocracy*, *symbol*, *interpretation*).

The comparison of DD and FA reveals, in a quantitative way, fundamental differences between the two realms. The interesting data are shown in table 1.

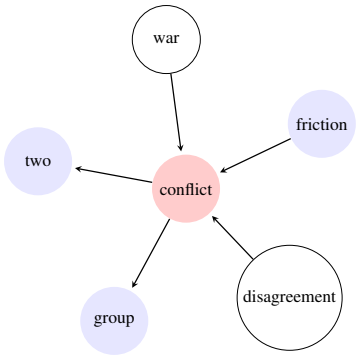

Figure 3: Neighborhood *conflict* in the DD core
First, we note that the neighborhood has a lower density than in the FA core. We also see that there is no cycle and there seems to be a flow going from source nodes to sink nodes. As it generally happens in the neighborhood subgraphs of the DD core, source nodes are rather specific words whereas sink nodes are generic words.

	FA core	DD core
# vertices	4'843	1'496
# edges	61'544	4'766
density	2.5×10^{-3}	2.1×10^{-3}
avg degree	25.4	6.37
max in-degree	313	59
directed diameter	10	29
characteristic path length	4.26	10.42
efficiency	2.5×10^{-1}	1.2×10^{-1}
clustering coefficient	8.5×10^{-2}	5.1×10^{-2}
assortativity	5.5×10^{-2}	6.1×10^{-2}

Table 1: Comparison FA vs DD

Note that while the FA core is in fact larger than the DD core, its diameter is smaller. This illustrates in a beautiful way the nature of free association as compared to the more neutral dictionary. In particular, the characteristic path length is smaller in the FA graph, because humans use generalized event knowledge (McRae and Matsuki, 2009) in free association, producing semantic shortcuts. For example, FA contains a direct link *mirage→water*, whereas in DD, the shortest path between the two words is *mirage→refraction→wave→water*.

5 The Bricks of Meaning

5.1 Extraction of the seed

We already saw that most vertices of the core belong to directed 2- and 3-cycles. Whereas 2-cycles establish strong semantic links (*i.e.*, synonymy or antonymy relations) and provide cyclicity to the underlying directed graph, we claim that 3-cycles (*i.e.*, triangles) form the set of elementary concepts of the core.

These structues are common to DD and to FA, but we will see that the links in FA are somehow more direct than in DD.

We call **seed** the subgraph of the core induced by the set V_3 of vertices belonging to directed triangles and **shell** the subgraph of the core induced by the set $V \backslash V_3$ (*i.e.*, the set of vertices with a null 3-cycle multiplicity), see Fig. 4.

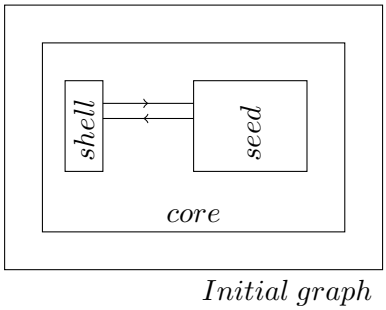

Figure 4: Composition of the FA graph
The graph of FA contains a giant SCC (the core). The subgraph of the core induced by the set of nodes belonging to at least one triangle also forms a giant component we call the 'seed'. The subgraph of the core induced by the set of nodes not belonging to any triangle is called the 'shell' and is composed of many small SCCs, including single vertices. Although the shell has a low density, its nodes are very well connected to the seed.

The shell contains 530 nodes and 309 edges. There are 7'035 edges connecting the shell to the seed. The shell consists of of many small SCCs and although its average degree is low (1.17), its vertices have on average many (13.27) connections to the seed.

The seed contains 4'313 vertices (89% of the core) and 54'197 edges. The first thing to notice is that it has 100 times more co-links (7'895) and 20 times more triangles (13'119) than an equivalent random graph. We call **shortcuts** the 32'773 edges of the seed that do not belong to 3-cycles, see Fig. 5.

The seed obviously also contains cycles whose length is greater than 3. One can check that there exist only 5 basic motifs involving 2 attached triangles and 1 shortcut for creating 4- and 5-cycles, and that linking 2 isolated triangles with 2 shortcuts also per-

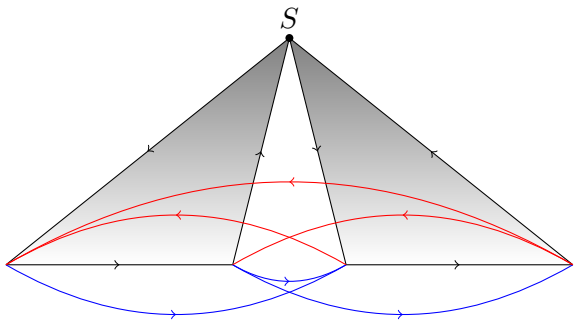

Figure 5: Shortcut edges between two triangles sharing a single vertex S
Two triangles can share 0, 1 or 2 vertices. For each of these three basic motifs, we count the maximum number of shortcut edges (*i.e.*, edges not belonging to 3-cycles) that can be added. By linking two triangles, these shortcuts permit to move two basic semantic units closer together and create longer cycles (*i.e.*, 4, 5, and 6-cycles). Long cycles can be thus considered as groupings of basic semantic units. In the case of two triangles sharing one vertex for example, it is possible to add at most 6 shortcuts, whereas, for two triangles sharing two vertices, at most 2 shortcuts can be added.

mit to form 4-, 5- and 6-cycles. All longer cycles are simply made of a juxtaposition of these basic motifs.

Furthermore, there is a limit on the number of shortcuts that can possibly be added in the seed before it gets saturated, as all its vertices belong to at least one triangle. We show that at most 16 shortcuts can be added between two isolated triangles, at most 6 between 2 triangles sharing 2 vertex and at most 2 between 2 triangles sharing 2 vertices (see Fig. 5).

5.2 The elementary lexical fields

Once the seed is isolated, we go on digging into its structure. We focus on the arrangements of triangles as they constitute the set of elementary concepts.

We start by removing all shortcuts from the seed and convert it then to an undirected graph, in order to get a homogeneous simplicial 2-complex.

Let **t** be the graph operator which transforms a graph G into the intersection graph $\mathbf{t}G$ of its 2-simplices (*i.e.*, triangles sharing an edge). We apply **t** to the homogeneous simplicial 2-complex found previously. The result represents the links between the basic semantic units of the seed. We call **seed-crux** the giant WCC in the intersection graph.

We enumerate the 8'380 maximal cliques of FA seed-crux and get the list of words composing each

Distance	Acc	κ	KS
original	–	0.404	30
1	74	0.522	42
2	97	0.899	89
∞	99	0.899	89

Table 2: Accuracy, κ, and *count*$(p < 0.05)$ for KS

clique. By removing the ones that are subsets of bigger lists, we finally obtain 3'577 lists of words .

These lists of words have a rather small and homogeneous size (between 4 and 17) and 95% have a size comprised between 4 and 10. More interestingly, they clearly define well-delimited lexical fields. We will show this through two experiments in the following sections. A few examples include *(honest, trustworthy, reliable, responsible)*, *(stress, problem, worry, frustration)* and *(data, process, computer, information)*.

From a topological perspective, we deduce that bunches of triangles (*i.e.*, cliques of elementary concepts) span the seed in a homogeneous way. These bunches form a set of cohesive lexical fields and constitute essential bricks of semantic knowledge.

5.3 Semantic similarity of the lexical fields

In order to quantify the relative meaning of words in the lexical fields of the seed-crux, we define the following semantic similarity metric based on the Wordnet *WUP* metric (Wu and Palmer, 1994) for a given set of words L:

$$S_\ell(L) = 2 \sum_{w_i,w_j \in L, w_i \neq w_j} S_w(w_i, w_j)/(|L|(|L|-1))$$

where $S_w(w_i, w_j) = \max_{S_k \ni w_i \text{and} S_\ell \ni w_j} \{wup(S_k, S_\ell)\}$ and wup is the WUP semantic metric and S_k and S_ℓ are Wordnet synsets.

The average value of S_ℓ for the set of cliques of seed-crux is 0.6 whereas it is only 0.43 for randomly sampled set of words. This suggests the corresponding lists of words are indeed semantically related. We will show the strength of this relation in the following experiment with human raters.

5.4 Human evaluation of the lexical fields

To validate our findings, we conducted an empirical evaluation through human annotators. Starting from

the 1'204 4-groups, we designed the following experiment: We corrupt the groups by exchanging one of the 4 elements with a randomly chosen word at a distance from the group of 1, 2, and "infinity" (*i.e.*, any word of the whole core). We presented 100 random samples for each of the 3 distances as well as 100 unperturbed groups (*original*) to annotators at Amazon Mechanical Turk[1], asking which word fits the group the least. Intuitively, the closer the randomly chosen words get to the group, the closer the distribution of the votes for each sample should be to the uniform distribution. We collected 10 votes for each of the 4 problems of 100 random samples. We calculated accuracy (*i.e.*, the relative frequency of correctly identified random words) for the 3 random confounder experiments and Fleiss' κ. Further, we used the Kolmogorov-Smirnov (KS) test for how uniform the label distribution is, reporting the relative frequency of samples that are significantly ($p < 0.05$) different from the uniform distribution. The results of this experiment are summarized in Table 2 and show clearly that the certainty about the "odd man out" increases together with the distance.

5.5 Error analysis

If we view our results as a resource for a downstream task, it is important to know about possible downsides. First, we note that there are words which are not in a triangle and will thus be missing in the intersection graph. This is an indication that the corresponding word is less well embedded contextually, so conversely, any prediction made about it from the data may be less reliable. Additionally, semantic leaps caused by generalized event knowledge may lead to lesser-connected groups such as (*steel*, *pipe*, *lead*, *copper*). Jumps like these may or may not be desired in a subsequent application.

6 The Case of the EAT FA dataset

The Edinburgh Associative Thesaurus (EAT) (Kiss et al., 1973) is a large dataset of free associations. We extract the EAT FA seed-crux with the previously described methods.

We start by generating the initial graph (23'219 vertices and 325'589 edges), then extract its core (7'754 vertices and 247'172 edges) and its seed (7'500 vertices and 238'677 edges). It is interesting to notice at this stage that the EAT seed contains 74% of the words belonging to the USF seed. After generating the seed-crux which contains 63'363 vertices, 6'825'731 edges, and 342'490 maximal cliques, we finally obtain 40'998 lists of words.

These lists comprise between 4 and 233 words but 80% of them have a relatively small size between 4 and 20. Although we find exceptions for this graph, most of the extracted lists again form well-delimited lexical fields (*e.g.*, *(health, resort, spa, bath, salts)* or *(god, devil, angel, satan)*.

Comparing the two association experiments, we see that the local topologies are quite similar. Both FA cores have a high density of connected triangles, whereas cycles in the DD graph tend to be longer and most triangles are isolated. This can be attributed to the different ways in which DD and FA are obtained, the former being built rationally by following a humanly-driven process and the latter reflecting an implicit collective semantic knowledge.

7 Related Work

A number of metrics like *Latent Semantic Analysis* (Deerwester et al., 1990) and *Word Association Spaces* (Steyvers et al., 2004) have been recently developed for quantifying the relative meaning of words. As the topological properties of free association graphs reflect key aspects of semantic knowledge, we believe some graph theory metrics could be used efficiently to derive new ways of measuring semantic similarity between words.

Topological analysis of the Florida Word Associations (FA) was started by (Steyvers and Tenenbaum, 2005; Gravino et al., 2012), who extracted global statistics. We follow the basic methodology of these studies, but extend their approach. First, we conduct deeper analyses by examining the neighborhood of nodes and extracting the statistics of cycles. Second, we compare the properties of FA and DD graphs.

Word clustering based on graphs has been the subject of various earlier studies. Close to our work is (Widdows and Dorow, 2002). These authors recognize that nearest-neighbor-based clustering of co-occurrence give rise to semantic groups. This type of approach has since been applied in various modified forms, *e.g.*, by (Biemann, 2006) who performs label-

[1] `http://www.mturk.com`

propagation based on randomized nearest neighbors, or Matsuo et al. (2006) who perform greedy clustering. Hierarchical clustering algorithms (*e.g.*, (Jonyer et al., 2002; Manning et al., 2008)) are related as well, however, the key difference is that in hierarchical clustering, the granularity of a cluster is difficult to determine.

Dorow et al. (2005) recognize that triangles form semantically strongly cohesive groups and apply clustering coefficients for word sense disambiguation. Their work focuses on undirected graphs of corpus co-occurrences whereas our work builds on directed associations. Building on this work, we take finer topological graph structures into account, which is one of the main contributions in this paper.

8 Conclusion

The cognitive process of discrete free association being an epiphenomenon of our semantic memory at work, the cumulative set of free associations of the USF dataset can be viewed as the projection of a collective semantic memory.

To analyze the semantic memory, we use the tools of graph theory, and compare it also to dictionary graphs. In both cases, triangles play a crucial role in the local topology and they form the set of elementary concepts of the underlying graph. We also show that cohesive lexical fields (taking the form of cliques of concepts) constitute essential bricks of meaning, and span the core homogeneously at the global level; 89% of all words in the core belong to at least one triangle, and 77% belong to cliques of triangles containing 4 words (i.e., pairs of triangles sharing an edge or forming tetrahedras). As the words of a graph of free associations acquire their meaning from the set of associations they are involved in (Deese, 1962), we go a step further by examining the neighborhood of nodes and extracting the statistics of cycles. We further check through human evaluation that the clustering is strongly related to meaning, and furthermore, the meaning becomes measurably more confused as one walks away from a cluster.

-¿ -¿I call the pairs of triangles sharing an edge the 2-clovers ;-)

Comparing dictionaries to free association, we find the free association graph being more concept driven, with words in small clusters being on the same level of abstraction. Moreover, we think that graphs of free associations could find interesting applications for *Word Sense Disambiguation* (*e.g.*, (Heylighen, 2001; Agirre and Soroa, 2009)), and could be used for detecting psychological disorders (*e.g.*, depression, psychopathy) or whether someone is lying (Hancock et al., 2013; Kent and Rosanoff, 1910).

Finally, we believe that studying the dynamics of graphs of free associations may be of particular interest for observing the change in meaning of certain words (Deese, 1967), or more generally to follow the cultural evolution arising among a social group.

Abstract

Creating a language-independent meaning representation would benefit many cross-lingual NLP tasks. We introduce the first unsupervised approach to this problem, learning clusters of semantically equivalent English and French relations between referring expressions, based on their named-entity arguments in large monolingual corpora. The clusters can be used as language-independent semantic relations, by mapping clustered expressions in different languages onto the same relation. Our approach needs no parallel text for training, but outperforms a baseline that uses machine translation on a cross-lingual question answering task. We also show how to use the semantics to improve the accuracy of machine translation, by using it in a simple reranker.

1 Introduction

Identifying a language-independent semantics is a major long term goal of computational linguistics, and is interesting both theoretically and for practical applications. It assumes that semantically equivalent sentences in any language can be mapped onto a common meaning representation. Such a representation would be of great utility for tasks such as translation, relation extraction, summarization, question answering, and information retrieval. Regardless of whether it is even possible to create such a semantics, we show that an incomplete version can be useful for downstream tasks.

Semantic machine translation aims to map a source language to a language-independent meaning representation, and then generate the target language translation from this. It is hoped this would alleviate the difficulties of simpler models when translating between languages with very different word ordering and syntax (Vauquois, 1968). Despite many attempts to define interlingual representations (Mitamura et al., 1991; Beale et al., 1995; Banarescu et al., 2013), state-of-the-art machine translation still uses phrase-based models (Koehn et al., 2007). The major obstacle to defining interlinguas has been devising a meaning representation that is language-independent, but capable of expressing the limitless number of meanings that natural languages can express (Dorr et al., 2004).

Our approach avoids this problem by utilizing the methods of distributional semantics. Recent work has shown that paraphrases of expressions can be learned by clustering those with similar arguments (Poon and Domingos, 2009; Yao et al., 2011; Lewis and Steedman, 2013)—for example learning that *X wrote Y* and *X is the author of Y* are equivalent if they appear in a corpus with similar *(X, Y)* argument-pairs such as {*(Shakespeare, Macbeth), (Dickens, Oliver Twist)*}. We extend this to the multilingual case, aiming to also map the French equivalents *X a écrit Y* and *Y est un roman de X* on to the same cluster as the English paraphrases. Conceptually, we treat a foreign expression as a paraphrase of an English expression. The cluster identifier can be used as a predicate in a logical form, suggesting that the fundamental predicates of an interlingua can be learnt in an unsupervised manner via clustering.

In this paper we focus on learning binary relations between named entities. This problem is much simpler than attempting complete interlingual semantic

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 681–692,
Seattle, Washington, USA, 18-21 October 2013.

interpretation, but the approach could be generalized. This class of expressions has proved extremely useful in the monolingual case, with direct applications for question answering and relation extraction (Poon and Domingos, 2009; Mintz et al., 2009), and we demonstrate how to use them to improve machine translation. It is important to be able to extract knowledge across languages, as many facts will not be expressed in all languages—either due to less-complete encyclopedias being available in some languages, or facts being most relevant to a single country.

In contrast to most previous work on machine translation and cross-lingual clustering, our method requires no parallel text (see Section 8 for discussion of some exceptions). It instead exploits an alignment between named-entities in different languages. The limited size of parallel corpora is a significant bottleneck for machine translation (Resnik and Smith, 2003), whereas our approach can be used on much larger monolingual corpora. This means it is potentially useful for language-pairs where little parallel text is available, for domain adaptation, or for semi-supervised approaches.

2 Basic Approach

Our work builds on clustering-based approaches to monolingual distributional semantics, aiming to create clusters of semantically equivalent predicates, based on their arguments in a corpus. In each language, we first map each sentence in a large monolingual corpus onto a simple logical form, by extracting binary predicates between named entities. Then, we cluster predicates both within and between languages into those with similar arguments.

When parsing a new sentence, instead of using the monolingual predicate, we use the cluster identifier as a language-independent semantic relation, as shown in Figure 1. The resulting logical form can be used for inference in question answering.

Unlike traditional approaches to translation, this does not require parallel text—but it does impose some additional constraints on language resources. Our approach requires:

- A large amount of factual text, as we rely on the same facts being expressed in different languages. We use Wikipedia, which contains articles in 250 languages, including 121 with at least 10,000 articles.[1] Other domains, such as Newswire, may also be effective.
- A method for extracting binary relations from sentences. This is straightforward from dependency parses, which are available for many languages. It is also possible without a parser, with some language-specific work (Fader et al., 2011). We describe our approach in Section 3.
- A method for linking entities in the training data to some canonical representation. McNamee et al. (2011) report good results on this task in 21 languages. We describe our method for this in Section 4.1.

3 Predicate Extraction

Our method relies on extracting binary predicates between entities from sentences. Various representations have been suggested for binary predicates, such as Reverb patterns (Fader et al., 2011), dependency paths (Lin and Pantel, 2001; Yao et al., 2011), and binarized predicate-argument relations derived from a CCG-parse (Lewis and Steedman, 2013). Our approach is formalism-independent, and is compatible with any method of expressing binary predicates.

We choose the CCG-based parser of Lewis and Steedman (2013) for several reasons. It outputs a logical form derived automatically from the CCG-parse, containing predicates such as: $write_{arg0,arg1}(shakespeare,macbeth)$. By using the close relationship between the CCG syntax and semantics, it is able to generalize over many semantically equivalent syntactic constructions (such as passives, conjunctions and relative clauses), meaning we can map both *Shakespeare wrote Macbeth* and *Macbeth was written by Shakespeare* to the same logical form. Using a dependency-based representation, these would have different predicates, which would need to be clustered later. CCG also has a well developed theory of operator semantics (Steedman, 2012), so is able to represent semantic operators such as quantifiers, negation and tense—understanding these is crucial to high performance on question answering or translation tasks. As in

[1] As of June 2013.

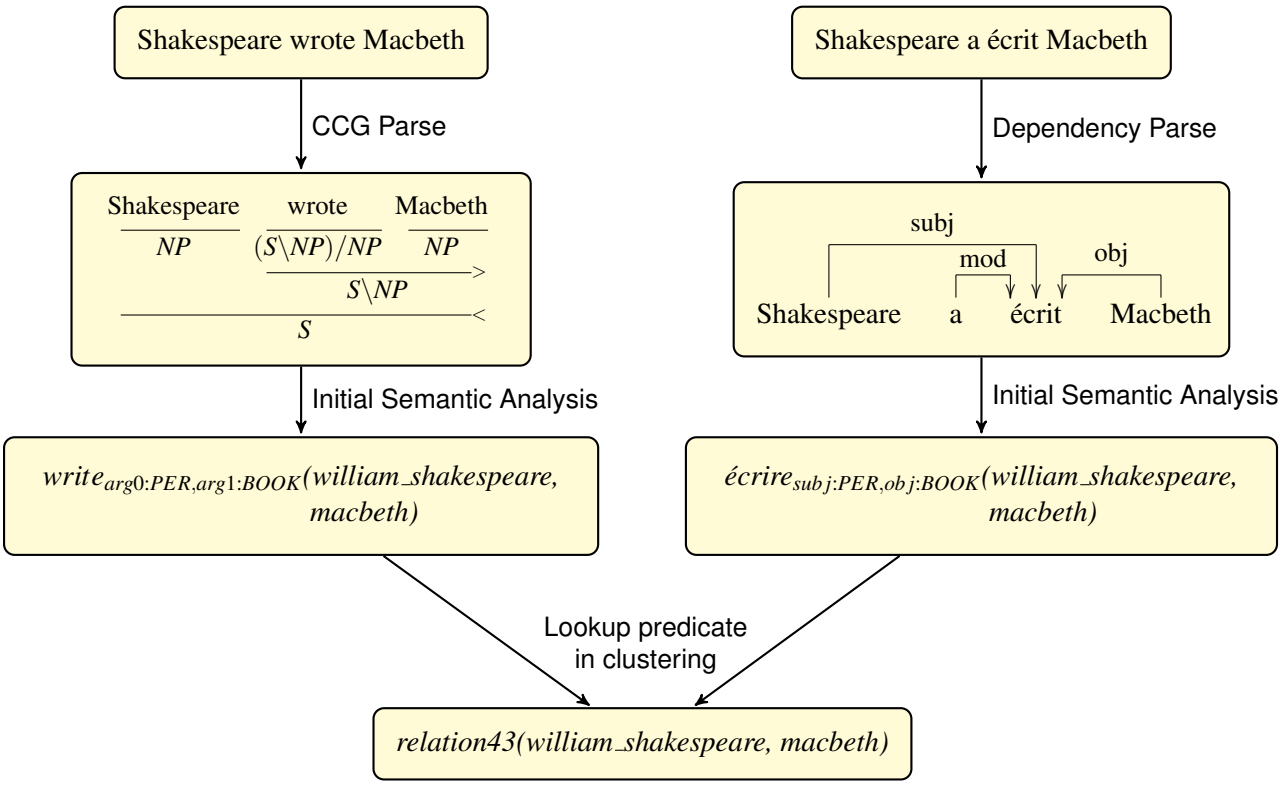

Figure 1: Example showing how our system can map sentences in different languages to the same meaning representation, assuming we have clustered the equivalent predicates $write_{arg0:PER,arg1:BOOK}$ and $écrire_{subj:PER,obj:BOOK}$

Lewis and Steedman (2013), clusters derived from the output from the parser can be integrated into the lexicon, allowing us to build logical forms which capture both operator and lexical semantics.

Accurate CCG syntactic parsers are currently only available for English, whereas dependency treebanks and parsers exist for many languages (Buchholz and Marsi, 2006). Consequently, for French we use the dependency path representation, which captures the nodes and edges connecting two named entities in a dependency parse. The extraction of these paths is language-independent, and does not depend on the dependency grammar used, which means our approach could be adapted to new languages with minimal work.

4 Entity Semantics

4.1 Entity Linking

As discussed, our approach assumes that semantically similar predicates will have similar argument entities. This requires us to be able to identify coreferring entities across languages during training. In the monolingual case, it suffices to represent entities by the string used in the sentence. This is inadequate in the multilingual case, as many entities may be referred to by different names in different languages—for example the *United States* translates as *les États-Unis* in French and *die Vereinigte Staaten* in German. This problem is worsened by the ambiguity of named-entity strings—for example, in the context of a sports article, *United States* may refer specifically to a team, rather than a country.

Recent work on multilingual named-entity linking (McNamee et al., 2011) shows how to link named entities in multiple languages onto English Wikipedia articles, which can be used as unique identifiers for entities. This means that we could gain the information we need from unrestricted text. However, as we use Wikipedia itself for our training corpora, we can bootstrap entity information directly from its markup. Wikipedia contains cross-language links, e.g. between the United States articles in different languages, allowing us to determine the equivalence of entities in differ-

ent languages. Wikipedia links also help us automatically disambiguate entities to a given article. For unlinked named-entity mentions, we perform some simple heuristic co-reference—based on word-overlap with previously mentioned entities in the document, whether the mention name is the title of a Wikipedia article, or whether the mention name is a Freebase (Bollacker et al., 2008) alias of an entity. We emphasise that this does not mean our approach is only applicable to the Wikipedia corpus.

4.2 Entity Typing

It has become standard in clustering approaches to distributional semantics to assign types to predicates before clustering, and only cluster predicates with the same type (Schoenmackers et al., 2010; Berant et al., 2011; Yao et al., 2012). This is useful for resolving ambiguity—for example the phrase *born in* may express a place-of-birth or date-of-birth relation depending on whether its second argument has a *LOC* or *DAT* type. Ambiguous expressions may translate differently in other languages—for example, the two interpretations of *was born in* translate in French as *est né à* and *est né en* respectively. The type of a predicate is determined by the type of its arguments, and predicates with different types are treated as distinct.

Lewis and Steedman (2013) induce an unsupervised model of entity types using Latent Dirichlet Allocation (Blei et al., 2003), based on selectional preferences of verbs and argument-taking nouns. When applied cross-linguistically, we found this technique tended to create language-specific topics. Instead, we exploit the fact that many Wikipedia entities are linked to the Freebase database, which has a detailed manually-built type-schema. This means for a Wikipedia entity, we can look up its set of types in Freebase.[2] We use the simplified type-set of 112 types created by Ling and Weld (2012). Where entities have multiple types (for example, Shakespeare is both an *author* and a *person*), we create a separate relation for each type.

[2]Named entities not present in Freebase are ignored during training.

5 Relation Clustering

Predicates are clustered into those which are semantically equivalent, based on their argument-pairs in a corpus. The initial semantic analysis is run over the corpora, and for each predicate we build a vector containing counts for each of its argument-pairs (we divide these counts by the overall frequency of an argument-pair in the corpus, so that rarer argument-pairs are more significant). These vectors are used to compute similarity between predicates.

First, we run the clustering algorithm on each language independently, and then we attempt to find an alignment between the clusters. Duc et al. (2011) and Täckström et al. (2012) use similar two-step approaches. Running the clustering on both languages simultaneously was found to produce many clusters only containing predicates from a single language. This appears to be because even if predicates in two different languages are truth-conditionally equivalent, the language biases the sample of entity-pairs found in a corpus. For example, the French verb *écrire* may contain more French author/book pairs than the English equivalent *write*. This difference can make the verbs appear to represent different predicates to the clustering algorithm. Our two-step approach also means that advances in monolingual clustering should directly lead to improved cross-lingual clusters.

5.1 Monolingual Clustering

Following Lewis and Steedman (2013), we use the Chinese Whispers algorithm (Biemann, 2006) for monolingual clustering—summarized in Algorithm 1. The algorithm is non-parametric, meaning that the number of relation clusters is induced from the data, and highly scalable. We create a separate graph for each type of predicate in each language—for example, predicates between types *AUTHOR* and *BOOK* in French (so only predicates with the same type will be clustered). We create one node per predicate in the graph, and edges represent the distributional similarity between the predicates.

The distributional similarity between a pair of predicates is calculated as the cosine-similarity of their argument pair vectors in the corpus. Many more sophisticated approaches to determining similarity have been proposed (Kotlerman et al., 2010;

Weisman et al., 2012), and future work should explore these. We prune nodes with less than 25 occurrences, edges of weight less than 0.05, and a short list of stop predicates. We find many of our French dependency paths do not have a clear semantic interpretation, so add the requirement that dependency paths contain at least one content word, contain at most 5 edges, and that one of the dependencies connected to the root is subject, object or the French preposition *de*.

Data: Set of predicates P
Result: A cluster assignment r_p for all $p \in P$
$\forall p \in P : r_p \longleftarrow$ unique cluster identifier;
while *not converged* **do**
  randomize order of P
  for $p \in P$ **do**
    $r_p \longleftarrow \arg\max_r \sum_{p'} \mathbb{1}_{r=r_{p'}} sim(p, p')$
  end
end

Algorithm 1: Chinese Whispers algorithm, used for monolingual predicate clustering. $sim(p, p')$ is the distributional similarity between p and p', and $\mathbb{1}_{r=r'}$ is 1 iff r=r' and 0 otherwise

5.2 Cross-lingual Cluster Alignment

We use a simple greedy procedure to find an alignment between the monolingual clusters in different languages. First, the entity-pair vectors for each predicate in a relation cluster are merged. Then, the cosine similarity between entity-pair vectors for clusters in different languages is calculated—we base this only on argument-pairs that occur in both languages, to reduce the potential bias of some entities being more relevant to one language. Clusters are then greedily aligned, in order of their similarity, as in Algorithm 2 (pruning similarities less than 0.01). This means that clusters are aligned with their most similar foreign cluster. We only attempt to align clusters with the same argument types.

6 Cross Lingual Question Answering Experiments

We evaluate our system on English and French, using Wikipedia for corpora. The English corpus is POS-tagged and CCG-parsed with the C&C tools

Data: Sets of monolingual relation clusters R_{L1} and R_{L2}
Result: An alignment between the monolingual clusters A
$A \longleftarrow \{\}$;
while $R_{L1} \neq \{\} \wedge R_{L2} \neq \{\}$ **do**
  $(r1, r2) \longleftarrow \arg\max_{(r_1, r_2) \in R_{L1} \times R_{L2}} sim(r1, r2)$;
  $A \longleftarrow A \cup \{(r1, r2)\}$;
  $R_{L1} \longleftarrow R_{L1} / \{r1\}$;
  $R_{L2} \longleftarrow R_{L2} / \{r2\}$;
end

Algorithm 2: Cluster alignment algorithm

English	French
X invades Y	X envahit Y invasion de Y par X
X orbits Y	X est un satellite de Y X est une lune de Y
X is a skyscraper in Y	X est un gratte-ciel de Y
X is a novel by Y	X est un roman de Y
X joins Y X is a member of Y	X adhère à Y X entre dans Y X rejoint Y

Table 1: Some example cross-lingual clusters. Predicates are given in a human-readable form, and predicate types are suppressed.

(Clark and Curran, 2004). The French corpus is tagged with MElt (Denis et al., 2009) and parsed with MaltParser (Nivre et al., 2007), trained on the French Treebank (Candito et al., 2010). Wikipedia markup is filtered using Wikiprep (Gabrilovich and Markovitch, 2007)—replacing internal links with the name of their target article, to help entity linking. Some example clusters learnt by our model are shown in Table 1. We find that the cross-lingual clusters typically contain more French expressions than English, possibly due to the differing sizes of the corpora—adjusting the parameters in Section 5 results in larger clusters, but introduces noise.

6.1 Experimental Setup

We evaluate our system on a cross-lingual question answering task, similar to monolingual QA evaluations by Poon and Domingos (2009) and Lewis and

Steedman (2013). A question is asked in language *L*, and is answered by the system from a corpus of language *L'*. Human annotators are shown the question, answer entity, and the sentence that provided the answer, and are then asked whether the answer is a reasonable conclusion based on the sentence. Whilst this task is much easier than full translation, it is both a practical application for our approach, and a reasonably direct extrinsic evaluation for our cross-lingual clusters.

Following Poon and Domingos (2009) and Lewis and Steedman (2013), the question dataset is automatically generated from the corpus. This approach has the advantage of evaluating on expressions in proportion to their corpus frequency, so understanding frequent expressions is more important than rare ones. We then sample 1000 questions for each language, by extracting binary relations matching certain patterns ($X \overset{nsubj}{\leftarrow} verb \overset{dobj}{\rightarrow} Y$, $X \overset{nsubj}{\leftarrow} verb \overset{pobj}{\rightarrow} Y$ or $X \overset{nsubj}{\leftarrow} be \overset{dobj}{\rightarrow} noun \overset{pobj}{\rightarrow} Y$), and removing one of the arguments. For example, from the sentence *Obama lives in Washington* we create the questions *X lives in Washington?*, and *Obama lives in X?*.[3] Answers are judged by fluent bilingual humans, and do not have to match the entity that originally instantiated *X*. Multiple answers can be returned for the same question.

Our system attempts this task by mapping both the question and candidate answer sentences (which will be in a different language to the question) on to a logical form using the clusters, and determining whether they express the same relation. This tests the ability of our approach to cluster expressions into those which are semantically equivalent between languages. It is possible for entities to have multiple types (see Section 4.2), and answers are ranked by the number of types in which the entailment relation is predicted to hold.

[3]Questions are given in a declarative form, to make the tasks simpler for the machine translation baseline. We found the machine translation performed poorly on questions such as *What is Obama the president of?*, as inverted word-orders and long-range dependencies are difficult to handle with re-ordering models and language models (though are straightforward to handle for a CCG system (Clark et al., 2004)). We find that machine translation performs much better on declarative equivalents, such as: *Obama is the president of X*.

6.2 Baseline

Our baseline makes use of the Moses machine translation system (Koehn et al., 2007), and is similar to previous approaches to cross-lingual question answering such as Ahn et al. (2004). We train a Moses model on the Europarl corpus (Koehn, 2005). First, the question is translated from language *L* to *L'*, taking the 50-best translations. As the questions are typically shorter than corpus sentences, this is substantially easier for the machine-translation than translating the corpus. These are then parsed, and patterns are extracted (as in Section 3). We also manually supply a translation of the named-entity in the question (based on the Freebase entity name translation), to avoid penalizing the translation system for failing to translate named-entities that have not been seen in its training data. These patterns are then used to find answers to the questions. Answers are ranked by the score of the best translation that produced the pattern. Figure 2 illustrates this pipeline.

The choice of languages is very favourable to the machine-translation system, English and French have similar word-order, and there is a large amount of parallel text available (Koehn and Monz, 2006). Our system works with any word-order, and does not require parallel text for training, so we would expect better performance relative to machine-translation on other language pairs. Future work will experiment with more diverse languages. The sentences to be translated are also very short, reducing the potential for error.

6.3 Results

Results are shown in Table 3, based on a sample of 100 answers from the output of each of the systems. Unsurprisingly, the machine-translation has high accuracy on this task, given the choice of languages and the short queries. Pleasingly, our clusters achieve similar accuracy, with much greater recall, with no usage of parallel text.

Examining the results, we see that the distribution of answers is highly skewed for all systems, with many answers to a smaller number of questions (multiple answers can be returned to the same question). This is due to the Zipfian nature of language, the difficulty of the task (which is far from

Question	Answer
X dies in Moscow	**Sergueï Guerassimov** meurt d'une crise cardiaque le mardi 26 novembre 1985 à Moscou
Germany invades X	... depuis l'invasion de la **Pologne** par l'Allemagne et l'URSS
X wins the FA Cup	**Portsmouth FC** remporte la FA Challenge Cup en s'imposant en finale face à Wolverhampton Wanderers FC

X est une ville de Kirghizistan	**Il'chibay** is a village in the Issyk Kul Province of Kyrgyzstan

Table 2: Example questions correctly answered using our clusters, with the answer entity highlighted in bold.

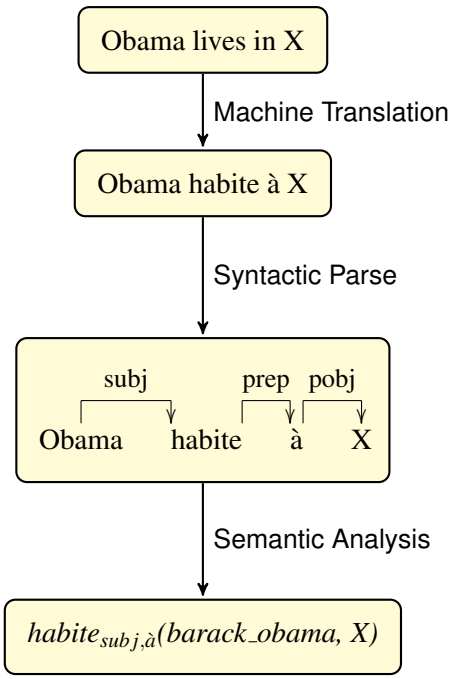

Figure 2: Pipeline used by baseline system for answering French questions. The pattern extracted from the translated sentence is used to search for answers in an English corpus.

English→ French	Answers	Correct
Baseline	269	86%
Clusters (best 270)	270	100%
Clusters (all)	1032	72%
French→ English	**Answers**	**Correct**
Baseline	274	85%
Clusters (all)	401	93%

Table 3: Results on wide-coverage Question Answering task. Best-N results are shown to illustrate the accuracy of our cluster-based system at the same rank as the baseline. It is not possible to give a recall figure, as the total number of correct answers in the corpus is unknown. English→ French results are from the full French Wikipedia corpus, whereas French→ English results are from a 10% sample.

solved in the monolingual case), and the possibility that questions may have no answers in the foreign corpus. This is particuarly true for the clustering approach—although the clustering system finds more answers with the English corpus, the baseline system answers slightly more unique questions (57 vs 66). The 1032 answers found by the clusters in the French corpus came from just 56 questions (compared to 29 unique questions answered by the baseline). This suggests that the translations found by the clustering can be more useful than those of Moses on this task—for example, it may find an equivalence between a rare French term and a common related English term, where machine translation may only find a more literal translation.

Despite this, we see the clusters have learnt to

paraphrase a variety of relations between languages with high accuracy, suggesting that there is much potential for the use of unsupervised clusters in cross-lingual semantic applications. Some examples answers are given in Table 2. Most of the errors are caused by a small number of questions.

7 Translation Reranking Experiments

Ultimately, we would like to be able to translate using semantic parsing with cross-lingual clusters. As a step towards this, we investigated whether we could rerank the output of a machine translation system, on the basis of whether the semantic parse of the source sentence is consistent with that of candidate translations.

We sample French sentences where we can produce a semantic parse (i.e. we can extract a predicate between named entities that maps to a cross-lingual cluster). These sentences are translated to English using Moses, taking the 50-best list, and semantic parses are produced for each of these. If the semantic parse for the 1-best translation does not match the source semantic parse, we take the parse from the 50-best list that most closely matches it—otherwise we discard the sentence from our evaluation, as our semantics agrees with the machine-translation.

To ensure that the evaluation focuses on the clusters, we try to exclude several other factors that might affect the results. The coverage of our CCG parsing and semantic analysis drops significantly on noisy translated sentences, and potentially acts as a language model by failing to produce any semantic parse on ungrammatical output sentences. We therefore only consider sentences where we can produce a semantic parse for the 1-best machine translation output. We also try to avoid penalizing the machine-translation system for failing to translate named entities correctly, so we do not attempt to rerank sentences where the entities from the source sentence are not present in the 1-best translation.

Human annotators were shown the source sentence, the 1-best translation, and the translation chosen by the reranker (the translations were shown in a random order). To focus the evaluation on the semantic relations we are modelling, we ask the annotators which sentence best preserves the meaning between the named entities that have different relations in the semantic parse. This avoids our system being penalized for choosing a translation that is worse in aspects other than the relations it is modelling. An example is shown in Table 4. The data was annotated jointly by two fluent bilingual speakers, who reported high agreement on this task.

	Percentage of translations preferred
1-best Moses translation	5%
Cluster-based Reranker	39%
No preference	56%

Table 5: Human preference judgements for the translation reranking experiment, based on a sample of 87 sentences. Results show the percentage of sentences for which the annotators preferred the original translation, the reranked translation, or neither. As discussed in the text, results where annotators had no preference were typically due to syntactic parse errors.

Results are shown in Table 5, and are highly encouraging, with the original Moses output being preferred to the reranked translation in only 5% of cases where our model makes a positive prediction.

Inspecting the results, we see that many of the cases where the annotators had no preference were caused by syntactic parse errors. For example, if the 1-best translation is correct, but a prepositional phrase is incorrectly attached, it will appear to have an incorrect semantics. A similar translation in the 50-best list may be correctly parsed, and consequently selected by our reranker. However, a human will have no preference between these translations. Incorporating K-Best parsing into our pipeline may help mitigate against such cases.

This preliminary experiment suggests that there is potential for future improvements in machine translation using cross-lingual distributional semantics. The system only attempts to rerank a very small proportion of sentences, but we believe the coverage could be greatly improved by including relations between common nouns (rather than just named-entities)—future work should explore this.

8 Related Work

Our work builds on recent progress in monolingual distributional semantics (Poon and Domingos, 2009; Yao et al., 2011; Lewis and Steedman, 2013) by

Source	Le Princess Elizabeth arrive à Dunkerque le 3 août 1999
Machine translation 1-best	Le Princess Elizabeth is to manage to Dunkirk on 3 August 1999
Reranked translation	The Princess Elizabeth arrives at Dunkirk on 3 August 1999

Table 4: Example sentence that is reranked by our clusters. Human evaluators were asked which translation best preserved the meaning between *Princess Elizabeth* and *Dunkirk*.

clustering typed predicates into those which are semantically equivalent. We also show how to bootstrap semantic information about entities from the Wikipedia markup, and believe this makes it an interesting corpus for future work on monolingual distributional semantics.

Cross-language Latent Relational Analysis (Duc et al., 2011) is perhaps the most similar previous work to ours, which moves the work of Turney (2005) into a multilingual setting. Duc et al. (2011) aim to compute, for example, that the 'latent relation' between *(Obama, US)* in an English corpus is similar to that between *(Cameron, UK)* in a foreign corpus. This is solved by finding all textual patterns between the two entity-pairs, and computing their overall similarity. Like us, they compute similarity between expressions in different languages based on named-entity arguments and clustering (unlike us, they also rely on machine translation for computing similarity). A key difference is that their system aims to understand the overall relation between an entity-pair based on many observations, whereas our approach attempts to understand each sentence individually (as is required for tasks such as translation).

Various recent papers have explored the relationship between translation and monolingual paraphrases —for example Bannard and Callison-Burch (2005) create paraphrases by pivoting through a foreign translation, and Callison-Burch et al. (2006) show that including monolingual paraphrases improves the quality of translation by reducing sparsity. The success of these approaches depends on the many-to-many relationship between equivalent expressions in different languages. Our approach aims to model this relationship explicitly by clustering all equivalent paraphrases in different languages.

Current state-of-the-art machine translation systems circumvent the problem of full semantic interpretation, by using phrase-based models learnt from large parallel corpora (Brown et al., 1993). Although this approach has been very successful, it has significant limitations—for example, when translating between languages with very different word-orders (Birch et al., 2009), or with little parallel text.

Semantic machine translation aims to map the source language to an interlingual semantic representation, and then generate the target language sentence from this. Jones et al. (2012) show how this can be done on a small dataset using hyperedge replacement grammars. A major obstacle to this is designing a suitable meaning representation, which involves choosing a set of primitive concepts which are abstract enough to be capable of expressing meaning in any language (Dorr et al., 2004). A recent proposal for this is the Abstract Meaning Representation (Banarescu et al., 2013), which uses English verbs as a set of predicates. This is a less abstract form of semantic interpretation than our proposal, as semantically equivalent paraphrases may be given a different representation. Such an approach also relies on annotating large amounts of text with the semantic representation—whereas our unsupervised approach offers a way to build such an interlingua using only a method for extracting predicates from sentences.

Whilst almost all recent work on machine-translation has relied on parallel text, there have been several interesting approaches that do not. Rapp (1999) learns to translate words based on small seed bilingual dictionary. Klementiev et al. (2012a) exploit a variety of interesting indirect sources of information to learn a lexicon—for example assuming that equivalent Wikipedia articles in different languages will use semantically similar words. The Polylingual Topic Model (Mimno et al., 2009) makes use of similar intuitions. Whilst we exploit equivalent Wikipedia articles for entity linking, we do not require aligned articles. Incorporating such techniques into our model would be a natural next

step, allowing us to learn a more complete lexicon. To our knowledge, ours is the first approach to learn to translate semantic relations, rather than words and phrases.

Several other recent papers have learnt cross-lingual word clusters, and used these to improve cross-lingual tasks such as document-classification (Klementiev et al., 2012b), parsing (Täckström et al., 2012) and semantic role labelling (Kozhevnikov and Titov, 2013) in resource-poor languages. Cross-lingual word clusters are learnt by aligning monolingual clusters on the basis of parallel text—in language-pairs where parallel text is available, this offers an interesting complement to our method of clustering based on named entities.

9 Conclusions and Future Work

We have demonstated that our previous work on monolingual distributional semantics can simply be extended to learn a language-independent semantics of relations from unlabelled text, and that this semantics is powerful enough to aid applications such as question answering and translation reranking.

There is much potential for future extensions to address the limitations of the process described here. As we use a flat clustering of relations, we are only able to model synonyms and not hypernyms. More sophisticated clustering techniques, such as those used by Berant et al. (2011), seem to offer a way to address this. Our system clusters relations with similar named-entity arguments, but this means it does not cluster relations whose arguments are rarely named entities. However, using cross-lingual clusters of common nouns, such as those from Täckström et al. (2012), it should be possible to cluster relations that take semantically similar common noun arguments. Embedding cluster-identifiers in a logical form allows us to also model logical operators, such as negation and quantifiers, which may help to improve the translation of these. It would also be interesting to experiment with more diverse languages types.

Abstract

In this paper we propose a two-stage method to acquire contradiction relations between typed lexico-syntactic patterns such as X_{drug} *prevents* $Y_{disease}$ and $Y_{disease}$ *caused by* X_{drug}. In the first stage, we train an SVM classifier to detect contradiction pattern pairs in a large web archive by exploiting the *excitation* polarity (Hashimoto et al., 2012) of the patterns. In the second stage, we enlarge the first stage classifier's training data with new contradiction pairs obtained by combining the output of the first stage's classifier and that of an *entailment* classifier. We acquired this way 750,000 typed Japanese contradiction pattern pairs with an estimated precision of 80%. We plan to release this resource to the NLP community.

1 Introduction

The ability to detect contradictory information in text has many practical applications. Among those, Murakami et al. (2009) pointed out that a contradiction recognition system can detect conflicts and anomalies in large bodies of texts and flag them to help users identify unreliable information. For example, many Japanese web pages claim that *agaricus prevents cancer*, where agaricus is a species of mushroom found in a variety of commercial products. Although this has been accepted by many Japanese people, by Googling keywords "agaricus", "promotes" and "cancer", we can find pages claiming that "agaricus promotes cancer", some of which point to a study authorized by the Japanese Ministry of Health, Labour and Welfare[1] reporting that a commercial product containing agaricus promoted cancer. Obviously, the existence of these pages casts serious doubt on the ability of agaricus to prevent cancer and encourages readers to dig more about this subject.

The above example suggests that recognizing contradictory information can guide users to a *true* fact. Likewise, we believe that contradiction recognition is also useful when dealing with non-factual information that occupy most of our daily lives. For instance, there is a big controversy recently whether Japan should join an economic partnership agreement called the *Trans Pacific Partnership (TPP)*, and quite serious but contradictory claims are plentiful in the mass media and on the web, e.g., *TPP will wipe out Japan's agricultural businesses* and *TPP will strengthen Japan's agricultural businesses*. Neither of these are facts; they are *predictions* that can only be realized or disputed after the underlying decision-making is done: joining or refusing the TPP.

Furthermore, after reading documents including contradictory predictions, one should notice that each of them is supported by a *convincing* theory that has no obvious defect, e.g., "Exports of Japan's agricultural products will increase thanks to the TPP" or "A large amount of low-price agricultural products will be imported to Japan due to the TPP". Even if one of these predictions may just happen to be true because of unexpected reasons such as minor fluctuations in the Japanese yen, we must survey such theories that support contradictory predictions, conduct balanced decision-making, and prepare counter measures for the expected problems after examining multiple viewpoints. Contradiction recognition should be useful to select documents to be surveyed.

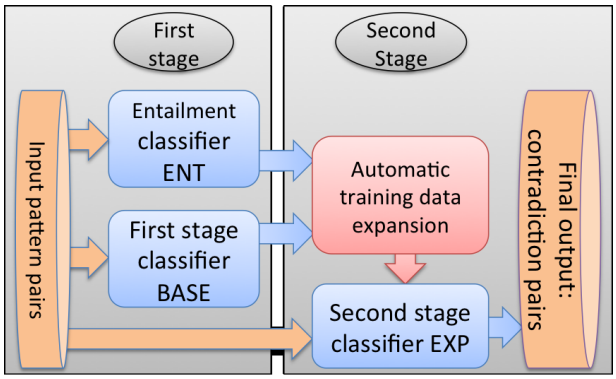

Figure 1: Method workflow

We have developed a method for recognizing pairs of contradictory binary patterns such as ⟨"*X promotes Y*", "*X prevents Y*"⟩ and ⟨"*X will wipe out Y*", "*X will strengthen Y*"⟩. To solve the problem described above, we can easily develop a system that can find contradictory text fragments from the web like "*agaricus promotes cancer*" and "*agaricus prevents cancer*" from the discovered contradictory pattern pairs.

Our method is a two-stage procedure with three supervised classifiers (Fig. 1). In the first stage, we build a classifier **BASE** to recognize contradictions between binary patterns, and a classifier **ENT** to recognize entailment. In the second stage, we combine the contradiction pairs recognized by **BASE** and the entailment pairs recognized by **ENT** to expand **BASE**'s training data and train a new contradiction classifier, **EXP**. This expansion using entailment is one key idea of this work: we acquired 750,000 contradiction pairs with 80% precision using the expanded training data, more than doubling the 285,000 pairs acquired at the same precision level without expansion. We also demonstrate that this result is not trivial by showing that our method outperforms an alternative one based on *Integer Linear Programming* inspired by the successful entailment recognition method of Berant et al. (2011).

As another technical contribution of this work, we exploit the recently proposed semantic polarity of *excitation* (Hashimoto et al., 2012) to recognize contradictions between binary patterns. Hashimoto et al. (2012) previously showed that excitation polarities are useful to recognize contradictions between phrases that consist of a noun and a predicate, such as "promote cancer" and "prevent cancer". While it is trivial to extend this framework to contradictions between *unary* patterns such as "promote X" and "prevent X" by replacing the common nouns in each pair with a variable, the information represented in unary patterns is often vague, and it is unlikely that a contradiction between unary patterns directly leads to the discovery of unreliable information to be flagged or to a meaningful survey of complex problems. As exemplified by the *agaricus* and *TPP* examples, contradictions between *binary* patterns that include two variables such as "X promotes Y" or "X will wipe out Y" are more useful than those between unary patterns. We also show that it is not trivial to recognize contradictions between binary patterns using contradictions between unary patterns.

Most works dealing with contradiction recognition up till now (Harabagiu et al., 2006; Bobrow et al., 2007; Kawahara et al., 2008; Kawahara et al., 2010; Ohki et al., 2011) focus on recognizing contradictions between full sentences or documents, not text fragments that match our relatively short patterns (survey in Section 5). We expect that the contradictory pattern pairs we acquired can be used as building blocks in such full-fledged contradiction recognition for full sentences or documents, similarly to antonym pairs in Harabagiu et al. (2006).

Also, we should emphasize that our method focuses on the most challenging part of contradiction recognition according to the classification of De Marneffe et al. (2008). Since we discard patterns with negations, an evident source of contradictions like ⟨"*X causes Y*", "*X does not cause Y*"⟩, most of our output are non-trivial contradictions related to high-level semantic phenomena, e.g., contradiction pairs related to antonyms like ⟨"X が Y を上げる", "X が Y を下げる"⟩ (⟨"*X increases Y*", "*X decreases Y*"⟩), lexical contradictions like ⟨"X が Y に勝つ", "Y が X に勝つ"⟩ (⟨"*X wins against Y*", "*Y wins against X*"⟩), or contradictions due to common-sense knowledge like ⟨"X が Y を安心させる", "X が Y を裏切る"⟩ (⟨"*X reassures Y*", "*X betrays Y*"⟩). We believe acquiring such contradictions in a large scale is a valuable contribution.

The following is the outline of this paper. Section 2 details our target and our proposed method. Evaluation results are discussed in Section 3. Sec-

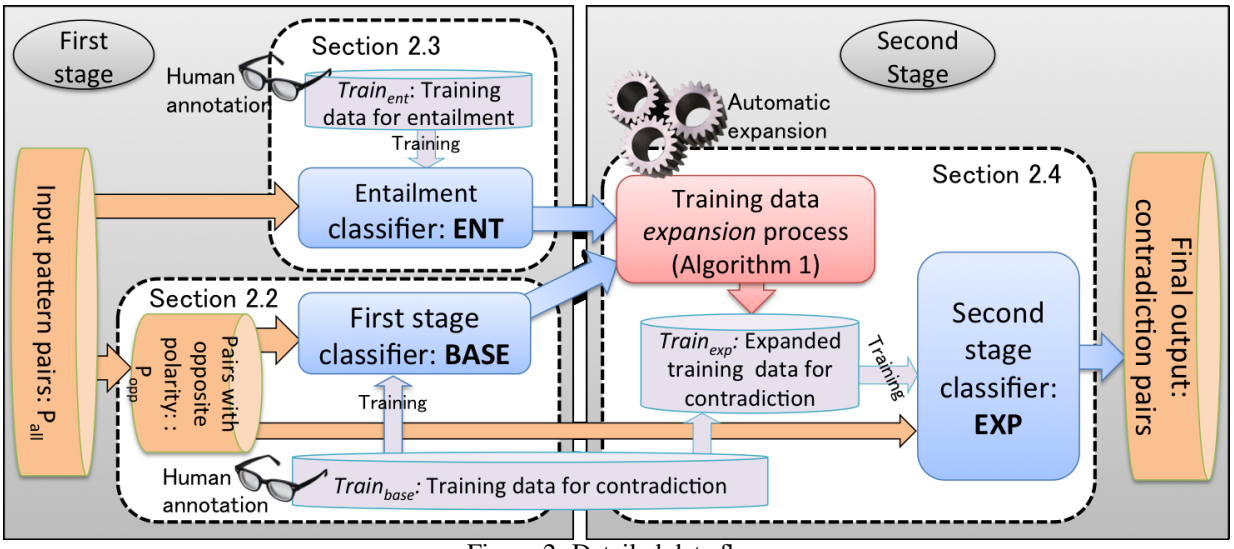

Figure 2: Detailed data flow

tion 4 details our features set, and Section 5 related work. Section 6 provides a conclusion.

2 Proposed method

As showed in Figure 1, our method consists of three supervised classifiers. Classifiers **BASE** and **EXP** recognize contradiction relations between binary patterns, and **ENT** recognizes entailment relations between binary patterns. The contradiction pairs recognized by **BASE** and the entailment pairs recognized by **ENT** are combined to generate new contradiction pairs, part of which are then added to **BASE** training data to train the **EXP** classifier. Our final output is the set of all binary pattern pairs regarded as contradictions by **EXP**. Since the dependencies between these three classifiers, their distinct sets of training data, and the two data sets to be classified (we describe those in the two sections below) is a bit complex, we show a complete description of the whole process in Figure 2.

The key idea is in the scheme that expands the training data. Logically speaking, patterns p and r are contradictory if there exists a pattern q such that p entails q and q contradicts r. For example, since "*X causes Y*" entails "*X promotes Y*" and "*X promotes Y*" contradicts "*X prevents Y*", then "*X causes Y*" contradicts "*X prevents Y*". Hence, by combining entailment and contradiction pairs, we can obtain more contradiction pairs.

Following this property of contradiction relations, we collect a set of pattern pairs $\{\langle p, r\rangle\}$ for which there exists a pattern q such that **ENT** recognizes that p entails q and **BASE** recognizes that q contradicts r. Then we rank these pairs based on a novel scoring function called *Contradiction Derivation Precision (CDP)* and expand **BASE** training data by adding to it the top-ranked pairs according to CDP in order to train **EXP**. This ranking scheme selects highly accurate contradiction pairs and prevents errors caused by **BASE** and **ENT** from being propagated to **EXP**.

In the following, after defining the patterns for which we acquire contradiction relations, we describe **BASE**, **EXP**, **ENT**, and our expansion scheme.

2.1 Patterns

In this work, a binary pattern is a word sequence on the path of dependency relations connecting two nouns in a syntactic dependency tree, like "*X causes Y*", and we say a noun pair *co-occurs with* a pattern if the two nouns are connected by this pattern in the dependency tree of a sentence in the corpus.

We focus on *typed* binary patterns, which place semantic class restrictions on the noun pairs they co-occur with, e.g., "$Y_{organization}$ *is in* $X_{location}$". Subscripts *organization* and *location* indicate the semantic classes of the X and Y slots. Since typed patterns can distinguish between multiple senses of ambiguous patterns, they greatly reduce errors due to pattern ambiguity (De Saeger et al., 2009; Schoenmackers et al., 2010; Berant et al., 2011). We automatically induced semantic classes from our corpus using the EM-based noun clustering algo-

rithm presented in Kazama and Torisawa (2008), and clustered one million nouns into 500 relatively clean semantic classes, including for example classes of *diseases* and of *chemical substances*.

The binary patterns and their co-occurring noun pairs were extracted from our corpus of 600 million Japanese web pages dependency parsed with KNP (Kurohashi and Nagao, 1994). We restricted our patterns to the most frequent 3.9 million patterns of the form "*X-[case particle] Y-[case particle] predicate*" such as "*X-ga Y-ni aru*" ("*X is in Y*") which do not contain any negation, number, symbol or punctuation character. Based on our observation that patterns in meaningful contradiction and entailment pairs tend to share many co-occurring noun pairs, we used as input to our classifiers the set P_{all} of 792 million pattern pairs for which both patterns share three co-occurring noun pairs.

2.2 BASE: First stage Classifier for Contradiction

Below, we detail **BASE**: its training data and input data to be classified, and some experimental results.

Our first stage classifier for contradictions, **BASE**, is an SVM that uses commonsensical surface and lexical resources based features, such as n-grams extracted from patterns, which will be detailed in Section 4. An important point to be stressed here is that we restricted the pattern pairs to be classified by **BASE** by exploiting their *excitation* polarity, a semantic orientation proposed by Hashimoto et al. (2012). Excitation characterizes unary patterns as *excitatory*, *inhibitory*, or *neutral*. *Excitatory* unary patterns, such as "*cause X*" or "*increase X*", entail that the function, effect, purpose, or role of their argument's referent is activated or enhanced, and *inhibitory* unary patterns, such as "*prevent X*" or "*X disappears*", entail that the function, effect, purpose, or role of their argument's referent is deactivated or suppressed. Neutral unary patterns like "*close to X*" are neither excitatory nor inhibitory.

We exploited *excitation* to restrict the input of **BASE**. Based on the result of Hashimoto et al. (2012) showing that two unary patterns with opposite polarity have a higher chance to be a contradiction, we extracted from set P_{all} the set P_{opp} of binary pattern pairs that contain unary patterns with opposite excitation polarities as sub-patterns. $\langle$"*Y cause X*", "*Y prevent X*"$\rangle$ is an example of such a pair since the unary sub-patterns "cause X" and "prevent X" are respectively excitatory and inhibitory. We used here 6,470 excitation unary patterns hand-labeled as either excitatory (4,882 patterns) or inhibitory (1,588 patterns). Set P_{opp} contains 8 million pattern pairs with roughly 38% *true* contradiction pairs, and is the input to **BASE**. We will show in experiments at the end of this section that this restriction is necessary to obtain good performance for **BASE**. We also tried to add the excitation polarities in **BASE**'s feature set and classify P_{all}, but the performance was worse.

Training Data Another key feature of **BASE** is that it is distantly supervised. We did not use training samples that are directly manually annotated. Instead we automatically generated training data from a smaller set of (non-)contradiction unary pattern pairs. We first prepared a set of roughly 800 unary pattern pairs hand-labeled by three human annotators as contradictions (238 pairs) and non-contradictions (558 pairs) using majority vote. The inter-annotator agreement was 0.78 (Fleiss' kappa). Inspired by Hashimoto et al. (2012), we selected these unary pattern pairs among pairs with high distributional similarity, with and without restricting them to having opposite excitation polarity, such as to get a fair distribution of contradictions and non-contradictions.

We then extracted from set P_{all} all 256,000 pattern pairs containing a contradictory unary pattern pair, and all 5.2 million pattern pairs containing a non-contradictory unary pattern pair, which we respectively used as positive and negative training data (estimated 79% and 73% accuracy from 200 hand-labeled samples). Table 1 shows some examples.

The optimal composition of training data for **BASE** was determined according to preliminary experiments using our development set (1,000 manually labelled samples. See Section 3.1). We trained 20 different classifiers using from 6,250 to 50,000 positive samples (4 sets) and from 12,500 to 200,000 negative samples (5 sets), doubling the amounts in each step, for a total of 20 configurations. We could not try a larger training data due to long training time but we do not expect it to be a problem because the worst performance was observed with large train-

Table 1: Examples of training samples for **BASE** obtained from unary pattern pairs

Binary pattern pair (the unary pattern pair that extracted it is underlined)	Unary pattern pair label
Y も X が悪い (X is bad in Y too) - Y でも X が良い (X is good even in Y)	contradiction
Y も X に向かう (Y too heads toward X) - Y も X を出る (Y too comes out of X)	contradiction
X にY を 加える (add Y to X) - X をY に 入れる (insert X into Y)	non-contradiction
Y も X に来る (Y too comes to X) - Y とは X に行く (go to X with Y)	non-contradiction

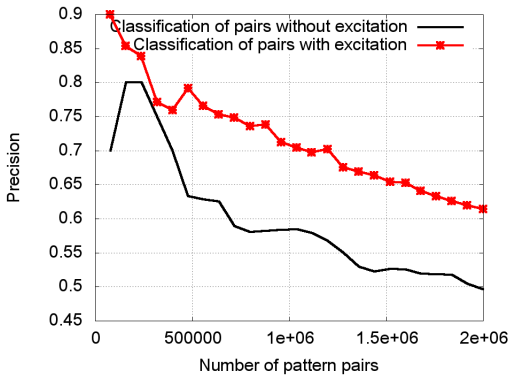

Figure 3: Effect of the restriction using excitation

ing data (25,000 positives and 200,000 negatives; the difference from the optimal setting was 2.3% in average precision). The optimal training data set, $Train_{base}$, consists of 12,500 positives and 100,000 negatives samples as described above and is the one we use in our experiments below and in Section 3.

Since **BASE** input for classification data is P_{opp} we also tried sampling $Train_{base}$ from P_{opp}. We obtained 56.27% average precision for our classifier **BASE**, and 52.99% when restricting the source of training data to pairs in P_{opp}. We believe that the difference lies in the size of the sets from which we sampled our training data: while there are 5.46 million binary pattern pairs in P_{all} with a hand-labeled unary pattern pair in P_{all}, there are only 237,000 pairs in P_{opp}. We believe this much smaller sample source lead to a lower performance because it included much less variations of the patterns.

To train **BASE** and other classifiers mentioned in this paper, we used the SVM tool *TinySVM*[2] with a polynomial kernel of degree 2, the setting which showed the best performance during our preliminary experiments.

Effect of Excitation Polarities We also empirically examined the effect of the restriction on the patterns using excitation polarities. We used our test set (2,000 manually annotated samples described in Section 3.1) and 250 manually annotated samples (majority vote from 3 annotators) from top ranked pairs of P_{all} to draw precision curves for **BASE** over the top 2 million binary pairs from both P_{opp} and P_{all}. In each case we assumed that pairs were distributed uniformly (i.e., with a constant interval) in the ranked list of pairs of P_{opp} and P_{all}, and computed precision accordingly. Since the pairs sets are reasonably large and were sampled randomly we thought this was a reasonable hypothesis. The precision over P_{opp} is higher than that over P_{all} with a large margin, suggesting that the restriction using excitation polarities is beneficial.

[2] http://chasen.org/~taku/software/TinySVM/

2.3 ENT: First stage Classifier for Entailment

ENT is an SVM classifier for entailment trained using 27,500 hand-annotated binary pattern pairs (set $Train_{ent}$, 45% of positive entailment pairs) created for some previous work (Kloetzer et al., 2013). It essentially uses the same feature set as that for **BASE** with the addition of several *distributional* similarity measures (see Section 4 below for more details). This classifier is given all pairs of P_{all} as input and scores each of them. For this study, we considered the 44.5 million pattern pairs with a positive SVM score as entailment pairs. Manual annotation of 200 random samples revealed that the precision of these pairs was 63% and that the top 7.1 million pairs had 80% precision (result interpolated from the top 16% of the annotated samples).

2.4 Second stage: Training Data Expansion and Classifier EXP

Below, we show how we combine **BASE**'s top output (hereafter C) and **ENT**'s top output (hereafter E) in the second stage of our method to expand $Train_{base}$ and train a new classifier, **EXP**.

The training data expansion process is based on the following logical constraint: if a pattern p entails a pattern q and pattern q contradicts a third pattern r, then p must contradict r. For example, because "X

Table 2: Examples of triplets $\langle p, q, r \rangle$ where p entails q, q contradicts r, and hence p contradicts r

Pattern p	Pattern q	Pattern r	X/Y examples	$SVM\ Score(p,r)$	$CDP(p,r)$
Y から X が消える X disappears from Y	Y から X が無くなる X vanishes from Y	Y が X に満ちる Y is full of X	怒り/眼 anger/eye	0.3	0.98
Y に X を停止する stop X in Y	Y に X を終える finish X in Y	Y から X を始める start X in Y	4月/活動 April/activity	-0.3	0.61
X は Y を示す X shows Y	X が Y を持つ X have Y	X は Y を失う X loses Y	チーム/自信 team/confidence	0.07	0.45

Algorithm 1 Training data expansion: C is the top 5% output of **BASE**, E is the top output of **ENT** (score > 0)

1: **procedure** EXPAND(C, E)
2: Compute the set of expanded pairs $C' = \{\langle p, r\rangle \mid \exists q : \langle p, q\rangle \in E, \langle q, r\rangle \in C\}$.
3: Rank the pairs in C' using *CDP*.
4: Add the N top-ranked pairs in $C' \setminus C$ as new positive samples to $Train_{base}$.
5: Remove incoherent negative training samples using *negative cleaning*.
6: **end procedure**

causes Y" (pattern p) entails "*X promotes Y*" (pattern q) and the latter contradicts "*X prevents Y*" (pattern r), we conclude that "*X causes Y*" (p) contradicts "*X prevents Y*" (r). We call the former contradiction $\langle q, r\rangle$ a *source* contradiction pair, and the later pair $\langle p, r\rangle$ an *expanded* contradiction pair. Based on this idea, we combine C and E to aggressively expand $Train_{base}$. This process is described in Algorithm 1, and Table 2 shows examples of triples $\langle p, q, r\rangle$ obtained in our experiments.

Expanding pairs from C and E compounds the errors made by **BASE** and **ENT**, hence it is crucial to select a highly precise subset of the expanded pairs. Taking the top pairs according to their SVM score would achieve this, but since **BASE** already handles correctly such pairs, they should not help much as new training data. We therefore propose a new scoring function for selecting highly precise expanded pairs: *Contradiction Derivation Precision* (CDP).

CDP was designed according to the following assumption: a source contradiction pair that derives *correct* expanded pairs with a high *precision* should be *reliable*. Probably, *all* the expanded pairs derived from such a reliable source pair will be *correct* and should be included in the new training data .

In our formulation of CDP, correctness of an expanded pair is judged according to the pair's SVM score using **BASE**. In other words, we regard an expanded pair that has an SVM score above some threshold α as a *true* contradiction. A source contradiction pair that derives *true* contradiction pairs with a high *precision* is regarded as a *reliable* source contradiction pair. CDP, which is defined over a expanded pairs, is the maximum precision among that of the source contradiction pairs that derive a given expanded pair.

We first define $CDPsub(q, r)$ over a source contradiction pair $\langle q, r\rangle$ as the ratio of expanded pairs obtained from $\langle q, r\rangle$ whose SVM score is above threshold α. This ratio corresponds to the *precision* of the expanded pairs derived from the source contradiction pair $\langle q, r\rangle$.

$$CDPsub(q,r) = \frac{|\{\langle p, r\rangle \in Ex(q,r) \mid Sc(p,r) > \alpha\}|}{|Ex(q,r)|}$$

Here $Ex(q, r)$ is the set of expanded pairs derived from a source pair $\langle q, r\rangle$, and Sc is the SVM score given by **BASE**. In our experiments, we set $\alpha = 0.46$ such that pattern pairs for which **BASE** gives a score over α corresponds to the top 5% of **BASE**'s output. $CDP(p, r)$ over an expanded pair is defined as follows, where $Source(p, r)$ is the set of source contradiction pairs that were derived into the expanded pair $\langle p, r\rangle$.

$$CDP(p,r) = max_{\langle q,r\rangle \in Source(p,r)} CDPsub(q,r)$$

We then expand the top 5% contradictions of **BASE**'s output (set C) and pattern pairs scored positively by **ENT** (set E), rank all expanded pairs not already in C according to CDP, and add the top N pairs with the highest CDP values as positives to $Train_{base}$ to train **EXP**. The value of N shall be determined empirically in later experiments using a development set. Note that, since $CDP(p, r)$ is independent of $\langle p, r\rangle$'s SVM score, even pairs that were assigned a negative score by **BASE** can become highly ranked by CDP (second triplet in Table 2)

and be added to train **EXP**, hence we expect **EXP** to learn something new from these pairs.

Finally, after the addition of expanded pairs, we remove incoherent training samples. We propose to remove from the *negative* training samples of **EXP** any pattern pair that may conflict with the newly added positives; we call this step *negative cleaning*. Intuitively, since the content word pairs in a pattern pair should present some of the strongest evidence for determining the patterns (non-)contradiction status, we remove any negative sample that shares a content word pair with one of the added expanded pairs. The final training data for **EXP**, set $Train_{exp}$, consists of the following: **(1)** positive samples from $Train_{base}$, **(2)** (positive) expanded pairs, and **(3)** negative training samples from $Train_{base}$, cleaned using *negative cleaning*. We confirmed in our experiments that *negative cleaning* was necessary to train a strong **EXP** classifier (details omitted for reason of space).

After training **EXP** with $Train_{exp}$, we classify P_{opp} with **EXP** to produce the final output of the whole method. Note that while this expansion process can be re-iterated with **EXP**'s output, our experiments failed to show any improvement with subsequent iterations.

3 Evaluation

This section presents our experimental results. We describe first how we constructed test and development data, and then report comparison results between our method and others including **BASE** and an Integer Linear Programming-based (ILP) method.

3.1 Development and Test Data

We asked three human annotators to label 3,000 binary pattern pairs randomly sampled from P_{opp} as contradiction or non-contradiction to be used as development (1,000 pairs) and test (2,000 pairs) sets. We considered a pattern pair as a true contradiction relation if at least two out of the three annotators marked it as positive. The inter-rater agreement score (Fleiss Kappa) was 0.523, indicating moderate agreement (Landis and Koch, 1977). As a definition of contradiction, we used the notion of *incompatibility* (i.e., two statements are extremely unlikely to be simultaneously true) proposed by De Marneffe et al. (2008). We then say binary patterns such as "*X causes Y*" and "*X prevents Y*" are contradictory if the above definition holds for any noun pair that can instantiate the patterns' variables in the provided semantic class pair.

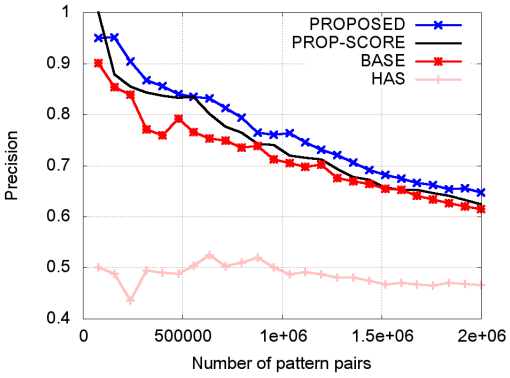

Figure 4: Precision of all the compared methods

Because our semantic classes are obtained by automatic clustering and have no meaningful labels, we followed Szpektor et al. (2007) and provided the annotators with three random noun pairs that co-occur with the patterns as a proxy for the class pair. The annotators marked a given pattern pair as positive if the contradiction relation between the patterns held for all three noun pairs presented.

3.2 Experimental Results

Here we show how our proposed method outperforms baseline methods. We compare the following four methods:

- **PROPOSED**: our proposed method. N, the number of newly added positive training samples during the training data expansion process, was set to 6,000 according to preliminary experiments using the development set. We tried 50 different values of N from 1,000 up to 50,000, adding 1,000 each time, and chose the N value giving the highest average precision against our development set (1,000 samples).
- **BASE**: our first stage classifier.
- **PROP-SCORE**: same as **PROPOSED** except for the use of **BASE**'s SVM score instead of CDP. N was set to 30,000 in the same way we set N for **PROPOSED**.
- **HAS**: an adaptation of the contradiction extraction method presented in Hashimoto et al.

(2012). For a binary pattern pair we first extracted its unary pattern pair with opposite polarity (or one at random in case there are two) and scored it based on our implementation of Hashimoto et al. (2012); the score is based on the distributional similarity between unary patterns and an excitation score obtained using a minimally supervised method based on the spin model. We then scored the binary pattern pair by the score of this unary pattern pair.

We ranked the pattern pairs of our test set (2,000 random pairs from set P_{opp}) based on the score produced by each method. For each tested method we assumed that pairs in the test set were distributed uniformly like explained in Section 2.2. The precision curves we obtained are shown in Figure 4.

PROPOSED clearly outperformed **BASE** and acquired around 750,000 contradiction pattern pairs with an estimated precision of 80%, out of which some examples are shown in Table 3. These pairs cover 26,941 content word pairs and reduce to 272,164 *untyped* pairs, showing that **PROPOSED** does not just acquire a handful of contradictions in many different class pairs. Also, when matching these pairs against an antonyms database (extracted from the dictionary of the morphical analyzer JUMAN) we found that only 100,886 of these pattern pairs contain an antonym pair, which means that most of the extracted pairs' contradictions are due to more complex phenomena than simple antonymy.

With the same precision, **BASE** and **PROP-SCORE** acquired only 285,000 pairs (covering 11,794 content word pairs) and 636,000 pairs respectively. This implies that our two-stage method can more than double the number of highly precise contradiction pairs we acquire as well as increasing their variety, and that ranking expanded pairs using our scoring function CDP is better than with SVM score, though even **PROP-SCORE** performs better than **BASE** in our setting. Finally, the poor performance of **HAS** suggests that extending the Hashimoto et al.'s framework to recognition of binary patterns is not a trivial task.

As to why adding only 6,000 top pairs ranked by CDP performs better than adding 30,000 pairs ranked by SVM score, the pattern pairs added in **PROP-SCORE** had high SVM scores given by **BASE** and as such are already handled nicely by **BASE**. Hence, we think the effect of adding a new sample from **PROP-SCORE** is smaller than that in **PROPOSED**, because in **PROPOSED** we add to the training data pattern pairs with both high and low (possibly negative) SVM scores.

Table 3: Examples of pairs acquired by **PROPOSED**: contradiction (label +) and non-contradiction (label -)

Lab.	Pattern pairs (with rank)	X/Y example
+	Y で X が終わる - Y より X を開始する X finished Y - X started from Y Rank 228,039	販売/昨日 sale/yesterday
+	X が Y に勝つ - Y が X に勝つ X wins against Y - Y wins against X Rank: 258,068	日本/ベトナム Japan/Vietnam
-	X は Y を失う - X には Y はある X lose Y - Have Y in X Rank 474,143	人/興味 people/interest
+	Y に X を無くす - Y にも X をもつ Lose X in Y - Have X in Y too Rank 522,534	自信/自分 confidence/ oneself
-	Y は X まで落ちる - X に Y を上げる Y falls down to X - raise Y to X Rank 538,901	9 位/順位 9th/ranking
+	X に Y が存在する - X から Y を防ぐ Y exists in X - Keep Y out X Rank 620,430	中/ウイルス inside/virus
-	X から Y を外す - X は Y で答える Remove Y off X - X answer with Y Rank 652,530	僕/目 I (or me)/eyes
+	Y を X から追い出す - X に Y が残る Kick out Y from X - Y remains in X Rank 697,177	体/疲労 body/fatigue
+	Y が X を安心させる - Y が X がを裏切る X reassures Y - X betrays Y Rank: 749,916	僕/彼女 I/her

Finally, while the quality of the entailment pairs plays a very important role in the assumption that was the base of CDP, these results show that even a simple rule such as "Use entailment pairs with SVM score over 0 to expand contradictions before ranking them with CDP" is sufficient to make the method work. Though it may be possible to design a more complex CDP formula which takes entailment score into account, we did not explore this direction in this work.

Comparison with an ILP-based method Finally, we would like to compare our method with an ILP-based method. The interaction between contradiction and entailment that forms the basis for our expansion method has a natural interpretation as an optimization problem. We thus compared our method to the following ILP formulation of this interaction inspired by Berant et al. (2011), using our test set:

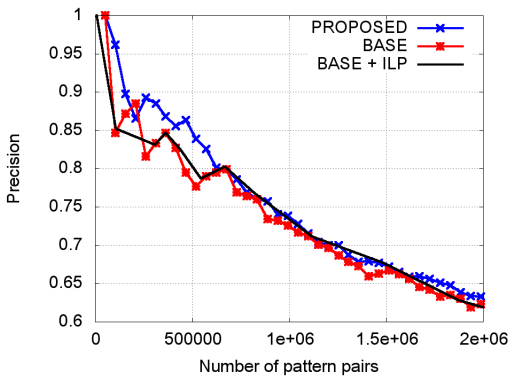

Figure 5: Comparison between **PROPOSED**, **BASE** and **BASE+ILP** on a restricted test set (1,306 samples)

(1) $G = argmax \sum_{p \neq q} (e(p,q) - \beta) * E_{pq} + (c(p,q) - \beta) * C_{pq}$

(2) s.t. $\forall_{p,q,r}\ E_{pq} + C_{qr} - C_{pr} \leq 1$

(3) $\forall_{p,q}\ E_{pq} + C_{pq} \leq 1$

(4) $\forall_{p,q}\ E_{pq} \in \{0,1\}$ **(5)** $\forall_{p,q}\ C_{pq} \in \{0,1\}$

The objective in Equation (1) is a sum over the weights of every pair of patterns $\langle p,q \rangle$, where E_{pq} indicates whether a pair $\langle p,q \rangle$ is an entailment pair (Equation (4)), and C_{pq} indicates whether it is a contradiction pair (Equation (5)). $e(p,q)$ and $c(p,q)$ are the score given respectively by **ENT** and **BASE**, and β is a prior defining the weight of a pair as neither entailment nor contradiction that shall be set before any experimentation. Equation (2) states the transitivity relation which is the basis of our expansion method. Finally, Equation (3) states that a given pattern pair cannot be a contradiction pair and an entailment pair at the same time. Since our patterns are class-dependent, we solved separate ILP instances for each semantic class pair.

We drew a precision curve for each of **BASE**, **PROPOSED** and **BASE+ILP**. To draw the curve for **BASE+ILP**, we incrementally raised the sample's non-contradiction non-entailment prior β (more details in Berant et al. (2011)). Because of the computational difficulty of ILP (NP-complete) and the size of our data, the computation for the ILP-based method ran out of memory on a 72GB machine for 116 class pairs out of the 1,031 that our test set covers. For this reason, we only used the 1,306 samples of the test set covered by the remaining 915 class pairs. We also measured the performance of **BASE** and **PROPOSED** on the same restricted test set.

Figure 5 shows that under these conditions the ILP-based method performance resembles **BASE** and is worse than **PROPOSED** on all data points. **PROPOSED** performs slightly worse in this setting compared to when classifying the whole of P_{opp}, but this only means that its performance is good for the 116 class pairs we ignored in this experiment. While this comparison is only made in a restricted setting, our expansion method still outperforms ILP and is clearly more scalable. The ILP results could be improved by adding more constraints (*contradiction is symmetric*, *entailment is transitive*), but this would also make the problem even more intractable in terms of computational costs.

4 Features

In this section we present the features used in our classifiers, which are mainly categorized into three: surface features (i.e., those reflecting the patterns' content itself), features based on external lexical resources, and distributional similarity based features; all features are listed in Table 4. **ENT** uses all the features while **BASE** and **EXP** use all except for the distributional similarity based ones. The optimality of the feature sets was confirmed through ablation tests using the development set (results omitted for the sake of space).

Since patterns with a contradiction or entailment relation are often superficially similar, for instance, in case structure or inflection, we use a number of *surface* features based on string similarity measures, extending the feature sets used by Malakasiotis and Androutsopoulos (2007) for entailment recognition. They include bag-of-words features such as n-grams and similarity scores concerning the bag-of-words such as their Euclidian distance.

To complement the surface features with knowledge about the content words, we used lexical databases including such as antonymy, synonymy, entailment, or allography. The presence of such word pairs is usually a good indicator of (non-)contradiction or (non-)entailment at the pattern level. More specifically, for any word pair $\langle wp, wq \rangle$ taken from a pattern pair $\langle p,q \rangle$ we mark the presence of $\langle wp, wq \rangle$ in each of the lexical resources as a binary feature. We used the Japanese lexical resources distributed by the *ALAGIN Forum*[3]: the verb entailment database (117,000 verb

[3] http://www.alagin.jp/

Table 4: Features summary, computed over a pair of patterns $\langle p, q \rangle$

surface	**Similarity measures:** common elements ratios, Dice coefficient, Jaccard and discounted Jaccard scores, Cosine, Euclidian, Manhattan, Levenshtein and Jaro distances; *computed over:* the patterns' 1-, 2- and 3-grams sets of: characters, morphemes, their stems & POS; content words and stems

dis.s.	**Distributional similarity measures:** Common elements ratios, Jaccard and discounted Jaccard scores, sets and sets intersection cardinality, DIRT (Lin and Pantel, 2001), Weeds (Weeds and Weir, 2003) and Hashimoto (Hashimoto et al., 2009) scores; *computed over*: patterns' co-occurring noun pairs, POS tags of those, nouns co-occurring in each variable slot, nouns co-occurring with each unary sub-patterns
other	binary feature for each semantic class pair and individual semantic classes
	patterns frequency rank in the given semantic class pair

pairs; Alagin ID A-2), the databases of synonyms, antonyms and meronyms (respectively 111,000, 5000 and 2500 pairs; Alagin ID A-9), and the allographic word database (2.7 million pairs; Alagin ID A-7). We also used the information concerning allographic words in the dictionary of the morphological analyzer JUMAN[4].

Distributional similarity values between patterns are based on the idea that patterns that appear in similar contexts tend to have similar meanings and as such are useful to recognize entailment (Lin and Pantel, 2001). We computed as features several distributional similarity measures on the sets of each pattern's co-occurring noun pairs and their POS tags, of nouns co-occurring in each variable slot, and with each of the pattern's unary sub-patterns.

We also added a few more uncategorizable features. See Table 4 for more details.

5 Related Work

A number of previous work dealt with the recognition of contradictions between sentences. Harabagiu et al. (2006) proposed a contradiction detection method that focuses on negation, antonymy and some discourse information. Kawahara et al. (2010) also used negations and antonyms to extract contrastive/contradictory statements from the web to present users with a bird ' s-eye view of statements about a given topic. Bobrow et al. (2007) showed a method using logical forms with relatively precise results. Ohki et al. (2011) proposed a method to recognize *confinment*, a novel semantic relation related to both entailment and contradiction. While we do not deal ourselves directly with sentences, we expect that the binary pattern pairs we acquire can play a role similar to that of basic linguistic resources such as antonyms and negations in these works. Closer to our work, Ritter et al. (2008) presented a method for detecting contradictions between *functional* relations like "*X was born in Y*", but these constitute only a part of the semantic relations expressed by the binary patterns we deal with in this paper.

Other works analyzed contradictions from linguistic/semantic viewpoints. Voorhees (2008) analyzed the contradiction recognition-task of the RTE3 contest. Magnini and Cabrio (2010) examined relations between contradictions and textual entailment samples. De Marneffe et al. (2008) presented a typology of contradictions, and showed that contradictions can arise from a multitude of phenomena. They showed contradictions based on lexical or world knowledge are challenging and require a high-level understanding of language and/or the world. As stated in the introduction, these are the types of contradictions our method focuses on.

6 Conclusion

This paper showed how to acquire a large number of contradiction pairs between lexico-syntactic binary patterns by exploiting **(1)** the interaction between contradiction and entailment, and **(2)** *excitation* polarities. In the end, we could acquire 750,000 typed contradiction pattern pairs with an estimated 80% precision. The resulting contradiction pairs covered ones deeply related to world knowledge such as the pair $\langle$"*X reassures Y*", "*X betrays Y*"$\rangle$. We expect our work to lead to a high level analysis of textual information, such as flagging unreliable information or identifying important documents to be surveyed for understanding complex social problems. We plan to release the data we acquired to the NLP community through the *ALAGIN Forum*[5].

Sarcasm as Contrast between a Positive Sentiment and Negative Situation

Abstract

A common form of sarcasm on Twitter consists of a positive sentiment contrasted with a negative situation. For example, many sarcastic tweets include a positive sentiment, such as "love" or "enjoy", followed by an expression that describes an undesirable activity or state (e.g., "taking exams" or "being ignored"). We have developed a sarcasm recognizer to identify this type of sarcasm in tweets. We present a novel bootstrapping algorithm that automatically learns lists of positive sentiment phrases and negative situation phrases from sarcastic tweets. We show that identifying contrasting contexts using the phrases learned through bootstrapping yields improved recall for sarcasm recognition.

1 Introduction

Sarcasm is generally characterized as ironic or satirical wit that is intended to insult, mock, or amuse. Sarcasm can be manifested in many different ways, but recognizing sarcasm is important for natural language processing to avoid misinterpreting sarcastic statements as literal. For example, sentiment analysis can be easily misled by the presence of words that have a strong polarity but are used sarcastically, which means that the opposite polarity was intended. Consider the following tweet on Twitter, which includes the words "yay" and "thrilled" but actually expresses a negative sentiment: "*yay! it's a holiday weekend and i'm on call for work! couldn't be more thrilled! #sarcasm.*" In this case, the hashtag #sarcasm reveals the intended sarcasm, but we don't always have the benefit of an explicit sarcasm label.

In the realm of Twitter, we observed that many sarcastic tweets have a common structure that creates a positive/negative contrast between a sentiment and a situation. Specifically, sarcastic tweets often express a positive sentiment in reference to a negative activity or state. For example, consider the tweets below, where the positive sentiment terms are underlined and the negative activity/state terms are *italicized*.

(a) Oh how I love *being ignored*. #sarcasm

(b) Thoroughly enjoyed *shoveling the driveway* today! :) #sarcasm

(c) Absolutely adore it when *my bus is late* #sarcasm

(d) I'm so pleased mom *woke me up* with vacuuming my room this morning. :) #sarcasm

The sarcasm in these tweets arises from the juxtaposition of a positive sentiment word (e.g., love, enjoyed, adore, pleased) with a negative activity or state (e.g., being ignored, bus is late, shoveling, and being woken up).

The goal of our research is to identify sarcasm that arises from the contrast between a positive sentiment referring to a negative situation. A key challenge is to automatically recognize the stereotypically negative "situations", which are activities and states that most people consider to be unenjoyable or undesirable. For example, stereotypically unenjoyable activities include going to the dentist, taking an exam, and having to work on holidays. Stereotypically undesirable states include being ignored, having no friends, and feeling sick. People recognize

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 704–714,
Seattle, Washington, USA, 18-21 October 2013.

these situations as being negative through cultural norms and stereotypes, so they are rarely accompanied by an explicit negative sentiment. For example, *"I feel sick"* is universally understood to be a negative situation, even without an explicit expression of negative sentiment. Consequently, we must learn to recognize phrases that correspond to stereotypically negative situations.

We present a bootstrapping algorithm that automatically learns phrases corresponding to positive sentiments and phrases corresponding to negative situations. We use tweets that contain a sarcasm hashtag as positive instances for the learning process. The bootstrapping algorithm begins with a single seed word, "love", and a large set of sarcastic tweets. First, we learn *negative situation phrases* that follow a positive sentiment (initially, the seed word "love"). Second, we learn *positive sentiment phrases* that occur near a negative situation phrase. The bootstrapping process iterates, alternately learning new negative situations and new positive sentiment phrases. Finally, we use the learned lists of sentiment and situation phrases to recognize sarcasm in new tweets by identifying contexts that contain a positive sentiment in close proximity to a negative situation phrase.

2 Related Work

Researchers have investigated the use of lexical and syntactic features to recognize sarcasm in text. Kreuz and Caucci (2007) studied the role that different lexical factors play, such as interjections (e.g., "gee" or "gosh") and punctuation symbols (e.g., '?') in recognizing sarcasm in narratives. Lukin and Walker (2013) explored the potential of a bootstrapping method for sarcasm classification in social dialogue to learn lexical N-gram cues associated with sarcasm (e.g., "oh really", "I get it", "no way", etc.) as well as lexico-syntactic patterns.

In opinionated user posts, Carvalho et al. (2009) found oral or gestural expressions, represented using punctuation and other keyboard characters, to be more predictive of irony[1] in contrast to features representing structured linguistic knowledge in Portuguese. Filatova (2012) presented a detailed description of sarcasm corpus creation with sarcasm annotations of Amazon product reviews. Their annotations capture sarcasm both at the document level and the text utterance level. Tsur et al. (2010) presented a semi-supervised learning framework that exploits syntactic and pattern based features in sarcastic sentences of Amazon product reviews. They observed correlated sentiment words such as "yay!" or "great!" often occurring in their most useful patterns.

Davidov et al. (2010) used sarcastic tweets and sarcastic Amazon product reviews to train a sarcasm classifier with syntactic and pattern-based features. They examined whether tweets with a sarcasm hashtag are reliable enough indicators of sarcasm to be used as a gold standard for evaluation, but found that sarcasm hashtags are noisy and possibly biased towards the hardest form of sarcasm (where even humans have difficulty). González-Ibáñez et al. (2011) explored the usefulness of lexical and pragmatic features for sarcasm detection in tweets. They used sarcasm hashtags as gold labels. They found positive and negative emotions in tweets, determined through fixed word dictionaries, to have a strong correlation with sarcasm. Liebrecht et al. (2013) explored N-gram features from 1 to 3-grams to build a classifier to recognize sarcasm in Dutch tweets. They made an interesting observation from their most effective N-gram features that people tend to be more sarcastic towards specific topics such as school, homework, weather, returning from vacation, public transport, the church, the dentist, etc. This observation has some overlap with our observation that stereotypically negative situations often occur in sarcasm.

The cues for recognizing sarcasm may come from a variety of sources. There exists a line of work that tries to identify facial and vocal cues in speech (e.g., (Gina M. Caucci, 2012; Rankin et al., 2009)). Cheang and Pell (2009) and Cheang and Pell (2008) performed studies to identify acoustic cues in sarcastic utterances by analyzing speech features such as speech rate, mean amplitude, amplitude range, etc. Tepperman et al. (2006) worked on sarcasm recognition in spoken dialogue using prosodic and spectral cues (e.g., average pitch, pitch slope, etc.) as well as contextual cues (e.g., laughter or response to questions) as features.

[1] They adopted the term 'irony' instead of 'sarcasm' to refer to the case when a word or expression with prior positive polarity is figuratively used to express a negative opinion.

While some of the previous work has identified specific expressions that correlate with sarcasm, none has tried to identify contrast between positive sentiments and negative situations. The novel contributions of our work include explicitly recognizing contexts that contrast a positive sentiment with a negative activity or state, as well as a bootstrapped learning framework to automatically acquire positive sentiment and negative situation phrases.

3 Bootstrapped Learning of Positive Sentiments and Negative Situations

Sarcasm is often defined in terms of contrast or "saying the opposite of what you mean". Our work focuses on one specific type of contrast that is common on Twitter: the expression of a positive sentiment (e.g., "love" or "enjoy") in reference to a negative activity or state (e.g., "taking an exam" or "being ignored"). Our goal is to create a sarcasm classifier for tweets that explicitly recognizes contexts that contain a positive sentiment contrasted with a negative situation.

Our approach learns rich phrasal lexicons of positive sentiments and negative situations using only the seed word "love" and a collection of sarcastic tweets as input. A key factor that makes the algorithm work is the presumption that if you find a positive sentiment or a negative situation in a sarcastic tweet, then you have found the source of the sarcasm. We further assume that the sarcasm probably arises from positive/negative contrast and we exploit syntactic structure to extract phrases that are likely to have contrasting polarity. Another key factor is that we focus specifically on tweets. The short nature of tweets limits the search space for the source of the sarcasm. The brevity of tweets also probably contributes to the prevalence of this relatively compact form of sarcasm.

3.1 Overview of the Learning Process

Our bootstrapping algorithm operates on the assumption that many sarcastic tweets contain both a positive sentiment and a negative situation in close proximity, which is the source of the sarcasm.[2] Although sentiments and situations can be expressed in numerous ways, we focus on positive sentiments that are expressed as a verb phrase or as a predicative expression (predicate adjective or predicate nominal), and negative activities or states that can be a complement to a verb phrase. Ideally, we would like to parse the text and extract verb complement phrase structures, but tweets are often informally written and ungrammatical. Therefore we try to recognize these syntactic structures heuristically using only part-of-speech tags and proximity.

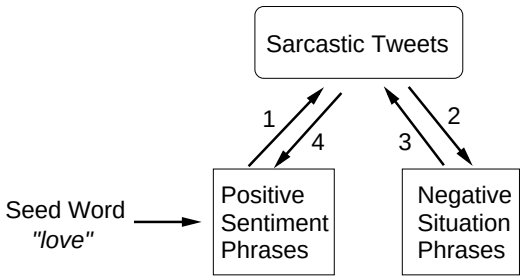

Figure 1: Bootstrapped Learning of Positive Sentiment and Negative Situation Phrases

The learning process relies on an assumption that a positive sentiment verb phrase usually appears to the left of a negative situation phrase and in close proximity (usually, but not always, adjacent). Pictorially, we assume that many sarcastic tweets contain this structure:

[+ VERB PHRASE] [– SITUATION PHRASE]

This structural assumption drives our bootstrapping algorithm, which is illustrated in Figure 1. The bootstrapping process begins with a single seed word, "love", which seems to be the most common positive sentiment term in sarcastic tweets. Given a sarcastic tweet containing the word "love", our structural assumption infers that "love" is probably followed by an expression that refers to a negative situation. So we harvest the n-grams that follow the word "love" as negative situation candidates. We select the best candidates using a scoring metric, and add them to a list of negative situation phrases.

Next, we exploit the structural assumption in the opposite direction. Given a sarcastic tweet that contains a negative situation phrase, we infer that the negative situation phrase is preceded by a positive sentiment. We harvest the n-grams that precede the negative situation phrases as positive sentiment candidates, score and select the best candidates, and

[2] Sarcasm can arise from a negative sentiment contrasted with a positive situation too, but our observation is that this is much less common, at least on Twitter.

add them to a list of positive sentiment phrases. The bootstrapping process then iterates, alternately learning more positive sentiment phrases and more negative situation phrases.

We also observed that positive sentiments are frequently expressed as predicative phrases (i.e., predicate adjectives and predicate nominals). For example: *"I'm taking calculus. It is awesome. #sarcasm"*. Wiegand et al. (2013) offered a related observation that adjectives occurring in predicate adjective constructions are more likely to convey subjectivity than adjectives occurring in non-predicative structures. Therefore we also include a step in the learning process to harvest predicative phrases that occur in close proximity to a negative situation phrase. In the following sections, we explain each step of the bootstrapping process in more detail.

3.2 Bootstrapping Data

For the learning process, we used Twitter's streaming API to obtain a large set of tweets. We collected 35,000 tweets that contain the hashtag #sarcasm or #sarcastic to use as positive instances of sarcasm. We also collected 140,000 additional tweets from Twitter's random daily stream. We removed the tweets that contain a sarcasm hashtag, and considered the rest to be negative instances of sarcasm. Of course, there will be some sarcastic tweets that do not have a sarcasm hashtag, so the negative instances will contain some noise. But we expect that a very small percentage of these tweets will be sarcastic, so the noise should not be a major issue. There will also be noise in the positive instances because a sarcasm hashtag does not guarantee that there is sarcasm in the body of the tweet (e.g., the sarcastic content may be in a linked url, or in a prior tweet). But again, we expect the amount of noise to be relatively small.

Our tweet collection therefore contains a total of 175,000 tweets: 20% are labeled as sarcastic and 80% are labeled as not sarcastic. We applied CMU's part-of-speech tagger designed for tweets (Owoputi et al., 2013) to this data set.

3.3 Seeding

The bootstrapping process begins by initializing the positive sentiment lexicon with one seed word: *love*. We chose this seed because it seems to be the most common positive sentiment word in sarcastic tweets.

3.4 Learning Negative Situation Phrases

The first stage of bootstrapping learns new phrases that correspond to negative situations. The learning process consists of two steps: (1) harvesting candidate phrases, and (2) scoring and selecting the best candidates.

To collect candidate phrases for negative situations, we extract n-grams that follow a positive sentiment phrase in a sarcastic tweet. We extract every 1-gram, 2-gram, and 3-gram that occurs immediately after (on the right-hand side) of a positive sentiment phrase. As an example, consider the tweet in Figure 2, where "love" is the positive sentiment:

I love waiting forever for the doctor #sarcasm

Figure 2: Example Sarcastic Tweet

We extract three n-grams as candidate negative situation phrases:

waiting, waiting forever, waiting forever for

Next, we apply the part-of-speech (POS) tagger and filter the candidate list based on POS patterns so we only keep n-grams that have a desired syntactic structure. For negative situation phrases, our goal is to learn possible verb phrase (VP) complements that are themselves verb phrases because they should represent activities and states. So we require a candidate phrase to be either a unigram tagged as a verb (V) or the phrase must match one of 7 POS-based bigram patterns or 20 POS-based trigram patterns that we created to try to approximate the recognition of verbal complement structures. The 7 POS bigram patterns are: V+V, V+ADV, ADV+V, "to"+V, V+NOUN, V+PRO, V+ADJ. Note that we used a POS tagger designed for Twitter, which has a smaller set of POS tags than more traditional POS taggers. For example there is just a single V tag that covers all types of verbs. The V+V pattern will therefore capture negative situation phrases that consist of a present participle verb followed by a past participle verb, such as "being ignored" or "getting hit".[3] We also allow verb particles to match a V tag in our patterns. The remaining bigram patterns capture verb phrases that include a verb and adverb, an

[3]In some cases it may be more appropriate to consider the second verb to be an adjective, but in practice they were usually tagged as verbs.

infinitive form (e.g., "to clean"), a verb and noun phrase (e.g., "shoveling snow"), or a verb and adjective (e.g., "being alone"). We use some simple heuristics to try to ensure that we are at the end of an adjective or noun phrase (e.g., if the following word is tagged as an adjective or noun, then we assume we are *not* at the end).

The 20 POS trigram patterns are similar in nature and are designed to capture seven general types of verb phrases: verb and adverb mixtures, an infinitive VP that includes an adverb, a verb phrase followed by a noun phrase, a verb phrase followed by a prepositional phrase, a verb followed by an adjective phrase, or an infinitive VP followed by an adjective, noun, or pronoun.

Returning to Figure 2, only two of the n-grams match our POS patterns, so we are left with two candidate phrases for negative situations:

waiting, waiting forever

Next, we score each negative situation candidate by estimating the probability that a tweet is sarcastic given that it contains the candidate phrase following a positive sentiment phrase:

$$\frac{|\ \text{follows(–candidate, +sentiment) \& sarcastic}\ |}{|\ \text{follows(–candidate, +sentiment)}\ |}$$

We compute the number of times that the negative situation candidate immediately follows a positive sentiment in sarcastic tweets divided by the number of times that the candidate immediately follows a positive sentiment in all tweets. We discard phrases that have a frequency < 3 in the tweet collection since they are too sparse.

Finally, we rank the candidate phrases based on this probability, using their frequency as a secondary key in case of ties. The top 20 phrases with a probability $\geq .80$ are added to the negative situation phrase list.[4] When we add a phrase to the negative situation list, we immediately remove all other candidates that are subsumed by the selected phrase. For example, if we add the phrase "waiting", then the phrase "waiting forever" would be removed from the candidate list because it is subsumed by "waiting". This process reduces redundancy in the set of phrases that we add during each bootstrapping iteration. The bootstrapping process stops when no more candidate phrases pass the probability threshold.

3.5 Learning Positive Verb Phrases

The procedure for learning positive sentiment phrases is analogous. First, we collect phrases that potentially convey a positive sentiment by extracting n-grams that precede a negative situation phrase in a sarcastic tweet. To learn positive sentiment verb phrases, we extract every 1-gram and 2-gram that occurs immediately before (on the left-hand side of) a negative situation phrase.

Next, we apply the POS tagger and filter the n-grams using POS tag patterns so that we only keep n-grams that have a desired syntactic structure. Here our goal is to learn simple verb phrases (VPs) so we only retain n-grams that contain at least one verb and consist only of verbs and (optionally) adverbs. Finally, we score each candidate sentiment verb phrase by estimating the probability that a tweet is sarcastic given that it contains the candidate phrase preceding a negative situation phrase:

$$\frac{|\ \text{precedes(+candidateVP,–situation) \& sarcastic}\ |}{|\ \text{precedes(+candidateVP,–situation)}\ |}$$

3.6 Learning Positive Predicative Phrases

We also use the negative situation phrases to harvest predicative expressions (predicate adjective or predicate nominal structures) that occur nearby. Based on the same assumption that sarcasm often arises from the contrast between a positive sentiment and a negative situation, we identify tweets that contain a negative situation and a predicative expression in close proximity. We then assume that the predicative expression is likely to convey a positive sentiment.

To learn predicative expressions, we use 24 copular verbs from Wikipedia[5] and their inflections. We extract positive sentiment candidates by extracting 1-grams, 2-grams, and 3-grams that appear immediately after a copular verb and occur within 5 words of the negative situation phrase, on either side. This constraint only enforces proximity because predicative expressions often appear in a separate clause or sentence (e.g., *"It is just great that my iphone was stolen"* or *"My iphone was stolen. This is great."*)

[4] Fewer than 20 phrases will be learned if < 20 phrases pass this threshold.

[5] http://en.wikipedia.org/wiki/List_of_English_copulae

We then apply POS patterns to identify n-grams that correspond to predicate adjective and predicate nominal phrases. For predicate adjectives, we retain ADJ and ADV+ADJ n-grams. We use a few heuristics to check that the adjective is not part of a noun phrase (e.g., we check that the following word is not a noun). For predicate nominals, we retain ADV+ADJ+N, DET+ADJ+N and ADJ+N n-grams. We excluded noun phrases consisting only of nouns because they rarely seemed to represent a sentiment. The sentiment in predicate nominals was usually conveyed by the adjective. We discard all candidates with frequency < 3 as being too sparse. Finally, we score each remaining candidate by estimating the probability that a tweet is sarcastic given that it contains the predicative expression near (within 5 words of) a negative situation phrase:

$$\frac{|\ \text{near(+candidatePRED,–situation) \& sarcastic}\ |}{|\ \text{near(+candidatePRED,–situation)}\ |}$$

We found that the diversity of positive sentiment verb phrases and predicative expressions is much lower than the diversity of negative situation phrases. As a result, we sort the candidates by their probability and conservatively add only the top 5 positive verb phrases and top 5 positive predicative expressions in each bootstrapping iteration. Both types of sentiment phrases must pass a probability threshold of $\geq .70$.

3.7 The Learned Phrase Lists

The bootstrapping process alternately learns positive sentiments and negative situations until no more phrases can be learned. In our experiments, we learned 26 positive sentiment verb phrases, 20 predicative expressions and 239 negative situation phrases.

Table 1 shows the first 15 positive verb phrases, the first 15 positive predicative expressions, and the first 40 negative situation phrases learned by the bootstrapping algorithm. Some of the negative situation phrases are not complete expressions, but it is clear that they will often match negative activities and states. For example, "getting yelled" was generated from sarcastic comments such as "I love getting yelled at", "being home" occurred in tweets about "being home alone", and "being told" is often being told what to do. Shorter phrases often outranked longer phrases because they are more general, and will therefore match more contexts. But an avenue for future work is to learn linguistic expressions that more precisely characterize specific negative situations.

Positive Verb Phrases (26): missed, loves, enjoy, cant wait, excited, wanted, can't wait, get, appreciate, decided, loving, really like, looooove, just keeps, loveee, ...
Positive Predicative Expressions (20): great, so much fun, good, so happy, better, my favorite thing, cool, funny, nice, always fun, fun, awesome, the best feeling, amazing, happy, ...
Negative Situations (239): being ignored, being sick, waiting, feeling, waking up early, being woken, fighting, staying, writing, being home, cleaning, not getting, crying, sitting at home, being stuck, starting, being told, being left, getting ignored, being treated, doing homework, learning, getting up early, going to bed, getting sick, riding, being ditched, getting ditched, missing, not sleeping, not talking, trying, falling, walking home, getting yelled, being awake, being talked, taking care, doing nothing, wasting, ...

Table 1: Examples of Learned Phrases

4 Evaluation

4.1 Data

For evaluation purposes, we created a gold standard data set of manually annotated tweets. Even for people, it is not always easy to identify sarcasm in tweets because sarcasm often depends on conversational context that spans more than a single tweet. Extracting conversational threads from Twitter, and analyzing conversational exchanges, has its own challenges and is beyond the scope of this research. We focus on identifying sarcasm that is self-contained in one tweet and does not depend on prior conversational context.

We defined annotation guidelines that instructed human annotators to read isolated tweets and label

a tweet as *sarcastic* if it contains comments judged to be sarcastic based solely on the content of that tweet. Tweets that do not contain sarcasm, or where potential sarcasm is unclear without seeing the prior conversational context, were labeled as *not sarcastic*. For example, a tweet such as *"Yes, I meant that sarcastically."* should be labeled as *not sarcastic* because the sarcastic content was (presumably) in a previous tweet. The guidelines did not contain any instructions that required positive/negative contrast to be present in the tweet, so all forms of sarcasm were considered to be positive examples.

To ensure that our evaluation data had a healthy mix of both sarcastic and non-sarcastic tweets, we collected 1,600 tweets with a sarcasm hashtag (#sarcasm or #sarcastic), and 1,600 tweets without these sarcasm hashtags from Twitter's random streaming API. When presenting the tweets to the annotators, the sarcasm hashtags were removed so the annotators had to judge whether a tweet was sarcastic or not without seeing those hashtags.

To ensure that we had high-quality annotations, three annotators were asked to annotate the same set of 200 tweets (100 sarcastic + 100 not sarcastic). We computed inter-annotator agreement (IAA) between each pair of annotators using Cohen's kappa (κ). The pairwise IAA scores were κ=0.80, κ=0.81, and κ=0.82. We then gave each annotator an additional 1,000 tweets to annotate, yielding a total of 3,200 annotated tweets. We used the first 200 tweets as our Tuning Set, and the remaining 3000 tweets as our Test Set.

Our annotators judged 742 of the 3,200 tweets (23%) to be sarcastic. Only 713 of the 1,600 tweets with sarcasm hashtags (45%) were judged to be sarcastic based on our annotation guidelines. There are several reasons why a tweet with a sarcasm hashtag might not have been judged to be sarcastic. Sarcasm may not be apparent without prior conversational context (i.e., multiple tweets), or the sarcastic content may be in a URL and not the tweet itself, or the tweet's content may not obviously be sarcastic without seeing the sarcasm hashtag (e.g., *"The most boring hockey game ever #sarcasm"*).

Of the 1,600 tweets in our data set that were obtained from the random stream and did not have a sarcasm hashtag, 29 (1.8%) were judged to be sarcastic based on our annotation guidelines.

4.2 Baselines

Overall, 693 of the 3,000 tweets in our Test Set were annotated as sarcastic, so a system that classifies every tweet as sarcastic will have 23% precision. To assess the difficulty of recognizing the sarcastic tweets in our data set, we evaluated a variety of baseline systems.

We created two baseline systems that use n-gram features with supervised machine learning to create a sarcasm classifier. We used the LIBSVM (Chang and Lin, 2011) library to train two support vector machine (SVM) classifiers: one with just unigram features and one with both unigrams and bigrams. The features had binary values indicating the presence or absence of each n-gram in a tweet. The classifiers were evaluated using 10-fold cross-validation. We used the RBF kernel, and the cost and gamma parameters were optimized for accuracy using unigram features and 10-fold cross-validation on our Tuning Set. The first two rows of Table 2 show the results for these SVM classifiers, which achieved F scores of 46-48%.

We also conducted experiments with existing sentiment and subjectivity lexicons to see whether they could be leveraged to recognize sarcasm. We experimented with three resources:

Liu05 : A positive and negative opinion lexicon from (Liu et al., 2005). This lexicon contains 2,007 positive sentiment words and 4,783 negative sentiment words.

MPQA05 : The MPQA Subjectivity Lexicon that is part of the OpinionFinder system (Wilson et al., 2005a; Wilson et al., 2005b). This lexicon contains 2,718 subjective words with positive polarity and 4,910 subjective words with negative polarity.

AFINN11 The AFINN sentiment lexicon designed for microblogs (Nielsen, 2011; Hansen et al., 2011) contains 2,477 manually labeled words and phrases with integer values ranging from -5 (negativity) to 5 (positivity). We considered all words with negative values to have negative polarity (1598 words), and all words with positive values to have positive polarity (879 words).

We performed four sets of experiments with each resource to see how beneficial existing sentiment

Table 2: Experimental results on the test set

lexicons could be for sarcasm recognition in tweets. Since our hypothesis is that sarcasm often arises from the contrast between something positive and something negative, we systematically evaluated the positive and negative phrases individually, jointly, and jointly in a specific order (a positive phrase *followed by* a negative phrase).

First, we labeled a tweet as sarcastic if it contains any positive term in each resource. The *Positive Sentiment Only* section of Table 2 shows that all three sentiment lexicons achieved high recall (75-78%) but low precision (30-34%). Second, we labeled a tweet as sarcastic if it contains any negative term from each resource. The *Negative Sentiment Only* section of Table 2 shows that this approach yields much lower recall and also lower precision of 22-24%, which is what would be expected of a random classifier since 23% of the tweets are sarcastic. These results suggest that explicit negative sentiments are not generally indicative of sarcasm.

Third, we labeled a tweet as sarcastic if it contains both a positive sentiment term and a negative sentiment term, in any order. The *Positive and Negative Sentiment, Unordered* section of Table 2 shows that this approach yields low recall, indicating that relatively few sarcastic tweets contain both positive and negative sentiments, and low precision as well.

Fourth, we required the contrasting sentiments to occur in a specific order (the positive term must precede the negative term) and near each other (no more than 5 words apart). This criteria reflects our observation that positive sentiments often closely precede negative situations in sarcastic tweets, so we wanted to see if the same ordering tendency holds for negative sentiments. The *Positive and Negative Sentiment, Ordered* section of Table 2 shows that this ordering constraint further decreases recall and only slightly improves precision, if at all. Our hypothe-

sis is that when positive and negative sentiments are expressed in the same tweet, they are referring to different things (e.g., different aspects of a product). Expressing positive and negative sentiments about the same thing would usually sound contradictory rather than sarcastic.

4.3 Evaluation of Bootstrapped Phrase Lists

The next set of experiments evaluates the effectiveness of the positive sentiment and negative situation phrases learned by our bootstrapping algorithm. The results are shown in the *Our Bootstrapped Lexicons* section of Table 2. For the sake of comparison with other sentiment resources, we first evaluated our positive sentiment verb phrases and negative situation phrases independently. Our positive verb phrases achieved much lower recall than the positive sentiment phrases in the other resources, but they had higher precision (45%). The low recall is undoubtedly because our bootstrapped lexicon is small and contains only verb phrases, while the other resources are much larger and contain terms with additional parts-of-speech, such as adjectives and nouns.

Despite its relatively small size, our list of negative situation phrases achieved 29% recall, which is comparable to the negative sentiments, but higher precision (38%).

Next, we classified a tweet as sarcastic if it contains both a positive verb phrase and a negative situation phrase from our bootstrapped lists, in any order. This approach produced low recall (11%) but higher precision (56%) than the sentiment lexicons. Finally, we enforced an ordering constraint so a tweet is labeled as sarcastic only if it contains a positive verb phrase that precedes a negative situation in close proximity (no more than 5 words apart). This ordering constraint further increased precision from 56% to 70%, with a decrease of only 2 points in recall. This precision gain supports our claim that this particular structure (positive verb phrase followed by a negative situation) is strongly indicative of sarcasm. Note that the same ordering constraint applied to a positive verb phrase followed by a negative *sentiment* produced much lower precision (at best 40% precision using the Liu05 lexicon). Contrasting a positive sentiment with a negative *situation* seems to be a key element of sarcasm.

In the last experiment, we added the positive predicative expressions and also labeled a tweet as sarcastic if a positive predicative appeared in close proximity to (within 5 words of) a negative situation. The positive predicatives improved recall to 13%, but decreased precision to 63%, which is comparable to the SVM classifiers.

4.4 A Hybrid Approach

Thus far, we have used the bootstrapped lexicons to recognize sarcasm by looking for phrases in our lists. We will refer to our approach as the Contrast method, which labels a tweet as sarcastic if it contains a positive sentiment phrase in close proximity to a negative situation phrase.

The Contrast method achieved 63% precision but with low recall (13%). The SVM classifier with unigram and bigram features achieved 64% precision with 39% recall. Since neither approach has high recall, we decided to see whether they are complementary and the Contrast method is finding sarcastic tweets that the SVM classifier overlooks.

In this hybrid approach, a tweet is labeled as sarcastic if either the SVM classifier or the Contrast method identifies it as sarcastic. This approach improves recall from 39% to 42% using the Contrast method with only positive verb phrases. Recall improves to 44% using the Contrast method with both positive verb phrases and predicative phrases. This hybrid approach has only a slight drop in precision, yielding an F score of 51%. This result shows that our bootstrapped phrase lists are recognizing sarcastic tweets that the SVM classifier misses.

Finally, we ran tests to see if the performance of the hybrid approach (Contrast $\cup$ SVM) is statistically significantly better than the performance of the SVM classifier alone. We used paired bootstrap significance testing as described in Berg-Kirkpatrick et al. (2012) by drawing 10^6 samples with repetition from the test set. These results showed that the Contrast $\cup$ SVM system is statistically significantly better than the SVM classifier at the $p < .01$ level (i.e., the null hypothesis was rejected with 99% confidence).

4.5 Analysis

To get a better sense of the strength and limitations of our approach, we manually inspected some of the

tweets that were labeled as sarcastic using our bootstrapped phrase lists. Table 3 shows some of the sarcastic tweets found by the Contrast method but not by the SVM classifier.

i love *fighting* with the one i love
love *working* on my last day of summer
i enjoy tweeting [user] and *not getting* a reply
working during vacation is awesome .
can't wait *to wake* up early to babysit !

Table 3: Five sarcastic tweets found by the Contrast method but not the SVM

These tweets are good examples of a positive sentiment (love, enjoy, awesome, can't wait) contrasting with a negative situation. However, the negative situation phrases are not always as specific as they should be. For example, "working" was learned as a negative situation phrase because it is often negative when it follows a positive sentiment ("I love working..."). But the attached prepositional phrases ("on my last day of summer" and "during vacation") should ideally have been captured as well.

We also examined tweets that were incorrectly labeled as sarcastic by the Contrast method. Some false hits come from situations that are frequently negative but not always negative (e.g., some people genuinely like waking up early). However, most false hits were due to overly general negative situation phrases (e.g., "I love *working* there" was labeled as sarcastic). We believe that an important direction for future work will be to learn longer phrases that represent more specific situations.

5 Conclusions

Sarcasm is a complex and rich linguistic phenomenon. Our work identifies just one type of sarcasm that is common in tweets: contrast between a positive sentiment and negative situation. We presented a bootstrapped learning method to acquire lists of positive sentiment phrases and negative activities and states, and show that these lists can be used to recognize sarcastic tweets.

This work has only scratched the surface of possibilities for identifying sarcasm arising from positive/negative contrast. The phrases that we learned were limited to specific syntactic structures and we required the contrasting phrases to appear in a highly constrained context. We plan to explore methods for allowing more flexibility and for learning additional types of phrases and contrasting structures.

We also would like to explore new ways to identify stereotypically negative activities and states because we believe this type of world knowledge is essential to recognize many instances of sarcasm. For example, sarcasm often arises from a description of a negative event followed by a positive emotion but in a separate clause or sentence, such as: *"Going to the dentist for a root canal this afternoon. Yay, I can't wait."* Recognizing the intensity of the negativity may also be useful to distinguish strong contrast from weak contrast. Having knowledge about stereotypically undesirable activities and states could also be important for other natural language understanding tasks, such as text summarization and narrative plot analysis.

Abstract

Personal profile information on social media like LinkedIn.com and Facebook.com is at the core of many interesting applications, such as talent recommendation and contextual advertising. However, personal profiles usually lack organization confronted with the large amount of available information. Therefore, it is always a challenge for people to find desired information from them. In this paper, we address the task of personal profile summarization by leveraging both personal profile textual information and social networks. Here, using social networks is motivated by the intuition that, people with similar academic, business or social connections (e.g. *co-major*, *co-university*, and *co-corporation*) tend to have similar experience and summaries. To achieve the learning process, we propose a collective factor graph (CoFG) model to incorporate all these resources of knowledge to summarize personal profiles with local textual attribute functions and social connection factors. Extensive evaluation on a large-scale dataset from LinkedIn.com demonstrates the effectiveness of the proposed approach.

1 Introduction

Web 2.0 has empowered people to actively interact with each other, forming social networks around mutually interesting information and publishing a large amount of useful user-generated content (UGC) online (Lappas et al., 2011; Tan et al., 2011). One popular and important type of UGC is the personal profile, where people post detailed information on online portals about their education, experiences and other personal information. Social websites like Facebook.com and LinkedIn.com have created a viable business as profile portals, with the popularity and success partially attributed to their comprehensive personal profiles.

Generally, online personal profiles provide valuable resources for businesses, especially for human resource managers to find talents, and help people connect with others of similar backgrounds (Yang et al., 2011a; Guy et al., 2010). However, as there is always large-scale information of experience and education fields, it is hardly for us to find useful information from the profile. Therefore, it is always a challenge for people to find desired information from them. For this regard, it is highly desirable to develop reliable methods to generate a summary of a person through his profile automatically.

To the best of our knowledge, this is the first research that explores automatic summarization of personal profiles in social media. A straightforward approach is to consider personal profile summarization as a traditional document summarization problem, which treating each personal profile independently and generate a summary for each personal profile individually. For example, the well-known extraction and ranking approaches (e.g. PageRank, HITS) extract a certain amount of important sentences from a document according to some ranking measurements to form a summary (Wan and Yang, 2008; Wan, 2011).

However, such straightforward approaches are not sufficient to benefit from the carrier of personal profiles. As the centroid of social networking, people are usually connected to others with similar

Seattle, Washington, USA, 18-21 October 2013.

background in social media (e.g. *co-major*, *co-corporation*). Therefore, it is reasonable to leverage social connection to improve the performance of profile summarizing. For example if there are *co-major*, *co-university*, *co-corporation* or other academic and business relationships between two persons, we consider them sharing similar experience and having similar summaries.

The remaining challenge is how to incorporate both the profile textual information and the connection knowledge in the social networks. In this study, we propose a collective factor graph model (CoFG) to summarize the text of personal profile in social networks with local textual information and social connection information. The CoFG framework utilizes both the local textual attribute functions of an individual person and the social connection factor between different persons to collectively summarize personal profile on one person.

In this study, we treat the profile summarization as a supervised learning task. Specifically, we model each sentence of the profile as a vector. In the training phase, we use the vectors with the social connection between each person to build the CoFG model; while in the testing phase, we perform collective inference for the importance of each sentence and select a subset of sentences as the summary according to the trained model. Evaluation on a large-scale data from LinkedIn.com indicates that our proposed joint model and social connection information improve the performance of profile summarization.

The remainder of our paper is structured as follows. We go over the related work in Section 2. In Section 3, we introduce the data we collected from LinkedIn.com and the annotated corpus we constructed. In Section 4, we present some motivational analysis. In Section 5, we explain our proposed model and describe algorithms for parameter estimation and prediction. In Section 6, we present our experimental results. We sum up our work and discuss future directions in Section 7.

2 Related Work

In this section, we will introduce the related work on the traditional topic-based summarization, social-based summarization and factor graph model respectively.

2.1 Topic-based Summarization

Generally, traditional topic-based summarization can be categorized into two categories: extractive (Radev et al., 2004) and abstractive (Radev and McKeown, 1998) summarization. The former selects a subset of sentences from original document(s) to form a summary; the latter reorganizes some sentences to form a summary where several complex technologies, such as information fusion, sentence compression and reformulation are necessarily employed (Wan and Yang, 2008; Celikyilmaz and Hakkani-Tur, 2011; Wang and Zhou, 2012). This study focuses on extractive summarization.

Radev et al. (2004) proposed a centroid-based method to rank the sentences in a document set, using various kinds of features, such as the cluster centroid, position and TF-IDF features. Ryang and Abekawa (2012) proposed a reinforcement learning approach on text summarization, which models the summarization within a reinforcement learning-based framework.

Compared to unsupervised approaches, supervised learning for summarization is relatively rare. A typical work is Shen et al., (2007) which present a Conditional Random Fields (CRF) based framework to treat the summarization task as a sequence labeling problem. However, different from all existing studies, our work is the first attempt to consider both textual information and social relationship information for supervised summarization.

2.2 Social-based Summarization

As web 2.0 has empowered people to actively interact with each other, studies focusing on social media have attracted much attention recently (Meeder et al., 2011; Rosenthal and McKeown, 2011; Yang et al., 2011a). Social-based summarization is exactly a special case of summarization where the social connection is employed to help obtaining the summarization. Although topic-based summarization has been extensively studied, studies on social-based summarization are relative new and rare.

Hu et al., (2011) proposed an unsupervised PageRank-based social summarization approach by incorporating both document context and user context in the sentence evaluation process. Meng et al., (2012) proposed a unified optimization framework to produce opinion summaries of tweets through

integrating information from dimensions of topic, opinion and insight, as well as other factors (e.g. topic relevancy, redundancy and language styles).

Unlike all the above studies, this paper focuses on a novel task, profile summarization. Furthermore, we employ many other kinds of social information in profiles, such as *co-major*, and *co-corporation* between two people. They are shown to be very effective for profile summarization.

2.3 Factor Graph Model

As social network has been investigated for several years (Leskovec et al., 2010; Tan et al., 2011; Lu et al., 2010; Guy et al., 2010) and Factor Graph Model (FGM) is a popular approach to describe the relationship of social network (Tang et al., 2011a; Zhuang et al., 2012). Factor Graph Model builds a graph to represent the relationship of nodes on the social networks, and the factor functions are always considered to represent the relationship of the nodes.

Tang et al. (2011a) and Zhuang et al. (2012) formalized the problem of social relationship learning into a semi-supervised framework, and proposed Partially-labeled Pairwise Factor Graph Model (PLP-FGM) for learning to infer the type of social ties. Dong et al. (2012) gave a formal definition of link recommendation across heterogeneous networks, and proposed a ranking factor graph model (RFG) for predicting links in social networks, which effectively improves the predictive performance. Yang et al., (2011b) generated summaries by modeling tweets and social contexts into a dual wing factor graph (DWFG), which utilized the mutual reinforcement between Web documents and their associated social contexts.

Different from all above researches, this paper proposes a pair-wise factor graph model to collectively utilize both textual information and social connection factor to generate summary of profile.

3 Data Collection and Statistics

The personal profile summarization is a novel task and there exists no related data for accessing this issue. Therefore, in this study, we collect a data set containing personal summaries with the corresponding knowledge, such as the self-introduction and personal profiles. In this section, we will introduce this data set in detail.

3.1 Data Collection

We collect our data set from LinkedIn.com[1]. It contains a large number of personal profiles generated by users, containing various kinds of information, such as personal overview, summary, education, experience, projects and skills.

Figure 1: An example of a profile webpage from LinkedIn.com

In this study, the data set is crawled in the following ways. To begin with, 10 random people's public profiles are selected as seed profiles, and then the profiles from their "People Also Viewed" field were collected. The data is composed of 3,182 public profiles[3] in total. We do not collect personal names in public profiles to protect people's privacy. Figure 1 shows an example of a person's profile from LinkedIn.com. The profile includes following fields:

- *Overview*: It gives a structure description of a person's general information, such as current/previous position and workplace, brief

[1] http://www.linkedin.com

[2] The information of the example is a pseudo one.

[3] We collect all the data from LinkedIn.com at Dec 17, 2012.

education background and general technical background.

- *Summary*: It summarizes a person's work, experience and education.
- *Experience*: It details a person's work experience.
- *Education*: It details a person's education background.

Among these fields, the *Overview* is required and the others are optional, such as *Project*, *Course* and *Interest groups*. However, compared with *Overview*, *Summary*, *Experience*, *Education* fields, they seem to be less important for summarization of personal profiles. Thus, we ignore them in our study.

3.2 Data Statistics of Major Fields

We collected 3,182 personal profiles from LinkedIn.com. Table 1 shows the statistics of major fields in our data collection.

Field	#Non-empty fields	Average field length
Overview	3,182	45.1
Summary	921	25.8
Experience	3,148	192.1
Education	2,932	33.6

Table 1: Statistics of major fields in our data set, i.e. the number of non-empty fields and the average length for each field

From Table 1, we can see that,

- The information of each profile is incomplete and inconsistent, That is, not all kinds of fields are available in each personal's profile.
- Most people provide their experience and education information. However, the *Summary* fields are popularly missing (Only about 30% of people provide it). This is mainly because writing summary is normally more difficult than other fields. Therefore, it is highly desirable to develop reliable automatic methods to generate a summary of a person through his/her profile.
- The length of the *Experience* field is the longest one, and work experience always could represent general information of people.

3.3 Corpus Construction and Annotation

Among the 921 profiles that contain the summary, we manually select 497 profiles with high quality summary to construct the corpus for our research. These high-quality summaries are all written by the authors themselves. Here, the quality is measured by manually checking that whether they are well capable of summarizing their profiles. That is, they are written carefully, and could give an overview of a person and represent the education and experience information of a person.

After carefully seeing the profiles, we observe that the *Experience* field contains the most abundant information of a person. Thus, we treat the text of *Experience* field as the source of summary for each profile. Besides, we collect social context information from *Education* and *Experience* field, and these social contexts are including by LinkedIn explicitly. Table 2 shows the average length of summary and experience fields we used for evaluating our summarization approach.

Field	Average length
Summary (*the summary of the profile*)	37.2
Experience (*the source text for the summarizing*)	372.0

Table 2: Average length of the high-quality summary and corresponding experience fields

From Table 2, we can see that,

- Compared with the average length of 25.8 in Table 1, summaries of high quality have longer length because they contain more information of the profiles.
- The compression ratio of our proposed corpus is 0.1 (37.2/372.0).

4 Motivation and Analysis

In this section, we propose the motivation of social connection to address the task of personal profile summarization. To preliminarily support the motivation, some statistics of the social connection are provided.

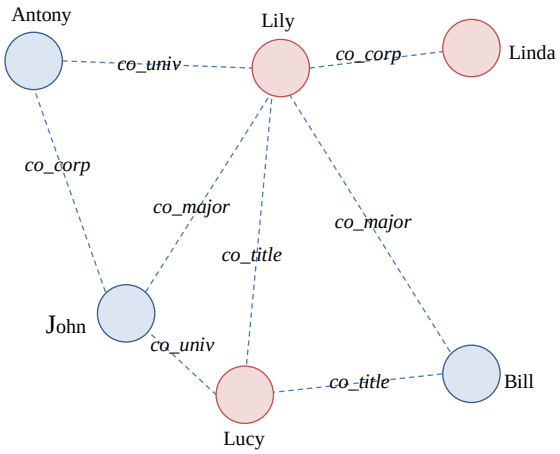

Figure 2: An example of personal profile network. *Red is for female, blue is for male, and the dotted line means the social connection between two persons.*

We first describe the social connections which we used. Figure 2 shows an example of social connection between people from the profiles of LinkedIn. We find that people are sometimes connected by several social connections. For example, John and Lucy are connected by *co_unvi* relationship, while Lily and Linda are connected by *co_corp* relationship. From LinkedIn, four kinds of social relationship between people are extracted from the *Education* field and *Experience* field. They are:

- *co_major* denotes that two persons have the same major at school
- *co_univ* denotes that two persons are graduated from the same university
- *co_title* denotes that two persons have the same title at corporation.
- *co_corp* denotes that two persons work at the same corporation.

Our basic motivation of using social connection lies in the fact that "connected" people will tend to hold related experience and similar summaries.

We then give the statistics of edges of social connection. Table 3 shows basic statistics across these edges. From Table 3, we can see that the number of users is 497 while the number of social connection edges is 14,307. The latter is much larger than the former. The number of the edges from *Education* field is similar with the number of the edges from *Experience* filed. Among all the relationships, *co_unvi* is the most common one.

	Numbers
# users	**497**
co_major	1,288
co_unvi	6,015
# education field	**7,303**
co_title	3,228
co_corp	3,776
# experience field	**7,004**
# total edges	**14,307**

Table 3: The statistic of edges for our main datasets

5 Collective Factor Graph Model

In this section, we propose a collective factor graph (CoFG) model for learning and summarizing the text of personal profile with local textual information and social connection.

5.1 Overview of Our Framework

To generate summaries for profiles, a straightforward approach is to treat each personal profile independently and generating a summary for each personal profile individually. As we mentioned on Section 3.3, we use the sentences of *Experience* field as a text document and consider it as the source of summary for each profile.

Instead, we formalize the problem of personal profile summarization in a pair-wise factor graph model and propose an approach referred to as Loopy Belief Propagation algorithm to learn the model for generating the summary of the profile. Our basic idea is to define the correlations using different types of factor functions. An objective function is defined based on the joint probability of the factor functions. Thus, the problem of collective personal profile summarization model learning is cast as learning model parameters that maximizes the joint probability of the input continuous dynamic network.

The overview of the proposed method is a supervised framework (as shown in Figure 3). First, we treat each sentence of the training data and testing data as vectors with textual information (local textual attribute functions); Second, all the vectors are connected by social connection relationships (social connection factors) and we model these vectors and their relationships into the collective factor graph; third, we propose Loopy Belief Prop-

agation algorithm to learn the model and predict the sentences of testing data; finally, we select a subset of sentences of each testing profile as the summary according to the models with top-*n* prediction score. Thus, the core issues of our framework are 1) how to define the collective factor graph model to connection profiles with social connection; 2) how to learn and predict the proposed CoFG model; 3) how to predict the sentences from the testing data with the proposed CoFG model, and generate the summary by the predict scores. We will discuss these issues on the following subsections.

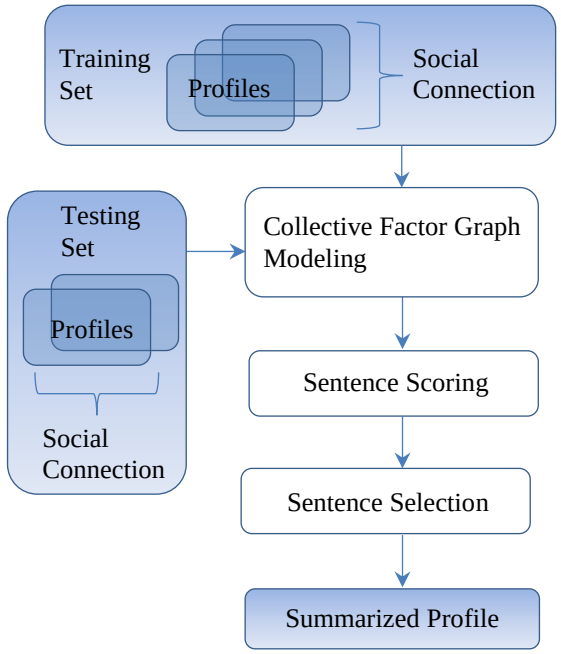

Figure 3: The overview of our proposed framework

5.2 Model Definition

Formally, given a network $G=(V,S^L,S^U,X)$, each sentence s_i is associated with an attribute vector x_i of the profile and a label y_i indicating whether the sentence is selected as a summary of the profile (The value of y_i is binary. 1 means that the sentence is selected as a summary sentence, whereas 0 stands for the opposite). V denotes the authors of the profiles, S^L denotes the labeled training data, and S^U denotes the unlabeled testing data. Let $X=\{x_i\}$ and $Y=\{y_i\}$. Then, we have the following formulation

$$P(Y \mid X,G)=\frac{P(X,G \mid Y)P(Y)}{P(X,G)} \quad (1)$$

Here, G denotes all forms of network information. This probabilistic formulation indicates that labels of skills depend on not only local attributes X, but also the structure of the network G. According to Bayes' rule, we have

$$P(Y \mid X,G)=\frac{P(X,G \mid Y)P(Y)}{P(X,G)} \propto P(X \mid Y)P(Y \mid G) \quad (2)$$

Where $P(Y \mid G)$ represents the probability of labels given the structure of the network and $P(X \mid Y)$ denotes the probability of generating attributes X associated to their labels Y. We assume that the generative probability of attributes given the label of each edge is conditionally independent, thus we have

$$P(Y \mid X,G) \propto P(Y \mid G)\prod_i P(x_i \mid y_i) \quad (3)$$

Where $P(x_i \mid y_i)$ is the probability of generating attributes x_i given the label y_i. Now, the problem becomes how to instantiate the probability $P(Y \mid G)$ and $P(x_i \mid y_i)$. We model them in a Markov random field, and thus according to the Hammersley-Clifford theorem (Hammersley and Clifford, 1971), the two probabilities can be instantiated as follows:

$$P(x_i \mid y_i)=\frac{1}{Z_1}\exp\left\{\sum_{j=1}^{d}\alpha_j f_j(x_{ij},y_i)\right\} \quad (4)$$

$$P(Y \mid G)=\frac{1}{Z_2}\exp\left\{\sum_i \sum_{j\in NB(i)} g(i,j)\right\} \quad (5)$$

Where Z_1 and Z_2 are normalization factors. Eq. 4 indicates that we define an attribute function $f(x_i,y_i)$ for each attribute x_{ij} associated with sentence s_i. α_j is the weight of the j^{th} attribute. Eq. 5 represents that we define a set of correlation factor functions $g(i,j)$ over each pair (i,j) in the network. $NB(i)$ denotes the set of social relationship neighbors nodes of i.

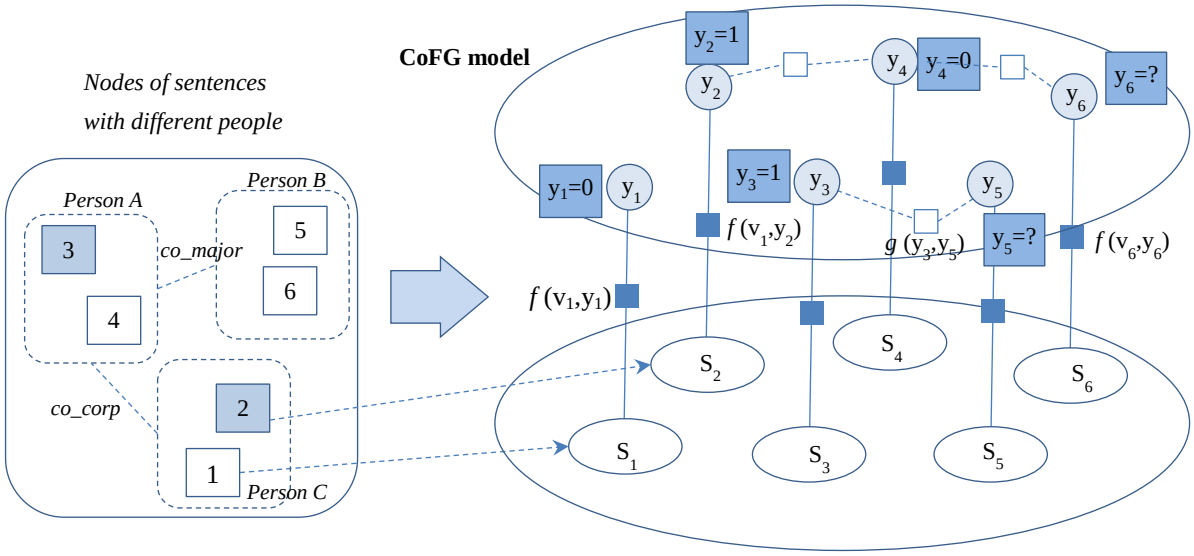

Figure 4: Graph representation of CoFG

The left figure shows the personal profile network. Each dotted line indicates a social connection. Each dotted square denotes a person, and the grey square denotes the sentence selected in the summary, and the white square denotes a sentence that is not selected as the summary..

The right figure shows the CoFG model derived from left figure. Each eclipse denotes a sentence vector of a person, and each circle indicates the hidden variable y_i. $f(v_i,y_i)$ indicates the attribute factor function. $g(y_i,y_j)$ indicates the social connection factor function.

We now briefly introduce possible ways to define the attribute functions $\{f(x_{ij}, y_i)\}_j$, and factor function $g(i, j)$.

Local textual attribute functions $\{f(x_{ij}, y_i)\}_j$: It denotes the attribute value associated with each sentence *i*. We define the local textual attribute as a feature (Lafferty et al., 2001). We can accumulate all the attribute functions and obtain local entropy for a person:

$$\frac{1}{Z_1}\exp\left(\sum_i\sum_k \alpha_k f_k(x_{ik}, y_i)\right) \qquad (6)$$

The textual attributes include following features (Shen et al., 2007; Yang et al., 2011b):

1) *BOW*: the bag-of-words of each sentence, we use unigram features as the basic textual features for each sentence.
2) *Length*: the number of terms of each sentence.
3) *Topic_words*: these are the most frequent words in the sentence after the stop words are removed.
4) *PageRank_scores*: as shown in the related work section, a document can be treated as a graph and applying a graph-based ranking algorithm (Wan and Yang., 2008). We thus use the PageRank score to reflect the importance of each sentence.

Social connection factor function $g(y_i, y_j)$: For the social correlation factor function, we define it through the pairwise network structure. That is, if the person of sentence *i* and the person of sentence *j* have a social relationship, a factor function for this social connection is defined (Tang et al., 2011a; Tang et al., 2011b), i.e.,

$$g(y_i, y_j) = \exp\left\{\beta_{ij}(y_i - y_j)^2\right\} \qquad (7)$$

The person-person social relationships are defined on Section 4, e.g. *co_major*, *co_univ*, *co_title*, and *co_corp*. We define that if two persons have at least one social connection edge, they have a social relationship. In addition, β_{ij} is the weight of the function, representing the influence degree of *i* on *j*.

To better understand our model, one example of factor decomposition is given in Figure 4. In this example, there are six sentences from three profiles. Among them, four sentences are labeled (two are labeled with the category of "1", i.e, $y=1$ and the other two are labeled with the category of "0', i.e., $y=0$) and two sentences are unlabeled (they are represented by y=?). We have six attribute functions. For example, $f(v_1, y_i)$ denotes the set

of local textual attribute functions of y_i. We also have five pairwise relationships (e.g., (y_2, y_4), (y_3, y_5)) based on the structure of the input personal profile social network. For example, $g(y_3, y_5)$ denotes social connection between y_3 and y_5, while they share the *co_major* relationship on the left figure.

5.3 Model Learning

We now address the problem of estimating the free parameters. The objective of learning the CoFG model is to estimate a parameter configuration $\theta = (\{\alpha\}, \{\beta\})$ to maximize the log-likelihood objective function $L(\theta) = \log P_\theta(Y \mid X, G)$, i.e.,

$$\theta^* = \arg\max L(\theta) \quad (9)$$

To solve the objective function, we adopt a gradient descent method. We use β (the weight of the social connection factor function $g(y_i, y_j)$) as the example to explain how we learn the parameters (the algorithm also applies to tune α by simply replacing β with α). Specifically, we first write the gradient of each β_k with regard to the objective function (Eq. 9) :

$$\frac{L(\theta)}{\beta_k} = E\left[g(i,j)\right] + E_{P_{\beta k}(Y|X,G)}\left[g(i,j)\right] \quad (10)$$

Where $E[g(i,j)]$ is the expectation of factor function $g(i,j)$ given the data distribution (essentially it can be considered as the average value of the factor function $g(i,j)$ over all pair in the training data); and $E_{P_{\beta k}(Y|X,G)}[g(i,j)]$ is the expectation of factor function $g(i,j)$ under the distribution $P_{\beta k}(Y \mid X, G)$ given by the estimated model. A similar gradient can be derived for parameter α_j.

We approximate the marginal distribution $E_{P_{\beta k}(Y|X,G)}[g(i,j)]$ using LBP (Tang et al., 2011; Zhuang et al., 2012). With the marginal probabilities, the gradient can be obtained by summing over all triads. It is worth noting that we need to perform the LBP process twice for each iteration: one is to estimate the marginal distribution of unknown variables $y_i = ?$ and the other is to estimate the marginal distribution over all pairs. In this way, the algorithm essentially performs a transfer learning over the complete network. Finally, with the obtained gradient, we update each parameter with a learning rate η. The learning algorithm is summarized in Figure 5.

Input: Network G, Learning rate η
Output: Estimated parameters θ
Initialize $\theta \leftarrow 0$
Repeat
1) Perform LBP to calculate the marginal distribution of unknown variables, i.e., $P(y_i \mid x_i, G)$
2) Perform LBP to calculate the marginal distribution of each variables, i.e., $P(y_i, y_j \mid X_{(i,j)}, G)$
3) Calculate the gradient of β_k according to Eq. 10 (for α with a similar formula)
4) Update parameter θ with the learning rate η

$$\theta_{\text{new}} = \theta_{\text{old}} + \eta \frac{L(\theta)}{\theta}$$

Until *Convergence*

Figure 5: The Learning Algorithm for CoFG model

5.4 Model Prediction and Summary Generated

We can see that in the learning process, the learning algorithm uses an additional loopy belief propagation to infer the label of unknown relationships. With the estimated parameter θ, the summarization process is to find the most likely configuration of Y for a given profile. This can be obtained by

$$Y^* = \arg\max L(Y \mid X, G, \theta) \quad (11)$$

Finally, we select a subset of sentences of each testing profile as the summary according to the trained models with top-*n* prediction scores by Y^* (Tang et al., 2011b; Dong et al, 2012).

6 Experimentation

In this section, we describe the settings of our experiment and present the experimental results of our proposed CoFG model.

Table 4: Performances of different approaches to profile summarization in terms of different measurements

6.1 Experiment Settings

In the experiment, we use the corpus collected from LinkedIn.com that contains 497 profiles (see more details in Section 3). The existing summaries in these profiles are served as the reference summary (the standard answers). As discussed in subsection 3.3, the average length of summary is about 40 words. Thus, we extract 40 words to construct the summary for each profile. We use 200 personal profiles as the testing data, and the remaining ones as the training data.

We use the ROUGE-1.5.5 (Lin and Hovy, 2004) toolkit for evaluation, a popular tool that has been widely adopted by several evaluations such as DUC and TAC (Wan and Yang, 2008; Wan, 2011). We provide four of the ROUGE F-measure scores in the experimental results: ROUGE-2 (bigram-based), ROUGE-L (based on longest common subsequences), ROUGE-W (based on weighted longest common subsequence, weight=1.2), and ROUGE-SU4 (based on skip bigram with a maximum skip distance of 4).

6.2 Experimental Results

We compare the proposed CoFG approach with three baselines illustrated as follows:

- **Random**: we randomly select sentences of each profile to generate the summary for the profile.
- **HITS**: we employ the HITS algorithm to perform profile summarization (Wan and Yang, 2008). In detail, we first consider the words as hubs the sentences as authorities; Then, we rank the sentences with the authorities' scores for each profile individually; Finally, the highest ranked sentences are chosen to constitute the summary.
- **PageRank**: we employ the PageRank algorithm to perform profile summarization (Wan and Yang, 2008). In detail, we first connect the sentences of the profile with cosine text-based similar measure to construct a graph; Then, we apply PageRank algorithm to rank the sentence through the graph for each profile individually; Finally, the highest ranked sentences are chosen to constitute the summary.
- **MaxEnt**: as a supervised learning approach, maximum entropy uses textual attribute as features to train a classification model. Then, the classification model is employed to predict which sentences can be selected to generate the summary. For the implementation of MaxEnt, we employ the tool of *mallent toolkits*[4].

Table 4 shows the comparison results of our approach (CoFG) and the baseline approaches. From Table 4, we can see that 1) either HITS or PageRank outperforms the approach of random selection; 2) The supervised approach i.e. MaxEnt, outperforms both the HITS algorithm and the PageRank approach; 3) CoFG model performs best and it greatly outperforms both the unsupervised and supervised learning baseline approaches in terms of the ROUGE-2 F-measure score. This result verifies the effectiveness of considering the social connection between the sentences in different profiles,

Figure 6 shows the performance of our proposed CoFG model with different sizes of training data. From Figure 6, we can see that CoFG model with social connection always performs better than MaxEnt, and the performance of our approach descends slowly when the training dataset becomes small. Specifically, the performance of CoFG using only 10% training data achieves better performance than MaxEnt using 100% training data.

[4] http://mallet.cs.umass.edu/

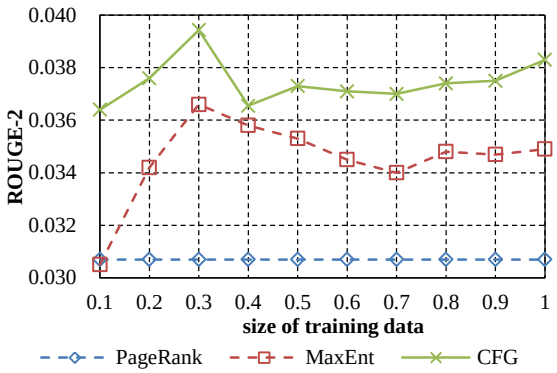

Figure 6: The performance of CoFG with different training data size

Table 5 shows the contribution of the social edges with CoFG. Specifically, CoFG is our proposed approach with both education and experience information, CoFG-*edu* means that the CoFG model considers the social edges of education field (*co_major*, *co_univ*) only, and CoFG-*exp* means that the CoFG model considers the social edges of work experience field (*co_title*, *co_corp*) only. MaxEnt can be considered as using textual information only.

	ROUGE-2
MaxEnt	0.0349
CoFG	0.0383
CoFG-*edu*	0.0382
CoFG-*exp*	0.0381

Table 5: ROUGE-2 F-Measure score of the contribution of social edges

From Table 5, we can see that all of our proposed approaches, i.e., CoFG-*edu*, CoFG-*exp*, and CoFG, outperform the baseline approach, i.e., MaxEnt. However, the performance of CoFG-*edu*, CoFG-*exp* and CoFG are similar. This result is mainly due to the fact that the information of social connection is redundant. For example, two persons who are connected by *co_major* (education field) might also be connected by *co_corp* (experience field).

7 Conclusion and Future Work

In this paper, we present a novel task named profile summarization and propose a novel approach called collective factor graph model to address this task. One distinguishing feature of the proposed approach lies in its incorporating the social connection. Empirical studies demonstrate that the social connection is effective for profile summarization, which enables our approach outperform some competitive supervised and unsupervised baselines.

The main contribution of this paper is to explore social context information to help generate the summary of the profiles, which represents an interesting research direction in social network mining. In the future work, we will explore more kinds of social context information and investigate better ways of incorporating them into profile summarization and a wider range of social network mining.

Abstract

Recently, much research focuses on event storyline generation, which aims to produce a concise, global and temporal event summary from a collection of articles. Generally, each event contains multiple sub-events and the storyline should be composed by the component summaries of all the sub-events. However, different sub-events have different part-whole relationship with the major event, which is important to correspond to users' interests but seldom considered in previous work. To distinguish different types of sub-events, we propose a mixture-event-aspect model which models different sub-events into local and global aspects. Combining these local/global aspects with summarization requirements together, we utilize an optimization method to generate the component summaries along the timeline. We develop experimental systems on 6 distinctively different datasets. Evaluation and comparison results indicate the effectiveness of our proposed method.

1 Introduction

With the rapid growth of the World Wide Web, information explosion has become an important issue to modern people. Those who search for information from the Internet often get lost and confused by the overwhelmingly large collection of web documents. So how to get a concise and global picture for a given event subject is an urgent problem to be solved. Although many document understanding systems have been proposed, such as multi-document summarization systems, to generate a compressed summary by extracting the major information from the collection of documents, they ignored the dynamic development information of an event. Intuitively, each event is long-running and contains multiple sub-events, including related events. Users are likely to prefer a summary of all occurrences of all the sub-events along the timeline of the event. This motivates us to study the task of generating event storyline from a collection of web documents related to an event subject.

The research of event storyline summarization is popular in recent years. Its task is to summarize a collection of web documents by extracting representative information based on all the sub-events and generate a global summary. Generally, generating such a global storyline is quite interesting for the following main reasons: (1) It can help people catch the whole incident based on an overall temporal structured summary for a given subject, and understand the cause, climax, development process and result of an event. (2) It can also make people know what other events are related, or the effect of this incident to subsequent events, which can present the evolution of an event along a timeline.

Though several methods of generating event storyline have been proposed recently, there are still some problems unresolved. As event storyline summarization is a process to generate component summaries based on the multiple sub-events, which is different from traditional summarization focusing on only one subject, so how to exactly extract all the sub-events is the first challenge. Moreover, users tend to bias to the sub-events which have global

Seattle, Washington, USA, 18-21 October 2013.

consistency with the given event subject, so the sub-events should not be considered equally when generating the component summaries. It is also a great challenge to generate a qualified summary based on the different types of sub-events. The component summaries should be correlative across different dates based on the global collection (Yan et al., 2011a).

Mei and Zhai (Mei and Zhai, 2005) proposed to use theme or topic to model different sub-events, which is to some extent similar to our method. To be different, in this paper we introduce "local/global" property to distinguish different part-whole relationship between the sub-events and the major event, which have not been considered before in storyline generation or summarization, to improve the quality of the storyline. The local/global property corresponds to the elements of an event, such as the place, characters and other body information. These information reflects the relationship between the sub-events and the major event. Some sub-events have distinctive body information and little relevance with each other. They generally occur for a local period, which we name as "local-sub-events". While other sub-events often share common properties with each other and have close relationship with the major event and we call them as "global-sub-events". Here we give some examples to illustrate the difference. For the event "Connecticut school shooting" which occurred on Dec.14 2012, its sub-events such as "Obama's speech for this massacre" or "Gun control Act" have little word co-occurrences and distinctive event body information to each other, while the process and result of this tragedy can be regarded as global-sub-events which have a lot of word co-occurrences and share common properties with the major event.

Inspired by these, to detect different types of sub-events based on word co-occurrences between sub-events and the major event, we propose a mixture-event-aspect (MEA) model to formalize different types of sub-events into local/global aspects, which are implicated with clusters of sentences. Then combining the local/global aspects with summarization requirements together, we utilized an optimization approach to get the optimal component summaries along the timeline. We evaluate our method on 6 distinctively different datasets. Performance comparisons among different system-generated storylines demonstrate the necessity to distinguish different types of sub-events and also indicates the effectiveness of the proposed mixture-event-aspect model.

The rest of the paper is organized as follows. We briefly review the related work in section 2. In section 3 we present the details of optimized event storyline generation based on mixture-event-aspect model. Experiments and results are discussed in Section 4. Finally we draw a conclusion of this study in Section 5.

2 Related Work

Our work is related to several lines of research in the literature including multi-document summarization (MDS), topic detection and tracking (TDT), temporal text mining (TXM) and temporal news summarization (TNS).

Multi-document summarization is a process to generate a summary by reducing documents in size while retaining the main information. To date, different features and ranking strategies have been studied. Radev et al. (Radev et al., 2004) proposed to implement MEAD as a centroid-based summarizer by combining several predefined features to score the sentence. LexPageRank (Erkan and Radev, 2004) is the representative work which is based on PageRank (Page et al., 1999) algorithm. Some methods have been proposed to extend the conventional graph-based models recently including multi-layer graph incorporated with different relationship (Wan, 2008), ToPageRank based on the topic information (Pei et al., 2012) and DivRank (Mei et al., 2010) balancing the prestige and diversity.

Topic detection and tracking (TDT) aims to group news articles based on the topics discussed in them, detect some novel and previously unreported events and track future events related to the topics (Wang et al., 2012). Kumaran and Allan (Kumaran and Allan, 2004) showed how performance on new event detection could be improved by the use of text classification techniques as well as by using named entities in a new way. Makkonen et al. (Makkonen et al., 2004) proposed a method that incorporated simple semantics into TDT by splitting the term space into groups of terms. Krause et al. Wang et al. (Wang et al., 2007) and Wang et al. (Wang et al.,

2009) worked on topic tracking from multiple news streams. Their methods extracted meaningful topics from multi-source news collections and tracked different topics as they evolved from one to another along the timeline.

Our work is also related to temporal text mining and temporal news summarization. The task of temporal news summarization is to generate news summaries along the timeline from massive data. Chieu et al. (Chieu and Lee, 2004) built a system that extracted events relevant to a query from a collection of related documents and placed such events along a timeline. Yan et al. (Yan et al., 2011b) designed an evolutionary timeline summarization approach to construct a timeline of a topic by optimizing the relevance, coverage, coherence, and diversity. Lin et al. (Lin et al., 2012) explored the problem of generating storylines from microblogs for user input queries. They first proposed a language model with dynamic pseudo relevance feedback to obtain relevant tweets and then generated storylines via graph optimization.

3 Approach Details

In this section, we first propose a mixture-event-aspect model to detect local/global sub-events based on part-whole relationship with the major event and then present a new method to estimate the bursty of each aspect on a certain date. Afterwards we utilize an optimization method based on local/global aspects to extract the qualified summary.

3.1 Mixture-Event-Aspect Model

The key challenge to our storyline generation task is to detect and distinguish different types of sub-events contained in the article collection. In the collection, each sentence is assigned with a certain date and sentences that are assigned with the same date are grouped into the same sub-collection. Considering the consistency of content between the sub-events and the major event, we model different sub-events into two types: local-sub-event and global-sub-event, and introduce local/global aspects correspondingly. Generally, local aspects which correspond to local-sub-events have distinctive words distribution from each other and sustain for a local context while the global aspects corresponding to global-sub-events have coincident words distribution with the major event. To capture specific words, Titov and McDonald (Titov and McDonald, 2008) proposed a multi-grain topic model, relying on word co-occurrences within short paragraphs and Li et al. (Li et al., 2010) proposed a entity-aspect model based on word co-occurrences within single sentences. Inspired by these ideas, we rely on word co-occurrences within local period context to detect mixed local and global aspects implicated in the whole collection. We name this model as "Mixture-Event-Aspect (MEA)" model which can simultaneously detect local/global aspects and cluster sentences and words into different aspects.

3.1.1 Model Description

Our mixture-event-aspect (MEA) model can be extended from both the Probabilistic Latent Semantic Analysis (PLSA) (Hofmann, 1999) and Latent Dirichlet Allocation (LDA) (Blei et al., 2003). We model two distinct types of aspects: global aspects and local aspects, based on their relationship with the major event. The distribution of global aspects is fixed for the collection while the distribution of local aspects is fixed to a local period of sub-collections. That means a sentence is sampled either from the mixture of the global aspects or from the local aspects specific for the local context. Here we take the event "Connecticut school shooting" as an example. For the sentence "On Sunday, President Obama came to Connecticut to give a lecture, expressing his sorrow for ... and calling for an end to such incidents", the words such as "Obama", "lecture", "express" are only occurred for the local period of two days and have no co-occurrence with other neighboring period sentences, so we sample the sentence as a local aspect sentence. But for the sentence "All schools in Newtown, the northeastern U.S. state of Connecticut were in lockdown after a shooting was reported at a local elementary school", the words such as "Connecticut", "shooting", "elementary" have high co-occurrence frequency in the whole collection, so we sample the sentence as a global aspect sentence.

To detect aspects, we first divide words into two types: aspect words and background words. Background words are commonly used in the whole event corpus while aspect words are clearly associat-

ed with the aspects of the sentences they occur in. Stop words are removed using a standard stop word list. In order to get the distribution of local aspects, we implement a mechanism called "Time Window" which covers S_p sequential time-based sub-collections. We associate each time window with a distribution over local aspects and a distribution defining preference of local aspects versus global aspects.

draw $\varphi^B \sim Dir(\beta)$, $\psi_c(v) \sim Dir(\lambda)$, $\pi \sim Dir(\gamma)$
draw $\varphi^{gl} \sim Dir(\beta)$ for A_{gl} times
draw $\varphi^{loc} \sim Dir(\beta)$ for A_{loc} times
choose a distribution of global aspects $\theta^{gl} \sim Dir(\alpha^{gl})$
For each time window v in collection c
    choose $\theta^{loc}_{c,v} \sim Dir(\alpha^{loc})$
    choose $\rho_{c,v} \sim Beta(\alpha^{mix})$
For each sentence s in collection c
    choose window $\nu_{c,s} \sim \psi_c$
    choose $\eta_{c,s} \sim \rho_{c,\nu_{c,s}}$
    if $\eta_{c,s} = gl, z_{c,s} \sim \theta^{gl}$
    if $\eta_{c,s} = loc, z_{c,s} \sim \theta^{loc}_{c,v}$
For each word w of sentence s in collection c
    draw $y_{c,s,n} \sim Multi(\pi)$
    draw $w_{c,s,n} \sim Multi(\varphi^B)$ if $y_{c,s,n} = 1$
    draw $w_{c,s,n} \sim Multi(\varphi^{z_{c,s}})$ if $y_{c,s,n} = 2$

Figure 1: The Collection Generation Process

Formally, let $C = \{C_t | t = 1, 2, 3, ..., T\}$ be T time based sub-collections related to the event subject, C_t represents the collection of sentences which are assigned with the date t. Let v be a time window containing S_p sequential sub-collections, $v = \{C_t | t = i, i+1, ..., i+S_p-1\}$. We draw a background unigram language model which generates words for all sub-collections, and draw A_{gl} global aspect unigram language models for global aspects and A_{loc} word distributions for local aspects. We assume these word distributions have a uniform Dirichlet prior $Dir(\beta)$. There is also a multinomial distribution π that controls in each sentence how often the word occurs as a background word or an aspect word. π has a Dirichlet prior with parameter γ. We assign each window v with an distribution over local aspects and a distribution ρ defining preference for local aspects versus global aspects. ρ has a Beta prior α^{mix}. A sentence can be sampled using any window which is chosen according to a categorical distribution.

In Figure 2 the corresponding graphical model is presented. This model allows for fast approximate inference with collapsed Gibbs sampling.

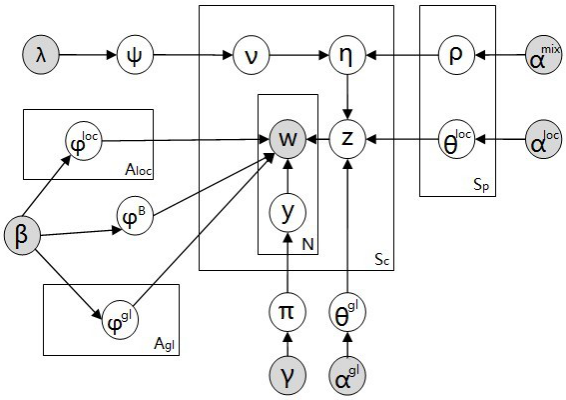

Figure 2: Mixture-Event-Aspect Model

Let S_C denotes the number of sentences in collection C, $N_{c,s}$ denotes the number of words in sentence s of collection c, and $w_{c,s,n}$ denotes the n^{th} word in sentence s. There are two kinds of hidden variables: $z_{c,s}$ for each sentence to indicate the aspect a sentence belongs to, and $y_{c,s,n}$ for each word to indicate whether a word is generated from the background model or the aspect model.

3.1.2 Inference via Gibbs Sampling

In order to estimate the hidden parameters in the model, we try to maximize distribution $p(\mathbf{z},\mathbf{y}|\mathbf{w}; \alpha, \beta, \gamma, \lambda)$, where **z**, **y** and **w** represent the set of all z, y and w variables, respectively. Given a sentence s in the collection c, we apply Gibbs Sampling to estimate the conditional probability for local/global aspects using the following rules:

$$p(v_{c,s} = v_h, \eta_{c,s} = gl, z_{c,s} = a | v', z', y, w) \propto \frac{n^c_{h*}+\lambda}{n^c_{(.)}+S^*_p\lambda} \cdot \frac{n^{c,v_h}_{gl}+\alpha^{mix}_{gl}}{n^{c,v_h}_{(.)}+\sum_{r' \in gl,loc} \alpha^{mix}_{r'}} \cdot \frac{n^c_{gl,a}+\alpha^{gl}}{n^c_{gl}+A_{gl}\alpha^{gl}} \cdot \frac{\prod_{l=1}^{L}\prod_{i=0}^{E(l)-1}(C^a_{(l)}+i+\beta)}{\Pi_{i=0}^{E(.)-1}(C^a_{(.)}+i+L\beta)}$$

$$p(v_{c,s}=v_h,\eta_{c,s}=loc,z_{c,s}=a|v^{'},z^{'},y,w)\propto \frac{n^c_{h^*}+\lambda}{n^c_{(.)}+S^*_p\lambda}\cdot\frac{n^{c,v_h}_{loc}+\alpha^{mix}_{loc}}{n^{c,v_h}_{(.)}+\sum\limits_{r^{'}\in gl,loc}\alpha^{mix}_{r^{'}}}\cdot\frac{n^{c,v_h}_{loc,a}+\alpha^{loc}}{n^{c,v_h}_{loc}+A_{loc}\alpha^{loc}}\cdot\frac{\prod_{l=1}^{L}\prod_{i=0}^{E(l)-1}(C^a_{(l)}+i+\beta)}{\prod_{i=0}^{E(.)-1}(C^a_{(.)}+i+L\beta)}$$

where $n^c_{h^*}$ =#$\{s_i|v_{c,s_i}=v_{i-s_p+h^*+1}\}$, denotes the number of times a sentence s_i in collection c is assigned to its h^{*th} window and for each sentence s_i, we have $h=i-S_p+1+h^*$. S^*_p is the number of windows that contain sentence s. $n^c_{(.)}$ denotes the number of sentences in collection c. S_p represents the number of dates a window covered. n^{c,v_h}_{gl} and n^{c,v_h}_{loc} are the number of sentences in window v_h that are assigned to global or local aspects. $n^{c,v_h}_{(.)}$ is the number of sentences assigned to window v_h. $n^c_{gl,a}$ is the number of sentences in all global aspects that are assigned to aspect a and $n^{c,v_h}_{loc,a}$ is the number of local aspect sentences in the window v_h are assigned to aspect a. A_{gl} is the number of global aspects in collection C while A_{loc} is the number of local aspects. $E(l)$ represents the number of times of word l occurs in the current sentence and is assigned to be an aspect word, while $E(.)$ is the total number of words in the current sentence that are assigned to be an aspect word.

Then we compute the assignments of the considered word. We sample the hidden variables $y_{c,s,n}$ for each word with the following rules:

$$p(y_{c,s,n}=1|z,y^{'})\propto\frac{C^{\pi}_{(1)}+\gamma}{C^{\pi}_{(.)}+2\cdot\gamma}\cdot\frac{C^B_{(w_{c,s,n})}+\beta}{C^B_{(.)}+L\cdot\beta}$$

$$p(y_{c,s,n}=2|z,y^{'})\propto\frac{C^{\pi}_{(2)}+\gamma}{C^{\pi}_{(.)}+2\cdot\gamma}\cdot\frac{C^a_{(w_{c,s,n})}+\beta}{C^a_{(.)}+L\cdot\beta}$$

where $C^{\pi}_{(1)}$ and $C^{\pi}_{(2)}$ are the numbers of words assigned to be background words and aspect words. $C^{\pi}_{(.)}$ is the total number of words. $C^B_{(.)}$ is the total number of background words and $C^a_{(.)}$ is the number of words assigned to aspect a.

By using the samples from Gibbs sampling, we can effectively make the following estimations:

$$\varphi^B_w=\frac{C^B_w+\beta}{C^B_{\cdot}+L\cdot\beta},\ \varphi^a_w=\frac{C^a_w+\beta}{C^a_w+L\cdot\beta},\ \psi_{h^*}=\frac{n^c_{h^*}+\lambda}{n^c_{(.)}+S^*_p\lambda}$$
$$\pi_y=\frac{C^{\pi}_y+\gamma}{C^{\pi}_{\cdot}+2\cdot\gamma},\ \rho^{c,v}_{\eta}=\frac{n^{c,v}_{\eta}+\alpha^{mix}_{\eta}}{n^{c,v}+\sum\limits_{r\in(gl,loc)}\alpha^{mix}_r}$$
$$\theta^{gl}_a=\frac{n^c_{gl,a}+\alpha^{gl}}{n^c_{gl}+A_{gl}\alpha^{gl}},\ \theta^{loc}_a=\frac{n^{c,v}_{loc,a}+\alpha^{loc}}{n^{c,v}_{loc}+A_{loc}\alpha^{loc}}$$

The hyper-parameters like $\alpha,\beta,\gamma,\lambda$ can be estimated using standard methods introduced in (Minka, 2000).

3.2 Bursty Period Detection

We borrow the definition of "bursty" from (Lappas et al., 2009) to measure the popularity of the event on a certain date. Intuitively, each aspect have different bursties on different dates. In this section, we try to obtain the temporal aspect sequences of an event based on the bursty periods of all the aspects. During its bursty period, one aspect should (1)be more popular than other aspects (2) be continuously more popular than other time. Following these intuitions, we design a method to measure the bursty of each aspect and get the bursty period.

Let A_k be the k^{th} aspect obtained from the mixture-event-aspect model, we estimate the bursty of A_k at a certain date t as follows.

$$bursty(A_{k,t})=p(t|A_k)=\frac{p(A_k|t)\cdot p(t)}{\sum\limits_{t^{'}}p(A_k|t^{'})p(t^{'})}$$

where $p(A_k|t)$ is measured by the number of sentences assigned to aspect A_k in date t divided by the total number of sentences in date t. $p(t)$ is estimated by the total number of sentences in aspect A_k divided by the overall number of sentences in the collection C.

After getting the bursty of aspect A_k at each date, we can find the most popular date and expand on both sides to obtain the whole burst period in which the bursties are higher than the neighboring aspects and continuous higher than other dates.

3.3 Optimization-based Storyline Generation

With the methods discussed in previous sections, we can get the local/global aspect sequence. Each aspect contains numbers of sentences and we are aiming to select the most representative ones to compose the final storyline. Considering users' bias and the length requirement, different aspects should have different proportions in the last storyline. For global aspects which correspond more to users' interest, they should share a larger proportion in the final storyline than local aspects. Thus, we use an optimization method to determine if a sentence is selected to be an summary sentence or to be discarded based on the multiple local/global aspects and finally get the optimal storyline. We formalize this problem as selecting a subset of sentences S from the aspect A_k

to minimize the information loss.

$$\arg\min \sum_{A_k \in C, S \in A_k} \sum_{z \in A_k - S, s \in S} O(z, s)$$

where $O(z, s)$ is the cost function which measures the cost of representing sentence z with sentence s. Generally, this is an NP-hard problem (Cheung et al., 2009) but we can use POPSTAR, an implementation of an approximate solution proposed by Resende and Werneck (Resende and Werneck, 2004). To model different costs between global or local aspects and determine the proportions of different aspects in the final storyline, we utilize a function $\zeta(s)$. When sentences z and s are local aspect sentences, $\zeta(s) = \chi$, or, $\zeta(s) = 1 - \chi$. Formally, we incorporate two kinds of decreasing/increasing logistic functions, $\ell_1(x) = 1/(1 + e^x)$ and $\ell_2(x) = e^x/(1 + e^x)$, to define the cost function as

$$O(z, s) = \zeta(s) \cdot \ell_1(S(s)) \cdot \ell_2(S(z)) \cdot D_{KL}(s, z)$$

where $S(s)$ and $S(z)$ are the ranking scores of sentences s and z among the aspect A_k with LexPageRank algorithm. $D_{KL}(s, z)$ is used to measure the similarity between sentence s and z with Kullback-Leibler divergence here.

With this optimization method, we get the representative sentences of each aspect for the given event subject. Combining all the representative sentences together based on the aspect sequence, we finally generate the storyline.

4 Experiments and Evaluation

4.1 Datasets

To evaluate our framework for event storyline generation, we conduct our experiments on the datasets amounting to 12418 articles for 6 event subjects from 6 famous news websites, which provide date edited by professional editors. Each article consists of three parts, title, publish-time and news content. Table 1 and Table 2 give the brief description of the 12418 articles. To generate reference summary, we invite 12 undergraduate students with good English ability to read the sentences, and for each event subject we ask two students to label human storylines.

4.2 Evaluation Metrics

We use the ROUGE[1] (Lin and Hovy, 2003) (Recall Oriented Understudy for Gisting Evaluation) toolkit to evaluate our framework, which has been widely applied for summarization evaluation. It evaluates the quality of a summary by counting the overlapping units between the candidate summary and reference summaries. There are many kinds of ROUGE metrics to measure the system-generated summarization such as ROUGE-N, ROUGE-L, ROUGE-W, and ROUGE-U, of which the most important one is ROUGE-N with 3 sub-metrics: precision, recall, and F-score.

$$ROUGE - N = \frac{\sum_{S \in RS} \sum_{N-gram \in S} Count_{match}(N - gram)}{\sum_{S \in RS} \sum_{N-gram \in S} Count(N - gram)}$$

where RS represents the reference summaries. N-gram∈RS in the metrics denotes the N-grams in reference summaries. $Count_{match}(N - gram)$ is the maximum number of N-grams co-occurring in the candidate summary and in the set of reference summaries. $Count(N - gram)$ is the number of N-grams in the reference summaries.

The ROUGE toolkit can report separate scores for 1, 2, 3, and 4-gram. In the experimental results we report three ROUGE F-measure scores: ROUGE-1, ROUGE-2, ROUGE-W metrics. The higher the ROUGE scores, the better the summary is.

4.3 Algorithms for Comparison

Given a collection of news articles, we first decompose them into sentences, and then assign each sentence with a certain date, afterwards stop-words removing and words stemming are performed. We choose the following algorithms as baseline systems. Specifically, baseline 2 and 3 are summarization

Table 1: News sources of the 6 datasets

News Sources	Number of Articles
CNN	2357
Fox News	1936
New York Times	2178
ABC	2113
Washington Post	1405
Xinhua	2429

Table 2: Event subjects of the datasets

Event Subjects	Number of Articles
Connecticut school shooting	1792
The earthquake in Tokyo, Japan	2046
The U.S. presidential election	2573
Sandy hurricane attacked America	1827
American curiosity rover landed on Mars	1651
The 30th London Olympic Games	2529

[1] http://www.isi/edu/licensed-sw/see/rouge/

systems which are similar to our storyline generation system. Then we choose baseline 4, 5 to evaluate the effectiveness of the proposed method. It must be said that all the systems are required to generate the same number of summary words with the human reference. We conduct the same preprocessing for all algorithms for fairness.

• Random : The method selects sentences randomly from the sentence collection.

• LexPageRank (LexRank): This method applies the graph-based multi-document summarization algorithm which first constructs a sentence connectivity graph based on the cosine similarity and then chooses top-ranked sentences with PageRank.

• Chieu : This method was proposed by Chieu (Chieu and Lee, 2004), utilizing interest and burstiness to rank sentences, and choosing the top-ranked query related sentences to construct the timeline.

• LDA+LexPageRank (LDALR) : This method first applies standard LDA to detect latent topics from the collection and clusters sentences to multiple aspects, then utilizes PageRank to generate the most representative component summaries from all the aspects.

• MEA+LexPageRank (MEALR) : This method applies the proposed mixture-event-aspect model to cluster sentences into multiple aspects and then utilizes PageRank to generate the most representative component summaries from all the aspects.

• MEA+Optimization (MEAOp) : This method extracts local/global aspects with the proposed mixture-event-aspect model, and then utilizes the optimization method to get the qualified summary.

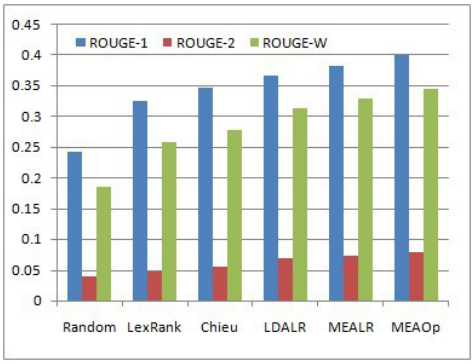

Figure 3: Overall performance for comparison

4.4 Overall Performance Comparison

We experiment with all the baselines and our framework on the 6 datasets. We take the average F-score performance in terms of 3 ROUGE-F scores: ROUGE-1, ROUGE-2 and ROUGE-SU4. The overall results are shown in Figure 3 and details are listed in Tables 3.

Figure 3 and Table 3 show the performance of these systems on the same datasets. The local/global optimization balance parameter $\chi = 0.5$. From Figure 3 and Table 3 we have following observations:

• Generally, the Random gets the worst performance;

• The LexRank system outperforms Random algorithm. This is due to the fact that LexRank ranks all the sentences based on eigenvector centrality and the global relationship between sentences, which tends to select the most informative sentences as the summary.

• The results of Chieu (Chieu and Lee, 2004) system are better than those of LexRank. This may be mainly for the reason that Chieu used the date dimension to filter away uninteresting sentences by paraphrasing and defined two different ranking measures: interest and burtiness, to select top-ranked informative sentences.

• The LDALR system outperforms the Chieu sys-

tem. This may be for the fact that Chieu's method is actually based on flat clustering-based summarization, which is not as effective as LDA topic model to extract latent sub-events.

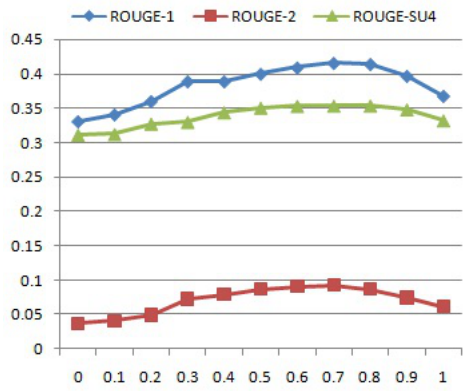

Figure 4: Examine the performance of the balance parameter χ

• The MEALR system outperforms the LDALR system. This may be mainly for the reason that MEALR utilizes the mixture-event-aspect model to detect the more salient sub-events based on the sub-whole relationship, which seems to satisfy users' bias to different sub-events.

• The MEAOp system which utilizes our method outperforms all the baselines, indicating the effectiveness of detecting different types of sub-events with mixture-event-aspect model and the necessity to distinguish different proportions of the component summaries based on local/global aspects.

4.5 Parameter Tuning

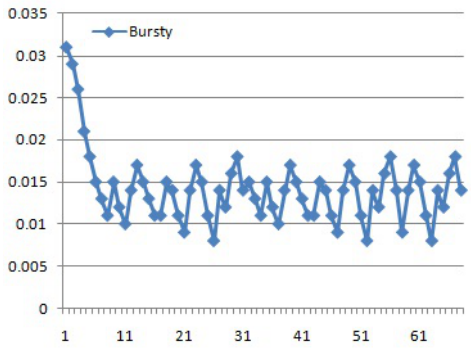

Figure 5: Aspect sequence of event "Connecticut school shooting" (X-axis is the number of days after Dec. 14, 2012. Y-axis is $bursty(A_{k,t})$)

In this section, we compare the performance of the parameters. The hyper-parameters such as α, β, γ, λ can be estimated using standard methods introduced by Minka (Minka, 2000). So we mainly examine the local/global optimization balance parameter χ. We try to evaluate the influence of this parameter on the three kinds of ROUGE measure results respectively. Figure 4 shows the performance of the balance parameters χ. It is obvious that when the balance parameter χ is set to 0.7 this method performs best.

4.6 Sample Output and Case Study

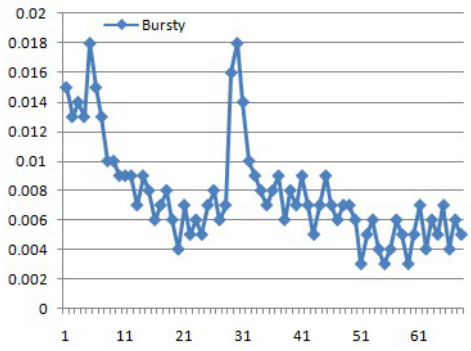

Figure 6: Bursties of sub-event "Gun control debate" (X-axis is the number of days after Dec. 14, 2012. Y-axis is $bursty(A_{k,t})$)

We take the event "Connecticut school shooting" as an example to show the usefulness of our method. Figure 5 shows the aspect sequence based on the bursty periods of all aspects. We select a sub-event "Gun control debate" and Figure 6 shows the bursties of this sub-event on the whole timeline. Table 4 shows part of the storylines for the event "Connecticut school shooting" generated by human and our method. Through observation, we find that the peak of the event "Connecticut school shooting" is around the date when it occurred, and the sub-event "Gun control debate" has two bursty periods around the two peaks. Compared with the human summary, our framework can extract the important sub-events contained in the collection, and satisfy users' interest on different sub-events based on the part-whole relationship with the event subject.

From the sample output and the human storylines, we also get some observations. (1) The component summary of global aspect tend to share larger pro-

Table 4: Selected part of storyline generated by MEAOp and human

Storyline Generated by human:
December 14, 2012 **Global Aspect**
Shooting massacre occurred in a primary school in Connecticut town, Sandy hoot Newton. 20-year-old Adam lanza broke into the primary school after shotting his mother, and in 10 minutes shot more than 100 times, killing twenty children and eight adult, including himself. The youngest death was a children in preschool students.
December 15, 2012 **Global Aspect**
Photos of the teachers and students shoot in the Connecticut massacre are released as well as the shooter's. The shooter was very smart but lonely.
December 16-17, 2012 **Local Aspect**
President Obama arrived in the locality of school shooting, mourned for the victims and made a speech.
December 18-20, 2012 **Local Aspect**
American gun control bill was put on the agenda again.
Storyline Generated by MEAOp:
December 14, 2012 **Global Aspect**
Children and adults gunned down in Connecticut school massacre. 20 children, six adults and the shooter are dead after shooting at Sandy Hoot Elementary School in Newtown, Connecticut. Three law enforcement officials say Adam Lanza, 20, was the shooter, and that he died apparently by his own hand. Suspect's mother, Nancy Lanza, found dead in suspects home in Newtown, law enforcement source says. Ryan Lanza, older brother of Adam Lanza, questioned by police but not labeled a suspect.
December 15-16, 2012 **Global Aspect**
Victims' names released Saturday; all of the slain children were either 6 or 7 years old. Understanding school lockdowns in regards to Connecticut shooting. Connecticut gunman recalled as intelligent but remote.
December 17, 2012 **Local Aspect**
President obama leads interfaith preyer vigil in newtown connecticut. A tearful Obama says "we've endured too many of these tragedies".
December 18-20, 2012 **Local Aspect**
Moderate dems join gun control debate call for commission on us violence gains. Gun debate gains traction as some lawmakers say its time to act.

portion in the final storyline. This is mainly for the reason that when researching for an event subject, users bias more to the information about the global-sub-events that have closely connection and coincident properties with the major event based on the part-whole relationship. So it is really necessary to distinguish different sub-events with distinctive properties. (2) Our system performs better for the persistent event, such as "The U.S. presidential election". This may be for the fact that these events are usually long running and have more global-sub-events than local-sub-events.

5 Conclusion

In this work, we study the task of event storyline generation and present a novel method. We innovatively introduce the properties of different sub-events based on word co-occurrences to determine the part-whole relationship with the major event and develop a mixture-event-aspect (MEA) model to formalize different types of sub-events into local/global aspects. Based on these local/global aspects, we utilize an optimization method to get the optimal component summaries along the aspect sequence. We conduct experiments with our method and various baselines on real web datasets. Through our experiments we notice that our method generates overall better storyline than other baselines. This indicates the effectiveness to detect different types of sub-events with the proposed mixture-event-aspect model and the necessity to distinguish different proportions of the component summaries based on local/global aspects.

Automatically Determining a Proper Length for Multi-document Summarization: A Bayesian Nonparametric Approach

Tengfei Ma and Hiroshi Nakagawa
The University of Tokyo
7-3-1 Hongo, Bunkyo-ku, Tokyo
{matf@r., nakagawa@}dl.itc.u-tokyo.ac.jp

Abstract

Document summarization is an important task in the area of natural language processing, which aims to extract the most important information from a single document or a cluster of documents. In various summarization tasks, the summary length is manually defined. However, how to find the proper summary length is quite a problem; and keeping all summaries restricted to the same length is not always a good choice. It is obviously improper to generate summaries with the same length for two clusters of documents which contain quite different quantity of information. In this paper, we propose a Bayesian nonparametric model for multi-document summarization in order to automatically determine the proper lengths of summaries. Assuming that an original document can be reconstructed from its summary, we describe the "reconstruction" by a Bayesian framework which selects sentences to form a good summary. Experimental results on DUC2004 data sets and some expanded data demonstrate the good quality of our summaries and the rationality of the length determination.

1 Introduction

Text summarization is the process of generating a short version of a given text to indicate its main topics. As the number of documents on the web exponentially increases, text summarization has attracted increasing attention, because it can help people get the most important information within a short time.

In most of the existing summarization systems, people need to first define a constant length to restrict all the output summaries. However, in many cases it is improper to require all summaries are of the same length. Take the multi-document summarization as an example, generating the summaries of the same length for a 5-document cluster and a 50-document cluster is intuitively improper. More specifically, consider two different clusters of documents: one cluster contains very similar articles which all focus on the same event at the same time; the other contains different steps of the event but each step has its own topics. The former cluster may need only one or two sentences to explain its information, while the latter needs to include more.

Research on summary length dates back in the late 90s. Goldstein et al. (1999) studied the characteristics of a good summary (single-document summarization for news) and showed an empirical distribution of summary length over document size. However, the length problem has been gradually ignored later, since researchers need to fix the length so as to estimate different summarization models conveniently. A typical instance is the Document Understanding Conferences (DUC)[1], which provide authoritative evaluation for summarization systems. The DUC conferences collect news aritcles as the input data and define various summarization tasks, such as generic multi-document summarization, query-focused summarization and update summarization. In all the DUC tasks, the output is restricted within a length. Then human-generated

[1] After 2007, the DUC tasks are incorporated into the Text Analysis Conference (TAC).

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 736–746,
Seattle, Washington, USA, 18-21 October 2013.

summaries are provided to evaluate the results of different summarization systems. Limiting the length of summaries contributed a lot to the development of summarization techniques, but as we discussed before, in many cases keeping the summaries of the same size is not a good choice.

Moreover, even in constant-length summarization, how to define a proper size of summaries for the summarization tasks is quite a problem. Why does DUC2007 main task require 250 words while Update task require 100 words? Is it reasonable? A short summary may sacrifice the coverage, while a long summary may cause redundance. Automatically determining the best size of summaries according to the input documents is valuable, and it may deepen our understanding of summarization.

In this work, we aim to find the proper length for document summarization automatically and generate varying-length summaries based on the document itself. The varying-length summarization is more robust for unbalanced clusters. It can also provide a recommended size as the predefined summary length for general constant-length summarization systems. We advance a Bayesian nonparametric model of extractive multi-document summarization to achieve this goal. As far as we are concerned, it is the first model that can learn appropriate lengths of summaries.

Bayesian nonparametric (BNP) methods are powerful tools to determine the size of latent variables (Gershman and Blei, 2011). They let the data "speak for itself" and allow the dimension of latent variables to grow with the data. In order to integrate the BNP methods into document summarization, we follow the assumption that the original documents should be recovered from the reconstruction of summaries (Ma and Wan, 2010; He et al., 2012). We use the Beta process as a prior to generate binary vectors for selecting active sentences that reconstruct the original documents. Then we construct a Bayesian framework for summarization and use the variational approximation for inference. Experimental results on DUC2004 dataset demonstrate the effectiveness of our model. Besides, we reorganize the original documents to generate some new datasets, and examine how the summary length changes on the new data. The results prove that our summary length determination is rational and necessary on unbalanced data.

2 Related Work

2.1 Research on Summary Length

Summary length is an important aspect for generating and evaluating summaries. Early research on summary length (Goldstein et al., 1999) focused on discovering the properties of human-generated summaries and analyzing the effect of compression ratio. It demonstrated that an evaluation of summarization systems must take into account both the compression ratios and the characteristics of the documents. Radev and Fan (2000) compared the readability and speedup in reading time of 10% summaries and 20% summaries[2] for topic sets with different number of documents. Sweeney et al. (2008) developed an incremental summary containing additional sentences that provide context. Kaisser et al. (2008) studied the impact of query types on summary length of search results. Other than the content of original documents, there are also some other factors affecting summary length especially in specific applications. For example, Sweeney and Crestani (2006) studied the relation between screen size and summary length on mobile platforms. The conclusion of their work is the optimal summary size always falls into the shorter one regardless of the screen size.

In sum, the previous works on summary length mostly put their attention on the empirical study of the phenomenon, factors and impacts of summary length. None of them automatically find the best length, which is our main task in this paper. Nevertheless, they demonstrated the importance of summary length in summarization and the reasonability of determining summary length based on content of news documents (Goldstein et al., 1999) or search results (Kaisser et al., 2008). As our model is mainly applied for generic summarization of news articles, we do not consider the factor of screen size in mobile applications.

2.2 BNP Methods in Document Summarization

Bayesian nonparametric methods provide a Bayesian framework for model selection and adaptation using nonparametric models (Gershman

[2] 10% and 20% are the compression rates, and the documents are from search results in information retrieval systems.

and Blei, 2011). A BNP model uses an infinite-dimensional parameter space, but invokes only a finite subset of the available parameters on any given finite data set. This subset generally grows with the data set. Thus BNP models address the problem of choosing the number of mixture components or latent factors. For example, the hierarchical Dirichlet process (HDP) can be used to infer the number of topics in topic models or the number of states in the infinite Hidden Markov model (Teh et al., 2006).

Recently, some BNP models are also involved in document summarization approaches (Celikyilmaz and Hakkani-Tür, 2010; Chang et al., 2011; Darling and Song, 2011). BNP priors such as the nested Chinese restaurant process (nCRP) are associated with topic analysis in these models. Then the topic distributions are used to get the sentence scores and rank sentences. BNP here only impacts the number and the structure of the latent topics, but the summarization framework is still constant-length. Our BNP summarization model differs from the previous models. Besides using the HDP for topic analysis, our approach further integrates the beta process into sentence selection. The BNP method in our model are directly used to determine the number of summary sentences but not latent topics.

3 BNP Summarization

In this section, we first introduce the BNP priors which will be used in our model. Then we propose our model called BNP summarization.

3.1 The Beta Process and the Bernoulli process

The beta process(BP) (Thibaux and Jordan, 2007; Paisley and Carin, 2009) and the related Indian buffet process(IBP) (Griffiths and Ghahramani, 2005) are widely applied to factor/feature analysis. By defining the infinite dimensional priors, these factor analysis models need not to specify the number of latent factors but automatically determine it.

Definition of BP (Paisley et al., 2010): Let B_0 be a continuous measure on a space Θ and $B_0(\Theta) = \gamma$. If B_k is defined as follows,

$$\begin{aligned} B_k &= \sum_{k=1}^{N} \pi_k \delta_{\theta_k}, \\ \pi_k &\sim Beta(\frac{\alpha\gamma}{N}, \alpha(1-\frac{\gamma}{N})) \\ \theta_k &\sim \frac{1}{\gamma} B_0 \end{aligned} \quad (1)$$

(where δ_{θ_k} is the atom at the location θ_k; and α is a positive scalar), then as $N \to \infty$, $B_k \to B$ and B is a beta process: $B \sim BP(\alpha B_0)$.

Finite Approximation: The beta process is defined on an infinite parameter space, but sometimes we can also use its finite approximation by simply setting N to a large number (Paisley and Carin, 2009).

Bernoulli Process: The beta process is conjugate to a class of Bernoulli processes, denoted by $X \sim Bep(B)$. If B is discrete, of the form in (1), then $X = \sum_k b_k \delta_{\theta_k}$ where the b_k are independent Bernoulli variables with the probability $p(b_k = 1) = \pi_k$. Due to the conjugation between the beta process priors and Bernoulli process, the posterior of B given M samples $X_1, X_2, ...X_M$ where $X_i \sim Bep(B) for i = 1, , , M.$ is also a beta process which has updated parameters:

$$\begin{aligned} &B|X_1, X_2, ..., X_M \\ &\sim BP(\alpha + M, \tfrac{\alpha}{\alpha+M} B_0 + \tfrac{1}{c+M} \textstyle\sum_i X_i) \end{aligned} \quad (2)$$

Application of BP: Furthermore, marginalizing over the beta process measure B and taking $\alpha = 1$, provides a predictive distribution on indicators known as the Indian buffet process (IBP) (Thibaux and Jordan, 2007). The beta process or the IBP is often used in a feature analysis model to generate infinite vectors of binary indicator variables(Paisley and Carin, 2009), which indicates whether a feature is used to represent a sample. In this paper, we use the beta process as the prior to select sentences.

3.2 Framework of BNP Summarization

Most existing approaches for generic extractive summarization are based on sentence ranking. However, these methods suffer from a severe problem that they cannot make a good trade-off between the coverage and minimum redundancy (He et al.,

2012). Some global optimization algorithms are developed, instead of greedy search, to select the best overall summaries (Nenkova and McKeown, 2012). One approach to global optimization of summarization is to regard the summarization as a reconstruction process (Ma and Wan, 2010; He et al., 2012) . Considering a good summary must catch most of the important information in original documents, the original documents are assumed able to be recovered from summaries with some information loss. Then the summarization problem is turned into finding the sentences that cause the least reconstruction error (or information loss). In this paper, we follow the assumption and formulate summarization as a Bayesian framework.

First we review the models of (Ma and Wan, 2010) and (He et al., 2012). Given a cluster of M documents $x_1, x_2, ..., x_M$ and the sentence set contained in the documents as $S = [s_1, s_2, ..., s_N]$, we denote all corresponding summary sentences as $V = [v_1, ..., v_n]$, where n is the number of summary sentences and N is the number of all sentences in the cluster. A document x_i and a sentence v_i or s_i here are all represented by weighted term frequency vectors in the space $\mathbb{R}^d$, where d is the number of total terms (words).

Following the reconstruction assumption, a candidate sentence v_i can be approximated by the linear combination of summary sentences: $s_i \simeq \sum_{j=1}^{n} w'_j v_j$, where w'_j is the weight for summary sentence v_j. Thus the document can also be approximately represented by a linear combination of summary sentences (because it is the sum of the sentences).

$$x_i \simeq \sum_{j=1}^{n} w_j v_j. \tag{3}$$

Then the work in (He et al., 2012) aims to find the summary sentence set that can minimize the reconstruction error $\sum_{i=1}^{N} ||s_i - \sum_{j=1}^{n} w'_j v_j||^2$; while the work in (Ma and Wan, 2010) defines the problem as finding the sentences that minimize the distortion between documents and its reconstruction $dis(x_i, \sum_{j=1}^{n} w_j v_j)$ where this distortion function can also be a squared error function.

Now we consider the reconstruction for each document, if we see the document x_i as the dependent variable, and the summary sentence set S as the independent variable, the problem to minimize the reconstruction error can be seen as a linear regression model. The model can be easily changed to a Bayesian regression model by adding a zero-mean Gaussian noise ϵ (Bishop, 2006), as follows.

$$x_i = \sum_{j=1}^{n} w_j v_j + \epsilon_i \tag{4}$$

where the weights w_j are also assigned a Gaussian prior.

The next step is sentence selection. As our system is an extractive summarization model, all the summary sentences are from the original document cluster. So we can use a binary vector $z_i =< z_{i1}, ..., z_{iN} >^T$ to choose the active sentences V (i.e. summary sentences) from the original sentence set S. The Equation (4) is turned into $x_i = \sum_{j=1}^{N} \phi_{ij} * z_{ij} s_j + \epsilon_i$. Using a beta process as a prior for the binary vector z_i, we can automatically infer the number of active component associated with z_i. As to the weights of the sentences, we use a random vector ϕ_i which has the multivariate normal distribution because of the conjugacy. $\phi_i \in \mathbb{R}^N$ is an extension to the weights $\{w_1, ...w_n\}$ in (4).

Integrating the *linear reconstruction* (4) and the *beta process*[3] (1), we get the complete process of summary sentence selection as follows.

$$\begin{aligned} x_i &= S(\phi_i \circ z_i) + \epsilon_i \\ S &= [s_1, s_2, ..., s_N] \\ z_{ij} &\sim Bernoulli(\pi_j) \\ \pi_j &\sim Beta(\frac{\alpha\gamma}{N}, \alpha(1 - \frac{\gamma}{N})) \\ \phi_i &\sim \mathcal{N}(0, \sigma_\phi^2 I) \\ \epsilon_i &\sim \mathcal{N}(0, \sigma_\epsilon^2 I) \end{aligned} \tag{5}$$

where N is the number of sentences in the whole document cluster. The symbol $\circ$ represents the elementwise multiplication of two vectors.

One problem of the reconstruction model is that the word vector representation of the sentences are sparse, which dramatically increase the reconstruction error. So we bring in topic models to reduce the

[3] We use the finite approximation because the number of sentences is large but finite

dimension of the data. We use a HDP-LDA (Teh et al., 2006) to get topic distributions for each sentence, and we represent the sentences and documents as the topic weight vectors instead of word weight vectors. Finally x_i is a K-dimensional vector and S is a $K * N$ matrix, where K is the number of topics in topic models.

4 Variational Inference

In this section, we derive a variational Bayesian algorithm for fast inference of our sentence selection model. Variational inference (Bishop, 2006) is a framework for approximating the true posterior with the best from a set of distributions $Q : q* = \arg\min_{q\in Q} KL(q(Z)|p(Z|X))$. Suppose $q(Z)$ can be partitioned into disjoint groups denoted by Z_j, and the q distribution factorizes with respect to these groups: $q(Z) = \prod_{j=1}^{M} q(Z_j)$. We can obtain a general expression for the optimal solution $q_j^*(Z_j)$ given by

$$\ln q_j^*(Z_j) = \mathbb{E}_{i\neq j}[\ln p(X, Z)] + const. \quad (6)$$

where $\mathbb{E}_{i\neq j}[\ln p(X, Z)]$ is the expectation of the logarithm of the joint probability of the data and latent variables, taken over all variables not in the partition. We will therefore seek a consistent solution by first initializing all of the factors $q_j(Z_j)$ appropriately and then cycling through the factors and replacing each in turn with a revised estimate given by (6) evaluated using the current estimates for all of the other factors.

Update for Z

$$p(z_{ij}|\pi_j, x_i, S, \phi_i) \propto p(x_i|z_{ij}, s_j, \phi_i)p(z_{ij}|\pi_j)$$

We use $q(z_{ij})$ to approximate the posterior:

$$\begin{aligned}
&q(z_{ij}) \\
&\propto \exp\{\mathrm{E}[\ln(p(x_i|z_{ij}, z_i^{-j}, S, \phi_i)) + \ln(p(z_{ij}|\pi))]\} \\
&\propto \exp\{\mathrm{E}[\ln(\pi_j)]\}* \\
&\exp\{\mathrm{E}[-\frac{1}{2\sigma_\epsilon^2}\left(x_i^{-j} - s_j z_{ij}\phi_{ij}\right)^T\left(x_i^{-j} - s_j z_{ij}\phi_{ij}\right)]\} \\
&\propto \exp\{\overline{\ln(\pi_j)}\}* \\
&\exp\{-\frac{\left(\overline{\phi_{ij}^2} * \overline{z_{ij}^2} * \overline{s_j^T s_j} - 2\overline{\phi_{ij}} * \overline{z_{ij}} * \overline{s_j}^T * \overline{x_i^{-j}}\right)}{2\sigma_\epsilon^2}\}
\end{aligned} \quad (7)$$

where $x_i^{-j} = x_i - S^{-j}(\phi_i^{-j} \circ z_i^{-j})$, and the symbol $^-$ indicates the expectation value. The $\overline{\phi_{ij}^2}$ can be extended to this form:

$$\overline{\phi_{ij}^2} = \overline{\phi_{ij}}^2 + \Delta_i^j \quad (8)$$

where Δ_i^j means the j^{th} diagonal element of Δ_i which is defined by Equation 13.

As z_i is a binary vector, we only calculate the probability of $z_{ij} = 1$ and $z_{ij} = 0$.

$$\begin{aligned}
&q(z_{ij} = 1) \propto \exp\{\overline{\ln(\pi_j)}\} * \\
&\exp\{-\frac{1}{2\sigma_\epsilon^2}\left(\overline{\phi_{ij}^2} * \overline{s_j^T s_j} - 2\overline{\phi_{ij}} * \overline{s_j}^T * \overline{x_i^{-j}}\right)\} \\
&q(z_{ij} = 0) \propto \exp\{\overline{\ln(1 - \pi_j)}\}
\end{aligned} \quad (9)$$

The expectations can be calculated as

$$\overline{\ln(\pi_j)} = \varphi(\frac{\alpha\gamma}{N} + \overline{n_j}) - \varphi(\alpha + M) \quad (10)$$

$$\overline{\ln(1 - \pi_j)} = \varphi(\alpha(1 - \frac{\gamma}{N}) + M - \overline{n_j}) - \varphi(\alpha + M) \quad (11)$$

where $\overline{n_j} = \sum_{i=1}^{M} z_{ij}$.

Update for π

$$p(\pi_j|Z) \propto p(\pi_j|\alpha, \gamma, N)p(Z|\pi_j)$$

Because of the conjugacy of the beta to Bernoulli distribution, the posterior of π is still a beta distribution:

$$\pi_j \sim Beta(\frac{\alpha\gamma}{N} + \overline{n_j}, \alpha(1 - \frac{\gamma}{N}) + M - \overline{n_j}) \quad (12)$$

Update for Φ

$$p(\phi_i|x_i, Z, S) \propto p(x_i|\phi_i, Z, S)p(\phi_i|\sigma_\phi^2)$$

The posterior is also a normal distribution with mean μ_i and covariance Δ_i.

$$\Delta_i = \left(\frac{1}{\sigma_\epsilon^2}\overline{\tilde{S}_i^T \tilde{S}_i} + \frac{1}{\sigma_\phi^2} I\right)^{-1} \quad (13)$$

$$\mu_i = \Delta_i \left(\frac{1}{\sigma_\epsilon^2}\overline{\tilde{S}_i}^T x_i\right) \quad (14)$$

Here $\tilde{S}_i \equiv S \circ \tilde{z}_i$ and $\tilde{z}_i \equiv [z_i, ..., z_i]^T$ is a $K \times N$ matrix with the vector z_i repeated K(the number of the latent topics) times.

$$\overline{\tilde{S}_i} = S * \overline{\tilde{z}_i} \quad (15)$$

$$\overline{\tilde{S}_i^T \tilde{S}_i} = (S^T S) \circ (\overline{z_i} * \overline{z_i}^T + Bcov_i) \quad (16)$$

$$Bcov_i = \text{diag}[\overline{z_{i1}}(1 - \overline{z_{i1}}), ..., \overline{z_{iN}}(1 - \overline{z_{iN}})] \quad (17)$$

Update for σ_ϵ^2

$$p(\sigma_\epsilon^2|\Phi, X, Z, S) \propto p(X|\Phi, Z, S, \sigma_\epsilon^2)p(\sigma_\epsilon^2)$$

By using a conjugate prior, inverse gamma prior $InvGamma(u, v)$, the posterior can be calculated as a new inverse gamma distribution with parameters

$$\begin{aligned} u' &= u + MK/2 \\ v' &= v + \frac{1}{2}\sum_{i=1}^{M}(||x_i - S(\overline{z_i} \circ \overline{\phi_i})|| + \xi_i) \end{aligned} \quad (18)$$

where

$$\begin{aligned} \xi_i = \textstyle\sum_{j=1}^{N}(\overline{z_{ij}^2} * \overline{\phi_{ij}^2} * s_j^T s_j - \overline{z_{ij}}^2 * \overline{\phi_{ij}}^2 * s_j^T s_j) \\ + \textstyle\sum_{j \neq l} \overline{z_{ij}} * \overline{z_{il}} * \Delta_{i,jl} * s_j^T s_l \end{aligned}$$

Update for σ_ϕ^2

$$p(\sigma_\phi^2|\Phi) \propto p(\Phi|\sigma_\phi^2)p(\sigma_\phi^2)$$

By using a conjugate prior, inverse gamma prior $InvGamma(e, f)$, the posterior can be calculated as a new inverse gamma distribution with parameters

$$\begin{aligned} e' &= e + MN/2 \\ f' &= f + \frac{1}{2}\sum_{i=1}^{M}\left((\overline{\Phi})^T\overline{\Phi} + trace(\Delta_i')\right) \end{aligned} \quad (19)$$

5 Experiments

To test the capability of our BNP summarization systems, we design a series of experiments. The aim of the experiments mainly includes three aspects:

1. To demonstrate the summaries extracted by our model have good qualities and the summary length determined by the model is reasonable.
2. To give examples where varying summary length is necessary.
3. To observe the distribution of summary length.

We evaluate the performance on the dataset of DUC2004 task2. The data contains 50 document clusters, with 10 news articles in each cluster. Besides, we construct three new datasets from the DUC2004 dataset to further prove the advantage of variable-length summarization. We separate each cluster in the original dataset into two parts where each has 5 documents, hence getting the *Separate* Dataset; Then we randomly combine two original clusters in the DUC2004 dataset, and get two datasets called *Combined1* and *Combined2*. Thus each of the clusters in the combined datasets include 20 documents with two different themes.

5.1 Evaluation of Summary Qualities

First, we implement our BNP summarization model on the DUC2004 dataset, with summary length not limited. At the topic analysis step, we use the HDP model and follow the inference in (Teh et al., 2006). For the sentence selection step, we use the variational inference described in Section 4, where the parameters in the beta process (5) are set as $\gamma = 1, \alpha = 1$. The summaries that we finally generate have an average length of 164 words. We design several popular unsupervised summarization systems and compare them with our model.

- The *Random* model selects sentences randomly for each document cluster.
- The *MMR* (Carbonell and Goldstein, 1998) strives to reduce redundancy while maintaining relevance. For generic summarization, we replace the query relevance with the relevance to documents.
- The *Lexrank* model (Erkan and Radev, 2004) is a graph-based method which choose sentences based on the concept of eigenvector centrality.
- The *Linear* Representation model (Ma and Wan, 2010) has the same assumption as ours and it can be seen as an approximation of the constant-length version of our model.

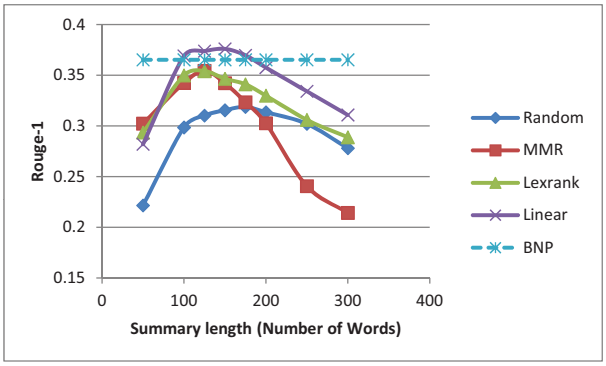

Figure 1: Rouge-1 values on DUC2004 dataset.

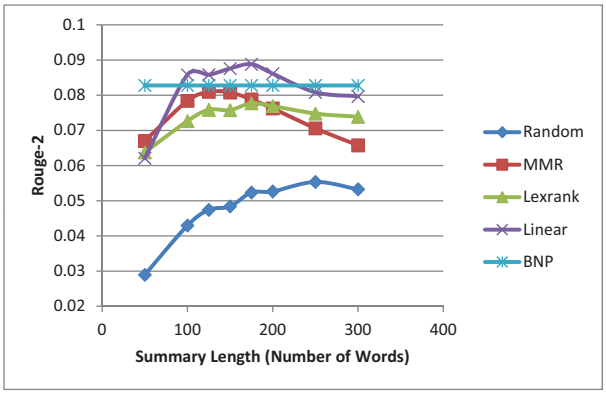

Figure 2: Rouge-2 values on DUC2004 dataset.

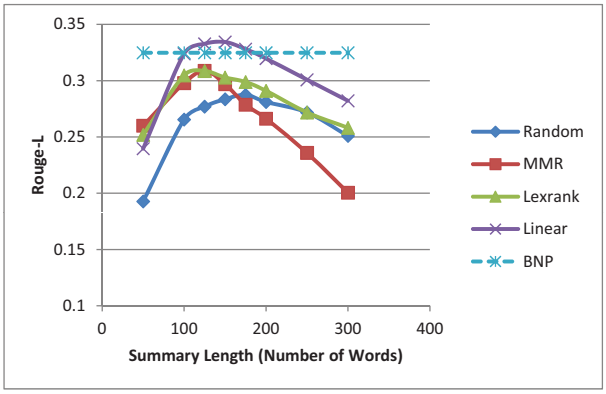

Figure 3: Rouge-L values on DUC2004 dataset.

All the compared systems are implemented at different predefined lengths from 50 to 300 words. Then we evaluate the summaries with ROUGE[4] tools (Lin and Hovy, 2003) in terms of the f-measure scores of Rouge-1 Rouge-2, and Rouge-L. The metric of Rouge f-measure takes into consideration the summary length in evaluation, so it is proper for our experiments. From Fig.1, Fig.2 and Fig.3, we can see that the result of BNP summarization (the dashed line) gets the second best value among all systems. It is only defeated by the *Linear* model but the result is comparable to the best in Fig.1 and Fig.3; while it exceeds other systems at all lengths. This proves the good qualities of our BNP summaries. The reason that the *Linear* system gets a little better result may be its weights for linear combination of summary sentences are guaranteed non-negative while in our model the weights are zero-mean Gaussian variables. This may lead to less redundance in sentence selection for the *Linear* Representation model.

Turn to the length determination. We take advantage of the *Linear* Representation model to approximate the constant-length version of our model. Comparing the summaries generated at different predefined lengths, Fig.4 shows the the model gets the best performance (Rouge values) at the length around 164 words, the length learned by our BNP model. This result partly demonstrates our length determination is rational and it can be used as the recommended length for some constant-length summarization systems, such as the *Linear* .

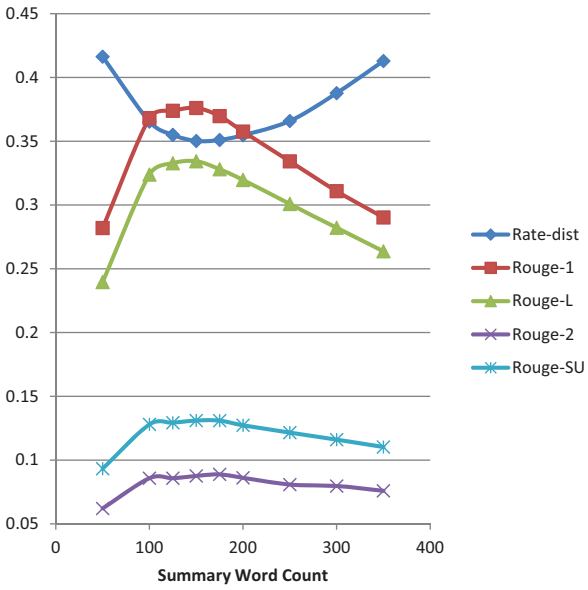

Figure 4: Rate-dist value V.S. summary word length.

[4]we use ROUGE1.5.5 in this work.

5.2 A New Evaluation Metric

The Rouge evaluation requires golden standard summaries as the base. However, in many cases we cannot get the reference summaries. For example, when we implement experiments on our expanded datasets (the separate and combined clusters of documents), we do not have exact reference summaries. Louis and Nenkova (2009) advanced an automatic summary evaluation without human models. They used the Jensen-Shannon divergence(JSD) between the input documents and the summaries as a feature, and got high correlation with human evaluations and the rouge metric. Unfortunately, it was designed for comparison at a constant-length, which cannot meet our needs. To extend the JSD evaluation to compare varying-length summaries, we propose a new measure based on information theory, the rate-distortion (Cover and Thomas, 2006).

Rate-Distortion: The distortion function $d(x, \hat{x})$ is a measure of the cost of representing the symbol x to a new symbol $\hat{x}$; and the rate can indicate how much compression can be achieved. The problem of finding the minimum rate can be solved by minimizing the functional

$$\mathcal{F}[p(\hat{x}|x)] = I(X;\hat{X}) + \beta\mathbb{E}(d(x,\hat{x})). \qquad (20)$$

where $I(X;\hat{X})$ denotes the mutual information. The rate-distortion theory is a fundamental theory for lossy data compression. Recently, it has also been successfully employed for text clustering (Slonim, 2002) and document summarization (Ma and Wan, 2010). Slonim (2002) claims that the mutual information $I(X;\hat{X})$ measures the compactness of the new representation. Thus the rate-distortion function is a trade-off between the compactness of new representation and the expected distortion. Specifically in summarization, the summaries can be seen as the new representation $\hat{X}$ of original documents X. A good summary balances the compression ratio and the information loss, thus minimizing the function (20). So we use the function (20)(we set $\beta = 1$) to compare which summary is a better compression. The JS-divergence (JSD), which has been proved to have high correlation with manual evaluation (Louis and Nenkova, 2009) for constant-length summary evaluation, is utilized as the distortion in the function. In the following sections, we simply call the values of the function (20) *rate-dist*. In fact, the rate-dist values can be seen as the JSD measure with length regularization.

To check the effectiveness of rate-dist measure, we evaluate all summaries generated in Section 5.1 with the new measure (the lower the better). Fig. 5 shows that the results accord with the ones in Fig. 1 and Fig. 3. Moreover, in Fig. 4, the curve of rate-dist values has a inverse tendency of Rouge measures (Rouge-1, Rouge-2, Rouge-L and Rouge-SU4 are all listed here), and the best performance also occurs around the summary length of 164 words. This even more clearly reveals that the BNP summarization achieves a perfect tradeoff between compactness and informativeness. Due to the accordance with rouge measures, it is promising to be regarded as an alternative to the rouge measures in case we do not have reference summaries.

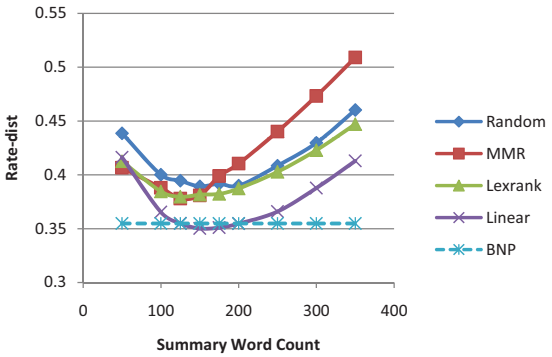

Figure 5: Comparison of BNP Summarization with other systems using rate-dist measure.

5.3 Necessity of Varying Summary Length

In this section, we discuss the necessity of length determination and how summary length changes according to the input data. As explained before, we generate three new datasets from the original DUC2004 dataset. Now we use them to indicate varying summary length is necessary when the input data varies a lot.

Table 1 shows the average summary length of different data sets. The results satisfy the intuitive expectation of summary length change. When we split a 10-document cluster into two 5-document parts, we expect the average summary length of the new clusters to be a little smaller than the original cluster but much larger than half of the original length,

because all the documents concentrate on the same themes. When we combine two clusters into one, the summary length should be smaller than the sum of the summary lengths of two original clusters due to some unavoidable common background information but much larger than the summary length of original clusters.

Original	Separate	Combined1	Combined2
164	115	250	231

Table 1: Average summary length (number of words) on different datasets

We also run the Linear Representation system at different lengths on the new datasets and evaluate the qualities. As we do not have golden standard for the new datasets, so we only use the rate-dist measure here. Results in Table 2,3,4 show the summaries which do not change the predefined length [5] perform significantly worse than the BNP summarization. All the comparison is statistically significant. So varying summary length is necessary when the input changes a lot, and our model can just give a good match to the new data. This characteristic also can be used to give recommended summary length for extractive summarization systems when given unknown data.

	Predefined	Unchanged	BNP
Length	665 bytes	164 words	115 words
Rate-dist	0.4130	0.4404	0.4007

Table 2: Comparison of summary lengths on Separate Dataset.

	Predefined	Unchanged	BNP
Length	665 bytes	164 words	250 words
Rate-dist	0.3768	0.3450	0.3238

Table 3: Comparison of summary lengths on Combined1 Dataset.

Then we observe the summary length distributions and compression ratios according to document size(the length of the whole documents in a cluster). The average summary length increases (Fig. 6),

[5]665 bytes is the DUC2004 requirement and 164 words is the best length on original data

	Predefined	Unchanged	BNP
Length	665 bytes	164 words	231 words
Rate-dist	0.3739	0.3464	0.3326

Table 4: Comparison of summary lengths on Combined2 Dataset.

while the compression ratios decreases (Fig. 7) as document size grows. The rule of the compression ratio here agrees with the rule in (Goldstein et al., 1999), although that work is done for single-document summarization.

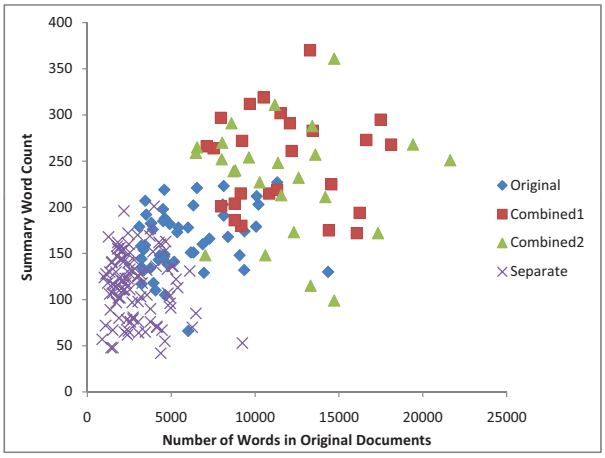

Figure 6: The distribution of summary word length.

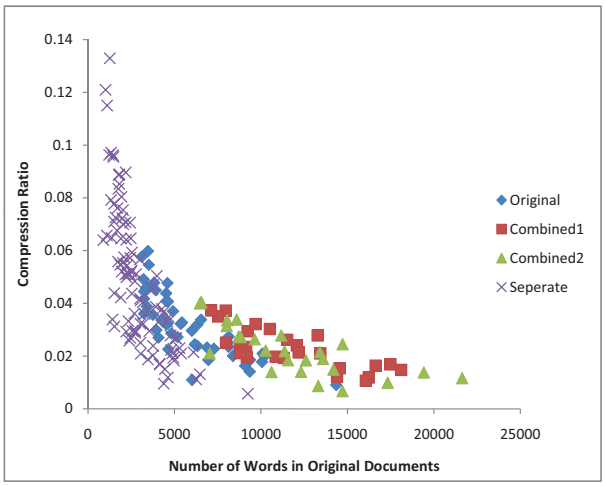

Figure 7: Compression ratio versus document word length.

6 Conclusion and Future Work

In this paper, we present a new problem of finding a proper summary length for multi-document summarization based on the document content. A Bayesian nonparametric model is proposed to solve this problem. We use the beta process as the prior to construct a Bayesian framework for summary sentence selection. Experimental results are shown on DUC2004 dataset, as well as some expanded datasets. We demonstrate the summaries we extract have good qualities and the length determination of our system is rational.

However, there is still much work to do for variable-length summarization. First, Our system is extractive-base summarization, which cannot achieve the perfect coherence and readability. A system which can determine the best length even for abstractive summarization will be better. Moreover, in this work we only consider the aspect of data compression and evaluate the performance using an information-theoretic measure. In future we may consider more human factors, and prove the summary length determined by our system agrees with human preference. In addition, in the experiments, we only use the imbalanced datasets as the example that intuitively needs varying the summary length. However, the data type is also important to impact the summary length. In future, we may extend the work by studying more cases that need varying summary length.

Abstract

We present a method which exploits automatically generated scientific discourse annotations to create a content model for the summarisation of scientific articles. Full papers are first automatically annotated using the CoreSC scheme, which captures 11 content-based concepts such as Hypothesis, Result, Conclusion etc at the sentence level. A content model which follows the sequence of CoreSC categories observed in abstracts is used to provide the skeleton of the summary, making a distinction between dependent and independent categories. Summary creation is also guided by the distribution of CoreSC categories found in the full articles, in order to adequately represent the article content. Finally, we demonstrate the usefulness of the summaries by evaluating them in a complex question answering task. Results are very encouraging as summaries of papers from automatically obtained CoreSCs enable experts to answer 66% of complex content-related questions designed on the basis of paper abstracts. The questions were answered with a precision of 75%, where the upper bound for human summaries (abstracts) was 95%.

1 Introduction

The publication boom of the last few years, especially in the life sciences, has highlighted the need to facilitate automatic access to the information content of articles. Researchers, curators, reviewers all need to process a continuously expanding flow of articles whether the purpose is to follow the state of the art, curate large knowledge bases or have a good working knowledge of their own and related disciplines to assess progress in research. While a lot of effort has concentrated on information extraction of particular types of entities and relations from the scientific literature (Cohen and Hersh, 2005; Kim et al., 2009; Ananiadou et al., 2010; Kim et al., 2011), with a view to support scientists in obtaining relevant information from scientific articles and abstracts, less work has focussed on automatically combining such information in the form of a cohesive summary which preserves the context. Researchers rely to a great extent on author-written abstracts, but the latter suffer from a number of problems; they are less structured, vary significantly in terms of length, are often not self-contained and have been written independently of the main document (Teufel, 2010, p.83).

Teufel (2001; 2010), (Teufel and Moens, 2002) identify argumentative zones within scientific articles and use them to create use-targeted extractive summaries. Argumentative zones are annotations which designate the type of knowledge claim and rhetorical status for a sentence and how these relate to the communicative function of the entire paper. A selection of various combinations of argumentative zones are chosen for the use-targeted extractive summaries (rhetorical extracts), each of which fulfills a different role. For instance, purpose-oriented extracts less than 10 sentences long are generated containing a predetermined number of AIM, SOLUTION and BACKGROUND zones. As the emphasis of this approach was the identification of the argumentative zones, less attention was given to the sentence selection criteria for the extractive summaries.

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 747–757,
Seattle, Washington, USA, 18-21 October 2013.

The sentences chosen for the rhetorical extracts were either all sentences of a particular category (in the case of rare categories) (Teufel and Moens, 2002), selected according to a classifier trained on a relevance gold standard (Teufel and Moens, 2002), manually or randomly selected (Teufel, 2010, p.60).

More recently Contractor et al. (2012) have used automatically annotated argumentative zones (Guo et al., 2011) to guide the creation of extractive summaries of scientific articles. Here argumentative zones are used as features for the summariser, along with verbs, tf-idf values and sentence location. They use a standard approach to summarisation, with a binary classification recognising candidate sentences which are then fed into a clustering mechanism. Extracts can be created to summarise the entire paper or focus on specific user-specified aspects. The number of sentences to include in the summary is prespecified (either directly or using a compression ratio).

Our approach also makes use of the scientific discourse for summarisation purposes. We use the scientific discourse to create a content model for extractive summarisation, with a focus on representing the content of the full paper, while keeping the cohesion of the narrative. We first automatically annotate the articles with a scheme which captures fine-grained aspects of the content and conceptual structure of the papers, namely the Core Scientific Concepts (CoreSC) scheme (Liakata et al., 2010; Liakata et al., 2012). The CoreSC scheme is "uniquely suited to recovering common types of scientific arguments about hypotheses, explanations, and evidence" (White et al., 2011), which are not readily identifiable by other annotation schemes. Also, when compared to argumentative zoning and more specifically its extension for chemistry papers, AZ-II (Teufel et al., 2009), it was shown to provide a greater level of detail in terms of categories denoting objectives, methods and outcomes whereas AZ-II focusses on the attribution of knowledge claims and the relation with previous work (Liakata et al., 2010).

We then use the distribution of CoreSC categories observed in abstracts to create a content model which provides a skeleton for extractive summaries. The reasoning behind this is to try to preserve cohesion within the summaries and we hypothesise that the sequence of CoreSC categories is a good proxy for cohesion (see section 3.1). In creating the summary, instantiating the content model, we identify independent categories and dependent categories, and we argue that in order to preserve the cohesion of the text the independent categories should be determined first (see section 3.2). We also preserve in the summary the distribution of CoreSC categories found in the corresponding full paper.

Finally, we evaluate the extractive summaries in a complex real world question-answering task, in which we assess the usefulness of the summaries as well as to what extent the generated CoreSC summaries represent the content of the original article. Experts are presented with different types of summaries and are asked to answer article-specific questions on the basis of the summaries (see section 4.1). Our results show that automatically generated CoreSC summaries can answer 66% of complex questions with 75% precision, outperforming a baseline of microsoft autosummarise summaries (See section 4.2).

We have also peformed an intrinsic evaluation of the summaries using ROUGE and automatic measures for summary informativeness, such as the Jensen-Shannon divergence, yielding positive results (See section 4.2). However, as such measures have not yet reached maturity and are harder to interpret, we consider the user-based evaluation to be a more reliable measure of summary quality.

Code for generating the summaries can be obtained by contacting the first author and/or visiting http://www.sapientaproject.com/software.

2 Related work

The Core Scientific Concepts (CoreSC) Scheme: The CoreSC scheme consists of three layers; the first layer corresponds to eleven concepts (Background (BAC), Hypothesis (HYP), Motivation (MOT), Goal (GOA), Object (OBJ), Method (MET), Model (MOD), Experiment (EXP), Observation (OBS), Result (RES) and Conclusion (CON)); the second layer corresponds to properties of the concepts (e.g. New/Old) and the third layer provides identifiers which link instances of the same category. Liakata et al. (2010) created a corpus of 265 full scientific articles from chemistry and biochemistry annotated

with this scheme and trained classifiers using SVMs and CRFs in (Liakata et al., 2012), with an accuracy of >51% across the 11 concepts. Their data and CoreSC classification system are available online and can provide a good benchmark for comparison. Louis & Nenkova (2012) have successfully used the CoreSC corpus for evaluating syntax-based coherence models, which indicates the strong connection between coherence and discourse structure.

Summarisation for scientific articles: A lot of the work on summarising scientific articles has focussed on citation-based summaries. Qazvinian & Radev (2008) use sentences from papers citing the article to be summarised. Sentences are clustered together creating a topic, with the combination of clusters forming a citation summary network. Qazvinian & Radev (2010), (Qazvinian et al., 2010) also make use of citation sentences in other scientific papers to summarize the contributions of a paper. The drawback of citation summaries is that a paper must be already cited, so this type of summary will not be useful to a paper reviewer. Also, citations of articles will have been influenced by other citations rather than the paper itself.

Document models for summarisation: Our content model has some similarities with content modelling using global sentence ordering (Barzilay and Lee, 2004; Chen et al., 2009). In (Barzilay and Lee, 2004) unsupervised methods are used to create HMM topic sequence models for newswire text articles. Topics are assigned to texts according to the content model and extracts of fixed length are created by selecting the topics most likely to occur in summaries. While we use supervised methods to annotate papers with a fixed set of topics (CoreSCs) in scientific papers, our summary content model for extracts shares similar principles such as global ordering of sentences and non-recurrence. However, their evaluation involved newspaper articles and extracts which are a lot shorter (15 and 6 sentences, respectively).

It is not clear whether unsupervised topic modelling such as (Chen et al., 2009) can be applied to scientific articles (over 100 sentences long), which by nature include repetition of topics. It would be interesting to make comparisons with summaries using content models learnt from our data automatically, following a similar approach to (Sauper et al., 2010) which learns a content model jointly with a particular supervised task in web-based documents.

3 Extractive Summarisation using CoreSCs

In this section we describe how we use CoreSC discourse categories annotated at the sentence level to create extractive summaries of full papers, which we subsequently evaluate in a question answering task in section 4.

To generate summaries we follow classic text extraction techniques while making use of a document content model based on CoreSCs. Our aim is for the content model to reflect both the distribution of CoreSCs in the paper as well as the discourse model of human summaries, as the latter is indicated by the generic ordering of CoreSC categories in abstracts encountered in a corpus of 265 annotated full papers (Liakata and Soldatova, 2009; Liakata et al., 2012). While we do not consider abstracts to be adequate summaries, we at least consider them to be coherent summaries, which is why the content model reflects the distribution of CoreSCs in the abstracts.

To create our summaries, we employed automatically generated CoreSC annotations, which are the output of the classifiers described in (Liakata et al., 2012). These classifiers assign CoreSC categories to sentences on the basis of features local to a sentence, such as significant n-grams, verbs and word triples, as well as global features such as the position of the sentence within the document and within a paragraph and section headers. The following subsections give details about the creation of extractive summaries from CoreSC categories.

3.1 A content model for CoreSC extractive summaries

Building an extractive summary using a computational model of document structure is an idea shared by many previous approaches, whether the model is hand-crafted, based on rhetorical elements (McKeown, 1985; Teufel and Moens, 2002) or rhetorical relations (Marcu, 1998b; Marcu, 1998a) or whether it is a content model, learnt automatically from text as in (Barzilay and Lee, 2004), focussing on the local content or a combination of the local content and global structure (Sauper et al., 2010).

Our document content model is primarily based on the global discourse of the article as provided by the type and number of CoreSC categories. However, unlike (Teufel and Moens, 2002), who take a fixed number of AZ categories of specific type to create rhetorical extracts, the number of categories used from each CoreSC category depends on their distribution in the original article. Any and all types of CoreSC category could potentially appear in a summary, as our summaries are meant to be representative of the entire content of the paper. Also, the ordering of the categories in the summary is learnt to reflect the ordering of categories observed in abstracts of papers from the same domain.

Our model also caters for local discourse dependencies. For example, the selection of a particular 'Method' sentence for inclusion in the summary should influence the choice of 'Experiment' sentences, which refers to particular experimental procedures performed. This is not an issue of concern to (Teufel and Moens, 2002), but relates to the notion of NUCLEUS and SATELLITE clauses, which form the foundation of Rhetorical Structure Theory (Mann and Thompson, 1998), and guides the summarisation paradigm of (Marcu, 1998a; Marcu, 1998b). However, the difference here is that we define a-priori certain categories to be independent (have the property of playing the role of nucleus in the discourse) and specify their relation with particular types of dependent categories. Thus, nuclearity becomes a property of the CoreSC category, which is indirectly inherited by the sentence.

Therefore, when creating the CoreSC content model for summaries we addressed the following issues: (i) summary length; (ii) number of sentences from each CoreSC, (iii) the ordering in which sentences from each CoreSC category should appear and (iv) the extraction of sentences according to independent and dependent categories.

- **Summary length:** While the literature (Teufel, 2010, p.45) suggests that 20–30% of the original document is required for an adequately informative summary, (Teufel, 2010, p.55) assumes this is too long for scientific papers. For this reason and to allow better comparison between papers of varying lengths, we fixed our summary length to 20 sentences. This is reasonable considering we have 11 CoreSCs, any and all of which can appear in both abstracts and full papers.
- **Number of sentences from each category:** To reflect the content of the paper, the distribution of the CoreSC categories in the extract follows the distribution of CoreSCs in the full paper.

  For each CoreSC we determine the number of sentences to be selected ($n(selected(C))$) by multiplying the ratio of that category in the paper by 20. A difficulty arises if the ratio of a particular concept in the paper is very low (≤ 0.05) in which case we prefer to include one sentence. If a particular concept is not at all present in the paper, the number of selected sentences for that category will be 0.
- **Ordering of CoreSC categories in the summary:** According to a study of empirical summaries (Liddy, 1991), sentences of a particular textual type appear in a particular order. Since paper abstracts were the closest approximation of human summaries available to us, CoreSC category transitions found in abstracts have been adopted in our content model for extracts. The transitions were derived semi-empirically. First, we extracted initial, medium and final bi-grams of categories from paper abstracts together with transition probabilities.

  Using this information we manually constructed transitions of the CoreSC categories that best fit the observed frequencies and our own intuitions. This gave us the following sequence: MOT $>$ (HYP) $>$ OBJ $>$ GOA $>$ BAC $>$ MOD $>$ MET $>$ EXP $>$ OBS $>$ (HYP) $>$ RES $>$ CON. HYP appears twice in the sequence as annotators had distinguished two types of hypotheses, global hypotheses (stated together with other objectives) and hypotheses about particular observations. The model provides an amalgamated representation of CoreSC concepts in abstracts. Interestingly, our semi-empirically derived model closely follows the content model for abstracts described in (Liddy, 1991). It would be interesting to see how this compares to a Markov model of CoreSC categories learnt from the annotated abstracts.

3.2 Sentence extraction based on independent and dependent categories

Sentence extraction involves selecting the most relevant sentences to include in a summary. Typically, this entails ranking the sentences according to some measure of salience and selecting the top n-best sentences. For example, a sentence will be represented by a number of features associated with it, such as whether it contains certain high frequency words or cue phrases, its location in the document, location in a paragraph (Brandow et al., 1995; Kupiec et al., 1995). Other methods include clustering based on sentence similarity and choosing the centroids (Erkan and Radev, 2004) or choosing the best connected sentences (Mihalcea and Tarau, 2004).

When sentences are classified according to CoreSC categories features such as the ones described above for text extraction are taken into account. Liakata et al. (2012) report that the most salient features for classifying CoreSC categories are overall n-grams, verbs and direct objects whereas other features such as the location of the sentence, the neighbouring section headings and whether a sentence contains citations play an important role for some of the categories. Thus, classification into CoreSC categories already provides a selection bias for sentence extraction.

As explained in section 3.1, the number of CoreSC categories in the summaries is determined according to their distribution in the paper and the order of the categories is specified in the content model. Salience for sentence extraction in this case is determined by the need to select the most representative sentences for a category. There isn't much point, for example, in identifying that we need to include a Method sentence (MET) and that this should be followed by an Experiment sentence (EXP), if we are not sure that those are indeed the categories of the sentences we are about to select.

We therefore rank sentences according to the classifier confidence score (probability) with which they were assigned a CoreSC category in (Liakata et al., 2012). The intuition behind this is that sentences with high classifier confidence will be less noisy, high precision cases and more representative of a particular category. Indeed, (Liakata et al., 2012) report statistical significance for the correlation between high classifier confidence and agreement between manual and automatic classification

However, as mentioned in section 3.1, there is inter-dependence between sentences in the text, which is in turn inherited by the categories assigned to them. For example, the highest ranking MET sentence will be related to an Experiment (EXP) or Background (BAC) sentence, which may not be the ones with the highest confidence score in their category.

In order to preserve discourse cohesion it is important to select related sentences from different categories. We resolve this by distinguising the CoreSCs into independent categories, which by definition are expected to show nucleus behaviour, and dependent categories. We also specify the relation between independent and dependent categories. The independent categories include the categories with the lowest percentage of sentences in scientific articles as reported in (Liakata et al., 2012), namely: Motivation (MOT) (1%), Goal (GOA)(1%), Hypothesis (HYP)(2%), Object (OBJ)(3%), Model (MOD)(9%), Conclusion (CON)(9%) and Method (MET)(11%). Categories whose sentence selection semantically depends on the former are Experiment (EXP)(10%), Background (BAC)(19%), Result (RES)(21%) and Observation (OBS)(14%). The independent categories also have higher precision than recall, in contrast to the dependent categories. While MET and EXP are almost equally represented in the CoreSC corpus, EXP by definition provides the detailed steps of an experimental method and thus it is semantically dependent on some MET category. More specifically, the dependencies are considered to be as follows: EXP, BAC depend on MET, RES depends on CON and OBS depends on RES (OBS is double-dependent).

Sentence extraction is driven by first identifying the independent categories based on classifier confidence scores and then choosing the corresponding dependent categories on the basis of both relatedness to the independent categories and classifier confidence. We use sentence proximity (defined below) as a measure for relatedness and combine it with classifier confidence during sentence extraction.

The mechanism to select sentences for inclusion in the summary, which considers category dependencies, proceeds as follows:

- For an independent category CatI, order sentences by decreasing order of confidence score. The confidence score is the average confidence score of the SVM and CRF classifiers reported in (Liakata et al., 2012) for a sentence.
- For a dependent category Cat, for which we need n sentences, given the selected sentences m from the corresponding independent category CatI we do the following:
  - If $m = 0$, then treat Cat as independent category for this case.
  - Otherwise, for each selected sentence t_i in CatI, calculate its proximity score to every sentence c_j of the dependent category Cat. $Proximity$ is defined as $1 - Distance$ where $Distance$ is an absolute difference in sentence ids between c_j and t_i normalised by the maximum absolute distance found between all c_j and t_i pairs.
  - The classifier prediction score for each c_j is multiplied by the $Proximity(c_j, t_i)$ score and the sentences are re-ranked according to the new scores, where only the n highest ranking c_js are kept. The last two steps result in an $m \times n$ matrix.
  - If $m = 1$, then the choice for the n sentences for Cat is straightforward.
  - Otherwise, we pick the n highest ranking c_js, proceeding row-wise. Thus, the highest ranking c_js for the highest ranking independent sentences t_i are given priority and any c_j is chosen at most once.

Once the sentence ids are selected for each independent and each dependent category we plug them into the content model. Sentence order is preserved within each CoreSC category. For example, if two Result sentences are selected, the order in which they appear in the paper will be preserved in the summary.

4 Summary evaluation via question answering

4.1 Task Description and experimental setup

We evaluate the extractive CoreSC summaries in terms of how well they enable 12 chemistry experts/evaluators (with at least a Masters degree in chemistry) to answer complex questions about the papers. Our test corpus consists of 28 papers held out from the ART/CoreSC corpus, roughly 1/9, which were annotated automatically with the SVM and CRF classifiers described in (Liakata et al., 2012) trained on the remaining 8/9 of the corpus. For each of the 28 papers in the test corpus, we generated CoreSC summaries automatically using the method described in section 3. We compare the performance of the experts on a question answering (Q-A) task when given the CoreSC summaries and two other types of summary, amounting to a total of three experimental conditions (A,B,C). The other two types of summary are the original paper abstracts (summaries A), in the absence of human summaries, and summaries generated by Microsoft Office Word 2007 AutoSummarize (summaries B).

Microsoft Office Word 2007 AutoSummarize (MA) is a widely available commercial system with reportedly good results (Garcia-Hernandez et al., 2009) and performance equivalent to TextRank (Mihalcea and Tarau, 2004). MA works by assigning a score to each word in a sentence depending on its frequency in the document and sentences are ranked and extracted according to the combination of scores of the words they contain. MA therefore follows classic lexicalised text extraction techniques, is domain independent and is completely agnostic of the discourse. For the latter reason, we considered MA to be a suitable baseline the comparison with which would illustrate the effect of using CoreSC categories on the summary and the merits of having a discourse based model for summarisation.

Neither the paper title nor section headings were available to any of the summarising systems as our extractive system does not make direct use of them and we were not sure how they would influence MA.

To ensure that each evaluator considered only one type of summary per paper, so as to avoid bias from previous stimuli, and to make sure all experts were exposed to all papers and all types of summary, the 12 experts were assigned to four groups (G1-G4) and were allocated 28 summaries each according to the Latin Square design in Table 1.[1].

The experimental setup follows the paradigm of (Teufel, 2001). However, while (Teufel, 2001) developed a Q-A task to evaluate summaries showing the contribution of a scientific article in relation to previous work, the purpose of the Q-A task at hand

[1]Initially we had four experimental conditions but one was dropped, so is not presented in this context

is to show the usefulness of the extracted summaries in answering questions on the paper, and how they compare to a discourse-agnostic baseline. In the case of (Teufel, 2001) the task consists of a fixed set of five questions, the same for all articles tuned particularly to the relation of current and previous work. By contrast, the current Q-A task aims to show how well the summaries represent the content of the entire paper, which means that questions are individual to each paper and required domain knowledge to create.

Each of the 12 experts answered three content-based questions per summary, where the questions were individual to each paper. An example of the questions and the corresponding answers for a given paper can be found below.

Example 4.1.1

- **Q:What do DNJ imino sugars inhibit the action of?**
  A: They inhibit glycosidases and ceramide glucosyltransferases.
- **Q:What methods do the authors use to study the conformation of N-benzyl-DNJ?**
  A: They use resonant two-photon ionization (R2PI), ultraviolet–ultraviolet (UV–UV) hole burning, and infrared (IR) ion-dip spectroscopies in conjunction with electronic structure theory calculations.
- **Q:What is the conformation of the exocyclic hydroxymethyl group?**
  A: The exocyclic hydroxymethyl group is axial to the piperidine ring (gauche- to the ring nitrogen).

As one can see, the questions are complex wh-questions and correspond to answers with multiple components. Questions were complex, to minimise the likelihood of correct random answers. They were designed by a senior chemistry expert with knowledge of linguistics, so that they could be answered based on the abstracts (A). For this purpose, the senior expert chose abstracts that were at least three sentences long. Ideally, the questions and answers should have been set on the basis of the entire paper, but this was not possible given our timeframe for the experiment.The underlying assumption is that a good summary should cover most of the main points of the paper. One of the merits of setting the questions on the basis of the abstracts was that the answers to be identified were deemed sufficiently important to be expressed in the humanly created abstract. However, automatic summaries created in the way proposed here could potentially answer questions beyond the scope of the abstract and in cases of very short abstracts be much more informative.

Experts were told that summaries were automatically generated with no details about different types of summary; it is assumed that none of them is completely familiar with the work mentioned in the 28 papers.

On average, it took experts less than 10 minutes to read a summary and answer the three content-based questions.

	Papers (28)			
Evaluator groups	1–7	8–14	15–21	22-28
G1	A	B	-	C
G2	C	A	B	-
G3	-	C	A	B
G4	B	-	C	A

Table 1: Distribution of summaries to evaluators

4.2 Results and Discussion

We compared each evaluator's answers obtained after reading a summary against the model answers set by the senior expert, the author of the questions, based on the abstract (A) of the corresponding paper. If an evaluator's answer is identical to a model answer, then this counts as "matched".

For instance in example 4.1.1 above, "axial to the piperidine ring", "gauche- to the ring nitrogen" and "The OH6 group is axial (Gauche) to the ring nitrogen" were all considered correct, fully matched answers to the question "What is the conformation of the exocyclic hydroxymethyl group?". In the case of the second question in the same example all of the following were considered correct and fully matched: "Resonant two-photon ionization (R2PI), UV/UV hole-burn, and IR ion-dip spectroscopies in conjunction with electronic structure theory calculations", "R2PI UV/UV hole-burn IR ion-dip e- structure theory calculations" and "a combination of resonant two-photon ionization (R2PI), UV/UV hole-burn, and IR ion-dip spectroscopies in conjunction with electronic structure theory calculations".

If the answer requires listing more than one item (as is the case with questions one and two of example 4.1.1), all of the items have to be matched. Partially matched answers are counted as "partially matched". Non-matching answers can be of two

types. If an un-matched answer coincided with the answer the senior expert would have given after reading that particular summary, then it was marked as "un-matched:justified": Such answers were correct given the particular summary, but are not necessarily correct with respect to the paper and do not count as alternative answers. If the answer was un-matched and also unjustified given the content of the summary, then it was marked as "un-matched:unjustified" . These are cases of evaluator error. Similarly, cases where the evaluator gave "N/A" as an answer were marked as "justified" or "unjustified" according to whether the senior expert could find the answer in the summary or not. The results from marking answers are shown in Table 2.

Number of	A	B	C
Matched	240	126	135
Partially matched	0	4	3
Un-matched:justified	0	25	15
N/A:justified	0	71	71
Un-matched:unjustified	5	11	17
N/A:unjustified	7	15	11
All answers	252	252	252

Table 2: Matches between summary-based answers and model answers

	Micro-AVG			Macro-AVG		
S. types	R	P	F	R	P	F
A	1	0.95	0.98	1	0.95	0.97
B	0.64	0.70	0.67	**0.64**	0.64	0.60
C	**0.66**	**0.75**	**0.70**	**0.64**	**0.70**	**0.65**

Table 3: Precision, Recall and F-score for answering questions using the four types of summary. A: abstracts, B: autosummarize, C:automatic CoreSC summaries.

We report Precision, Recall and F-score (P-R-F) for answering questions given each type of summary (Table 3). To calculate these we define TP as matched answers, FN as N/A:justified and FP everything else (partially matched + un-matched:justified + un-matched:unjustified + N/A:unjustified). Here, the standard definition of recall (TP/(TP+FN)) demonstrates how many questions can be answered using the summary (summary coverage) and Precision (TP/(TP+FP)) how well the questions are answered (summary clarity).

We consider the F-measure to be an overall indicator of the summary usefulness. Micro-averaging is obtained by adding all answers from all papers to calculate TP, FN and FP whereas macro-averaging calculates P-R-F first per paper and then averages over all papers.

The rankings remain consistent regardless of the averaging method. Condition A (abstracts) shows perfect Recall (the evaluators are able to answer all the questions) whereas Precision is affected by unjustified failed matches (Table 2). The perfect recall is hardly surprising as the questions are designed on the basis of the abstract but provides a sanity check for the experiment. The precision sets an upper bound for precision with automatic summaries. Summaries of condition C provide answers to more questions (Recall) and with greater accuracy (Precision) than summaries B. When macro-averaging, the Recall score of summaries C is tied with that for summaries B but Precision is 6% higher.

To verify the statistical significance for the difference in precision and recall for summaries B and C respectively, we performed Monte Carlo sampling 10000 times, for the populations of answers for summaries B and C. During each iteration of sampling, precision and recall were calculated, creating populations of 10000 recalls and 10000 precisions propagated to be representative of the original population of answers. A t-test performed on the population of precision and the population of recalls showed statistical significance at 95% in both cases, with summaries C having a precision of 5% higher and a recall of 1.4-1.6% higher than summaries B (see Table 4). Therefore, we can say that CoreSC summaries C are overall better for answering questions than summaries B.

Comparison between B and C (B-C)	
precision	recall
t = -105.90 df = 19959.79 p-value $<$ 2.2e-16	t = -32.52 df = 19994.40 p-value $<$ 2.2e-16
alternative hypothesis: true difference in means $\neq$ 0	
95% confidence interval: -0.051 -0.049 sample estimates: mean of x mean of y 0.696 0.746	95% confidence interval: -0.016 -0.014 sample estimates: mean of x mean of y 0.639 0.655

Table 4: Test for statistical significance betwen summaries B (microsoft) and C (CoreSC)

The difference in precision between summaries B and C shows the advantage of having a con-

tent model: summaries C are significantly clearer. We had also expected CoreSC summaries to have a much higher coverage than summaries B, and therefore significantly higher recall. However, this difference was less pronounced perhaps because autosummarize favours shorter sentences, which are more likely to be found in the abstracts. We expect that a refinement in the sentence selection criterion, which would also take sentence length into account, will help to showcase further the benefits of using a CoreSC-based content model.

Analysis using ROUGE showed that while summaries C had a slightly higher ROUGE-1 measure than summaries B (0.75 vs 0.73), with respect to abstracts, ROUGE-L was the same for the two (0.70).

In table 5 we also report measurements on summary informativeness based on divergence (Kullback Leibler (KL) divergence and Jensen Shannon (JS) divergence), as in (Louis and Nenkova, 2013). KL divergence is asymmetric and reflects the average number of bits wasted by coding samples of a distribution P using another distribution Q. JS divergence is an information-theoretic measure, reflecting the average distance of the KL divergence between summary and input (the full paper in our case) from the mean vocabulary distributions. Compared to other measures, JS divergence has been found to produce the best predictions of summary quality (Louis and Nenkova, 2013). In practice, what JS divergence tells us is how 'different'/divergent the summary is from the original paper. Low divergence scores are indicative of greater overlap between the summaries and the original paper and are considered positive in terms of the summary information content.

type	KLI-S	KLS-I	UnJSD	SJSD
B	1.66	0.70	0.21	0.19
C	1.40	0.62	0.18	0.17
random	1.61	0.79	0.21	0.19

Table 5: Macro-averaged divergence scores for the 28 test summaries. B: Autosummarize, C: CoreSC, random: random summaries each 20 sentences long for each paper. KLI-S: Average Kullback Leibler divergence between input and summary. KLS-I: Kullback Leibler divergence between summary and input, since KL divergence is not symmetric. UnJSD: Jensen Shannon divergence between input and summary. No smoothing. SJSD:A version with smoothing.

One can see the that CoreSC summaries have consistently lower divergence (both KL and JS) than microsoft autosummarise summaries and random summaries of the same length. This is a positive outcome but since such automatic measures of summary quality have not yet reached maturity and are harder to interpret, we consider the manual evaluation a more reliable indicator of summary informativeness and usefulness. Note that it is not appropriate to use divergence to assess the abstracts as this measure is influenced by the length of a text, which varies dramatically in the case of abstracts.

5 Conclusions and future work

We have shown how a content model based on the scientific discourse as annotated by the CoreSC scheme can be used to produce extractive summaries. These summaries can be generated as alternatives to abstracts. Since they preserve the distribution of CoreSCs in the paper and are not produced independently of it, as is the case with many abstracts, they are potentially more representative of abstracts than the full article. We have tested the usefulness CoreSC based summaries in answering complex questions relating to the content of scientific papers. Extracts from automated CoreSCs are informative, outperform microsoft autosummarise summaries, in both intrinsic and extrinsic evaluation, and enable experts to answer 66% of complex questions with a precision of 75%.

In the future we would like to experiment further with refining the sentence selection method so as to consider criteria for local cohesion, such as lexical chains. We would also like to perform comparisons with automatically induced content models and check their viability for scientific articles. We also would like to perform a human based evaluation of coherence and explore the full potential of these summaries as alternatives to author-written abstracts. This work constitutes a very important step in producing automatic summaries of scientific papers and enabling experts to extract information from the papers, a major requirement for resource curation, which is dependent on constant reviewing of the literature.

Abstract

We present the first provably optimal polynomial time dynamic programming (DP) algorithm for best-first shift-reduce parsing, which applies the DP idea of Huang and Sagae (2010) to the best-first parser of Sagae and Lavie (2006) in a non-trivial way, reducing the complexity of the latter from exponential to polynomial. We prove the correctness of our algorithm rigorously. Experiments confirm that DP leads to a significant speedup on a probablistic best-first shift-reduce parser, and makes exact search under such a model tractable for the first time.

1 Introduction

Best-first parsing, such as A* parsing, makes constituent parsing efficient, especially for bottom-up CKY style parsing (Caraballo and Charniak, 1998; Klein and Manning, 2003; Pauls and Klein, 2009). Traditional CKY parsing performs cubic time exact search over an exponentially large space. Best-first parsing significantly speeds up by always preferring to explore states with higher probabilities.

In terms of incremental parsing, Sagae and Lavie (2006) is the first work to extend best-first search to shift-reduce constituent parsing. Unlike other very fast greedy parsers that produce suboptimal results, this best-first parser still guarantees optimality but requires exponential time for very long sentences in the worst case, which is intractable in practice. Because it needs to explore an exponentially large space in the worst case, a bounded priority queue becomes necessary to ensure limited parsing time.

*This work is mainly supported by DARPA FA8750-13-2-0041 (DEFT), a Google Faculty Research Award, and a PSC-CUNY Award. In addition, we thank Kenji Sagae and the anonymous reviewers for their constructive comments.

On the other hand, Huang and Sagae (2010) explore the idea of dynamic programming, which is originated in bottom-up constituent parsing algorithms like Earley (1970), but in a beam-based non best-first parser. In each beam step, they enable state merging in a style similar to the dynamic programming in bottom-up constituent parsing, based on an equivalence relation defined upon feature values. Although in theory they successfully reduced the underlying deductive system to polynomial time complexity, their merging method is limited in that the state merging is only between two states in the same beam step. This significantly reduces the number of possible merges, because: 1) there are only a very limited number of states in the beam at the same time; 2) a lot of states in the beam with different steps cannot be merged.

We instead propose to combine the idea of dynamic programming with the best-first search framework, and apply it in shift-reduce dependency parsing. We merge states with the same features set globally to further reduce the number of possible states in the search graph. Thus, our DP best-first algorithm is significantly faster than non-DP best-first parsing, and, more importantly, it has a polynomial time complexity even in the worst case.

We make the following contributions:

- *theoretically*, we formally prove that our DP best-first parsing reaches optimality with polynomial time complexity. This is the first time that exact search under such a probabilistic model becomes tractable.

- more interestingly, we reveal that our dynamic programming over shift-reduce parsing is in parallel with the bottom-up parsers, except that we have an extra order constraint given by the shift action to enforce left to right generation of

$$\textsf{re}_{\curvearrowright} \quad \frac{\ell : \langle j,\ S|s_1|s_0 \rangle : c}{\ell + 1 : \langle j,\ S|s_1{}^{\curvearrowright}s_0 \rangle : c + sc_{\textsf{re}_{\curvearrowright}}(j, S|s_1|s_0)}$$

Figure 1: Deductive system of basic non-DP shift-reduce parsing. Here ℓ is the step index (for beam search), S is the stack, c is the score of the precedent, and $sc_a(x)$ is the score of action a from derivation x. See Figure 2 for the DP version.

partial trees, which is analogous to Earley.

- *practically*, our DP best-first parser is only ∼2 times slower than a pure greedy parser, but is guaranteed to reach optimality. In particular, it is ∼20 times faster than a non-DP best-first parser. With inexact search of bounded priority queue size, DP best-first search can reach optimality with a significantly smaller priority queue size bound, compared to non-DP best-first parser.

Our system is based on a MaxEnt model to meet the requirement from best-first search. We observe that this locally trained model is not as strong as global models like structured perceptron. With that being said, our algorithm shows its own merits in both theory and practice. To find a better model for best-first search would be an interesting topic for future work.

2 Shift-Reduce and Best-First Parsing

In this section we review the basics of shift-reduce parsing, beam search, and the best-first shift-reduce parsing algorithm of Sagae and Lavie (2006).

2.1 Shift-Reduce Parsing and Beam Search

Due to space constraints we will assume some basic familiarity with shift-reduce parsing; see Nivre (2008) for details. Basically, shift-reduce parsing (Aho and Ullman, 1972) performs a left-to-right scan of the input sentence, and at each step, chooses either to *shift* the next word onto the stack, or to *reduce*, i.e., combine the top two trees on stack, either with left as the root or right as the root. This scheme is often called "arc-standard" in the literature (Nivre, 2008), and is the basis of several state-of-the-art parsers, e.g. Huang and Sagae (2010). See Figure 1 for the deductive system of shift-reduce dependency parsing.

To improve on strictly greedy search, shift-reduce parsing is often enhanced with beam search (Zhang and Clark, 2008), where b derivations develop in parallel. At each step we extend the derivations in the current beam by applying each of the three actions, and then choose the best b resulting derivations for the next step.

2.2 Best-First Shift-Reduce Parsing

Sagae and Lavie (2006) present the parsing problem as a search problem over a DAG, in which each parser derivation is denoted as a node, and an edge from node x to node y exists if and only if the corresponding derivation y can be generated from derivation x by applying one action.

The best-first parsing algorithm is an application of the Dijkstra algorithm over the DAG above, where the score of each derivation is the priority. Dijkstra algorithm requires the priority to satisfy the *superiority* property, which means a descendant derivation should never have a higher score than its ancestors. This requirement can be easily satisfied if we use a generative scoring model like PCFG. However, in practice we use a MaxEnt model. And we use the negative log probability as the score to satisfy the superiority:

$$x \prec y \Leftrightarrow x.score < y.score,$$

where the order $x \prec y$ means derivation x has a higher priority than y.[1]

The vanilla best-first parsing algorithm inherits the optimality directly from Dijkstra algorithm. However, it explores exponentially many derivations to reach the goal configuration in the worst case. We propose a new method that has polynomial time complexity even in the worst case.

[1]For simplicity we ignore the case when two derivations have the same score. In practice we can choose either one of the two derivations when they have the same score.

3 Dynamic Programming for Best-First Shift-Reduce Parsing

3.1 Dynamic Programming Notations

The key innovation of this paper is to extend best-first parsing with the "state-merging" method of dynamic programming described in Huang and Sagae (2010). We start with describing a parsing configuration as a non-DP *derivation*:

$$\langle i, j, ...s_2 s_1 s_0 \rangle,$$

where $...s_2 s_1 s_0$ is the stack of partial trees, $[i..j]$ is the span of the top tree s_0, and $s_1 s_2...$ are the remainder of the trees on the stack.

The notation $\mathbf{f}_k(s_k)$ is used to indicate the features used by the parser from the tree s_k on the stack. Note that the parser only extracts features from the top $d+1$ trees on the stack.

Following Huang and Sagae (2010), $\widetilde{\mathbf{f}}(x)$ of a derivation x is called *atomic features*, defined as the *smallest set* of features s.t.

$$\begin{aligned} &\widetilde{\mathbf{f}}(i, j, ...s_2 s_1 s_0) = \widetilde{\mathbf{f}}(i, j, ...s'_2 s'_1 s'_0) \\ \Leftrightarrow\ &\mathbf{f}_k(s_k) = \mathbf{f}_k(s'_k), \forall k \in [0, d]. \end{aligned}$$

The atomic feature function $\widetilde{\mathbf{f}}(\cdot)$ defines an equivalence relation $\sim$ in the space of derivations $\mathcal{D}$:

$$\begin{aligned} &\langle i, j, ...s_2 s_1 s_0 \rangle \sim \langle i, j, ...s'_2 s'_1 s'_0 \rangle \\ \Leftrightarrow\ &\widetilde{\mathbf{f}}(i, j, ...s_2 s_1 s_0) = \widetilde{\mathbf{f}}(i, j, ...s'_2 s'_1 s'_0) \end{aligned}$$

This implies that any derivations with the same atomic features are in the same *equivalence class*, and their behaviors are similar in shift and reduce. We call each equivalence class a DP *state*. More formally we define the space of all states $\mathcal{S}$ as:

$$\mathcal{S} \triangleq \mathcal{D}/\sim.$$

Since only the top $d+1$ trees on the stack are used in atomic features, we only need to remember the necessary information and write the state as:

$$\langle i, j, s_d...s_0 \rangle.$$

We denote a derivation x's state as $[x]_\sim$. In the rest of this paper, we always denote derivations with letters x, y, and z, and denote states with letters p, q, and r.

The deductive system for dynamic programming best-first parsing is adapted from Huang and Sagae (2010). (See the left of Figure 2.) The difference is that we do not distinguish the step index of a state.

This deductive system describes transitions between states. However, in practice we use one state's best derivation found so far to represent the state. For each state p, we calculate the prefix score, $p.pre$, which is the score of the derivation to reach this state, and the inside score, $p.ins$, which is the score of p's top tree $p.s_0$. In addition we denote the shift score of state p as $p.sh \triangleq sc_{\mathsf{sh}}(p)$, and the reduce score of state p as $p.re \triangleq sc_{\mathsf{re}}(p)$. Similarly we have the prefix score, inside score, shift score, and reduce score for a derivation.

With this deductive system we extend the concept of reducible states with the following definitions:

The set of all states with which a state p can legally reduce from the right is denoted $\mathcal{L}(p)$, or *left states*. (see Figure 3 (a)) We call any state $q \in \mathcal{L}(p)$ a *left state* of p. Thus each element of this set would have the following form:

$$\begin{aligned} \mathcal{L}(\langle i, j, s_d...s_0 \rangle) \triangleq \{ &\langle h, i, s'_d...s'_0 \rangle \mid \\ &\mathbf{f}_k(s'_{k-1}) = \mathbf{f}_k(s_k),\ \forall k \in [1, d] \} \end{aligned} \quad (1)$$

in which the span of the "left" state's top tree ends where that of the "right" state's top tree begins, and $\mathbf{f}_k(s_k) = \mathbf{f}_k(s'_{k-1})$ for all $k \in [1, d]$.

Similarly, the set of all states with which a state p can legally reduce from the left is denoted $\mathcal{R}(p)$, or *right states*. (see Figure 3 (a)) For two states p, q,

$$p \in \mathcal{L}(q) \Leftrightarrow q \in \mathcal{R}(p)$$

3.2 Algorithm 1

We constrain the searching time with a polynomial bound by transforming the original search graph with exponentially many derivations into a graph with polynomial number of states.

In Algorithm 1, we maintain a chart C and a priority queue Q, both of which are based on hash tables.

Chart C can be formally defined as a function mapping from the space of states to the space of derivations:

$$C : \mathcal{S} \rightarrow \mathcal{D}.$$

In practice, we use the atomic features $\widetilde{\mathbf{f}}(p)$ as the signature of state p, since all derivations in the same state share the same atomic features.

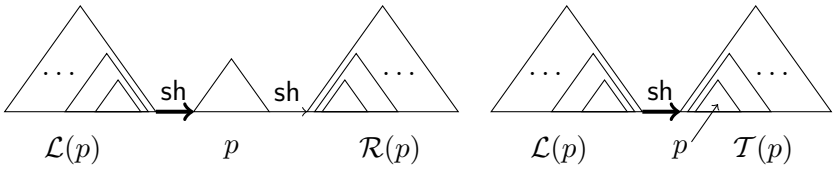
$$\textsf{sh} \quad \frac{\overset{\text{state } p\text{:}}{\langle \_, j, s_d ... s_0 \rangle : (c, \_)}}{\langle j, j+1, s_{d-1} ... s_0, w_j \rangle : (c + \xi, 0)} \; j < n$$

$$\textsc{Pred} \quad \frac{\langle \_, j, A \to \alpha . B \beta \rangle : (c, \_)}{\langle j, j, B \to . \gamma \rangle : (c{+}s,\ s)} \; (B \to \gamma) \in G$$

$$\textsf{re}_{\curvearrowright} \; \frac{\overset{\text{state } q\text{:}}{\langle k, i, s'_d ... s'_0 \rangle : (c', v')} \quad \overset{\text{state } p\text{:}}{\langle i, j, s_d ... s_0 \rangle : (\_, v)}}{\langle k, j, s'_d ... s'_1, s'_0 \frown s_0 \rangle : (c'{+}v{+}\delta,\ v'{+}v{+}\delta)} \; q \in \mathcal{L}(p)$$

$$\textsc{Comp} \; \frac{\langle k, i, A \to \alpha . B \beta \rangle : (c', v') \quad \langle i, j, B \rangle : (\_, v)}{\langle k, j, A \to \alpha B . \beta \rangle : (c'{+}v,\ v'{+}v)}$$

Figure 2: Deductive systems for dynamic programming shift-reduce parsing (Huang and Sagae, 2010) (left, omitting $\textsf{re}_{\curvearrowright}$ case), compared to weighted Earley parsing (Stolcke, 1995) (right). Here $\xi = sc_{\textsf{sh}}(p)$, $\delta = sc_{\textsf{sh}}(q) + sc_{\textsf{re}_{\curvearrowright}}(p)$, $s = sc(B \to \gamma)$, G is the set of CFG rules, $\langle i, j, B \rangle$ is a surrogate for any $\langle i, j, B \to \gamma . \rangle$, and $\_$ is a wildcard that matches anything.



(a) $\mathcal{L}(p)$ and $\mathcal{R}(p)$ (b) $\mathcal{T}(p) = \mathcal{R}(\mathcal{L}(p))$

Figure 3: Illustrations of left states $\mathcal{L}(p)$, right states $\mathcal{R}(p)$, and left corner states $\mathcal{T}(p)$. (a) Left states $\mathcal{L}(p)$ is the set of states that can be reduced with p so that $p.s_0$ will be the right child of the top tree of the result state. Right states $\mathcal{R}(p)$ is the set of states that can be reduced with p so that $p.s_0$ will be the left child of the top tree of the result state. (b) Left corner states $\mathcal{T}(p)$ is the set of states that have the same reducibility as shifted state p, i.e., $\forall p' \in \mathcal{L}(p)$, we have $\forall q \in \mathcal{T}(p), q \in \mathcal{R}(p')$. In both (a) and (b), thick sh arrow means shifts from multiple states; thin sh arrow means shift from a single state.

We use $C[p]$ to retrieve the derivation in C that is associated with state p. We sometimes abuse this notation to say $C[x]$ to retrieve the derivation associated with signature $\widetilde{\mathbf{f}}(x)$ for derivation x. This is fine since we know derivation x's state immediately from the signature. We say state $p \in C$ if $\widetilde{\mathbf{f}}(p)$ is associated with some derivation in C. A derivation $x \in C$ if $C[x] = x$. Chart C supports operation PUSH, denoted as $C[x] \leftarrow x$, which associate a signature $\widetilde{\mathbf{f}}(x)$ with derivation x.

Priority queue Q is defined similarly as C, except that it supports the operation POP that pops the highest priority item.

Following Stolcke (1995) and Nederhof (2003), we use the prefix score and the inside score as the priority in Q:

$$x \prec y \Leftrightarrow x.pre < y.pre \text{ or } (x.pre = y.pre \text{ and } x.ins < y.ins), \quad (2)$$

Note that, for simplicity, we again ignore the special case when two derivations have the same prefix score and inside score. In practice for this case we can pick either one of them. This will not affect the correctness of our optimality proof in Section 5.1.

In the DP best-first parsing algorithm, once a derivation x is popped from the priority queue Q, as usual we try to expand it with shift and reduce. Note that both left and right reduces are between the derivation x of state $p = [x]_\sim$ and an in-chart derivation y of left state $q = [y]_\sim \in \mathcal{L}(p)$ (Line 10 of Algorithm 1), as shown in the deductive system (Figure 2). We call this kind of reduction *left expansion*.

We further expand derivation x of state p with some in-chart derivation z of state r s.t. $p \in \mathcal{L}(r)$, i.e., $r \in \mathcal{R}(p)$ as in Figure 3 (a). (see Line 11 of Algorithm 1.) Derivation z is in the chart because it is the descendant of some other derivation that has been explored before x. We call this kind of reduction *right expansion*.

Our reduction with $\mathcal{L}$ and $\mathcal{R}$ is inspired by Nederhof (2003) and Knuth (1977) algorithm, which will be discussed in Section 4.

Algorithm 1 Best-First DP Shift-Reduce Parsing.

Let $\mathcal{L}_C(x) \triangleq C[\mathcal{L}([x]_\sim)]$ be in-chart derivations of $[x]_\sim$'s left states

Let $\mathcal{R}_C(x) \triangleq C[\mathcal{R}(p)]$ be in-chart derivations of $[x]_\sim$'s right states

12: **procedure** SHIFT(x, Q)
13: TRYADD($\mathsf{sh}(x)$, Q) ▷ shift
14: **procedure** REDUCE(A, B, Q)
15: **for** $(x, y) \in A \times B$ **do** ▷ try all possible pairs
16: TRYADD($\mathsf{re}_{\curvearrowleft}(x, y)$, Q) ▷ left reduce
17: TRYADD($\mathsf{re}_{\curvearrowright}(x, y)$, Q) ▷ right reduce
18: **function** TRYADD(x, Q)
19: **if** $[x]_\sim \notin Q$ **or** $x \prec Q[x]$ **then**
20: $Q[x] \leftarrow x$ ▷ insert x into Q or update $Q[x]$

3.3 Algorithm 2: Lazy Expansion

We further improve DP best-first parsing with lazy expansion.

In Algorithm 2 we only show the parts that are different from Algorithm 1.

Assume a *shifted* derivation x of state p is a direct descendant from derivation x' of state p', then $p \in \mathcal{R}(p')$, and we have:

$$\forall ys.t.\ [y]_\sim = q \in \text{REDUCE}(\{p'\}, \mathcal{R}(p')), x \prec y$$

which is proved in Section 5.1.

More formally, we can conclude that

$$\forall ys.t.\ [y]_\sim = q \in \text{REDUCE}(\mathcal{L}(p), \mathcal{T}(p)), x \prec y$$

where $\mathcal{T}(p)$ is the *left corner states* of shifted state p, defined as

$$\mathcal{T}(\langle i, i{+}1, s_d ... s_0 \rangle) \triangleq \{\langle i, h, s'_d ... s'_0 \rangle \mid \mathbf{f}_k(s'_k) = \mathbf{f}_k(s_k),\ \forall k \in [1, d]\}$$

which represents the set of all states that have the same reducibility as a shifted state p. In other words,

$$\mathcal{T}(p) = \mathcal{R}(\mathcal{L}(p)),$$

Algorithm 2 Lazy Expansion of Algorithm 1.

Let $\mathcal{T}_C(x) \triangleq C[\mathcal{T}([x]_\sim)]$ be in-chart derivations of $[x]_\sim$'s left-corner states

1: **function** PARSE($w_0 \dots w_{n-1}$)
2: $C \leftarrow \emptyset$ ▷ empty chart
3: $Q \leftarrow \{\text{INIT}\}$ ▷ initial priority queue
4: **while** $Q \neq \emptyset$ **do**
5: $x \leftarrow \text{POP}(Q)$
6: **if** GOAL(x) **then return** x ▷ found best parse
7: **if** $[x]_\sim \notin C$ **then**
8: $C[x] \leftarrow x$ ▷ add x to chart
9: SHIFT(x, Q)
10: REDUCE($x.\mathit{lefts}, \{x\}, Q$) ▷ left expansion
11: **else if** $x.\mathit{action}$ **is** sh **then**
12: REDUCE($x.\mathit{lefts}, \mathcal{T}_C(x), Q$) ▷ right expan.
13: **procedure** SHIFT(x, Q)
14: $y \leftarrow \mathsf{sh}(x)$
15: $y.\mathit{lefts} \leftarrow \{x\}$ ▷ initialize *lefts*
16: TRYADD(y, Q)
17: **function** TRYADD(x, Q)
18: **if** $[x]_\sim \in Q$ **then**
19: **if** $x.\mathit{action}$ **is** sh **then** ▷ maintain *lefts*
20: $y \leftarrow Q[x]$
21: **if** $x \prec y$ **then** $Q[x] \leftarrow x$
22: $Q[x].\mathit{lefts} \leftarrow y.\mathit{lefts} \cup x.\mathit{lefts}$
23: **else if** $x \prec Q[x]$ **then**
24: $Q[x] \leftarrow x$
25: **else** ▷ $x \notin Q$
26: $Q[x] \leftarrow x$

which is illustrated in Figure 3 (a). Intuitively, $\mathcal{T}(p)$ is the set of states that have p's top tree, $p.s_0$, which contains only one node, as the left corner.

Based on this observation, we can safely delay the REDUCE($\{x\}, \mathcal{R}_C(x)$) operation (Line 11 in Algorithm 1), until the derivation x of a shifted state is popped out from Q. This helps us eliminate unnecessary right expansion.

We can delay even more derivations by extending the concept of left corner states to reduced states. Note that for any two states p, q, if q's top tree $q.s_0$ has p's top tree $p.s_0$ as left corner, and p, q share the same left states, then derivations of p should always have higher priority than derivations of q. We can further delay the generation of q's derivations until p's derivations are popped out.[2]

[2]We did not implement this idea in experiments due to its complexity.

4 Comparison with Best-First CKY and Best-First Earley

4.1 Best-First CKY and Knuth Algorithm

Vanilla CKY parsing can be viewed as searching over a hypergraph(Klein and Manning, 2005), where a hyperedge points from two nodes x, y to one node z, if x, y can form a new partial tree represented by z. Best-first CKY performs best-first search over the hypergraph, which is a special application of the Knuth Algorithm (Knuth, 1977).

Non-DP best-first shift-reduce parsing can be viewed as searching over a graph. In this graph, a node represents a derivation. A node points to all its possible descendants generated from shift and left and right reduces. This graph is actually a tree with exponentially many nodes.

DP best-first parsing enables state merging on the previous graph. Now the nodes in the hypergraph are not derivations, but equivalence classes of derivations, i.e., states. The number of nodes in the hypergraph is no longer always exponentially many, but depends on the equivalence function, which is the atomic feature function $\widetilde{\mathbf{f}}(\cdot)$ in our algorithms.

DP best-first shift-reduce parsing is still a special case of the Knuth algorithm. However, it is more difficult than best-first CKY parsing, because of the extra topological order constraints from shift actions.

4.2 Best-First Earley

DP best-first shift-reduce parsing is analogous to weighted Earley (Earley, 1970; Stolcke, 1995), because: 1) in Earley the PRED rule generates states similar to shifted states in shift-reduce parsing; and, 2) a newly completed state also needs to check all possible left expansions and right expansions, similar to a state popped from the priority queue in Algorithm 1. (see Figure 2)

Our Algorithm 2 exploits lazy expansion, which reduces unnecessary expansions, and should be more efficient than pure Earley.

5 Optimality and Polynomial Complexity

5.1 Proof of Optimality

We define a *best derivation* of state $[x]_\sim$ as a derivation x such that $\forall y \in [x]_\sim$, $x \preceq y$.

Note that each state has a unique feature signature. We want to prove that Algorithm 1 actually fills the chart by assigning a best derivation to its state. Without loss of generality, we assume Algorithm 1 fills C with derivations in the following order:

$$x_0, x_1, x_2, \ldots, x_m$$

where x_0 is the initial derivation, x_m is the first goal derivation in the sequence, and $C[x_i] = x_i, 0 \leq i \leq m$. Denote the status of chart right after x_k being filled as C_k. Specially, we define $C_{-1} = \emptyset$

However, we do not have superiority as in non-DP best-first parsing. Because we use a pair of prefix score and inside score, (pre, ins), as priority (Equation 2) in the deductive system (Figure 2). We have the following property as an alternative for superiority:

Lemma 1. *After derivation x_k has been filled into chart, $\forall x$ s.t. $x \in Q$, and x is a best derivation of state $[x]_\sim$, then x's descendants can not have a higher priority than x_k.*

Proof. Note that when x_k pops out, x is still in Q, so $x_k \preceq x$. Assume z is x's direct descendant.

- If $z = \mathsf{sh}(x)$ or $z = \mathsf{re}(x, \_)$, based on the deductive system, $x \prec z$, so $x_k \preceq x \prec z$.
- If $z = \mathsf{re}(y, x)$, $y \in \mathcal{L}(x)$, assume $z \prec x_k$.

  $$z.pre = y.pre + y.sh + x.ins + x.re$$

  We can construct a new derivation $x' \sim x$ by appending x's top tree, $x.s_0$ to y's stack, and

  $$x'.pre = y.pre + y.sh + x.ins < z.pre$$

  So $x' \prec z \prec x_k \preceq x$, which contradicts that x is a best derivation of its state.

With induction we can easily show that any descendants of x can not have a higher priority than x_k. □

We can now derive:

Theorem 1 (Stepwise Completeness and Optimality)**.** *For any k, $0 \leq k \leq m$, we have the following two properties:*

$$\forall x \prec x_k, [x]_\sim \in C_{k-1} \quad \text{(Stepwise Completeness)}$$
$$\forall x \sim x_k, x_k \preceq x \quad \text{(Stepwise Optimality)}$$

Proof. We prove by induction on k.

1. For $k = 0$, these two properties trivially hold.

2. Assume this theorem holds for $k = 2, ..., i-1$. For $k = i$, we have:

a) *[Proof for Stepwise Completeness]*

(Proof by Contradiction) Assume $\exists x \prec x_i$ s.t. $[x]_\sim \notin C_{i-1}$.Without loss of generality we take a best derivation of state $[x]_\sim$ as x. x must be derived from other best derivations only. Consider this derivation transition hypergraph, which starts at initial derivation $x_0 \in C_{i-1}$, and ends at $x \notin C_{i-1}$.

There must be a best derivation x' in this transition hypergraph, s.t. all best parent derivation(s) of x' are in C_{i-1}, but not x'.

If x' is a reduced derivation, assume x''s best parent derivations are $y \in C_{i-1}, z \in C_{i-1}$. Because y and z are best derivations, and they are in C_{i-1}, from Stepwise Optimality on $k = 1, ..., i-1$, $y, z \in \{x_0, x_1, \ldots, x_{i-1}\}$. From Line 7-11 in Algorithm 1, x' must have been pushed into Q when the latter of y, z is popped.

If x' is a shifted derivation, similarly x' must have been pushed into Q.

As $x' \notin C_{i-1}$, x' must still be in Q when x_i is popped. However, from Lemma 1, none of x''s descendants can have a higher priority than x_i, which contradicts $x \prec x_i$.

b) *[Proof for Stepwise Optimality]*

(Proof by Contradiction) Assume $\exists x \sim x_i$ s.t. $x \prec x_i$. From Stepwise Completeness on $k = 1, ..., i$, $x \in C_{i-1}$, which means the state $[x_i]_\sim$ has already been assigned to x, contradicting the premise that x_i is pushed into chart.

□

Both of the two properties have very intuitive meanings. Stepwise Optimality means Algorithm 1 only fills chart with a best derivation for each state. Stepwise Completeness means every state that has its best derivation better than best derivation p_i must have been filled before p_i, this guarantees that the global best goal derivation is captured by Algorithm 1.

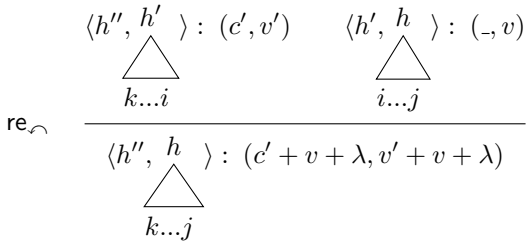

Figure 4: Example of shift-reduce with dynamic programming: simulating an edge-factored model. GSS is implicit here, and $\mathsf{re}_{\curvearrowleft}$ case omitted. Here $\lambda = sc_{\mathsf{sh}}(h'', h') + sc_{\mathsf{re}_{\curvearrowleft}}(h', h)$.

More formally we have:

Theorem 2 (Optimality of Algorithm 1)**.** *The first goal derivation popped off the priority queue is the optimal parse.*

Proof. (Proof by Contradiction.) Assume $\exists x$, x is the a goal derivation and $x \prec x_m$. Based on Stepwise Completeness of Theorem 1, $x \in C_{m-1}$, thus x has already been popped out, which contradicts that x_m is the first popped out goal derivation. □

Furthermore, we can see our lazy expansion version, i.e., Algorithm 2, is also optimal. The key observation is that we delay the reduction of derivation x' and a derivation of right states $\mathcal{R}([x']_\sim)$ (Line 11 of Algorithm 1), until shifted derivation, $x = \mathsf{sh}(x')$, is popped out (Line 11 of Algorithm 2). However, this delayed reduction will not generate any derivation y, s.t. $y \prec x$, because, based on our deductive system (Figure 2), for any such kind of reduced derivations y, $y.pre = x'.pre + x'.sh + y.re + y.ins$, while $x.pre = x'.pre + x'.sh$.

5.2 Analysis of Time and Space Complexity

Following Huang and Sagae (2010) we present the complexity analysis for our DP best-first parsing.

Theorem 3. *Dynamic programming best-first parsing runs in worst-case polynomial time and space, as long as the atomic features function satisfies:*

- **bounded***: $\forall$ derivation x, $|\widetilde{\mathbf{f}}(x)|$ is bounded by a constant.*
- **monotonic***:*

– **horizontal**: $\forall k,\ \mathbf{f}_k(s) = \mathbf{f}_k(t) \Rightarrow \mathbf{f}_{k+1}(s) = \mathbf{f}_{k+1}(t)$, *for all possible trees* s, t.
– **vertical**: $\forall k,\ \mathbf{f}_k(s^\frown s') = \mathbf{f}_k(t^\frown t') \Rightarrow \mathbf{f}_k(s) = \mathbf{f}_k(t)$ *and* $\mathbf{f}_k(s^\frown s') = \mathbf{f}_k(t^\frown t') \Rightarrow \mathbf{f}_k(s') = \mathbf{f}_k(t')$, *for all possible trees* s, s', t, t'.

In the above theorem, boundness means we can only extract finite information from a derivation, so that the atomic feature function $\widetilde{\mathbf{f}}(\cdot)$ can only distinguish a finite number of different states. Monotonicity requires the feature representation $\mathbf{f}_k$ subsumes $\mathbf{f}_{k+1}$. This is necessary because we use the features as signature to match all possible left states and right states (Equation 1). Note that we add the vertical monotonicity condition following the suggestion from Kuhlmann et al. (2011), which fixes a flaw in the original theorem of Huang and Sagae (2010).

We use the edge-factored model (Eisner, 1996; McDonald et al., 2005) with dynamic programming described in Figure 4 as a concrete example for complexity analysis. In the edge-factored model the feature set consists of only combinations of information from the roots of the two top trees s_1, s_0, and the queue. So the atomic feature function is

$$\widetilde{\mathbf{f}}(p) = (i, j, h(p.s_1), h(p.s_0))$$

where $h(s)$ returns the head word index of tree s.

The deductive system for the edge-factored model is in Figure 4. The time complexity for this deductive system is $O(n^6)$, because we have three head indexes and three span indexes as free variables in the exploration. Compared to the work of Huang and Sagae (2010), we reduce the time complexity from $O(n^7)$ to $O(n^6)$ because we do not need to keep track of the number of the steps for a state.

6 Experiments

In experiments we compare our DP best-first parsing with non-DP best-first parsing, pure greedy parsing, and beam parser of Huang and Sagae (2010).

Our underlying MaxEnt model is trained on the Penn Treebank (PTB) following the standard split: Sections 02-21 as the training set and Section 22 as the held-out set. We collect gold actions at different parsing configurations as positive examples from gold parses in PTB to train the MaxEnt model. We use the feature set of Huang and Sagae (2010).

	model score	accuracy	# states	time
greedy	-1.4303	90.08%	125.8	0.0055
beam*	-1.3302	90.60%	869.6	0.0331
non-DP	-1.3269	90.70%	$4,194.4$	0.2622
DP	-1.3269	90.70%	243.2	0.0132

Table 1: Dynamic programming best-first parsing reach optimality faster. *: for beam search we use beam size of 8. (All above results are averaged over the held-out set.)

Furthermore, we reimplemented the beam parser with DP of Huang and Sagae (2010) for comparison. The result of our implementation is consistent with theirs. We reach 92.39% accuracy with structured perceptron. However, in experiments we still use MaxEnt to make the comparison fair.

To compare the performance we measure two sets of criteria: 1) the internal criteria consist of the model score of the parsing result, and the number of states explored; 2) the external criteria consist of the unlabeled accuracy of the parsing result, and the parsing time.

We perform our experiments on a computer with two 3.1GHz 8-core CPUs (16 processors in total) and 64GB RAM. Our implementation is in Python.

6.1 Search Quality & Speed

We first compare DP best-first parsing algorithm with pure greedy parsing and non-DP best-first parsing without any extra constraints.

The results are shown in Table 1. Best-first parsing reaches an accuracy of 90.70% in the held-out set. Since that the MaxEnt model is locally trained, this accuracy is not as high as the best shift-reduce parsers available now. However, this is sufficient for our comparison, because we aim at improving the search quality and efficiency of parsing.

Compared to greedy parsing, DP best-first parsing reaches a significantly higher accuracy, with $\sim$2 times more parsing time. Given the extra time in maintaining priority queue, this is consistent with the internal criteria: DP best-first parsing reaches a significantly higher model score, which is actually optimal, exploring twice as many as states.

On the other hand, non-DP best-first parsing also achieves the optimal model score and accuracy.

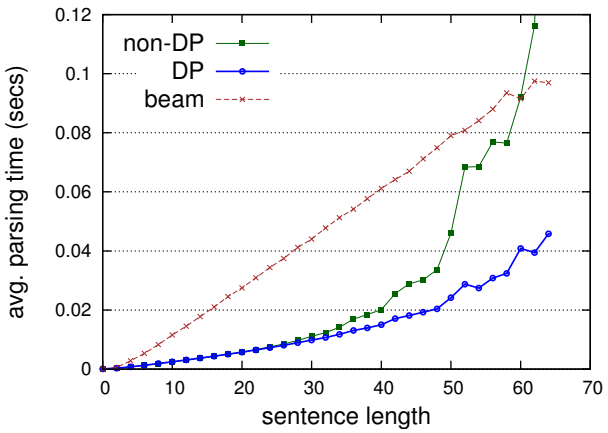

Figure 5: DP best-first significantly reduces parsing time. Beam parser (beam size 8) guarantees linear parsing time. Non-DP best-first parser is fast for short sentences, but the time grows exponentially with sentence length. DP best-first parser is as fast as non-DP for short sentences, but the time grows significantly slower.

However, it explores $\sim$17 times more states than DP, with an unbearable average time.

Furthermore, on average our DP best-first parsing is significantly faster than the beam parser, because most sentences are short.

Figure 5 explains the inefficiency of non-DP best-first parsing. As the time complexity grows exponentially with the sentence length, non-DP best-first parsing takes an extremely long time for long sentences. DP best-first search has a polynomial time bound, which grows significantly slower.

In general DP best-first parsing manages to reach optimality in tractable time with exact search. To further investigate the potential of this DP best-first parsing, we perform inexact search experiments with bounded priority queue.

6.2 Parsing with Bounded Priority Queue

Bounded priority queue is a very practical choice when we want to parse with only limited memory.

We bound the priority queue size at 1, 2, 5, 10, 20, 50, 100, 500, and 1000, and once the priority queue size exceeds the bound, we discard the worst one in the priority queue. The performances of non-DP best-first parsing and DP best-first parsing are illustrated in Figure 6 (a) (b).

Firstly, in Figure 6 (a), our DP best-first parsing reaches the optimal model score with bound 50, while non-DP best-first parsing fails even with bound 1000. Also, in average with bound 1000, compared to non-DP, DP best-first only needs to explore less than half of the number of states.

Secondly, for external criteria in Figure 6 (b), both algorithms reach accuracy of 90.70% in the end. In speed, with bound 1000, DP best-first takes $\sim 1/3$ time of non-DP to parse a sentence in average.

Lastly, we also compare to beam parser with beam size 1, 2, 4, 8. Figure 6 (a) shows that beam parser fails to reach the optimality, while exploring significantly more states. On the other hand, beam parser also fails to reach an accuracy as high as best-first parsers. (see Figure 6 (b))

6.3 Simulating the Edge-Factored Model

We further explore the potential of DP best-first parsing with the edge-factored model.

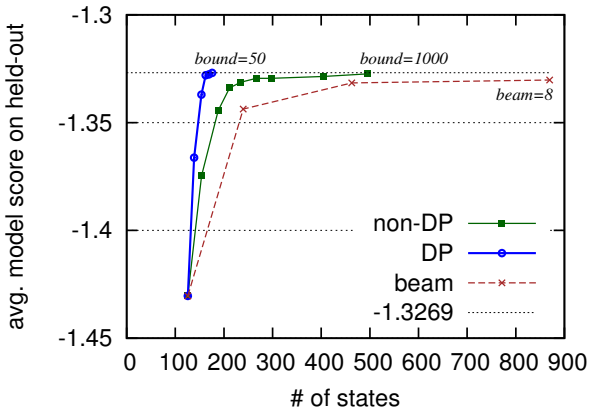
The simplified feature set of the edge-factored model reduces the number of possible states, which means more state-merging in the search graph. We expect more significant improvement from our DP best-first parsing in speed and number of explored states.

Experiment results confirms this. In Figure 6 (c) (d), curves of DP best-first diverge from non-DP faster than standard model (Figure 6 (a) (b)).

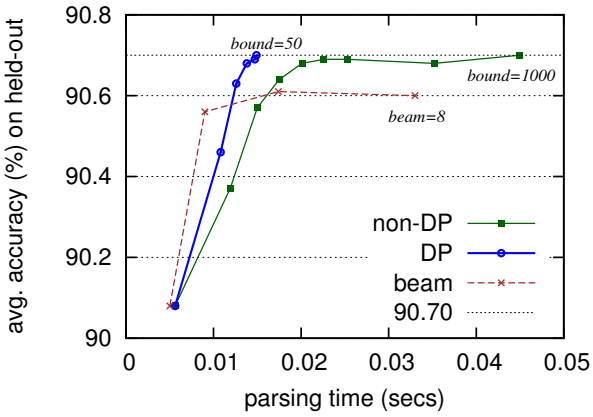
7 Conclusions and Future Work

We have presented a dynamic programming algorithm for best-first shift-reduce parsing which is guaranteed to return the optimal solution in polynomial time. This algorithm is related to best-first Earley parsing, and is more sophisticated than best-first CKY. Experiments have shown convincingly that our algorithm leads to significant speedup over the non-dynamic programming baseline, and makes exact search tractable for the first-time under this model.

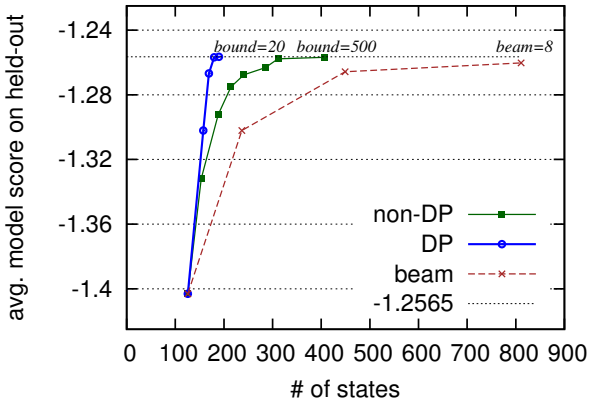
For future work we would like to improve the performance of the probabilistic models that is required by the best-first search. We are also interested in exploring A* heuristics to further speed up our DP best-first parsing.



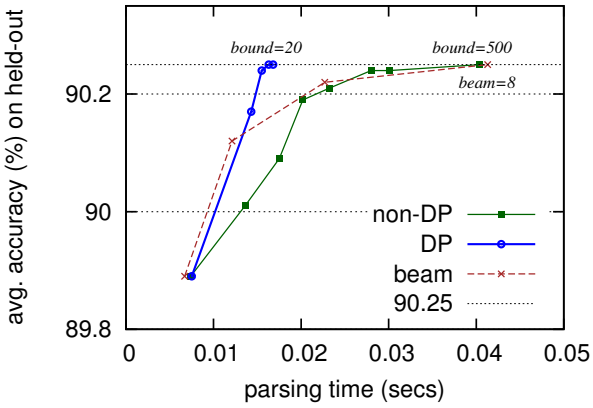
(a) search quality vs. # of states



(b) parsing accuracy vs. time



(c) search quality vs. # of states (edge-factored)



(d) parsing accuracy vs. time (edge-factored)

Figure 6: Parsing performance comparison between DP and non-DP. (a) (b) Standard model with features of Huang and Sagae (2010). (c) (d) Simulating edge-factored model with reduced feature set based on McDonald et al. (2005). Note that to implement bounded priority queue we use two priority queues to keep track of the worst elements, which introduces extra overhead, so that our bounded parser is slower than the unbounded version for large priority queue size bound.

Abstract

The problem of learning language models from large text corpora has been widely studied within the computational linguistic community. However, little is known about the performance of these language models when applied to the computer vision domain. In this work, we compare representative models: a window-based model, a topic model, a distributional memory and a commonsense knowledge database, ConceptNet, in two visual recognition scenarios: human action recognition and object prediction. We examine whether the knowledge extracted from texts through these models are compatible to the knowledge represented in images. We determine the usefulness of different language models in aiding the two visual recognition tasks. The study shows that the language models built from general text corpora can be used instead of expensive annotated images and even outperform the image model when testing on a big general dataset.

1 Introduction

Computational linguistics have created many tools for automatic knowledge acquisition which have been successfully applied in many tasks inside the language domain, such as question answering, machine translation, semantic web, etc. In this paper we ask whether such knowledge generalizes to the observed reality outside the language domain, where we use well-known image datasets as a proxy for observed reality.

In particular, we aim to determine which language model yields knowledge that is most suitable for use in Computer Vision. Therefore we test a variety of language models and a linguistically mined knowledge base within two computer vision scenarios:

Human action recognition : Recognizing <subject, verb, object> triples based on objects (e.g., car, horse) and scenes (the place that the actions occur, e.g., countryside, forest, office) recognized in images. In this scenario, we only consider images with human actions so the "human" subject is always present.

Objects in context : Predicting the most likely identity of an object given its context as expressed in terms of co-occurring objects.

Computer vision can greatly benefit from natural language processing as learning from images requires a prohibitively expensive annotation effort. A major goal of natural language processing is to obtain general knowledge from text and in this paper we test which model provides the best knowledge for use in the visual domain.

Within the two visual scenarios, we compare three state-of-the-art language models and a knowledge base: (1) A window-based model, which counts co-occurrence frequencies within a fixed window; (2) R-LDA (Séaghdha, 2010), an extension of LDA that enables generation of joint probabilities; (3) TypeDM (Baroni and Lenci, 2010), a strong Distributional Memory model; (4) ConceptNet (Speer and Havasi, 2013), an automatically generated semantic graph containing concepts with their relations.

We test the language models in two ways: (1) We directly compare the statistics of the linguistic models with statistics extracted from the visual domain.

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 769–779,
Seattle, Washington, USA, 18-21 October 2013.

(2) We compare the linguistic models inside the two computer vision applications, leading to a direct estimation of their usefulness.

To summarize, our main research questions are: (1) Is the knowledge from language compatible with the knowledge from vision? (2) Can the knowledge extracted from language help in computer vision scenarios?

2 Related Work

Using high level knowledge to aid image understanding has become a recent interest in the computer vision community. Objects, actions and scenes are detected and localized in images using low-level features. This detection and localization process is guided by reasoning and knowledge. Such knowledge is employed to disambiguate locations between objects in (Gupta and Davis, 2008). From the defined relationships between nouns (e.g., above, below, brighter, smaller), the system constrains which region in an image corresponds to which object/noun. Similarly, (Srikanth et al., 2005) exploit ontologies extracted from WordNet to associate words and images and image regions. (Yu et al., 2011) employ relations between scenes and objects introducing an active model to recognize scenes through objects. The reasoning knowledge limits the detector to search for an object within a particular region rather than on the whole image.

Language models have also been employed to generate descriptive sentences for images. (Ushiku et al., 2012) introduce an online learning method for multi-keyphrase estimation to generate a sentence using a grammar model to describe an image. Similarly, from objects and scenes detected in an image, (Yang et al., 2011) estimated a sentence structure to generate a sentence description composed of a noun, verb, scene and preposition.

The studies most similar to ours are (Teo et al., 2012) and (Lampert et al., 2009). In (Teo et al., 2012), the Gigaword corpus is used to extract relationships between tools and actions (e.g., knife - cut, cup - drink) by counting their co-occurences. These relationships are used to constrain and select the most plausible actions within a predefined set of actions in cooking videos. Instead of using this knowledge as a guidance during recognition, we compare different language models and build a general framework that is able to detect unseen actions through their components (verb - object - scene), hence our method does not limit the number of actions in images. (Lampert et al., 2009) use attributes of nouns (e.g., an animal: white, eat fish, water, etc.). They can detect animals without having seen training examples by manually defining the attributes of the target animal. In this work, rather than relying on manual definitions, our aim is to find the best language models built automatically from available corpora to extract relations from natural language.

Currently, human action recognition is popular and mostly studied in video using the Bag-of-Visual-Words method (Delaitre et al., 2010; Everts et al., 2013; Kuehne et al., 2012; Reddy and Shah, 2012; Wang et al., 2013). In this method one extracts small local visual patches of, say, 24 by 24 pixels by 10 frames at every 12^{th} pixel at every 5^{th} frame. For each patch local gradients or local movement (optical flow) histograms are calculated. Then these local visual features are mapped to abstract, predefined "visual words", previously obtained using k-means clustering on a set of random features. While results are good, there are two main drawbacks with this approach. First of all, human actions are semantic and more naturally recognized through their components (human, objects, scene) rather than through a bag of local gradient/motion patterns. Hence we use a component-based method for human action recognition. Second, the number of possible human actions is huge (the number of objects times the number of verbs). Obtaining annotated visual examples for each action is therefore prohibitively expensive. So we learn from language models how components combine into human actions.

3 Two Visual Recognition Scenarios

We now describe the two computer vision scenarios: human action recognition and objects in context.

3.1 Human Action Recognition

We want to identify a human action, defined as a <subject, verb, object> triple. We do this by recognizing the human, the object, and the scene and then determine the most likely verb based on these components. Scenes are only used here as features for

predicting/disambiguating the human action and the final task is to define the human action triple. As in most work in human action recognition, we simplify the problem by considering only images in which human actions occur. This means that a human is always present, leaving the problem of predicting the verb given the object and the scene. While this may seem like a strong assumption, the possibility of having no action in the image at all is largely unexplored in computer vision due to its difficulty.

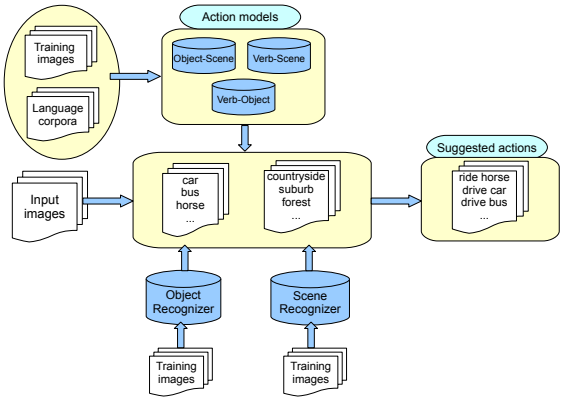

Figure 1: Human action suggestion: based on the objects and scenes recognized in an image, the system suggests the most plausible actions. The action models provide the relationships between objects - scenes - verbs

3.1.1 Human action recognition framework

Our general action recognition framework is presented in Figure 1. Given an image, an object recognizer will predict the probability of each object (e.g, bike, horse) presented in that image. Furthermore, a scene recognizer will provide the probabilities of each scene (e.g., countryside, suburb, forest) given the image. The action model is composed of the conditional probabilities that relate verbs, objects and scenes, which have been learned from training images or language corpora. Given the object and scene probabilities recognized in the image, the action model will guide the action prediction process and finally, the system will suggest the most proper actions (e.g., ride horse, drive car). We will now describe each component in detail:

- **Object and scene recognizers:** To train the object recognizer, we use a set of images where objects have been annotated with bounding boxes (to specify objects' locations). We follow the state-of-the-art method of (Uijlings et al., 2013). The method is based on multiple hierarchical segmentations to sample a limited set of high quality object locations in terms of bounding boxes. A Bag-of-Visual-Words method (Uijlings et al., 2010) is applied to these boxes to localize and recognize objects. For the scene recognizer, we trained the same Bag-of-Visual-Words method on complete images on a dataset annotated with 15 scenes. In both cases we use Support Vector Machines to learn the object/scene models. We use Platt's sigmoid function to obtain the final conditional probabilities $P(o_j|I)$ and $P(s_k|I)$.

- **Action models:** The model captures the relationship between Object - Scene, Verb - Scene and Verb - Object: the probability of an object given a scene $P(o_j|s_k)$, a verb given an object $P(v_i|o_j)$, and a verb given a scene $P(v_i|s_k)$. In one experiment we learn the probabilities from the training images, where each image has been annotated with an object, a verb (of an action) and a scene. All three probabilities are computed using frequency counts in the training set, for example:

$$P(o_j|s_k) = \frac{\#\text{images having } o_j, s_k}{\#\text{images having } s_k} \quad (1)$$

  We aim to replace this learning from annotated training images, which are expensive to obtain, with learning from language corpora. The details of how to extract the probability distributions from language models are explained in section 4.

3.1.2 Component integration

To combine these components in the framework, we use an energy-based model (Lecun et al., 2006) visualized in Figure 2, which includes the image I (an observed variable) and object O, scene S, and verb V. This energy-based formulation allows us to set different weights for energies which come from disparate sources (i.e. language and vision) using Gibbs measure.

Now given an image I, we can compute the score function $\mathbb{S}(a_{ij}; I)$ of an action a_{ij} as:

$$\mathbb{S}(a_{ij}; I) = \mathbb{S}(v_i, o_j; I) = \frac{1}{Z} \exp\left(-\sum_{F \in \mathcal{F}} E_F^{ij}\right),$$

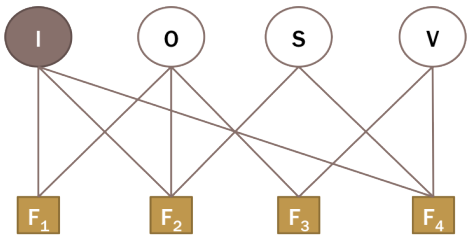

Figure 2: An energy-based model for action recognition

where we define each energy function E_F^{ij} to give lower energies to correct answers and higher energies to incorrect ones, with $\mathcal{S}$ is the set of all scenes:

$$E_{F_1}^{ij}(O, I) = -w_{F_1} \log P(o_j|I) \quad (2)$$

$$E_{F_2}^{ij}(S, I) = -w_{F_2} \log \sum_{S \in \mathcal{S}} P(o_j|S) \times P(S|I) \quad (3)$$

$$E_{F_3}^{ij}(V, O) = -w_{F_3} \log P(v_i|o_j) \quad (4)$$

$$E_{F_4}^{ij}(V, S) = -w_{F_4} \log \sum_{S \in \mathcal{S}} P(v_i|S) \times P(S|I) \quad (5)$$

Let P_i be the position of the correct action in the ranked list of predicted actions for a certain image I_i. The ranked list is sorted in the order of the score $\mathbb{S}$. We evaluate human action recognition in terms of this position average over all images, which we call Average Ranking (AR). Therefore we use Average Ranking as our loss-function:

$$\mathcal{L}(w_F) = AR_N = \frac{1}{N} \sum_{i=0}^{N} P_i. \quad (6)$$

Training the energy model involves finding the factors w_F^* that minimizes the loss:

$$w_F^* = \underset{w_F}{\operatorname{argmin}}\, \mathcal{L}(w_F) \quad (7)$$

As we have only four parameters to learn in our energy model, we do this by performing an exhaustive search and cross validation. We require $w_F \in \{0.0, 0.1, 0.2, ..., 0.9\}$ and set the constraint $\sum_{F \in \mathcal{F}} w_F = 1$. We note that the factor graph formulation of our framework would allow us to use more advanced learning algorithms. We plan to look into this once the model becomes more complex by adding, for example, information about the position of the objects and the human.

3.1.3 Dataset

Recently, researchers have released many image action datasets such as the 7 everyday actions (Delaitre et al., 2010), the Stanford 40 action dataset (Yao et al., 2011), the PASCAL action classification competition (Everingham et al., 2012), and the 89 action dataset (Le et al., 2013). The 89 action dataset was originally created for the recognition of 20 objects. Afterwards also actions were annotated. Therefore, the actions occurring with these objects are mostly unbiased, unlike in other action datasets. Hence we choose to use the 89 action dataset.

In the 89 action dataset, every image has been annotated with human actions, where each action is composed of a verb and an object. We additionally annotated every image with one of the 15 scenes from the 15 scene dataset (Lazebnik et al., 2006).

3.2 Objects in Context

Our other computer vision scenario is about objects in context. Context is useful in visual recognition for two reasons: Firstly, context can significantly reduce the number of possible object categories simplifying the problem. Secondly, when the object appearance is inconclusive for its identity, context can be used for disambiguation. For example, a grey rectangle on a desk may be recognized as a pen, while a grey rectangle on a table may be recognized as a knife. As the recognition systems are not always reliable, the use of context can greatly improve results.

For this scenario we choose a theoretical setting in which we want to predict the identity of one object given that the identities of all other objects in the image are known. We believe that our main conclusions on the linguistic models will transfer to a practical computer vision application where visual recognition systems predict the object identities.

Formally, we can describe this scenario as follows: Given an image I with N objects $\mathcal{O} = \{o_1, o_2, \cdots, o_N\}$, we want to predict the identity of object o_i given all other objects $\mathcal{O} \setminus o_i$. In this paper we use a Naive Bayes assumption, leading to:

$$P(o_i|\mathcal{O} \setminus o_i) = \frac{P(\mathcal{O} \setminus o_i|o_i) \times P(o_i)}{P(\mathcal{O} \setminus o_i)} \approx P(o_i) \times \prod_{o_j \in \mathcal{O} \setminus o_i} P(o_j|o_i). \quad (8)$$

In this scenario, we need conditional relations $P(o_j|o_i)$ and priors. We obtain these from language data or from images directly.

3.2.1 Dataset

For the objects in context scenario, we use the SUN object dataset (Xiao et al., 2010), which contains more than 16 thousand images, more than 79,000 objects whose locations are annotated using polygons. The dataset has been annotated by various people who could choose their own object categories, leading to duplicate categories such as "building" and "buildings", "person" and "person walking". Furthermore, for some images large parts are not annotated leading to an incomplete context. We therefore cleaned the object categories (mapping from around 7,500 objects to over 700 unique object categories) and considered only images whose content was sufficiently annotated.

In our experiments, we used the predefined training and testing parts of the SUN dataset and obtained around 4,500 images for learning the object relations and 10,600 images for testing the object prediction. We obtain conditional probabilities $P(o_j|o_i)$ from frequency counts.

4 Language models & distribution extraction

To extract probability distributions from texts, we use ConceptNet, the Window2 and 20 model, TypeDM and R-LDA. We will now describe how we estimate the four conditional probabilities $P(V|O), P(V|S), P(O|S), P(O|O)$ needed in the two visual scenarios for each language model.

4.1 ConceptNet

ConceptNet (Speer and Havasi, 2013) is a large semantic graph containing concepts and relations between them. It includes everyday basic, cultural and scientific knowledge, which have been automatically extracted from Internet using predefined rules. In this work we use the most current version, ConceptNet 5. As it was mined from free text using rules, the database has uncontrolled vocabulary and contains many false/nonesense statements.

To extract relations from ConceptNet5, we first examine all relations in the database and define those that are relevant to our scenarios (Figure 3). For

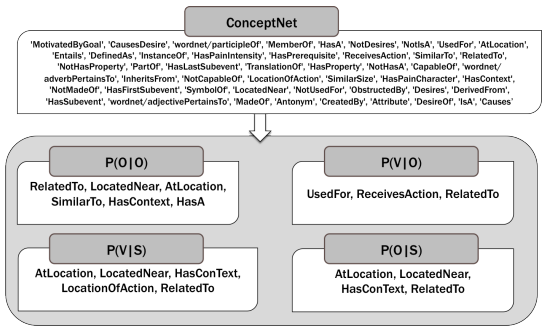

Figure 3: List of relations in ConceptNet

example, for the conditional probability of objects given scenes, relations such as "At Location", "Located Near" are extracted. For the human action recognition scenario, we used a list of 19 objects, 15 scenes and around 5 thousand verbs for computing $P(V|O), P(O|S), P(V|S)$. For the objects in context scenario, we used 700 objects for computing $P(O|O)$. Examples of relations extracted from ConceptNet are illustrated in Table 1, such as: Oil - Located near - Car, Horse - Related to - Zebra. From these relations, we define the four conditional probabilities using their frequency counts. For example, to compute the conditional probability of an object given a scene $P(o_i|s_j)$, we extract all triples having the form <object, rel, scene>, where "rel" can be "AtLocation", "LocatedNear", etc.

$$P(o_i|s_j) = \frac{freq(< o_i, rel, s_j >)}{\sum_{o_m \in \mathcal{O}} freq< o_m, rel, s_j >} \quad (9)$$

4.2 Window model

One of the most famous and basic statistical model is based on counting co-occurrences within a window of fixed width, which follows the tradition of hyperspace analogue to language (Lund and Burgess, 1996). We took the Window2, 20 models which have been built in (Bruni et al., 2012) using the ukWaC (1.9B tokens) and Wackypedia (820M tokens). As the Window2 model only looks at 2 words on the left and right of the current one, it reflects the relationships between words occurring near each other, while the Window20 searches for a broader view of how words are related to each other. The weights of each pairs of words are calculated using the Local Mutual Information (LMI). To compute the conditional probabilities, we use the LMI scor-

LocatedNear		RelatedTo		UsedFor		AtLocation

Table 1: Examples of relations extracted from ConceptNet 5

ing function provided by the models, for example:

$$P(v_i|o_j) = \frac{LMI_{v_i,o_j}}{\sum_{v_m \in \mathcal{V}} LMI_{v_m,o_j}} \quad (10)$$

4.3 Distributional Memory

Distributional Memory (Baroni and Lenci, 2010) (DM) is a multi-purpose framework for semantic modeling. This model is more complex than the Window models because it exploits different degrees of lexicalization for each relation. Distributional information is extracted as a set of weighted <word-link-word> tuples obtained from a dependency parse of corpora. In the Window model the relation between each word pair is decided by their co-occurences within a sliding window, while in DM this relation is defined by distributional properties of the two words. These distributional properties are based on a syntactic relation or lexico-syntactic pattern that links the two words. For example, the tuple <marine, use, bomb> encodes that marine co-occurs with bomb in the corpus, and the word "use" specifies the type of the syntagmatic link.

Distributional Memory contains three different models, corresponding to different ways to construct the weighted structure through the "link". The first model, LexDM is the most heavily lexicalized model with the most variety of links, whereas the DepDM has the minimum degree of lexicalization, thus having the smallest number of links. TypeDM, which was reported to achieve the best performance in different tasks including selectional preferences, is laying somewhere in the middle of the other two models. It shares the same lexical information as in LexDM but use a different scoring function, which focuses on the variety of surface forms, rather than the frequency of a link. Hence we choose the best model, TypeDM, to learn the relationships between verbs, objects and scenes. As in the window model, we compute conditional probabilities using the LMI scores provided by the model (Equation 10).

4.4 R-LDA

To model the relationships between verbs, objects and scenes, we adapt the R-LDA model (Séaghdha, 2010) (ROOTH-LDA), which has been used for the selectional preference task in order to obtain conditional probabilities of two words. Each relation m of $< w_1, w_2 >$ is generated by picking up a distribution over topics, then both elements of the relation m share the same topic assignment z_m, which keep two different w_1-topic and w_2-topic distributions sharing the same topic (Figure 4). The models are estimated by Gibbs sampling following (Heinrich, 2004). It is also noted that these models are generative, hence they also predict the probabilities of tuples that do not occur in the corpus.

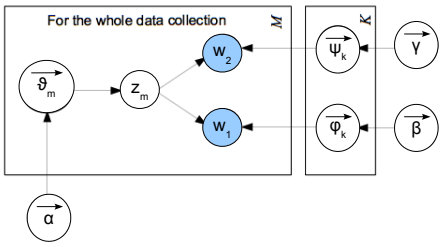

Figure 4: Generative graphical model of R-LDA: modeling the relations between two words

To model the relations between objects and verbs, we follow the data preparation in (Le et al., 2013), using the British National Corpus (BNC) which has been preprocessed and parsed using TreeTagger and Maltparser. Verbs are heads of sentences while objects are either direct or indirect objects related to those verbs by the parser. For the relations between verbs and scenes, we consider also verbs as heads

Table 2: Random R-LDA topics with the relations between Noun-Verb (first 2 columns) and between Noun-Noun (last 2 columns)

of sentences while scenes are all nouns occurring in the same sentence. For the relations between objects and scenes as well as objects and objects, we use all nouns to capture a general model[1]. The statistics of the BNC corpus with their corresponding relations are reported in Table 3.

	#Relations	#Tokens
Verb - Object	3.3M	6.7M
Noun - Noun	19.8M	39.7M
Verb - Noun	83.4M	166.8M

Table 3: The statistics of the dataset used for estimating R-LDA models for each relation type

Samples of topics extracted through R-LDA are illustrated in Table 3. It shows that Noun and Object share many similar terms in the same topic while Noun and Verb sharing the same topics tend to go often together (e.g., win, cup, beat, race).

5 Experiments

In this section we want to answer our two main research questions: (1) Is knowledge from language compatible with knowledge from vision? (2) Can we use knowledge extracted from language in computer vision scenarios?

5.1 Is knowledge from language and vision compatible?

In this section we compare statistics mined from texts with those mined from visual sources. Ideally, we want statistics from the language models to follow those of the image model, even though not all statistics from images can be reliably measured due to insufficient data. Therefore, we measure how well the estimated language models fit the estimated visual distributions using the the χ^2-distance:

$$\mathcal{X}^2 = \sum_{i=1}^{N} \frac{({P_I}^i - {P_L}^i)^2}{{P_I}^i} \tag{11}$$

where P_I and P_L are the probability distribution obtained from the image data and language models respectively.

For the conditional probabilities $P(V|O)$, $P(V|S)$, and $P(O|S)$ we compare language models with image statistics extracted from the 89 human action dataset. Table 4 shows the results. For the relations between verb and scene $P(V|S)$, there is not much fluctuation among different language models. For objects and scenes $P(O|S)$, R-LDA is closest to the image model. This is because R-LDA is good at measuring contextual and indirect relations by design, which is the case for object-scene relations. This also explains why TypeDM and Window20 are

Chi statistics	P(V|O)	P(V|S)	P(O|S)
R-LDA	17.8	11.6	**11.9**
Window2	11.6	**11.4**	32.6
Window20	11.7	**11.4**	23.7
TypeDM	**11.5**	13.3	23.2
ConceptNet	17.5	11.5	34.4

Table 4: $\mathcal{X}^2$ distance for relations between verbs, objects, scenes from different language models to image data

[1]Different from objects and verbs, which can be defined explicitly from the parsed corpora, scenes can only be defined from more restrained rules (e.g., followed by some prepositions), so here we take all nouns to have the most general model.

further away from the image model, followed by the Window2 model. Instead, human actions are found in language as the relation between verbs and their direct linguistic objects. Indeed, TypeDM is closest to the image model for $P(V|O)$ as it makes explicit use of this linguistic link. The Window2 and 20 models are almost as close to the image model for $P(V|O)$, while R-LDA is considerably further away due to its contextual nature. Finally, ConceptNet is the furthest away from the image model. To conclude, TypeDM is best for modelling direct verb-object relations, while R-LDA is better at capturing the more contextual object-scene relations.

To look closer at the difference between the statistics obtained from the image and language data, we give an example of the conditional probabilities of an object given a scene $P(O|S)$ in Figure 5. We see that the distribution extracted from language (TypeDM) is much smoother and contains more relations than the image model since it has been trained on general and large text corpora. The distribution from image data on the other hand is more sparse and tailored to this specific dataset. For example, given a "store", the probability that there is a "table" is 1, given "highway", the probability of a "car" is also 1 in the image dataset, while the highest conditional probability of the language model is only less than 60%.

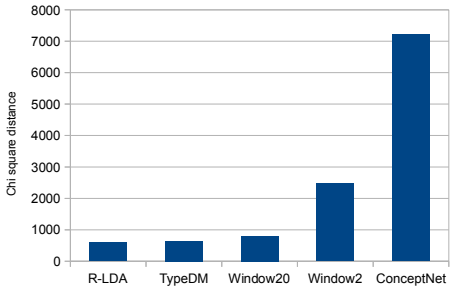

Figure 6: χ^2-distances between the tested language models and the image model for conditional probabilities of objects $P(O|O)$.

For the relations between objects and objects, we use the SUN dataset, which is much bigger and more general than the action dataset. As shown in Figure 6, R-LDA is most similar to the image model, closely followed by TypeDM and the Window20 model. All these three models are good at capturing broad contextual relations. The Window2 model has a significantly larger distance to the image model as it captures a narrow context of 2 words, which is apparently not enough to find co-occurences of objects. ConceptNet is the most inconsistent with this image data since not enough objects and their relations are extracted from it. To sum up, R-LDA achieves the best performance in modeling the relations between objects and objects among all language models.

5.2 Language Models for Visual Recognition

To measure the performance of the two visual recognition scenarios, we use the position p^i of the correct action found in the ranked list for each image i.

We report the average ranking over all images (AR_I) and over all objects or actions (AR_O, AR_A):

$$AR_I = \frac{\sum_{i=0}^{N} p^i}{N}; AR_O = \frac{\sum_{j=0}^{N_o} p_o^j}{N_o} \quad (12)$$

where N is the number of images, N_o is the number of objects and p_o^j is the average rank of all images having object j. The average rank over all actions AR_A is defined similarly to AR_O. The average rank over all image measures the performance over the image dataset, but infrequent objects/events have little impact on this performance. The average rank over objects or actions gives more weight to rare examples.

5.2.1 Human Action Recognition

We evaluate the performance of human action recognition in images based on objects and scenes individually, and then study the integration of them. The training set contains 1,104 images (for training the image relations) and the test set has 710 images. First, we test how the model predicts an action knowing the actual object and/or scene appearing in an image (given object/scene gold standard), i.e., O_{gs}, S_{gs} and $O_{gs}S_{gs}$ in the settings. After that, we test a complete model which is based on the output of our object recognizer and our scene recognizer (O_{rec}, S_{rec}, $O_{rec}S_{rec}$).

For each setting, we try different action models, either learnt from the training images (Image), or from each of the language models (TypeDM, R-LDA, Window2, Window20, ConceptNet).

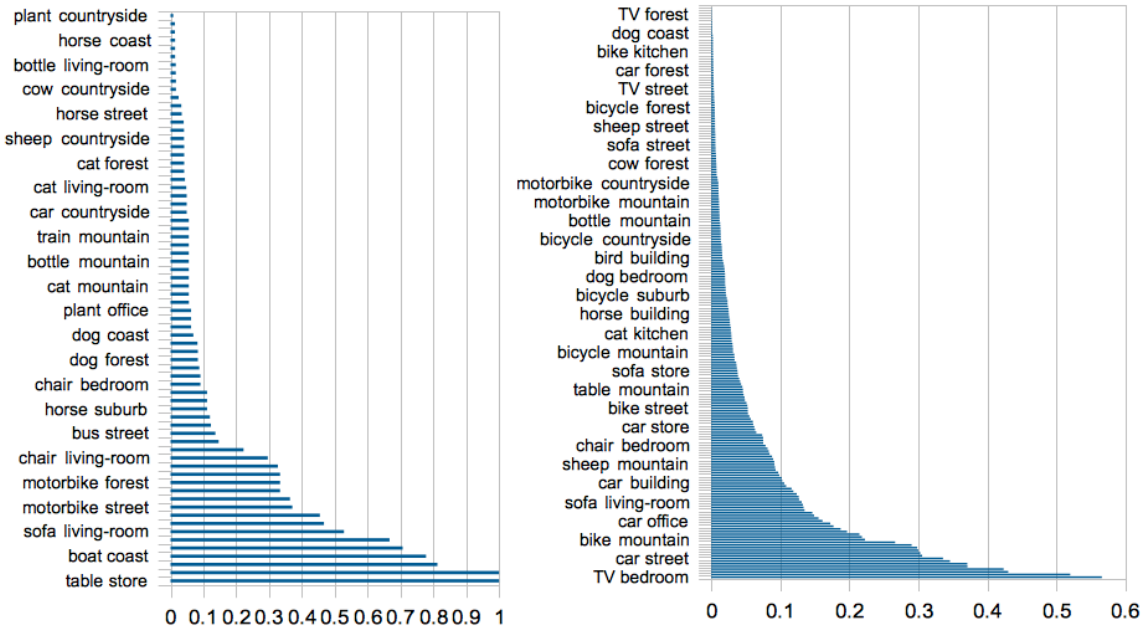

Figure 5: Probability distributions of scene over object extracted from: (left) image dataset; (right) TypeDM model (as there are many <object - scene> relations, only a few are shown on the Y-axises). The number of relations in the TypeDM is much bigger than in the image model, which shows a more general model than the image one.

Table 5 presents the average ranking over all images. Results show that the action model learnt directly from the training images achieves the best performance in all settings, even if we give more weight to infrequent actions by taking the average ranking over all actions, as presented in Table 6. One explanation may be that the action dataset has a limited domain of only 19 objects, while the language models were learnt from broad knowledge (See Figure 5). Another possibility is that verbs used for describing actions in images are more specific than verbs used in language. For example, in language one would "use the car", while in images such action would be labelled "drive a car".

	Image	**TypeDM**	**R-LDA**	**Window2**	**Window20**	**C.Net**
O_{gs}	0.3	16.1	63.4	16.4	18.3	86.1
O_{rec}	14.9	26.9	66.7	44.7	54.9	115.6
S_{gs}	35.7	181.7	174.9	168.5	174.8	252.5
S_{rec}	46.8	250.5	348	190.2	189.8	241.2
$O_{gs}S_{gs}$	**0.28**	**10.2**	**15.2**	**13.8**	**13.6**	**81.9**
$O_{rec}S_{rec}$	13.6	26.9	66.7	44.7	54.9	115.6

Table 5: Average rank over all images AR_I of the human action recognition using different settings: O_{gs}, O_{rec} use only objects (gold standard and object recognizer); S_{gs}, S_{rec} use only scenes, $O_{gs}S_{gs}$ and $O_{rec}S_{rec}$ integrate both objects and scenes together

If we look at the performance of the language models, TypeDM performs best by a significant margin. This makes sense, as the most powerful term for predicting an action is obviously $P(V|O)$, and we saw earlier that TypeDM produces probabilities $P(V|O)$ which are closest to the image model. For the same reason, the second and third best language model are the Window2 and Window20 models, although their performance is significantly lower when using the predictions for objects and/or scenes. This is somewhat surprising considering that TypeDM, Window2 and Window20 are all very close in distance to the image model. Of course, the distance is just an indication. R-LDA performs poorly because it is much more contextual. Finally, ConceptNet performs the worst.

Another observation is that using the scene identity should theoretically help in human action recognition: Using TypeDM, the use of the gold standard object identity yields an average ranking over all images of 16.1, while using both the scene and object identity yields an average ranking of 10.2, which is significantly better. It means that the use of the scene can disambiguate some actions (e.g. "ride a horse" vs. "feed a horse"). However, when using the recognition system, using the scene does not increase the overall performance. This shows that the

visual recognition system may not be strong enough for recognizing these 15 scenes. Another problem may be the limitation of 15 scenes only: while annotating we frequently found that it was hard for numerous images to put them into one of the 15 scenes. So a bigger scene database may help.

The main problem with most available annotated human action datasets is that they are very restricted and domain-specific. For example, in this dataset with 19 objects and 15 scenes, there are many photos of a person riding a motorbike on rocky mountains as a kind of sport. Consequently, the probability of "riding" given "mountain" learnt from the image dataset is high according to the image data (78%) but is uncommon in general. So the image dataset might be too restricted or biased for general knowledge to work well. In the next section we therefore use a more general dataset.

	Image	**TypeDM**	**R-LDA**	**Window2**	**Window20**	**C.Net**
AR_I	13.6	26.9	66.7	44.7	54.9	115.6
AR_A	16.4	30.8	64.7	45.3	51.9	131.7

Table 6: Average rank over all images vs. actions of the human action recognition using the $O_{rec}S_{rec}$ setting

5.2.2 Objects in Context

For every object in every image in the test set of the SUN database, we guess the identity of an object given the identity of all other objects in the image. In total, there are 78,306 object predictions within 10,652 images.

As shown in Figure 7, the R-LDA model outperforms all other models for both average rank over images and over objects. Interestingly, both R-LDA and TypeDM are better at predicting the correct objects in images than the model learnt from the image training set itself. It shows that for many cases, the relation statistics learnt from language data can help in visual recognition. These language models are even better than the information extracted from general, relatively unbiased image datasets, where annotation is limited. For the limited annotation, this hypothesis is further supported by looking at the average rank over objects, which gives more weight to rarely occurring objects. As seen in Figure 7, all language models except ConceptNet outperform the image model. We conclude that language models

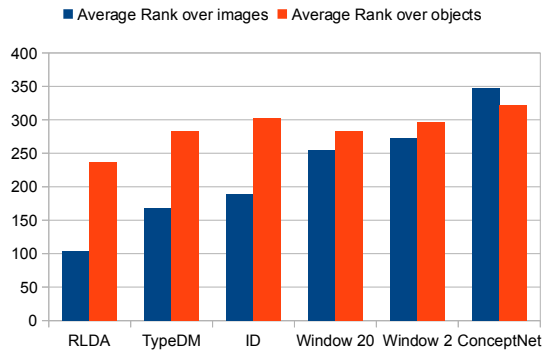

Figure 7: Average rank over all images and objects using different language models and ID (image data)

can aid visual models in large-scale visual recognition problems which use co-occurrence of objects as their context, especially when the annotation is limited, as is often the case.

6 Conclusion

In this paper, we investigated the problem of applying knowledge learnt from language corpora to visual recognition. We compared statistics of various language models mined on general corpora with statistics observed in image datasets. It shows that the generative R-LDA model is good at relating contextual relations (e.g., object - object, object - scene), while the syntactic based distributional model TypeDM is good at representing direct relations such as verb - object in images.

We have evaluated the performance of the language models in two visual scenarios: human action recognition and object prediction. It suggests that the language models need some tailoring when applied to restricted datasets, but for a bigger and more general dataset, the language models even outperform the model learnt from annotated images itself. This shows that language models built from available text corpora can be used for visual recognition instead of expensive annotated image data.

In the future, we want to further investigate the problem of domain adaptation when applying general language models to a new image dataset. This problem can be integrated into the energy-based model during the training phase. We plan to extend work on human action recognition by including the relative position between the human and object in the images.

Abstract

This paper presents DefMiner, a supervised sequence labeling system that identifies scientific terms and their accompanying definitions. DefMiner achieves 85% F_1 on a Wikipedia benchmark corpus, significantly improving the previous state-of-the-art by 8%.

We exploit DefMiner to process the ACL Anthology Reference Corpus (ARC) – a large, real-world digital library of scientific articles in computational linguistics. The resulting automatically-acquired glossary represents the terminology defined over several thousand individual research articles.

We highlight several interesting observations: more definitions are introduced for conference and workshop papers over the years and that multiword terms account for slightly less than half of all terms. Obtaining a list of popular defined terms in a corpus of computational linguistics papers, we find that concepts can often be categorized into one of three categories: resources, methodologies and evaluation metrics.

1 Introduction

Technical terminology forms a key backbone in scientific communication. By coining formalized terminology, scholars convey technical information precisely and compactly, augmenting the dissemination of scientific material. Collectively, scholarly compilation efforts result in reference sources such as printed dictionaries, ontologies and thesauri.

While online versions are now common in many fields, these are still largely compiled manually, relying on costly human editorial effort. This leads to resources that are often outdated or stale with respect to the current state-of-the-art. Another indirect result of this leads to a second problem: lexical resources tend to be general, and may contain multiple definitions for a single term. For example, the term "CRF" connotes "Conditional Random Fields" in most modern computational linguistics literature; however, there are many definitions for this acronym in Wikipedia. Because only one correct sense applies, readers may need to expend effort to identify the appropriate meaning of a term in context.

We address both issues in this work by automatically extracting terms and definitions directly from primary sources: scientific publications. Since most new technical terms are introduced in scientific publications, our extraction process addresses the bottleneck of staleness. Second, since science is organized into disciplines and sub-disciplines, we can exploit this inherent structure to gather contextual information about a term and its definition.

Aside from performance improvements, the key contributions of our work are in 1) recasting the problem as a sequence labeling task and exploring suitable learning architectures, 2) our proposal and validation of the the use of shallow parsing and dependency features to target definition extraction, and 3) analyzing the ACL Anthology Reference Corpus from statistical, chronological and lexical viewpoints.

This research is supported by the Singapore National Research Foundation under its International Research Centre @ Singapore Funding Initiative and administered by the IDM Programme Office.

2 Related Work

The task of definition mining has attracted a fair amount of research interest. The output of such systems can be used to produce glossaries or answer definition questions. The primary model for this task in past work has been one of binary classification: does a sentence contain a definition or not? Existing methods can be cast into three main categories, namely rule-based (Muresan and Klavans, 2002; Westerhout and Monachesi, 2007), supervised machine learning (Fahmi and Bouma, 2006; Westerhout, 2009), and semi-supervised approaches (Navigli and Velardi, 2010; Reiplinger et al., 2012).

Rule-based approaches are intuitive and efficient, and were adopted in early research. Here, system performance is largely governed by the quality of the rules. Muresan and Klavans (2002) developed a rule-based system to extract definitions from online medical articles. The system first selects candidates using hand-crafted cue-phrases (e.g. *is defined as*, *is called*; analogous to "IS-A" phrases), further filtering the candidates with grammar analysis. Westerhout and Monachesi (2007) augmented the set of rules with part-of-speech (POS) tag patterns, achieving an F_2 of 0.43.

While such manually-crafted expert rules have high precision, they typically suffer from low recall. Definitions can be expressed in a variety of ways, making it difficult to develop an exhaustive set of rules to locate all definition sentences. To address low recall, later research adopted data-driven machine learning approaches. Fahmi and Bouma (2006) made used of supervised machine learning to extract definitions from a corpus of Dutch Wikipedia pages in the medical domain. They showed that a baseline approach which simply classifies every first sentence as a definition works surprisingly well, achieving an accuracy of 75.9% (undoubtedly due to the regular structure and style for Wikipedia). Their final system, based on the important feature of sentence position, was augmented with surface-level features (bag-of-words, bigrams, etc.) and syntactic features (type of determiner, position of the subject in the sentence). Their study with three different learners – naïve Bayes, maximum entropy (MaxEnt) and the support vector machine (SVM) – showed that MaxEnt gave the best results (92.2% accurate).

Westerhout (2009) worked on a hybrid approach, augmenting a machine learner to a set of handwritten rules. A random forest classifier is used to exploit linguistic and structural features. Informed by Fahmi and Bouma (2006)'s study, she included article and noun types in her feature set. Lexico-structural cues like the layout of the text are also exploited. She evaluated the performance of different cue phrases including the presence of "IS-A" phrases, other verbs, punctuations and pronouns. The highest F_2 score of 0.63 is reported for the "IS-A" pattern.

Since 2009 the focus of the research shifted to methods not limited to feature engineering. Borg et al. (2009) implemented a fully automated system to extract and rank definitions based on genetic algorithms and genetic programming. They defined two sub-problems including 1) acquiring the relative importance of linguistic forms, and 2) learning of new linguistic forms. Starting with a small set of ten simple hand-coded features, such as having sequence "FW IS" (FW is a tag for foreign word) or containing keyword identified by the system, the system is able to learn simple rules such as "NN is a NN". However, their system is optimized for similar "IS-A" patterns, as was used in (Westerhout, 2009). Their system, achieving an average f-measure of 0.25, also performs poorer than machine learning systems which exploit more specific features.

To cope with the generality of patterns, Navigli and Velardi (2010) proposed the three-step use of directed acyclic graphs, called Word-Class Lattices (WCLs), to classify a Wikipedia dataset of definitions. They first replace the uncommon words in the sentences with a wildcard (*), generating a set of "star patterns". Star patterns are then clustered according to their similarity. For each cluster, a WCL is generated by aligning the sentences in the cluster to form a generalized sentence. Although they reported a higher precision and recall compared with previous work, the result for WCL (F_1 of 75.23%) is not significantly better than the baseline system which exploits only star patterns (F_1 of 75.05%) without generating the directed graphs.

Reiplinger et al. (2012) took a semi-supervised approach. They employed bootstrapping to extract glossary sentences from scientific articles in

the ACL Anthology Reference Corpus (ACL ARC) (Bird et al., 2008). Their results show that bootstrapping is useful for definition extraction. Starting from a few initial term-definition pairs and hand-written patterns as seeds, their system iteratively acquires new term-definition pairs and new patterns.

We note that these previous systems rely heavily on lexico-syntactic patterns. They neither sufficiently exploit the intrinsic characteristics of the term and definition, nor invest effort to localize them within the sentence[1]. Given the significant structure in definitions, we take a more fine-grained approach, isolating the term and its definition from sentences. According to Pearson (1996), a definition can be formally expressed as:

$$X = Y + \text{distinguishing characteristics},$$

where "X" is the *definiendum* (defined term; hereafter, *term*), and "Y + distinguishing characteristics" can be understood as the *definiens* (the term's definition; hereafter, *definition*). The connector "=" can be replaced by a verb such as "define", "call", a punctuation mark or other phrase. Our task is thus to find pairs of terms and their associated definitions in input scholarly articles. The sentence-level task of deciding whether a sentence s is a definition sentence or not, is thus a simplification of our task.

3 Methodology

Our DefMiner system is based on the sequence labeling paradigm – it directly assigns an annotation a_i from $A \in \{$(T)*erm*,(D)*efinition*,(O)*ther*$\}$ for each input word w_i. We post-process our labeler's results to achieve parity with the simplified definition sentence task: When we detect both a term's and definition's presence in a sentence, we deem the sentence a definition sentence. To be clear, this is a requirement; when we detect only either a term or a definition, we filter these out as false positives and do not include them as system output – by definition in DefMiner, terms must appear within the same sentence as their definitions.

To train our classifier, we need a corpus of definition sentences where all terms and definitions are annotated. While Navigli and Velardi (2010) compiled the WCL definition corpus from the English Wikipedia pages, we note that Wikipedia has stylistic conventions that make detection of definitions much easier than in the general case (i.e., "The first paragraph defines the topic with a neutral point of view"[2]). This makes it unsuitable for training a general extraction system from scholarly text.

As such, we choose to construct our own dataset from articles collected from the ACL ARC, following (Reiplinger et al., 2012). We compiled a corpus – the W00 corpus, named for its prefix in the ACL Anthology – derived from a total of 234 workshop papers published in 2000. Due to limited resources and time, only one individual (the first author) performed the corpus annotation. We built three disjoint prototype classifiers to further filter the sentences. The prototype classifiers are based on surface patterns, keyphrases and linguistic phenomena (# of NP, # of VP, etc.). We took all the 2,512 sentences marked as definition sentences by at least one of our individual prototypes and proceeded to annotate all of them. In total, 865 of the total 2,512 sentences were real definition sentences.

The annotation instance is a single token (including single word or punctuation mark). Each token w_i was marked with a_i from $A \in \{$T,D,O$\}$ depending on whether it is part of a term, a definition or neither (other). Therefore, a sentence that is not a definition sentence would have all its tokens marked as O. The corpus and its annotations are available for comparative study[3].

We use Conditional Random Fields (CRFs) (Lafferty et al., 2001) to extract the term and definition from input. We incorporate evidence (features) drawn from several levels of granularity: from the word-, sentence- and document-levels, not limiting ourselves to the window of previous n words. CRFs allow us to encode such features which may not be conditionally independent. We use the open source implementation, CRF++ (Kudo, 2005) in our work[4].

One straightforward approach is to train independent classifiers for terms and definitions, which we

[1] While Navigli and Velardi (2010) tagged *terms* and *definitions* explicitly in their corpus, their evaluation restricts itself to the task of definition sentence identification.

[2] http://en.wikipedia.org/wiki/Wikipedia:Manual_of_Style/Lead_section

[3] http://wing.comp.nus.edu.sg/downloads/term_definition_mining/

[4] http://code.google.com/p/crfpp/

test in Section 4.1. While simple, this is suboptimal as it ignores the correlation between the presence of the two components. Term identification (in the guise of key-word/-phrase extraction) is well studied and common features such as $tf.idf$ and English orthography achieve satisfactory results (Nguyen and Kan, 2007). In contrast, definitions exhibit more flexible structure and hence are more difficult to distinguish from normal English text.

As such, we further investigate a serial architecture where we perform the classifications in sequence. *I.e.*, first utilizing the results from *term* classification, and then incorporating them into *definition* classification. This two-stage architecture is explored later in Section 4.2

Our expanded feature set is an amalgamation of related works and utilizes a mix of simple lexical, orthography, dictionary lookup and corpus features (here, idf). Note that each feature class may derive more than one feature (e.g., for the POS tag feature, we extract features from not only the current word but the surrounding contextual words as well). We now enumerate the feature classes (FCs) that we exploit, marking whether they apply to the (W)ord, (S)entence or (D)ocument levels:

FC1) Lexical (W): The word, POS tag, stemmed word, and if the word contains a signal suffix[5].
FC2) Orthography (W): Whether the word is 1) capitalized or 2) mixed case; whether the word contains 3) hyphens or 4) digits.
FC3) Keyphrase List (W): Whether the word is in the keyphrase list of the origin document. We use the open source KEA keyphrase extraction system (Witten et al., 1999) to extract 20 keyphrases for each document.
FC4) Corpus (W): Discretized Inverse Document Frequency (idf), calculated as $log(\frac{N}{c})$, where N is the total number of documents and c is the number of occurrences of the word in all the documents. IDF values are discretize into eight uniform partitions.
FC5) Position (D,S): The 1) Section ID, 2) name and 3) the sentence's relative position in the document.
FC6) Has acronym (S): Whether the sentence contains an acronym. We use Stanford dependency parser (Cer et al., 2010) to parse the sentences. We deem the sentence to contain an acronym if the dependency type "abbrev" is present in the output of the parser.
FC7) Surface pattern (S): Whether the sentence contain one of the hand-crafted pattern, as listed in Table 1. The list is compiled from previous works and augmented based on our observations on the corpus.

[5]The suffixes we extract are "-ion","-ity","-tor","-ics","-ment","-ive" and "-ic".

<term > defined (as|by) <definition>
define(s)? <term> as <definition>
definition of <term> <definition>
<term> a measure of <definition>
<term> is DT <definition> (that|which|where)
<term> comprise(s)? <definition>
<term> consist(s)? of <definition>
<term> denote(s)? <definition>
<term> designate(s)? <definition>
<definition> (is|are|also) called <term>
<definition> (is|are|also) known as <term>

Table 1: Hand-crafted surface patterns used in DefMiner.

Long Distance Features. During development, we noticed that the syntactic variation of the definition might benefit from features that identify long-distance dependencies. As such, we further studied the impact of including additional features developed from the shallow (chunk) and dependency parses of the input. Compared to the above features, these features are much more computationally-intensive.

FC8) Shallow tag (W): Shallow parsing tag for each word (e.g., np, vp). We used OpenNLP toolkit to shallow parse the sentences. (Baldridge, 2005)
FC9) Shallow pattern (S): If the shallow parsing sequence contains one of the seven parse patterns listed in Table 2. We also give some example sentences which can be detected by the patterns.
FC10) Governor (W): The word that the current word depends on in a binary dependency relation. (e.g., for the phrase $computational\ linguistics$, the governor of the word $computational$ is $linguistics$).
FC11) Dependency path distance (W): Distance from the current word to the root of the sentence in the dependency tree.
FC12) Typed dependency path (W): The dependency path from the current word to the root of the sentence (recording the dependency types instead of the words in the path).

Pattern	Example
NP : NP	JavaRAP : An open-source implementation of the RAP
NP is * NP	IR is the activity of obtaining information resources
NP is * NP that/of/which	NLP is a subject which is well studied
NP or NP	Conditional Random field or CRF tackles ...
known as NP	The corpus of English Wikipedia pages, known as EnWiki
NP (* NP)	Hidden Markov Model (HMM) is used to solve ...
NP defined by/as * NP	The accuracy is defined by the production of ...

Table 2: Hand-crafted shallow parsing patterns used in DefMiner.

4 Evaluation

We now assess the overall effectiveness of DefMiner, at both the word and sentence level. Additionally, we want to ascertain the performance changes as we add features to an informed lexical baseline. We not only benchmark DefMiner's performance over our own W00 collection, but also compare DefMiner against previous published work on the definition sentence identification task on the WCL (English Wikipedia) corpus.

4.1 Single-Pass Extraction from W00

We run ten-fold cross validation on our annotated W00 corpus. We first evaluate our results at word level, calculating the precision, recall, and F_1 scores for each incrementally enhanced feature set. We present results on the corpus in the top portion of Table 3 (Rows 1–9).

We calculate both micro and macro- (category) averaged F_1 scores for term and definition extraction. F_{micro} assigns equal weight to every token, while F_{macro} gives equal weight to every category. As definition tokens greatly outnumber term tokens in our corpus (roughly 6:1), we feel that the macro-average is a better indicator of the balance between term and definition identification.

Our baseline system makes use of basic word and POS tag sequences as features (FC1), which are common to baselines in other sequence labeling works. We can see that most features result in performance improvements to the baseline, especially for recall. Interestingly, although the shallow parsing and dependency features we use are rather simple, they effectively improve the performance of the system. In System 7, we only use the seven shallow parsing patterns shown in Table 2, but the F_{macro} measure improves 3%. Our best single-stage system (System 9 in Table 3) boosts recall for term and definition classification by 7% and 5%, respectively, without sacrificing precision. The F_{macro} measure is improved from 0.44 to 0.48.

Unexpectedly, the inclusion of the position features cause performance to drop. One possible reason is that the authors of scientific papers have more flexibility to choose the positions to present definitions. This makes the position feature much less indicative (compared to running on a corpus of Wikipedia articles). Due to this observation, we exclude the position features when carrying out following experiments.

4.2 Serial Term and Definition Classification

We now investigate the two-stage, serial architecture where the system first performs term classification before definition classification (i.e., term$\succ$definition). We provision the second-stage definition classifier with three additional features from the first-stage term classification output: whether the current word (1) is a term, and (2) appears before or (3) after a term.

Row 10 shows this resulting system, which we coin as DefMiner. Interestingly, there is a 10% increase in the precision of definition classification. With the two-stage classifier, F_{macro} score further increases from 0.48 to 0.51. The results verify our intuition that term classification does help in definition classification. Pipelining in the opposite direction (definition$\succ$term; Row 11) does not show any improvement. We posit that since the advantage is only in a single direction, joint inference may be less likely to yield benefits.

To determine the upper bound performance that could result from proper term identification, we provided correct, oracular term labels from our ground truth annotations in our corpus to the second-stage definition classifier. This scenario effectively upper-bounds the performance that perfect term knowledge has on definition classification. The results of this system in Row 12 indicates a strong positive influence on definition extraction, improving definition extraction from 49% to 80%, a leap of 31%. This

System / Feature Class (*cf* Section 3)	Term			Definition			Overall	
	P	R	F_1	P	R	F_1	F_{micro}	F_{macro}
1: Baseline (FC1)	0.49	0.34	0.40	0.41	0.49	0.45	0.45	0.44
2: (1) + Orthography (FC2)	0.46	0.35	0.40	0.42	0.51	0.46	0.46	0.44
3: (2) + Dictionary (FC3)	0.48	0.36	0.41	0.41	0.49	0.44	0.44	0.43
4: (3) + Corpus (FC4)	0.50	0.35	0.41	0.40	0.52	0.45	0.45	0.44

6: (4) + Shallow parsing tag (FC8)	**0.51**	0.38	0.43	0.41	0.50	0.45	0.45	0.44
7: (6) + Shallow parse pattern (FC9)	0.50	0.40	**0.45**	0.42	0.52	0.47	0.47	0.47
8: (7) + Surface pattern (FC7)	0.49	0.39	0.44	0.43	0.53	0.48	0.48	0.47
9: (8) + Dependency + acronym (FC6,10,11,12)	0.50	**0.41**	**0.45**	0.45	0.54	0.49	0.49	0.48
10 [DefMiner]: (9) + 2-stage	0.50	**0.41**	**0.45**	**0.55**	**0.58**	**0.56**	**0.55**	**0.51**
11: (9) + Reverse 2-stage	0.50	0.40	0.44	0.45	0.54	0.49	0.49	0.48
12: (9) + Term Oracle	*N/A*	*N/A*	*N/A*	0.79	0.82	0.80	*N/A*	*N/A*

Table 3: 10-fold cross validation word-level performance over different system configurations on our W00 corpus.

motivates future work as how to improve the performance of the term classifier so as to reap the benefits possible with our two-stage classifier.

4.3 Comparative results over the WCL Dataset

For most of the related research reviewed, we could neither obtain their source code nor the corpora used in their work, making comparative evaluation difficult. To the best of our knowledge, Reiplinger et al. (2012) is the only attempt to extract definitions from the ACL ARC corpus, which is a superset of our W00 corpus. It would be desirable to have a direct comparison with their work, but their evaluation method is mainly based on human judges and their reported coverage of 90% is only for a sample, short list of domain terms they defined in advance.

To directly compare with the previous, more complex state-of-the-art system from (Navigli and Velardi, 2010), we evaluate DefMiner on the definition sentence detection task. For the sentence-level evaluation, we calculate the $P/R/F_1$ score based on whether the sentence is a definition sentence. We applied DefMiner on their whole WCL annotated corpus, reporting results in Table 4. We randomized the definition and none-definition sentences in their corpus and applied 10-folds cross validation. In each each iteration we used 90% of the sentences for training and 10% for testing.

Compared to their results reported in (Navigli and Velardi, 2010), DefMiner improves overall F_1 by 8%. While certainly less precise (precision of 92% versus 99%), recall is improved over their considerably more complex WCL-3 algorithm by almost 20%. Even using just the simple heuristic of only classifying sentences that have identified terms as well as definitions as definition sentences, DefMiner serves to competitively identify definition sentences.

System	Token Level		Sentence Level
	Term	Definition	
	P / R / F_1	P / R / F_1	P / R / F_1
DefMiner	.82/.78/.80	.82/.79/.81	.92/.79/.85
N&V '10	– / – / –	– / – / –	.99/.61/.77

Table 4: Comparative performance over the WCL.

4.4 Manual Inspection of DefMiner Output

To gauge the noise from our system outside of our cross-validation experiments, we conducted a manual inspection of results over other workshop papers from other years (2001 and 2002), as a sanity check. DefMiner identifies 703 and 1,217 sentences in W01 and W02 as definition sentences separately.

Overall, 77.8% of the extracted sentences are real definition sentences, while the remaining are false positives.

4.4.1 Analysis of Common Errors

The $P/R/F_1$ score by itself only gives a hint of the system's overall performance. We are also interested to study the common errors made by our system, which could help us engineer better features for improving DefMiner. As our two-stage classifier still lags behind the system with oracular term labels by 24% in F_1 for definition detection (Section 4.2), we believe there is still much room for improvement. We show three example misclassified sentences that represent the major types of errors we observed, where DefMiner's output annotations follow tokens marked as part of terms or definitions.

1) *A PSS/TERM thus contains abstract linguistic values for closed features (tense/DEF ,/DEF mood/DEF ,/DEF voice/DEF ,/DEF number/DEF ,/DEF gender/DEF ,/DEF etc/DEF ./DEF) .*

This first instance shows that DefMiner tends to mark the first several tokens as "TERM" while the real term appears somewhere else in the sentence. The actual term being defined is "closed features" instead of "PSS". Many terms in the training set appear at the beginning of the sentence and are preceded by a determinant. "PSS" is also likely to receive a high IDF and orthographic shape (capitalized) score and therefore are misclassified as terms. It may be useful to thus model the (usual) distance between the term and its definition in a feature in future work.

2) *Similarly , 'I'/TERM refers to an/DEF interior/DEF character/DEF and/DEF 'L'/DEF indicates/DEF the/DEF last/DEF character/DEF of/DEF a/DEF word/DEF .*

DefMiner is occasionally confused when encountering recursive definition or multiple definitions in a single sentence. Sentence 2 contains two parallel definitions. The classifier fails to classify "L" as a separate term, incorporating it as part of the definition. One possible improvement is to break the original sentence into clauses that are independent from each other, perhaps by using even simple surface cues such as coordinating conjunctions marked by commas or "and".

3) *Again one could argue that the ability to convey such uncertainty and reliability information to a non-specialist/TERM is a/DEF key/DEF advantage/DEF of/DEF textual/DEF summaries/DEF over/DEF graphs/DEF .*

Another difficult problem faced by the classifier is the lack of contextual information. In sentence 3), if we just look at part of the sentence "a non-specialist is a key advantage of textual summaries over graphs", without trying to understand the meaning of the sentence, we may well conclude that it is a definition sentence because of the cue phrase "is a". But clearly, the whole sentence is not a definition sentence. More sophisticated features based on the sentence parse tree have to be exploited to detect such false positive examples.

5 Insights from the Definitions Extracted from the ACL ARC

In this second half of the paper, we apply DefMiner to gain insights on the distributional and lexical properties of terms and definitions that appear in the large corpus of computational linguistics publications represented by the ACL ARC (Bird et al., 2008). The ARC consists of 10,921 scholarly publications from ACL venues, of which our earlier W00 corpus is a subset (*n.b.*, as such, there is a small amount of overlap). We trained a model using the whole of the W00 corpus and used the obtained classifier to identify a list of terms and definitions for each publication in the ACL ARC.

Inspecting such output gives us an understanding of the properties of definition components, eventually helping the community to define better features to capture them, as well as intrinsically deepening our knowledge of the natural language of definitions and the structure of scientific discourse.

5.1 Demographics

From a term's perspective we can introspect properties of the enclosing paper, the host sentence, the term itself and its definition.

At the *document* level, we can analyze document metadata: its venue (journal, conference or workshop published) and year of publication.

At the *sentence* level, we analyze the position of the sentences that are definition sentences.

Focusing on *terms*, we want to find out in more detail the technical terminology that is defined. Are they different from general keyphrases? What type of entities are defined? What words do these terms consist of? What structures are common?

We are interested in analogous questions when focusing on the accompanying *definitions*. How many words or clauses do definition sentences consist of? Do we lose a lot of recall by restricting definitions to a single sentence? Are embedded definitions (definitions embedded with other definitions) common?

We highlight some specific findings from our basic analyses here:

Where do definitions occur? As terms are usually defined on first use, we expect the distribution of definition sentences to skew towards the beginning portions of a scientific document as input. We count the occurrences of definition sentences in each of ten equally-sized (by number of sentences) non-overlapping partitions. The results are shown in Figure 1, aligning with our intuition: The first three quantiles contribute almost 40% of all detected definition sentences, while the last three quantiles contain only 17.8%.

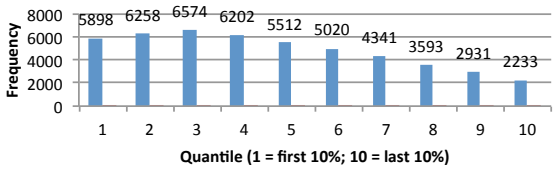

Figure 1: Occurrences of definitions within different segments of an article.

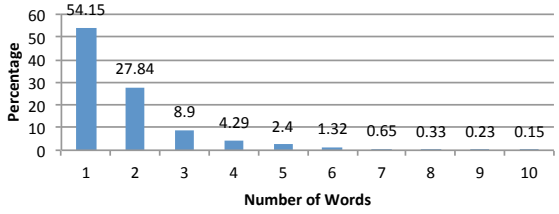
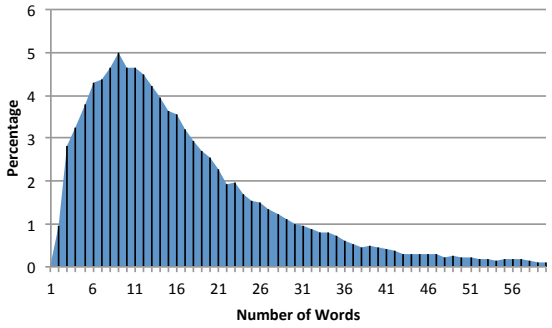
How long are the detected terms and definitions? Figure 2 shows the detected aggregate distributions. Over 54% of the detected terms are single tokens, where majority of the remaining 45% of terms being multi-word terms of six words or less. Among the single token terms, a further analysis reveals that 17.4% are detected as single-character variables, 34.9% are acronyms (consisting of more than one capitalized letters), while the remaining 47.7% are normal words. Definitions, in contrast, are longer and more varied, with a peak length of nine words. Slightly over half of the definitions have a length of 5–16 words; 75% have lengths between 3 and 23 words.



(t) Term length distribution.



(b) Definition length distribution.

Figure 2: Length distributions of (top) terms, (bottom) definitions.

In Table 5, we present the 10 most frequent POS tag bigrams for terms and definitions. We can see that among terms, a sequence of consecutive two nouns is most common, making up four out of the top five bigrams. We notice that determiners and prepositions are absent from the term list but are common in definitions.

5.2 Inspection of Definition over Time

The ACL ARC covers journal articles, conference and workshop proceedings over a few decades. As with other fields in recent years, the amount of computational linguistics literature has steadily increased over the number of years.

We study if definitions appear as frequently in different types of scientific articles (e.g. journals, conference papers or workshop papers). We also want to investigate if there is a significant shift in the distribution of definitions across years. In Figure 3, we present the density of definitions (defined as the

Term	Definition
NNP NNP	DT NN
NN NN	NNP NNP
NNP NN	NN IN
NN NNP	IN DT
JJ NN	NN NN
NN JJ	JJ NN
NNP :	NN :
: NNP	DT JJ
NN NNS	NNS IN
NN ”	NN NNS

Table 5: Most frequent POS bigrams for terms and definitions.

percentage of sentences that are identified as definition sentences), for these three different categories of publications[6].

In Figure 3, the three data series overlap each other, so we cannot conclude definitions appear more often in one type of papers than another. However, as a side effect, we see that while the definition density for journal papers remain relatively constant, for conference and workshop papers the number of definitions extracted per sentence has increased noticeably over time. The average number of definitions presented in conference papers, for instance, increased more than 100% in the 40 years represented in the ACL ARC.

The increasing number of definitions alone does not show that new knowledge is introduced at a faster rate, as definitions may be repeated. To control for this effect, we also need to know which definitions are new or defined in previous year(s). We studied this effect in more detail for the relatively smaller set of journal papers (Figure 4). For journal papers, the number of definitions of previously introduced terms in each year against the number of new definitions. We say a definition is new when the detected term was not identified in any article (not limited to journals) in previous years.

We see that the number of new terms being defined also increases with the years. But the increase is much slower than that for the total definitions. The area between the two lines denotes the definitions where the same term has been multiply defined from the same or previous years as the current year under investigation.

[6]The ACL ARC is organized by the venue of the publication, which is associated to a category. For the assigned category for each venue please refer to Appendix A.

5.3 Trends

We can use terms and definitions to also introspect how the computational linguistics literature has changed over time. Table 6 shows a subset of the most frequently defined terms in the ACL ARC, where we exclude single-character terms (“variables”).

WordNet (292)	Part Of Speech (45)
Precision (172)	Probablistic CFG (43)
Recall (167)	FrameNet (38)
Noun phrase (97)	Conditional Random Field (29)
Word sense disambiguation (60)	Inverse document frequency (28)
Support Vector Machine (60)	PropBank (27)
Hidden Markov Model (54)	Context Free Grammar (25)
Latent Semantic Analysis (57)	Accuracy (20)

Table 6: Subset of most frequently defined terms. Raw counts in parentheses. Variations of the same term (*e.g.* plurals, acronyms) are collapsed into one instance.

To be expected, these popular terms are mostly specific to computational linguistics. From our observation, we can fit these terms into one of three categories, including 1) resources (WordNet, FrameNet, PropBank), 2) methodologies (SVM, HMM, LSA), and 3) evaluation metrics (Precision, Recall, Accuracy). We feel that the final category of evaluation metrics is more general and would be shared among other scientific disciplines.

An interesting analysis that follows from this categorization is that we can study major trends and changes in the research directions of the community. This can help to draw the attention of researchers to emerging trends. We illustrate this approach in Figure 5 that focuses on three sequence labeling methodologies that have been used to address similar problems – namely, hidden Markov model (HMM), maximum entropy Markov model (MEMM), and conditional random fields (CRF) – during the period from 1989 to 2006 (where we have sufficient data points). From the early 90s, we see that HMM was a clear favorite. However since 2000, MEMM gained in popularity and use. Lafferty et al. (2001) introduced CRFs in 2001 and the new methodology was widely adopted soon after that.

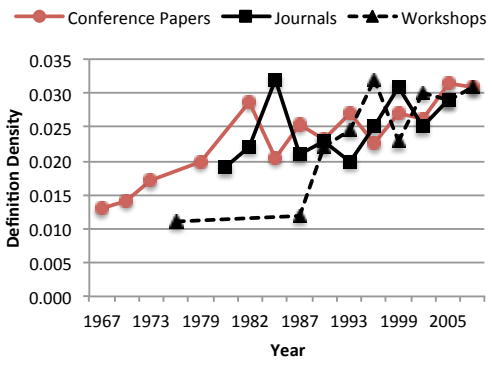


Figure 3: Occurrences of definitions across publication categories.

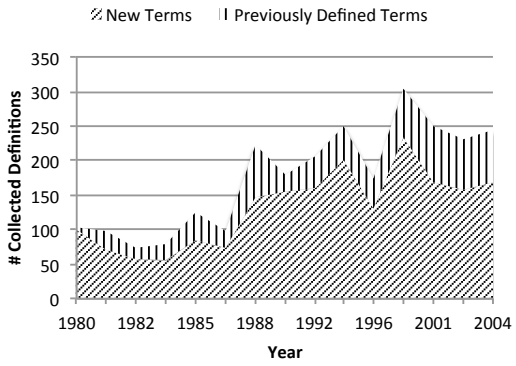

Figure 4: Relative proportions of new and recurring definitions in journal papers.

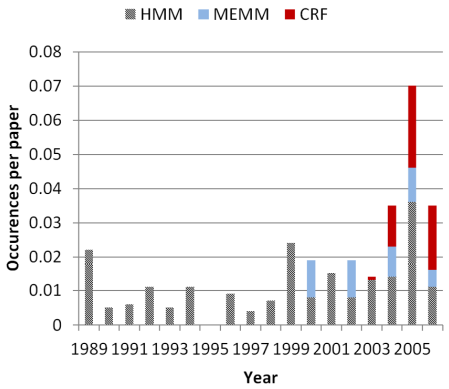

Figure 5: The occurrence of definitions for various sequence labeling methodologies over the years.

6 Conclusions and Future Work

We study the task of identifying definition sentences, as a two-part entity containing a term and its accompanying definition. Unlike previous work, we propose the harder task of delimiting the component term and definitions, which admits sequence labeling methodologies as a compatible solution.

Leveraging the current best practice of using conditional random fields, we contribute two additional ideas that lead to DefMiner, a state-of-the-art scholarly definition mining system. First, we show that shallow parsing and dependency parse features that may provide additional non-local information, are useful in improving task performance. Second, viewing the problem as two correlated subproblems of term and definition extraction, we measure the tightness and dependency of the correlation. We find that a two-stage sequential learning architecture (term first, definition second) leads to best performance. DefMiner outperforms the state of the art, and we feel is fit for macroscopic analysis of scientific corpora, despite significant noise.

We thus deployed DefMiner on the *ACL Anthology Reference Corpus*. We demonstrate how DefMiner can yield insights into both the structure and semantics of terms and definitions, in both static and diachronic modes. We think future work could pursue more in-depth analysis of the distributional and demographic properties of automatically extracted lexica. We can use the lexicon obtained from different years to carry out trend prediction, which we have illustrated here. Downstream systems may predict which term will become popular, or could alert an author if their definition of a term significantly differs from the original source.

We hope to tackle the annotation bottleneck in future work on definition extraction, common in many data-driven learning fields. We plan to explore iterative, semi-supervised methods to best manage human effort to maximize the effectiveness of future annotation.

In addition, with respect to modeling, although we showed that doing definition classification before term classification does not improve over our single-stage classifier, we hope to study whether suitable joint inference models can benefit from the interaction between the two classification processes.

Joint Learning and Inference for Grammatical Error Correction

Abstract

State-of-the-art systems for grammatical error correction are based on a collection of independently-trained models for specific errors. Such models ignore linguistic interactions at the sentence level and thus do poorly on mistakes that involve grammatical dependencies among several words. In this paper, we identify linguistic structures with interacting grammatical properties and propose to address such dependencies via joint inference and joint learning.

We show that it is possible to identify interactions well enough to facilitate a joint approach and, consequently, that joint methods correct incoherent predictions that independently-trained classifiers tend to produce. Furthermore, because the joint learning model considers interacting phenomena during training, it is able to identify mistakes that require making multiple changes simultaneously and that standard approaches miss. Overall, our model significantly outperforms the Illinois system that placed first in the CoNLL-2013 shared task on grammatical error correction.

1 Introduction

There has recently been a lot of work addressing errors made by English as a Second Language (ESL) learners. In the past two years, three competitions devoted to grammatical error correction for non-native writers took place: HOO-2011 (Dale and Kilgarriff, 2011), HOO-2012 (Dale et al., 2012), and the CoNLL-2013 shared task (Ng et al., 2013).

Nowadays **phone/phones* **has/have* many functionalities, **included/including* **∅/a* camera and **∅/a Wi-Fi receiver.

Figure 1: Examples of representative ESL errors.

Most of the work in the area of ESL error correction has addressed the task by building statistical models that specialize in correcting a specific type of a mistake. Figure 1 illustrates several types of errors common among non-native speakers of English: article, subject-verb agreement, noun number, and verb form. A significant proportion of research has focused on correcting mistakes in article and preposition usage (Izumi et al., 2003; Han et al., 2006; Felice and Pulman, 2008; Gamon et al., 2008; Tetreault and Chodorow, 2008; Gamon, 2010; Rozovskaya and Roth, 2010b). Several studies also consider verb-related and noun-related errors (Lee and Seneff, 2008; Gamon et al., 2008; Dahlmeier and Ng, 2012). The predictions made by individual models are then applied independently (Rozovskaya et al., 2011) or pipelined (Dahlmeier and Ng, 2012).

The standard approach of training individual classifiers considers each word independently and thus assumes that there are no interactions between errors and between grammatical phenomena. But an ESL writer may make multiple mistakes in a single sentence and these result in misleading local cues given to individual classifiers. In the example shown in Figure 1, the agreement error on the verb "have" interacts with the noun number error: a correction system that takes into account the context may infer, because of the word "phone", that the verb number is correct. For this reason, a system that consid-

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 791–802,
Seattle, Washington, USA, 18-21 October 2013.

ers noun and agreement errors separately will fail to identify and correct the interacting errors shown in Fig. 1. Furthermore, it may also produce inconsistent predictions.

Even though it is quite clear that grammatical errors interact, for various conceptual and technical reasons, this issue has not been addressed in a significant way in the literature. We believe that the reasons for that are three-fold: (1) Data: until very recently we did not have data that jointly annotates sufficiently many errors of interacting phenomena (see Sec. 2). (2) Conceptual: Correcting errors in interacting linguistic phenomena requires that one identifies those phenomena and, more importantly, can recognize reliably the interacting components (e.g., given a verb, identify the subject to enable enforcing agreement). The perception has been that this cannot be done reliably (Sec. 4). (3) Technical: The NLP community has started to better understand joint learning and inference and apply it to various phenomena (Roth and Yih, 2004; Punyakanok et al., 2008; Martins et al., 2011; Clarke and Lapata, 2007; Sutton and McCallum, 2007) (Sec. 5).

In this paper we present, for the first time, a successful approach to jointly resolving grammatical errors. Specifically:

• We identify two pairs of interacting phenomena, *subject-verb* and *article-NPhead* agreements; we show how to reliably identify these pairs in noisy ESL data, thereby facilitating the joint correction of these phenomena.

• We propose two joint approaches: (1) a *joint inference* approach implemented on top of individually learned models using an integer linear programming formulation (ILP, (Roth and Yih, 2004)), and (2) a model that *jointly learns* each pair of these phenomena. We show that each of these methods has its advantages, and that both solve the two challenges outlined above: the joint models exclude inconsistent predictions that violate linguistic constraints. The joint learning model exhibits superior performance, as it is also able to overcome the problem of the noisy context encountered by the individual models and to identify errors in contexts, where multiple changes need to be applied at the same time.

We show that our joint models produce state-of-the-art performance and, in particular, significantly outperform the University of Illinois system that placed first in the CoNLL-2013 shared task, increasing the F1 score by 2 and 4 points in different evaluation settings.

2 Task Description and Motivation

To illustrate the utility of jointly addressing interacting grammatical phenomena, we consider the corpus of the CoNLL-2013 shared task on grammatical error correction (Ng et al., 2013), which we found to be particularly well-suited for addressing interactions between grammatical phenomena. The task focuses on the following five common mistakes made by ESL writers: *article*, *preposition*, *noun number*, *subject-verb agreement*, and *verb form*, and we address two interactions: *article-NPhead* and *subject-verb*.

The training data for the task is from the NUCLE corpus (Dahlmeier et al., 2013), an error-tagged collection of essays written by non-native learners of English. The test data is an additional set of essays by learners from the same linguistic background. The training and the test data contain 1.2M and 29K words, respectively. Although the corpus contains errors of other types, the task focuses on five types of errors. Table 1 shows the number of mistakes[1] of each type and the error rates, i.e. the percentage of erroneous words by error type.

Error	**Number of errors and error rate**	
	Training	**Test**
Article	6658 (2.4%)	690 (10.0%)
Prep.	2404 (2.0%)	311 (10.7%)
Noun	3779 (1.6%)	396 (6.0%)
Verb Agr.	1527(2.0%)	124 (5.2%)
Verb Form	1453 (0.8%)	122 (2.5%)

Table 1: **Number of annotated errors in the CoNLL-2013 shared task.** Percentage denotes the error rates, i.e. the number of erroneous instances with respect to the total number of relevant instances in the data. For example, 10.7% of prepositions in the test data are used incorrectly. The numbers in the *revised* data set are slightly higher.

We note that the CoNLL-2013 data set is the first annotated collection that makes a study like ours feasible. The presence of a common test set that

[1]System performance in the shared task is evaluated on data with and without additional revisions added based on the input from participants. The number of mistakes in the revised test data is slightly higher.

contains a good number of interacting errors – article, noun, and verb agreement mistakes – makes the data set well-suited for studying which approach works best for addressing interacting phenomena. The HOO-2011 shared task collection (Dale and Kilgarriff, 2011) contains a very small number of noun and agreement errors (41 and 11 in test, respectively), while the HOO-2012 competition (Dale et al., 2012) only addresses article and preposition mistakes. Indeed, in parallel to the work presented here, Wu and Ng (2013) attempted the ILP-based approach of Roth and Yih (2004) in this domain. They were not able to show any improvement, for two reasons. First, the HOO-2011 data set which they used does not contain a good number of errors in interacting structures. Second, and most importantly, they applied constraints in an indiscriminate manner. In contrast, we show how to identify the interacting structures' components in a reliable way, and this plays a key role in the joint modeling improvements.

Lack of data hindered other earlier efforts for error correction beyond individual language phenomena. Brockett et al. (2006) applied machine-translation techniques to correct noun number errors on mass nouns and article usage but their application was restricted to a small set of constructions. Park and Levy (2011) proposed a language-modeling approach to whole sentence error correction but their model is not competitive with individually trained models. Finally, Dahlmeier and Ng (2012) proposed a decoder model, focusing on four types of errors in the data set of the HOO-2011 competition (Dale and Kilgarriff, 2011). The decoder optimized the sequence in which individual classifiers were to be applied to the sentence. However, because the decoder still corrected mistakes in a pipeline fashion, one at a time, it is unlikely that it could deal with cases that require simultaneous changes.

3 The University of Illinois System

Below, we briefly describe the University of Illinois system (henceforth *Illinois*; in the overview paper of the shared task the system is referred to as UI) that achieved the best result in the CoNLL-2013 shared task and which we use as our baseline model. For a complete description, we refer the reader to Rozovskaya et al. (2013).

The Illinois system implements five machine-learning independently-trained classifiers that follow the popular approach to ESL error correction borrowed from the context-sensitive spelling correction task (Golding and Roth, 1999; Carlson et al., 2001). A *confusion set* is defined that specifies a list of confusable words. Each occurrence of a confusable word in text is represented as a vector of features derived from a context window around the target. The problem is cast as a multi-class classification task and a classifier is trained on native or learner data. At prediction time, the model selects the most likely candidate from the confusion set.

The confusion set for prepositions includes the top 12 most frequent English prepositions. The article confusion set is as follows: {a,the,∅}[2]. The confusion sets for *noun*, *agreement*, and *form* modules depend on the target word and include its morphological variants (Table 2).

"Hence, the environmental ***factor/factors** also ***contributes/contribute** to various difficulties, ***included/including** problems in nuclear technology."	
Error type	**Confusion set**
Noun	{factor, factors}
Verb Agr.	{contribute, contributes}
Verb Form	{included, including, includes, include}

Table 2: **Confusion sets for noun number, agreement, and form classifiers.**

The *article* classifier is a discriminative model that draws on the state-of-the-art approach described in Rozovskaya et al. (2012). The model makes use of the Averaged Perceptron algorithm (Freund and Schapire, 1996) and is trained on the training data of the shared task with rich features.

The other models are trained on native English data, the Google Web 1T 5-gram corpus (henceforth, Google, (Brants and Franz, 2006)) with the Naïve Bayes (NB) algorithm. All models use word n-gram features derived from the 4-word window around the target word. In the *preposition* model, priors for preposition preferences are learned from the shared task training data (Rozovskaya and Roth, 2011).

[2] ∅ denotes noun-phrase-initial contexts where an article is likely to have been omitted. The variants "a" and "an" are conflated and are restored later.

Example	Predictions made by the Illinois system
"They believe that *such situation* must be avoided."	such situation → such a situations
"Nevertheless , electric *cars is* still regarded as a great trial innovation."	cars is → car are
"Every *students have* appointments with the head of the department."	No change

Table 3: **Examples of predictions of the Illinois system that combines independently-trained models.**

The words that are selected as input to classifiers are called *candidates*. Article and preposition candidates are identified with a closed list of words; noun-phrase-initial contexts for the article classifier are determined using a shallow parser[3] (Punyakanok and Roth, 2001). Candidates for the noun, agreement, and form classifiers are identified with a part-of-speech tagger[4], e.g. *noun* candidates are words that are tagged as NN or NNS. Table 4 shows the total number of candidates for each classifier.

	Classifier				
	Art.	**P**	**N**	**Agr.**	**F**
Train	254K	103K	240K	75K	175K
Test	6K	2.5K	2.6K	2.4K	4.8K

Table 4: **Number of candidate words by classifier type in training and test data.**

4 Interacting Mistakes

The approach of addressing each type of mistake individually is problematic when multiple phenomena interact. Consider the examples in Table 3 and the predictions made by the Illinois system. In the first and second sentences, there are two possible ways to correct the structures "such situation" and "cars is". In the former, either the article or the noun number should be changed; in the latter, either the noun number or the verb agreement marker[5]. In these examples, each of the independently-trained classifiers identifies the problem because each system makes a decision using the second error as part of its contextual cues, and thus the individual systems produce inconsistent predictions.

The second type of interaction concerns cases that require correcting more than one word at a time: the last example in Table 3 requires making changes both to the verb and the subject. Since each of the independent classifiers (for nouns and for verb agreement) takes into account the other word as part of its features, they both infer that the verb number is correct and that the grammatical subject "student" should be plural.

We refer to the words whose grammatical properties interact as *structures*. The independently-trained classifiers tend to fail to provide valid corrections in contexts where it is important to consider both words of the structure.

4.1 Structures for Joint Modeling

We address two linguistic structures that are relevant for the grammatical phenomena considered: *article-NPhead* and *subject-verb*. In the *article-NPhead* structures, the interaction is between the head of the noun phrase (NP) and the article that refers to the NP (first example in Table 3). In particular, the model should take into account that the article "a" cannot be combined with a noun in plural form. For subject-verb agreement, the subject and the verb should agree in number.

We now need to identify all pairs of candidates that form the relevant structures. *Article-NPhead* structures are pairs of words, such that the first word is a candidate of type article, while the second word is a noun candidate. Given an article candidate, the head of its NP is determined using the POS information (this information is obtained from the article feature vector because the NP head is a feature used by the article system)[6]. *Subject-verb* structures are pairs of noun-agreement candidates. Given a verb, its subject is identified with a dependency parser (Marneffe et al., 2006).

To evaluate the accuracy of subject and NP head

[3] http://cogcomp.cs.illinois.edu/page/software_view/Chunker

[4] http://cogcomp.cs.illinois.edu/page/software_view/POS

[5] Both of these solutions will result in grammatical output and the specific choice between the two depends on the wider essay context.

[6] Some heads are not identified or belong to a different part of speech.

predictions, a random sample of 500 structures of each type from the training data was examined by a human annotator with formal training in Linguistics. The human annotations were then compared against the automatic predictions. The results of the evaluation for subject-verb and article-NPhead structures are shown in Tables 5 and 6, respectively. Although the overall accuracy is above 90% for both structures, the accuracy varies by the distance between the structure components and drops significantly as the distance increases. For article-NPhead structures, *distance* indicates the position of the NP head with respect to the article, e.g. distance of 1 means that the head immediately follows the article. For subject-verb structures, *distance* is shown with respect to the verb: a distance of -1 means that the subject immediately precedes the verb. Although in most cases the subject is located to the left of the verb, in some constructions, such as existential clauses and inversions, it occurs after the verb.

Based on the accuracy results for identifying the structure components, we select those structures where the components are reliably identified. For article-NPhead, valid structures are those where the distance is at most three words. For subject-verb, we consider as valid those structures where the identified subject is located within two words to the left or three words to the right of the verb.

The valid structures are selected as input to the joint model (Sec. 5). The *joint learning* model considers only those valid structures whose components are *adjacent*. In adjacent structures the NP head immediately follows the article, and the verb immediately follows the subject. *Joint inference* is not restricted to adjacent structures.

The last column of Table 5 shows that valid subject-verb structures account for 67.5% of all verbs whose subjects are common nouns (51.7% are cases where the words are adjacent). Verbs whose subjects are common nouns account for 57.8% of all verbs that have subjects (verbs with different types of subjects, most of which are personal pronouns, are not considered here, since these subjects are not part of the noun classifier).

Valid article-NPhead structures account for 98.0% of all articles whose NP heads are common nouns (47.5% of those are adjacent structures), as shown in the last column of Table 6. 71.0% of articles in the training data belong to an NP whose head is a common noun; NPs whose heads belong to different parts of speech are not considered.

Note also that because a noun may belong both to an article-NPhead and a subject-verb structure, the structures contain an overlap.

Distance	**Accuracy**	**% of all subj. predictions**	**Cumul.**
-1	97.6%	51.7%	51.7%
1,2,3	100.0%	8.9%	60.6%
-2	88.2%	6.9%	67.5%
Other	80.8%	32.5%	100.0%

Table 5: **Accuracy of subject identification on a random sample of subject-verb structures from the training data.** The overall accuracy is 91.52%. For each distance, the following are shown: accuracy based on comparison with human evaluation; the percentage of all predictions that have this distance; the cumulative percentage.

Distance	**Accuracy**	**% of all head predictions**	**Cumul.**
1	94.8%	47.5%	47.5%
2	94.4%	44.0%	91.5%
3	92.3%	6.5%	98.0%
Other	89.1%	2.0%	100%

Table 6: **Accuracy of NP head identification on a random sample of article-NPhead structures from training data.** The overall accuracy is 94.45%. For each distance, the following are shown: accuracy based on comparison with human evaluation; the percentage of all predictions that have this distance; the cumulative percentage.

5 The Joint Model

In this section, we present the *joint inference* and the *joint learning* approaches. In the joint inference approach, we use the independently-learned models from the Illinois system, and the interacting target words identified earlier are considered only at inference stage. In the joint learning method, we jointly learn a model for the interacting phenomena.

The label space in the joint models corresponds to sequences of labels from the confusion sets of the individual classifiers: $\{a-sing, a-pl, the-sing, the-pl, \varnothing-sing, \varnothing-pl\}$ and $\{sing-sing, sing{-}pl, pl{-}sing, pl{-}pl\}$ for article-NPhead and subject-verb structures, respectively[7]. Invalid

[7]"sing" and "pl" refer to the grammatical number of noun

structures, such as *pl-sing* are excluded via hard constraints (when we run joint inference) or via implicit soft constraints (when we use joint learning).

5.1 Joint Inference

In the individual model approach, decisions are made for each word independently, ignoring the interactions among linguistic phenomena. The purpose of joint inference is to include linguistic (i.e. structural) knowledge, such as "plural nouns do not take an indefinite article", and "agreement consistency between the verb and the subject that controls it". This knowledge should be useful for resolving inconsistencies produced by individual classifiers.

The inference approach we develop in this paper follows the one proposed by Roth and Yih (2004) of training individual models and combining them at decision time via joint inference. The advantage of this method is that it allows us to build upon any existing independently-learned models that provide a distribution over their outcome, and produce a coherent global output that respects our declarative constraints. We formulate our component inference problems as integer linear program (ILP) instances as in Roth and Yih (2004).

The inference takes as input the individual classifiers' confidence scores for each prediction, along with a list of constraints. The output is the optimal solution that maximizes the linear sum of the confidence scores, subject to the constraints that encode the interactions. The joint model thus selects a hypothesis that both obtains the best score according to the individual models and satisfies the constraints that reflect the interactions among the grammatical phenomena at the level of linguistic structures, as defined in Sec. 4.

Inference The joint inference is enforced at the level of structures, and each structure corresponds to one ILP instance. All structures consist of two or three words: when an article-NPhead structure and a subject-verb structure include the same noun, the structure input to the ILP consists of an article-noun-verb triple. We formulate the inference problem as follows: Given a structure s that consists of n words, let w_i correspond to the i^{th} word in the structure. Let h denote a hypothesis from the hypothesis space H for s, and $score(w_i, h, l^i)$ denote the score assigned by the appropriate error-specific model to w_i under h for label l from the confusion set of word w_i. We denote by $e_{w,l}$ the Boolean variable that indicates whether the prediction on word w is assigned the value l ($e_{w,l} = 1$) or not ($e_{w,l} = 0$).

We assume that each independent classifier returns a score that corresponds to the likelihood of word w_i under h being labeled l^i. The softmax function (Bishop, 1995) is used to convert raw activation scores to conditional probabilities for the discriminative article model. The NB scores are also normalized and correspond to probabilities. Then the inference task is solved by maximizing the overall score of a candidate assignment of labels l to words w (this set of feasible assignments is denoted H here) subject to the constraints C for the structure s:

$$\hat{h} = \arg\max_{h \in H} score(h) =$$

$$= \arg\max_{h \in H} \sum_{i=1}^{n} score(w_i, h, l^i) e_{w_i, l^i}$$

subject to $C(s)$

Constraints In the $\{0, 1\}$ linear programming formulation described above, we can encode linguistic constraints that reflect the interactions among the linguistic phenomena. The inference enforces the following structural and linguistic constraints:

1. The indefinite article "a" cannot refer to an NP headed by a plural noun.
2. Subject and verb must agree in number.

In addition, we encode "legitimacy" constraints, that make sure that each w is assigned a single label. All constraints are encoded as hard constraints.

5.2 Joint Learning

We now describe how we *learn* the subject-verb and article-NPhead structures jointly. The joint model is implemented as a NB classifier and is trained in the same way as the independent models on the Google corpus with word n-gram features. Unlike the independent models, where the target corresponds to one

and verb agreement candidates. The candidates themselves are the surface forms of specific words that realize these grammatical properties. Note that a subject in subject-verb structures is always third person, since all subjects in subject-verb structures are common nouns; other subjects, including pronouns, are excluded. Thus the agreement distinction is singular vs. plural.

System	Adjacent structures		All distances	
	F1 (Orig.)	F1 (Revised)	F1 (Orig.)	F1 (Revised)
Illinois	31.20	42.14	31.20	42.14
NaïveVerb	31.19	42.20	31.13	42.16
NaïveNoun	31.03	41.87	30.91	41.70
This paper joint systems	**Joint Inference** (adjacent)		**Joint Inference** (all distances)	
	F1 (Orig.)	F1 (Revised)	F1 (Orig.)	F1 (Revised)
Subject-verb	31.90	42.94	31.97	42.86
Article-NPhead	31.63	42.48	31.79	42.59
Subject-verb + article-NPhead	**32.35**	**43.16**	**32.51**	**43.19**

Table 7: **Joint Inference Results.** All results are on the CoNLL-2013 test data using the original and revised gold annotations. *Adjacent* denotes a setting, where the joint inference is applied to structures with consecutive components (article-NPhead or subject-verb). *All distances* denotes a setting, where the constraints are applied to all valid structures, as described in Sec. 4.1. *Illinois* denotes the result obtained by the top CoNLL-2013 shared task system. In all cases, the candidates that are not part of the structures are handled by the respective components of the Illinois system. *NaïveVerb* and *NaïveNoun* denote heuristics, where a verb or subject are changed to ensure agreement. All improvements over the Illinois system are statistically significant (McNemar's test, $p < 0.01$).

word, here the target corresponds to two words that are part of the structure and the label space of the model is modified accordingly. Since we use features that can be computed from the small windows in the Google corpus, the joint learning model handles only adjacent structures (Sec. 4.1). Because the target consists of two words and the Google corpus contains counts for n-grams of length at most five, the features are collected in the three word window around the target.[8]

Unlike with the joint inference, here we do not explicitly encode linguistic constraints. One reason for this is that the NP head and subject predictions are not 100% accurate, so input structures will have noise. However, the joint model learns these constraints through the evidence seen in training.

6 Experiments

In this section, we describe our experimental setup and evaluate the performance of the joint approach. In the joint approach, the joint components presented in Sec. 5 handle the interacting structures described in Sec. 4. The individual classifiers of the Illinois system make predictions for the remaining words. The research question addressed by the experiments is the following: Given independently-trained systems for different types of errors, can we improve the performance by considering the phenomena that interact jointly? To address this, we report the results in the following settings:

1. *Joint Inference*: we compare the Illinois system that is a collection of individually-trained models that are applied independently with a model that uses joint inference encoded as declarative constraints in the ILP formulation and show that using joint inference results in a strong performance gain.
2. *Joint Learning*: we compare the Illinois system with a model that incorporates jointly-trained components for the two linguistic structures that we described in Sec. 4. We show that joint training produces an even stronger gain in performance compared to the Illinois model.
2. *Joint Learning and Inference*: we apply joint inference to the output of the joint learning system to account for dependencies not covered by the joint learning model.

We report F1 performance scored using the official scorer from the shared task (Dahlmeier and Ng, 2012). The task reports two types of evaluation: on the original gold data and on gold data with additional corrections. We refer to the results as *Original* and *Revised*.

6.1 Joint Inference Results

Table 7 shows the results of applying joint inference to the Illinois system. Both the article-NPhead and the subject-verb constraints improve the performance. The results for the joint inference are shown in two settings, adjacent and all structures, so that later we can compare joint inference with the joint learning model that handles only adjacent structures.

[8] Also note that when the article is ∅, the surface form of the structure corresponds to the NP head alone; this does not present a problem because in the NB model the context counts are normalized with the prior counts.

	Illinois system		Illinois-NBArticle	
	F1 (Orig.)	**F1 (Revised)**	**F1 (Orig.)**	**F1 (Revised)**
Illinois	31.20	42.14	31.71	41.38
This paper joint systems	**Joint Learning** (adjacent)		**Joint Learning** (adjacent)	
	F1 (Orig.)	**F1 (Revised)**	**F1 (Orig.)**	**F1 (Revised)**
Subject-verb	32.64*	43.37*	33.09*	**42.78***
Article-NPhead	33.89*	42.57*	33.16*	41.51
Subject-verb + article-NPhead	**35.12***	**43.73***	**34.41***	42.76*

Table 8: **Joint Learning Results.** All results are on the CoNLL-2013 test data using the original and revised gold annotations. *Illinois-NBArticle* denotes the Illinois system, where the discriminative article model is replaced with a NB classifier. *Adjacent* denotes a setting, where the structure components are consecutive (article-NPhead or subject-verb), as described in Sec. 4.1. *Illinois* denotes the result obtained by the top CoNLL-2013 shared task system. In all cases, the candidates that are not part of the structures are handled by the respective components of the Illinois system. Statistically significant improvements (McNemar's test, $p < 0.01$) over the Illinois system are marked with an asterisk (*).

It is also interesting to note that the key improvement comes from considering structures whose components are adjacent. This is not surprising given that the accuracy for subject and NP head identification drops as the distance increases.

For subject-verb constraints, we also implement a naïve approach that looks for contradictions and changes either the verb or the subject if they do not satisfy the number agreement. These two heuristics are denoted as *NaïveVerb* and *NaïveNoun*. The heuristics differ from the joint inference in that they enforce agreement by always changing either the noun (*NaïveNoun*) or the verb (*NaïveVerb*), while the joint inference does this using the scores produced by the independent models. In other words, the key is the objective function, while the components of the objective function are the same in the heuristics and the joint inference. The results in Table 7 show that simply enforcing agreement does not work well and that the ILP formulation is indeed effective and improves over the independently-trained models in all cases.

Recall that valid structures include only those whose components can be identified in a reliable way (Sec. 4.1). To evaluate the impact of that filtering, we perform two experiments with subject-verb structures (long-distance dependencies are more common in those constructions than in the article-NPhead structures): first, we apply joint inference to all subject-verb structures. We obtain F1 scores of 31.61 and 42.28, on original and revised gold data, respectively, which is significantly worse than the results on subject-verb structures in Table 7 (31.97 and 42.86, respectively) and only slightly better than the baseline performance of the Illinois system. Furthermore, when we apply joint inference to those structures which were excluded by filtering in Sec. 4.1, we find that the performance degrades compared to the Illinois system (30.85 and 41.58). These results demonstrate that the joint inference improvements are due to structures whose components can be identified with high accuracy and that it is essential to identify these structures; bad structures, on the other hand, hurt performance.

6.2 Joint Learning Results

Now we show experimental results of the joint learning (Table 8). Note that the joint learning component considers only those structures where the words are adjacent. Because the Illinois system presented in Sec. 3 makes use of a discriminative article model, while the joint model uses NB, we also show results, where the article model is replaced by a NB classifier trained on the Google corpus. In all cases, joint learning demonstrates a strong performance gain.

6.3 Joint Learning and Inference Results

Finally, we apply joint inference to the output of the joint learning system in Sec. 6.2. Table 9 shows the results of the Illinois model, the model that applies joint inference and joint learning separately, and both. Even though the joint learning performs better than the joint inference, the joint learning covers only adjacent structures. Furthermore, joint learning does not address overlapping structures of triples that consist of article, subject, and verb (6% of all structures). Joint inference allows us to ensure consistent predictions in cases not addressed by the

Example	Illinois system	JL and JI
"Moreover, the increased **technologies help** people to overcome different natural disasters.	No change	technology helps
"At that time,... **there are surveillances** in everyone's heart and criminals are more difficult to hide."	there are* surveillance*	there is surveillance
"In **such situation**, individuals will lose their basic privacy."	such a* situations*	such a situation
"In supermarket **monitor is** needed because we have to track thieves."	No change	monitors are

Table 10: **Examples of mistakes that are corrected by the joint model but not by the Illinois model.** *Illinois* denotes the result obtained by the top CoNLL-2013 shared task system from the University of Illinois. *JL* and *JI* stand for joint learning and joint inference, respectively. Inconsistent predictions are starred.

	F1 (Orig.)	F1 (Revised)
Illinois	31.20	42.14
Joint Inference	32.51	43.19
Joint Learning	35.12	43.73
Joint Learn. + Inf.	**35.21**	**43.74**

Table 9: **Joint Learning and Inference.** All results are on the CoNLL-2013 test data using the original and revised gold annotations. Results of the joint models that include the joint inference component are shown for structures of all distances. *Illinois* denotes the result obtained by the top CoNLL-2013 shared task system. All joint systems demonstrate a statistically significant improvement over the Illinois system; joint learning improvements are also statistically significant compared to the joint inference results (McNemar's test, $p < 0.01$).

joint learning model. Indeed, we can get a small improvement by adding joint inference on top of the joint learning on original annotations. Since the revised corrections are based on the participants' input and are most likely biased towards system predictions for corrections missed by the original annotators (Ng et al., 2013), it is more difficult to show improvement on revised data.

7 Discussion and Error Analysis

In the previous section, we evaluated the proposed joint inference and joint learning models that handle interacting grammatical phenomena. We showed that the joint models produce significant improvements over the highest-scoring CoNLL-2013 shared task system that consists of independently-trained classifiers: the joint approaches increase the F1 score by 4 F1 points on the original gold data and almost 2 points on the revised data (Table 9).

These results are interesting from the point of view of developing a practical error correction system. However, recall that the errors in the interacting structures are only a subset of mistakes in the CoNLL-2013 data set but the evaluation in Sec. 6 is performed with respect to all of these errors. From a scientific point of view, it is interesting to evaluate the impact of the joint models more precisely by considering the improvements on the relevant structures only. Table 11 shows how much the joint learning approach improves on the subset of relevant mistakes.

Structure	Performance (F1)	
	Illinois	Joint Learning
Subject-verb	39.64	**52.25**
Article-NPhead	30.65	**35.90**

Table 11: **Evaluation of the joint learning performance on the subset of the data containing interacting errors.** All results are on the CoNLL-2013 test data using the original annotations. *Illinois* denotes the result obtained by the top CoNLL-2013 shared task system. All improvements are statistically significant over the Illinois system (McNemar's test, $p < 0.01$).

Error Analysis To better understand where the joint models have an advantage over the independently-trained classifiers, we analyze the output produced by each of the approaches. In Table 10 we show examples of mistakes that the model that uses joint learning and inference is able to identify correctly, along with the original predictions made by the Illinois system.

Joint Inference vs. Joint Learning We wish to stress that the joint approaches do not simply perform better but also make coherent decisions by disallowing illegitimate outputs. The joint inference approach does this by enforcing linguistic constraints on the output. The joint learning model, while not explicitly encoding these constraints, learns them from the distribution of the training data.

Joint inference is a less expensive model, since it uses the scores produced by the individual classifiers and thus does not require additional training. Joint learning, on the other hand, is superior to joint inference, since it is better at modeling interactions where multiple errors occur simultaneously – it eliminates the noisy context present when learning the independent classifiers. Consider the first example from Table 10, where both the noun and the agreement classifiers receive noisy input: the verb "help" and the noun "technologies" act as part of input features for the noun and agreement classifiers, respectively. The noisy features prevent both modules from identifying the two errors.

Finally, an important distinction of the joint learning method is that it considers all possible output sequences *in training*, and thus it is able to better identify errors that require multiple changes, such as the last example in Table 10, where the Illinois system proposes no changes.

7.1 Error Correction: Challenges

We finalize our discussion with a few comments on the challenges of the error correction task.

Task Difficulty As shown in Table 1 in Sec. 2, only a small percentage of words have mistakes, while over 90% (about 98% in training) are used correctly. The low error rates are the key reason the error correction task is so difficult: it is quite challenging for a system to improve over a writer that already performs at the level of over 90%. Indeed, very few NLP tasks already have systems that perform at that level, even when the data is not as noisy as the ESL data.

Evaluation Metrics In the CoNLL-2013 competition, as well as the competitions alluded to earlier, systems were compared on F1 performance, and, consequently, this is the metric we optimize in this paper. Practical error correction systems, however, should be tuned to minimize recall to guarantee that the overall quality of the text does not go down. Indeed, the error sparsity makes it very challenging to identify mistakes accurately, and no system in the shared task achieves a precision over 50%. However, once the precision drops below 50%, the system introduces more mistakes than it identifies.

Clearly, optimizing the F1 measure does not ensure that the quality of the text improves as a result of running the system. Thus, it can be argued that the F1 measure is not the right measure for error correction. A different evaluation metric based on the *accuracy* of the data before and after running the system was proposed in Rozovskaya and Roth (2010c). When optimizing for this metric, the noun module, for instance, at recall point 20%, achieves a precision of 63.93%. This translates into accuracy of 94.46%, while the baseline on noun errors in the test data (i.e. the accuracy of the data before running the system) is 94.0% (Table 1). This means that the system improves the quality of the data.

Annotation Lastly, we believe that it is important to provide alternative corrections, as the agreement on what constitutes a mistake even among native English speakers can be quite low (Madnani et al., 2011).

8 Conclusion

This work presented the first successful study that jointly corrects grammatical mistakes. We addressed two pairs of interacting phenomena and showed that it is possible to reliably identify their components, thereby facilitating the joint approach.

We described two joint methods: a *joint inference* approach implemented via ILP and a *joint learning* model. The joint inference enforces constraints using the scores produced by the independently-trained models. The joint learning model learns the interacting phenomena as structures. The joint methods produce a significant improvement over a state-of-the-art system that combines independently-trained models and, importantly, produce linguistically legitimate output.

Abstract

Nilsson and Nivre (2009) introduced a tree-based model of persons' eye movements in reading. The individual variation between readers reportedly made application across readers impossible. While a tree-based model seems plausible for eye movements, we show that competitive results can be obtained with a linear CRF model. Increasing the inductive bias also makes learning across readers possible. In fact we observe next-to-no performance drop when evaluating models trained on gaze records of multiple readers on new readers.

1 Introduction

When we read a text, our gaze does not move smoothly and continuously along its lines. Rather, our eyes fixate at a word, then skip a few words, to jump to a new fixation point. Such rapid eye movements are called *saccades*. Sometimes we even jump backwards. Backward saccades are called *regressions*. Gaze can be recorded using eye tracking devices (Starr and Rayner, 2001). Since eye movements in reading give us important information about what readers find complicated in a text, and what readers find completely predictable, predicting eye movements on new texts has many practical applications in text-to-text generation and human computer interaction, for example.

The problem of predicting eye movements in reading is, for a reader r_i and a given sequence of word tokens $w_1 \dots w_n$, to predict a set of fixation points $F \subseteq \{w_1, \dots, w_n\}$, i.e., the fixation points of r_i's gaze. For each token w_j, the reader r_i may skip w_j or fixate at w_j. Models are evaluated on recordings of human reading obtained using eye tracking devices. The supervised prediction problem that we consider in this paper, also uses eye tracking data for learning models of eye movement.

Nilsson and Nivre (2009) first introduced this supervised learning task and used the Dundee corpus to train and evaluate a tree-based model, essentially treating the problem of predicting eye movements in reading as transition-based dependency parsing.

We follow Hara et al. (2012) in modeling only forward saccades and *not* regressions and refixations. While Nilsson and Nivre (2009) try to model a subset of regressions and refixations, they do *not* evaluate this part of their model focusing only on fixation accuracy and distribution accuracy, i.e., they evaluate how well they predict *a set of* fixation points rather than a sequence of points in order. This enables us to model eye movements in reading as a sequential problem of determining the length of forward saccades, increasing the inductive bias of our learning algorithm in a motivated way. Note that because we work with visual input, we do not tokenize our input in our experiments, i.e., punctuation does not count as input tokens.

Example Figure 1 presents an example sentence and gaze records from the Dundee corpus. The Dundee corpus contains gaze records of 10 readers in total. Note that there is little consensus on what words are skipped. 5/10 readers skip the first word. Generally, closed class items (prepositions, copulae, quantifiers) seem to be skipped more open, but we do see a lot of individual variation. While others for this reason have refrained from evaluation across readers (Nilsson and Nivre, 2009; Hara et al., 2012),

we show that our model predicts gaze better *across readers* than a previously proposed model (Nilsson and Nivre, 2009) does training and evaluating on the *same* readers. A final observation is that fixations are very frequent at the word level – in fact, even skilled readers make 94 fixations per 100 words (Starr and Rayner, 2001) – which motivates using F_1-score of skips as metric. We follow Nilsson and Nivre (2009) in reporting word-level accuracy, but find it particularly interesting that the simple model proposed here outperforms previous models by a large margin in F_1-score over skips.

Related work Below we use a sequential model rather than a tree-based model to bias our model toward predicting forward saccades. Nilsson and Nivre (2009), in contrast, present a more expressive tree-based model for modeling eye movements, with some constraints on the search space. The transition-based model uses consecutive classification rather than structured prediction. The features used in their model are very simple. In particular, they use use word lengths and frequencies, like us, as well as distances between tokens (important in a transition-based model), and, finally, the history of previous decisions.

Hara et al. (2012) use a linear CRF model for the same problem, like us, but they consider a slightly different problem, namely that of predicting eye movement when reading text on a specific screen. They therefore use screen position as a feature. In addition, they use word forms, POS, various measures of surprise of word length, as well as perplexity of bi- and trigrams. The features relating to screen position were the most predictive ones.

2 Our approach

We use linear CRFs to model eye movements in reading. We follow Hara et al. (2012) in using small window sizes (at most five words) for extracting features. Rather than using word forms, POS, etc., we use only word length and the log probability of words – both known to correlate well with likelihood of fixation, as well as fixation times (McDonald and Shillcock, 2012; Kliegl et al., 2004; Reingold et al., 2012). The model thus reflects a hypothesis that eye movements are largely unaffected by semantic content, that eye movements depend on the physical properties and frequency of words, and that there is a sequential dependence between fixation times. Tabel 1 gives the complete set of features. We also evaluated using word forms and POS on held-out data, but this did not lead to improvements. There is evidence for the impact of morphology on eye movements (Liversedge and Blythe, 2007; Bertram, 2011), but we did not incorporate this into our model. Finally, we did not incorporate predictability of tokens, although this is also known to correlate with fixation times (Kliegl et al., 2004). Hara et al. (2012) use perplexity features to capture this.

We use a publicly available implementation of linear CRFs[1] with default parameters (L_2-regularized, $C = 1$).

3 Predicting a reader's eye movements

In this experiment we consider exactly the same setup as Nilsson and Nivre (2009) considered. In the Dundee corpus, we have gaze data for 10 persons. The corpus consists of 2,379 sentences, 56,212 tokens and 9,776 types. The gaza data was recorded using a Dr. Bouis Oculometer Eyetracker, sampling the position of the right eye every millisecond. We use texts 1–16 (1911 sentences) for training, 17–18 (237 sentences) for development and 19–20 (231 sentences) for testing.

Results are presented in Table 2 and are slightly better than Nilsson and Nivre (2009), mainly because of better predictions of skips. Our error reduction over their model in terms of F_1 over skips is 9.4%. The baseline model used in Nilsson and Nivre (2009), the E-Z Reader (Reichle et al., 1998), obtained a fixation accuracy of 57.7%.

4 Predicting across readers

Hara et al. (2012) consider the problem of learning from the concatenation of the gaze data from the 10 persons in the Dundee corpus, but they also evaluate on data from these persons. In our second experiment, we consider the more difficult problem of learning from one person's gaze data, but evaluating on gaze data from another test person. This is a more realistic scenario if we want to use our model to predict eye movements in reading on anyone but our test persons. This has been argued to be impossible in previous work (Nilsson and Nivre, 2009; Hara et al., 2012).

Our results are presented in Table 3. Interestingly, results are very robust across reader pairs. In fact, only in 4/10 cases do we get the best results training on gaze data from the reader we evaluate on. Note also that the readers seem to form two groups – (a, b, h, i, j) and (c, d, e, f, g) – that provide good training material for each other. Training on concatenated data from all members in each group may be beneficial.

5 Learning from multiple readers

In our final experiment, we learn from the gaze records of nine readers and evaluate on the tenth. This is a realistic evaluation of our ability to predict fixations for new, previously unobserved readers. Interestingly we can predict the fixations of new readers better than Nilsson and Nivre (2009) predict fixations when the training and test data are produced by the same reader. The results are presented in Table 4. In fact our skip F_1 score is actually better than in our first experiments. As already mentioned, this result can probably be improved by using a subset of readers or by weighting training examples, e.g., by importance weighting (Shimodaira, 2000). For now, this is left for future work.

6 Discussion

Our contributions in this paper are: (i) a model for predicting a reader's eye movements that is competitive to state-of-the-art, but simpler, with a smaller search space than Nilsson and Nivre (2009) and a smaller feature model than Hara et al. (2012), (ii) showing that the simpler model is robust enough to model eye movements across readers, and finally, (iii) showing that even better models can be obtained training on records from multiple readers.

It is interesting that a model without lexical information is more robust across readers. This suggests that deep processing has little impact on eye movements. See Starr and Rayner (2001) for discussion. The features used in this study are well-motivated and account as well for the phenomena as previously proposed models. It would be interesting to incorporate morphological features and perplexity-based features, but we leave this for future work.

7 Conclusion

This study is, to the best of our knowledge, the first to consider the problem of learning to predict eye movements in reading across readers. We present a very simple model of eye movements in reading that performs a little better than Nilsson and Nivre (2009) in terms of fixation accuracy, evaluated on one reader at a time, but predicts skips significantly better. The true merit of the approach, however, is its ability to predict eye movements across readers. In fact, it predicts the eye movements of new readers better than Nilsson and Nivre (2009) do when the training and test data are produced by the same reader.

Using Paraphrases and Lexical Semantics to Improve the Accuracy and the Robustness of Supervised Models in Situated Dialogue Systems

Lina M. Rojas Barahona
Université de Lorraine/LORIA, Nancy
lina.rojas@loria.fr

Abstract

This paper explores to what extent lemmatisation, lexical resources, distributional semantics and paraphrases can increase the accuracy of supervised models for dialogue management. The results suggest that each of these factors can help improve performance but that the impact will vary depending on their combination and on the evaluation mode.

1 Introduction

One strand of work in dialog research targets the rapid prototyping of virtual humans capable of conducting a conversation with humans in the context of a virtual world. In particular, question answering (QA) characters can respond to a restricted set of topics after training on a set of dialogs whose utterances are annotated with dialogue acts (Leuski and Traum, 2008).

As argued in (Sagae et al., 2009), the size of the training corpus is a major factor in allowing QA characters that are both robust and accurate. In addition, the training corpus should arguably be of good quality in that (i) it should contain the various ways of expressing the same content (paraphrases) and (ii) the data should not be skewed. In sum, the ideal training data should be large (more data is better data) ; balanced (similar amount of data for each class targeted by the classifier) and varied (it should encompass the largest possible number of paraphrases and synonyms for the utterances of each class).

In this paper, we explore different ways of improving and complementing the training data of a supervised QA character. We expand the size and the quality (less skewed data) of the training corpus using paraphrase generation techniques. We compare the performance obtained on lemmatised vs. non lemmatised data. And we investigate how various resources (synonym dictionaries, WordNet, distributional neighbours) can be used to handle unseen words at run time.

2 Related work

Previous work on improving robustness of supervised dialog systems includes detecting and handling out of domain utterances for generating feedback (Lane et al., 2004) ; using domain-restricted lexical semantics (Hardy et al., 2004) ; and work on manual data expansion (DeVault et al., 2011). Our work follows up on this research but provides a systematic investigation of how data expansion, lemmatisation and synonym handling impacts the performance of a supervised QA engine.

3 Experimental Setup

We run our experiments on a dialog engine developed for a serious game called *Mission Plastechnologie*. In this game, the player must interact with different virtual humans through a sequence of 12 subdialogs, each of them occurring in a different part of the virtual world.

Training Data. The training corpus consists of around 1250 Human-Human dialogues which were manually annotated with dialog moves. As the following dialog excerpt illustrates, the dialogs are conducted in French and each dialog turn is manually annotated using a set of 28 dialog acts. For

Dialog Systems For our experiments, we use a hybrid dialog system similar to that described in (Rojas Barahona et al., 2012b; Rojas Barahona and Gardent, 2012). This system combines a classifier for interpreting the players utterances with an information state dialog manager which selects an appropriate system response based on the dialog move assigned by the classifier to the user turn. The classifier is a logistic regression classifier [1] which was trained for each subdialog in the game. The features used for training are the set of content words which are associated with a given dialog move and which remain after TF*IDF [2] filtering. Note that in this experiment, we do not use contextual features such as the dialog acts labeling the previous turns. There are two reasons for this. First, we want to focus on the impact of synonym handling, paraphrasing and lemmatisation on dialog management. Removing contextual features allows us to focus on how content features (content words) can be improved by these mechanisms. Second, when evaluating on the H-C corpus (see below), contextual features are often incorrect (because the system might incorrectly interpret and thus label a user turn). Excluding contextual features from training allows for a fair comparison between the H-H and the H-C evaluation.

Test Data and Evaluation Metrics We use accuracy (the number of correct classifications divided by the number of instances in the testset) to measure performance and we carry out two types of evaluation. On the one hand, we use 10-fold cross-validation on the EmoSpeech corpus (H-H data). On the other hand, we report accuracy on a corpus of 550 Human-Computer (H-C) dialogues obtained by having 22 subjects play the game against the QA character trained on the H-H corpus. As we shall see below, performance decreases in this second evaluation suggesting that subjects produce different turns when playing with a computer than with a human thereby inducing a weak out-of-domain effect and negatively impacting classification. Evaluation on the H-H corpus therefore gives a measure of how well the techniques explored help improving the dialog engine when used in a real life setting.

Correspondingly, we use two different tests for measuring statistical significance. In the H-H evaluation, significance is computed using the Wilcoxon signed rank test because data are dependent and are not assumed to be normally distributed. When building the testset we took care of not including paraphrases of utterances in the training partition (for each paraphrase generated automatically we keep track of the original utterance), however utterances in both datasets might be generated by the same subject, since a subject completed 12 distinct dialogues during the game. Conversely, in the H-C evaluation, training (H-H data) and test (H-C data) sets were collected under different conditions with different subjects therefore significance was computed using the McNemar sign-test (Dietterich, 1998).

4 Paraphrases, Synonyms and Lemmatisation

We explore three main ways of modifying the content features used for classification : lemmatising the training and the test data ; augmenting the training data with automatically acquired paraphrases ; and substituting unknown words with synonyms at run time.

Lemmatisation We use the French version of Treetagger [3] to lemmatise both the training and the test data. Lemmas without any filtering were used

1. We used MALLET (McCallum, 2002) for the LR classifier with L1 Regularisation.

2. TF*IDF = Term Frequency*Inverse Document Frequency

3. http://www.ims.uni-stuttgart.de/projekte/corplex/TreeTagger/

to train classifiers. We then compare performance with and without lemmatisation. As we shall see, the lemma and the POS tag provided by TreeTagger are also used to lookup synonym dictionaries and EuroWordNet when using synonym handling at run time.

Paraphrases : (DeVault et al., 2011) showed that enriching the training corpus with manually added paraphrases increases accuracy. Here we exploit automatically acquired paraphrases and use these not only to increase the size of the training corpus but also to better balance it [4]. We proceed as follows.

First, we generated paraphrases using a pivot machine translation approach where each user utterance in the training corpus (around 3610 utterances) was translated into some target language and back into French. Using six different languages (English, Spanish, Italian, German, Chinese and Arabian), we generated around 38000 paraphrases. We used Google Translate API for translating.

Category	Train Instances	Balanced Instances
greet	24	86
help	20	82
yes	92	123
no	55	117
ack	73	135
other	27	89
quit	38	100

studies	20	82
security_policies	24	86
μ	44.08	100.92
σ	$\pm$32.68	$\pm$23.32

TABLE 1: Skewed and Balanced Data on a sample subdialog. The category with lowest number of paraphrases is `greet`, with 62 paraphrases, hence $l_p = 62$. All categories were increased by 62 except `find_plans` and `yes` that were increased by half : 31.

Second, we eliminate from these paraphrases, words that are likely to be incorrect lexical translations by removing words with low normalized term frequency (< 0.001) across translations i.e., lexical translations given by few translations and/or translation systems. We then preprocessed the paraphrases in the same way the utterances of the initial training corpus were preprocessed i.e., utterances were unaccented, converted to lower-case and stop words were removed, the remaining words were filtered with TF*IDF. After preprocessing, duplicates were removed.

4. The Emospeech data is highly skewed with some classes being populated with many utterances and others with few.

```
Algorithm extendingDataWithParaphrases(trainingset ts)

15.  set i←i+1
16.  if i>‖c‖ then
17.   terminate
18. end
```

FIGURE 1: Algorithm for augmenting the training data with paraphrases.

Third, we added the paraphrases to the training data seeking to improve the balance between dialog moves per dialog, as shown in Figure 1. To this end, we look for the category c with the lowest number of paraphrases l_p (line 5). We then compute the deviation d_i for each dialog move c_i from the mean μ in the original training set (line 9). If the deviation d_i is lower than the standard deviation then we add l_p number of paraphrases instances (line 11). Conversely, if d_i is higher than the standard deviation, we reduce the number of instances to be added by half $\frac{l_p}{2}$ (line 13). Table 1 shows the original and the extended training data for the third sub-dialog in the Emospeech game. In this dialogue the player is supposed to ask information about the joystick plans ($find\_plans$, which is the mandatory goal). The categories cover mandatory and optional goals and general dialogue acts, such as greetings, asking for help, confirm and disconfirm, acknowledgment and out of topic questions (i.e. other).

Substituting Synonyms for Unknown Words A word is unknown, if it is a well-formed French

word [5] and if it does not appear in the training corpus. Conversely, a word is known if it is not unknown.

When an unknown word w is detected in a player utterance at runtime, we search for a word w' which occurs in the training data and is either a synonym of w or a distributional neighbour. After disambiguation, we substitute the unknown word for the synonym.

To identify synonyms, we make use of two lexical resources namely, the French version of EuroWordNet (EWN) (Vossen, 1998), which includes 92833 synonyms, hyperonyms and hyponyms pairs, and a synonym lexicon for French (DIC) [6] which contains 38505 lemmas and 254149 synonym pairs. While words are categorised into Noun, Verbs and Adjectives in EWN, DIC contains no POS tag information.

To identify distributional neighbours, we constructed semantic word spaces for each subdialog in the EmoSpeech corpus [7] using random indexing (RI) [8] on the training corpus expanded with paraphrases. Using the cosine measure as similarity metrics, we then retrieve for any unknown word w, the word w' which is most similar to w and which appear in the training corpus.

For lexical disambiguation, two methods are compared. We use the POS tag provided by TreeTagger. In this case, disambiguation is syntactic only. Or we pick the synonym with highest probability based on a trigram language model trained on the H-H corpus [9].

5 Results and Discussion

Table 2 summarises the results obtained in four main configurations : (i) with and without paraphrases ; (ii) with and without synonym handling ; (iii) with and without lemmatisation ; and (iv) when combining lemmatisation with synonym handling. We also compare the results obtained when evaluating using 10-fold cross validation on the training data (H-H dialogs) vs. evaluating the performance of the system on H-C interactions.

Overall Impact The largest performance gain is obtained by a combination of the three techniques explored in this paper namely, data expansion, synonym handling and lemmatisation (+8.9 points for the cross-validation experiment and +2.3 for the H-C evaluation).

Impact of Lexical Substitution at Run Time Because of space restrictions, we do not report here the results obtained using lexical resources without lemmatisation. However, we found that lexical resources are only useful when combined with lemmatisation. This is unsurprising since synonym dictionaries and EuroWordNet only contain lemmas. Indeed when distributional neighbours are used, lemmatisation has little impact (e.g., 65.11% using distributional neighbours without lemmatisation on the H-H corpus without paraphrases vs. 66.41% when using lemmatisation).

Another important issue when searching for a word synonym concerns lexical disambiguation : the synonym used to replace an unknown word should capture the meaning of that word in its given context. We tried using a language model trained on the training corpus to choose between synonym candidates (i.e., selecting the synonym yielding the highest sentence probability when substituting that synonym for the unknown word) but did not obtain a significant improvement. In contrast, it is noticeable that synonym handling has a higher impact when using EuroWordNet as a lexical resource. Since EuroWordNet contain categorial information while the synonym dictionaries we used do not, this suggests that the categorial disambiguation provided by TreeTagger helps identifying an appropriate synonym in EuroWordNet.

Finally, it is clear that the lexical resources used for this experiment are limited in coverage and quality. We observed in particular that some words which are very frequent in the training data (and thus which could be used to replace unknown words) do not occur in the synonym dictionaries. For instance when using paraphrases and dictionaries (fourth row and

5. A word is determined to be a well-formed French word if it occurs in the LEFFF dictionary, a large-scale morphological and syntactic lexicon for French (Sagot, 2010)

6. DICOSYN (http ://elsap1.unicaen.fr/dicosyn.html).

7. We also used distributional semantics from the Gigaword corpus but the results were poor probably because of the very different text genre and domains between the the Gigaword and the MP game.

8. Topics are Dialog acts while documents are utterances ; we used the S-Space Package `http://code.google.com/p/airhead-research/wiki/RandomIndexing`

9. We used SRILM (`http://www.speech.sri.com/projects/srilm`)

TABLE 2: Accuracy on the H-H and on the H-C corpus. The star denotes statistical significance with the Wilcoxon test ($p < 0.005$) used for the HH corpus and the McNemar test ($p < 0.005$) for the HC corpus.

fourth column in Table 2) 50% of the unknown words were solved, 17% were illformed and 33% remained unsolved. To compensate this deficiency, we tried combining the three lexical resources in various ways (taking the union or combining them in a pipeline using the first resource that would yield a synonym). However the results did not improve and even in some cases worsened due probably to the insufficient lexical disambiguation. Interestingly, the results show that paraphrases always improves synonym handling presumably because it increases the size of the known vocabulary thereby increasing the possibility of finding a known synonym.

In sum, synonym handling helps most when (i) words are lemmatised and (ii) unknown words can be at least partially (i.e., using POS tag information) disambiguated. Moreover since data expansion increases the set of known words available as potential synonyms for unknown words, combining synonym handling with data expansion further improves accuracy.

Impact of Lemmatisation When evaluating using cross validation on the training corpus, lemmatisation increases accuracy by up to 3.42 points indicating that unseen word forms negatively impact accuracy. Noticeably however, lemmatisation has no significant impact when evaluating on the H-C corpus. This in turn suggests that the lower accuracy obtained on the H-C corpus results not from unseen word forms but from unseen lemmas.

Impact of Paraphrases On the H-H corpus, data expansion has no significant impact when used alone. However it yields an increase of up to 8.27 points and in fact, has a statistically significant impact, for all configurations involving lemmatisation. Thus, data expansion is best used in combination with lemmatisation and their combination permits creating better, more balanced and more general training data. On the H-C corpus however, the impact is negative or insignificant suggesting that the decrease in performance on the H-C corpus is due to content words that are new with respect to the training data i.e., content words for which neither a synonym nor a lemma can be found in the expanded training data.

Conclusion

While classifiers are routinely trained on dialog data to model the dialog management process, the impact of such basic factors as lemmatisation, automatic data expansion and synonym handling has remained largely unexplored. The empirical evaluation described here suggests that each of these factors can help improve performance but that the impact will vary depending on their combination and on the evaluation mode. Combining all three techniques yields the best results. We conjecture that there are two main reasons for this. First, synonym handling is best used in combination with POS tagging and lemmatisation because these supports partial lexical semantic disambiguation. Second, data expansion permits expanding the set of known words thereby increasing the possibility of finding a known synonym to replace an unknown word with.

Abstract

Recognizing bridging anaphora is difficult due to the wide variation within the phenomenon, the resulting lack of easily identifiable surface markers and their relative rarity. We develop linguistically motivated discourse structure, lexico-semantic and genericity detection features and integrate these into a cascaded minority preference algorithm that models bridging recognition as a subtask of learning fine-grained information status (IS). We substantially improve bridging recognition without impairing performance on other IS classes.

1 Introduction

In *bridging* or *associative anaphora* (Clark, 1975; Prince, 1981; Gundel et al., 1993), the antecedent and anaphor are not coreferent but are linked via a variety of contiguity relations.[1] In Example 1, the phrases *a resident*, *the stairs* and *the lobby* are bridging anaphors with the antecedent *One building*.[2]

(1) *One building* was upgraded to red status while people were taking things out, and **a resident** called up **the stairs** to his girlfriend, telling her to keep sending things down to **the lobby**.

Bridging is an important problem as it affects linguistic theory and applications alike. For example, without bridging resolution, entity coherence between the first and second coordinated clause in Example 1 cannot be established. This is a problem both for coherence theories such as Centering (Grosz et al., 1995) (where bridging is therefore incorporated as an indirect realization of previous entities) as well as applications relying on entity coherence modelling, such as readability assessment or sentence ordering (Barzilay and Lapata, 2008).

Full bridging resolution needs (i) recognition that a bridging anaphor is present and (ii) identification of the antecedent and contiguity relation. In recent work, these two tasks have been tackled separately, with bridging recognition handled as part of information status (IS) classification (Markert et al., 2012; Cahill and Riester, 2012; Rahman and Ng, 2012). Each mention in a text gets assigned one IS class that describes its accessibility to the reader at a given point in a text, bridging being one possible class. We stay within this framework.

Bridging recognition is a difficult task, so that we had to report very low results on this IS class in previous work (Markert et al., 2012). This is due to the phenomenon's variety, leading to a lack of clear surface features for recognition. Instead, we formulate in this paper novel discourse structure and lexico-semantic features as well as features that distinguish bridging from generics (see Section 3). In addition, making up between 5% and 20% of definite descriptions (Gardent and Manuélian, 2005; Caselli and Prodanof, 2006) and around 6% of all NPs (Markert et al., 2012), bridging is still less frequent than many other IS classes and recognition of minority classes is well known to be more difficult. We therefore use a cascaded classification algorithm to address this problem (Omuya et al., 2013).

[1]We exclude *comparative anaphora* where anaphor and antecedent are in a similarity/exclusion relation, indicated by anaphor modifiers such as *other* or *similar* (Modjeska et al., 2003).

[2]Examples are from OntoNotes (Weischedel et al., 2011). Bridging anaphora are set in boldface; antecedents in italics.

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 814–820,
Seattle, Washington, USA, 18-21 October 2013.

2 Related Work

Most bridging research concentrates on antecedent selection only (Poesio and Vieira, 1998; Poesio et al., 2004a; Markert et al., 2003; Lassalle and Denis, 2011; Hou et al., 2013), assuming that bridging recognition has already been performed. Previous work on recognition is either limited to definite NPs based on heuristics evaluated on small datasets (Hahn et al., 1996; Vieira and Poesio, 2000), or models it as a subtask of learning fine-grained IS (Rahman and Ng, 2012; Markert et al., 2012; Cahill and Riester, 2012). Results within this latter framework for bridging have been mixed: We reported in Markert et al. (2012) low results for bridging in written news text whereas Rahman and Ng (2012) report high results for the four subcategories of bridging annotated in the Switchboard dialogue corpus by Nissim et al. (2004). We believe this discrepancy to be due to differences in corpus size and genre as well as in bridging definition. Bridging in Switchboard includes non-anaphoric, syntactically linked part-of and set-member relationships (such as *the building's lobby*), as well as comparative anaphora, the latter being marked by surface indicators such as *other, another etc*. Both types are much easier to identify than anaphoric bridging cases.[3] In addition, many non-anaphoric lexical cohesion cases have been annotated as bridging in Switchbard as well.

We also separate bridging recognition and antecedent selection. One could argue that a joint model is more attractive as potential antecedents such as *building* "trigger" subsequent bridging cases such as *stairs* (Example 1). However, bridging can be indicated by referential patterns without world knowledge about the anaphor/antecedent NPs, as the nonsense example 2 shows: *the wug* is clearly a bridging anaphor although we do not know the antecedent.[4]

(2) The blicket couldn't be connected to the dax. **The wug** failed.

Similarly, Clark (1975) distinguishes between bridging via necessary, probable and inducible parts/roles and argues that only in the first and maybe the second case the antecedent triggers the bridging anaphor in the sense that we already spontaneously think of the anaphor when we read the antecedent. Also, bridging recognition on its own can be valuable for applications: for example, prosody is influenced by IS status without needing antecedent knowledge (Baumann and Riester, 2013).

[3] See also the high results for our specific category for comparative anaphora (Markert et al., 2012).

[4] We thank an anonymous reviewer for pointing this out.

3 Characterizing Bridging Anaphora for Automatic Recognition

3.1 Properties of bridging anaphora

Bridging anaphors are rarely marked by surface features. Indeed, even the common practice (Vieira and Poesio, 2000; Lassalle and Denis, 2011; Cahill and Riester, 2012) to limit bridging to definite NPs does not seem to be correct: We report in previous work (Hou et al., 2013) that less than 40% of the bridging anaphora in our corpus are definites. Instead, bridging is diverse with regard to syntactic form and function: bridging anaphora can be definite NPs (Examples 4 and 6), indefinite NPs (Example 5) or bare NPs (Examples 3, 8 and 9). The only frequent syntactic property shared is that bridging NPs tend to have a simple internal structure with regards to modification. Bridging is also easily confused with generics: *friends* is used as bridging anaphor in Example 9 but generically in Example 10.

(3) . . . *meat* . . . The Communists froze **prices** instead.

(4) . . . *the fund's building* . . . **The budget** was only $400,000.

(5) . . . *employees* . . . **A food caterer** stashed stones in the false bottom of a milk pail.

(6) . . . *his truck* . . . The farmer at **the next truck** shouts, "Wheat!"

(7) . . . *the firms* . . . Crime was the reason that **26%** reported difficulty recruiting personnel and that **19%** said they were considering moving.

(8) . . . *the company* . . . His father was **chairman** and **chief executive** until his death in an accident five years ago.

(9) . . . *Josephine Baker* . . . **Friends** pitched in.

(10) Friends are part of the glue that holds life and faith together.

Bridging anaphora can have almost limitless variation. However, we observe that bridging anaphors are often licensed because of discourse structure

and/or lexical or world knowledge. With regard to discourse structure, Grosz et al. (1995) observe that bridging is often needed to establish entity coherence between two adjacent sentences (Examples 1, 2, 4, 5, 6, 7 and 9). With regard to lexical and world knowledge, relational noun phrases (Examples 3, 4, 8 and 9), building parts (Example 1), set membership elements (Example 7), or, more rarely, temporal/spatial modification (Example 6) may favor a bridging reading. Motivated by these observations, we develop discourse structure and lexico-semantic features indicating bridging anaphora as well as features designed to separate genericity from bridging.

3.2 Features

In Markert et al. (2012) we classify eight fine-grained IS categories for NPs in written text: *old*, *new* and 6 *mediated* categories (*syntactic*, *worldKnowledge*, *bridging*, *comparative*, *aggregate* and *function*). This feature set (Table 1, $f1$-$f13$) works well to identify *old*, *new* and several *mediated* categories. However, it fails to recognize most bridging anaphora which we try to remedy in this work by including more diverse features.

Discourse structure features (Table 2, $f1$-$f3$). Bridging occurs frequently in sentences where otherwise there would no entity coherence to previous sentences/clauses (see Grosz et al. (1995) and Poesio et al. (2004b) for discussions about bridging, entity coherence and centering transitions in the Centering framework). This is especially true for *topic* NPs (Halliday and Hasan, 1976) in such sentences.

We follow these insights by identifying coherence gap sentences (see Examples 1, 4, 5, 6, 7, 9 and also 2): a sentence has a coherence gap ($f1$) if it has none of the following three coherence elements: (1) entity coreference to previous sentences, as approximated via string match or presence of pronouns, (2) comparative anaphora approximated by mentions modified via a small set of comparative markers (see also Table 1, $f10$ *PreModByCompMarker*), or (3) proper names. We approximate the topic of a sentence via the first mention ($f2$).

$f3$ models that bridging anaphors do not appear at the beginning of a text.

Semantic features (Table 2, $f4$-$f10$). In contrast to generic patterns, our semantic features capture lexical properties of nouns that make them more likely to be the head of a bridging NP. We create $f4$-$f8$ to capture four kinds of bridging anaphora.

Löbner (1985) distinguishes between relational nouns that take on at least one obligatory semantic role (such as *friend*) and sortal nouns. It is likely that relational nouns are more frequently used as bridging than sortal nouns (see Examples 3, 4, 8 and 9). We extract a list containing around 4,000 relational nouns from WordNet and a list containing around 500 nouns that specify professional roles from the General Inquirer lexicon (Stone et al., 1966), then determine whether the NP head appears in these lists

or not ($f4$ and $f5$). The obligatory semantic role for a relational noun can of course also be filled NP internally instead of anaphorically and we use the features $f10$ (for instances such as *the Egyptian president*) and $f18$ (for complex NPs that are likely to fill needed roles NP internally) to address this.

Because part-of relations are typical bridging relations (see Example 1 and Clark (1975)), we use $f6$ to determine whether the NP is a part of the building or not, using again a list extracted from Inquirer.

$f7$ is used to identify set membership bridging cases (see Example 7), by checking whether the NP head is a number or indefinite pronoun (such as *none*, *one*, *some*) or modified by *each, one*. However, not all numbers are bridging cases (such as *1976*) and we use $f9$ to exclude such cases.

Lassalle and Denis (2011) note that some bridging anaphors are indicated by spatial or temporal modifications (see Example 6). We use $f8$ to detect this by compiling 20 such adjectives from Inquirer.

Features to detect generic nouns (Table 2, $f11$-$f15$). Generic NPs (Example 10) are easily confused with bridging anaphora. Inspired by Reiter and Frank (2010) who build on linguistic research, we develop features ($f11$-$f15$) to exclude generics.

First, hypothetical entities are likely to refer to generic entities (Mitchell et al., 2002), We approximate this by determining whether the NP appears in an if-clause ($f11$). Also the clause tense and mood may play a role to decide genericity (Reiter and Frank, 2010). This is often reflected by the main verb of a clause, so we extract its POS tag ($f12$).

Some NPs are commonly used generically, such as *children*, *men*, or *the dollar*. The ACE-2 corpus (distinct from our corpus) contains generic annotation . We collect all NPs from ACE-2 that are always used generically ($f13$). We also try to learn NPs that are uniquely identifiable without further description or anaphoric links such as *the sun* or *the pope*. We do this by extracting common nouns which are annotated as *worldKnowledge* from the training part of our corpus[5] and use these as lexical features ($f14$).

Finally, motivated by the ACE-2 annotation guidelines, we identify six quantifiers that may indicate genericity, such as *all*, *no*, *neither* ($f15$).

[5]This list varies for each run of our algorithm in 10-fold cross validation.

Other features for bridging (Table 2, $f16$-$f18$). Following Rahman and Ng (2012), we use unigrams ($f16$). We also extract heads of bridging anaphors from the training data as lexical features ($f17$) to learn typical nouns used for bridging that we did not cover in lexicon extraction ($f4$ to $f6$).

Feature $f18$ models that bridging anaphora most often have a simple internal structure and usually do not contain any other NPs.

Features for other IS categories (Table 2, $f19$-$f21$). We propose three features to improve other IS categories. In the relational feature $f19$, we separate coordination parent-child from other parent-child relations to help with the class *aggregate*. $f20$ determines whether a number is the object of an increase/decrease verb (using a list extracted from Inquirer) and therefore likely to be the IS class *function*. Frequent proper names are more likely to be hearer old and hence of the class *worldKnowledge*. $f21$ extracts proper names that occur in at least 100 documents in the Tipster corpus to approximate this.

4 Experiments and Results

Experimental setup. We perform experiments on the corpus provided in Markert et al. (2012)[6]. It consists of 50 texts taken from the WSJ portion of the OntoNotes corpus (Weischedel et al., 2011) with almost 11,000 NPs annotated for information status including 663 bridging NPs and their antecedents. All experiments are performed via 10-fold cross-validation on documents. We use gold standard mentions and the OntoNotes named entity and syntactic annotation layers for feature extraction.

Reimplemented baseline system (*rbls*). *rbls* uses the same features as Markert et al. (2012) (Table 1) but replaces the local decision tree classifier with LibSVM as we will need to include lexical features.

rbls + Table 2 feature set (*rbls*+*newfeat*). Based on *rbls*, all the new features from Table 2 are added.

Cascading minority preference system (*cmps*). Minority classes such as bridging suffer during standard multi-class classification. Inspired by Omuya

Table 3: Experimental results

et al. (2013), we develop a cascading minority preference system for fine-grained IS classification. For the five minority classes (*function*, *aggregate*, *comparative*, *bridging* and *worldKnowledge*) that each make up less than the expected $\frac{1}{8}$ of the data set, we develop five binary classifiers with LibSVM[7] using all features from Tables 1 and 2 and apply them in order from rarest to more frequent category. Whenever a minority classifier predicts true, this class is assigned. When all minority classifiers say false, we back off to the multiclass *rbls+newfeat* system.

cmps − Table 2 feature set (*cmps−newfeat*). To test the effect of using the minority preference system without additional features, we employ a *cmps* system with baseline features from Table 1 only.

Results and Discussion (Table 3). Our novel features in *rbls+newfeat* show improvements for *worldKnowledge*, *aggregate* and *function* as well as *bridging* categories compared to both baseline systems, although the performance for *bridging* is still low. In addition, the overall accuracy is significantly better than the two baseline systems (at the level of 1% using McNemar's test). Using the cascaded minority preference system *cmps* in addition improves bridging results substantially while the performance on other categories does not worsen. The algorithm needs both our novel feature classes as well as cascaded modelling to achieve this improvement as the comparison to *cmps−newfeat* shows: the latter lowers overall accuracy as it tends to overgenerate rare classes (including bridging) with low precision if the features are not strong enough. Our novel features (addressing linguistic properties of bridging) and the cascaded algorithm (addressing data sparseness) appear to be complementary.

To look at the impact of features in our best system, we performed an ablation study. Lexical features as well as semantic ones have the most impact. Discourse structure and genericity information features have less of an impact. We believe the latter to be due to noise involved in extracting these features (such as approximating coreference for the coherence gap feature) as well as genericity recognition still being in its infancy (Reiter and Frank, 2010).

5 Conclusions

This paper aims to recognize bridging anaphora in written text. We develop *discourse structure*, *lexico-semantic* and *genericity* features based on linguistic intuition and corpus research. By using a cascading minority preference system, we show that our approach outperforms the bridging recognition in Markert et al. (2012) by a large margin without impairing the performance on other IS classes.

A synchronous context free grammar for time normalization

Steven Bethard
University of Alabama at Birmingham
Birmingham, Alabama, USA
bethard@cis.uab.edu

Abstract

We present an approach to time normalization (e.g. *the day before yesterday*⇒2013-04-12) based on a synchronous context free grammar. Synchronous rules map the source language to formally defined operators for manipulating times (FINDENCLOSED, STARTATENDOF, etc.). Time expressions are then parsed using an extended CYK+ algorithm, and converted to a normalized form by applying the operators recursively. For evaluation, a small set of synchronous rules for English time expressions were developed. Our model outperforms HeidelTime, the best time normalization system in TempEval 2013, on four different time normalization corpora.

1 Introduction

Time normalization is the task of converting a natural language expression of time into a formal representation of a time on a timeline. For example, the expression *the day before yesterday* would be normalized to the formal representation 2013-04-12 (assuming that today is 2013-04-14) in the ISO-TimeML representation language (Pustejovsky et al., 2010). Time normalization is a crucial part of almost any information extraction task that needs to place entities or events along a timeline. And research into methods for time normalization has been growing since the ACE[1] and TempEval (Verhagen et al., 2010; UzZaman et al., 2013) challenges began to include time normalization as a shared task.

[1] http://www.itl.nist.gov/iad/mig/tests/ace/

Most prior work on time normalization has taken a rule-based, string-to-string translation approach. That is, each word in a time expression is looked up in a normalization lexicon, and then rules map this sequence of lexical entries directly to the normalized form. HeidelTime (Strötgen and Gertz, 2012), which had the highest performance in TempEval 2010 and 2013, and TIMEN (Llorens et al., 2012), which reported slightly higher performance in its own experiments, both follow this approach. A drawback of this approach though is that there is no nesting of rules: for example, in HeidelTime the rules for *yesterday* and *the day before yesterday* are completely separate, despite the compositional nature of the latter.

A notable exception to the string-to-string approach is the work of (Angeli et al., 2012). They define a target grammar of typed pre-terminals, such as YESTERDAY (a SEQUENCE) or DAY (a DURATION), and compositional operations, such as SHIFTLEFT (a (RANGE, DURATION) → RANGE). They apply an expectation-maximization approach to learn how words align to elements of the target grammar, and achieve performance close to that of the rule-based systems. However, their grammar does not allow for non-binary or partially lexicalized rules (e.g. SEQUENCE → DURATION *before* SEQUENCE would be impossible), and some of their primitive elements could naturally be expressed using other primitives (e.g. YESTERDAY as SHIFTLEFT(TODAY, 1 DAY)).

We present a synchronous grammar for time normalization that addresses these shortcomings. We first define a grammar of formal operations over temporal elements. We then develop synchronous rules that map time expression words to temporal opera-

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 821–826,
Seattle, Washington, USA, 18-21 October 2013.

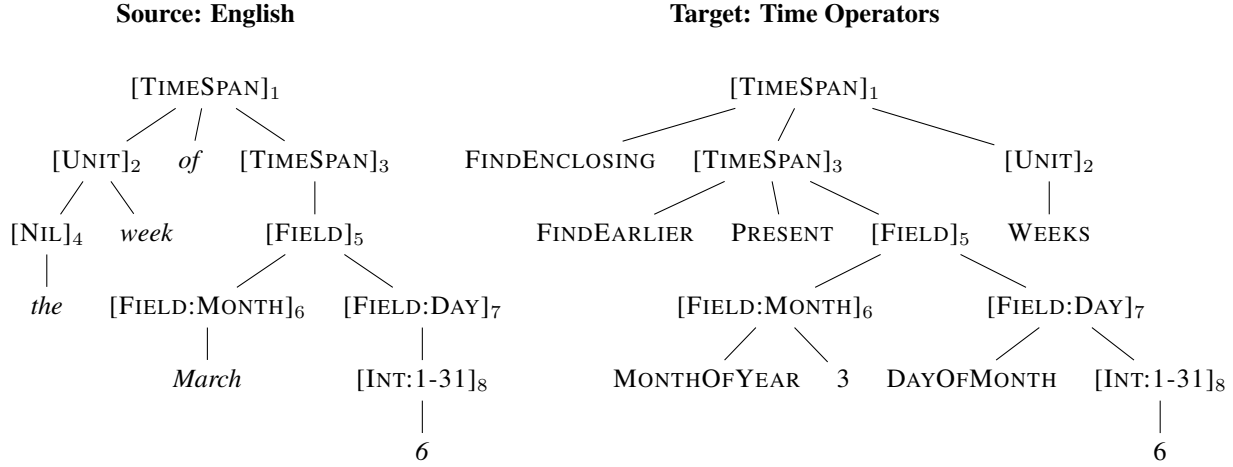

Figure 1: The synchronous parse from the source language *the week of March 6* to the target formal time representation FINDENCLOSING(FINDEARLIER(PRESENT, MONTHOFYEAR→3, DAYOFMONTH→6), WEEKS). Subscripts on non-terminals indicate the alignment between the source and target parses.

tors, and perform normalization by parsing with an extended CYK+ parsing algorithm. We evaluate this approach to time normalization on the TimeBank, AQUAINT, Timen and TempEval 2013 corpora.

2 Synchronous grammars

Our time grammar is based on the synchronous context free grammar formalism. Synchronous grammars allow two trees, one in the source language and one in the target language, to be constructed simultaneously. A synchronous context free grammar has rules of the form $X \rightarrow (\mathbf{S}, \mathbf{T}, A)$, where X is a non-terminal, $\mathbf{S}$ is the sequence of terminals and non-terminals that X expands to in the source language, $\mathbf{T}$ is the sequence of terminals and non-terminals that X expands to in the target language, and A is the alignment between the non-terminals of $\mathbf{S}$ and $\mathbf{T}$ (which must be the same).

For time normalization, the source side is the natural language text, and the target side is a formal grammar of temporal operators. Figure 1 shows a synchronous parse of *the week of March 6* [2]. The left side is the source side (an English expression), the right side is the target side (a temporal operator expression), and the alignment is shown via subscripts.

[2]Figure 1 corresponds to an interpretation along the lines of *the week of the last March 6*. The full grammar developed in this article would also produce an interpretation corresponding to *the week of the next March 6*, since the phrase is ambiguous.

3 Target time grammar

The right side of Figure 1 shows an example of our target formal representation: FINDENCLOSING(FINDEARLIER(PRESENT, MONTHOFYEAR→3, DAYOFMONTH→6), WEEKS). Each terminal in the parse is either a numeric value or an operator like FINDENCLOSING, WEEKS or MONTHOFYEAR. Each non-terminal combines terminals or non-terminals to create a [TIMESPAN], [PERIOD], [FIELD], [UNIT] or [INT]. The list of rules allowed by our target grammar (the right-hand side of our synchronous grammar) is given in Table 1.

Each of the target operators defines a procedure for creating a temporal object from others. For example, FINDENCLOSING takes a [TIMESPAN] and a [UNIT] and expands the start and end of the time span to fill a period of one unit. This could be used, for example, to define *today* as FINDENCLOSING(PRESENT, DAYS), where the PRESENT, which is instantaneous, is expanded out to the enclosing day. Note that we define things like *today* and *yesterday* in terms of primitive operations, rather than making them primitives themselves as in (Angeli et al., 2012).

The left side of Figure 1 shows the synchronous parse of the source language. Note that each of the non-terminals is aligned (shown as a subscript) with a non-terminal in the target parse[3], while terminals are not aligned and may freely appear or disappear

[3]We actually allow a slightly asynchronous grammar, where a non-terminal may be used 0 or more times on the target side.

[INT]	→	integer
[UNIT]	→	unit
[FIELD]	→	field [INT]
[FIELD]	→	[FIELD]*
[PERIOD]	→	SIMPLE [INT] [UNIT]
[PERIOD]	→	FRACTIONAL [INT] [INT] [UNIT]
[PERIOD]	→	UNSPECIFIED [UNIT]
[PERIOD]	→	WITHMODIFIER [PERIOD] modifier
[TIMESPAN]	→	PAST
[TIMESPAN]	→	PRESENT
[TIMESPAN]	→	FUTURE
[TIMESPAN]	→	FINDEARLIER [TIMESPAN] [FIELD]
[TIMESPAN]	→	FINDLATER [TIMESPAN] [FIELD]
[TIMESPAN]	→	FINDENCLOSING [TIMESPAN] [UNIT]
[TIMESPAN]	→	FINDENCLOSED [TIMESPAN] [FIELD]
[TIMESPAN]	→	STARTATENDOF [TIMESPAN] [PERIOD]
[TIMESPAN]	→	ENDATSTARTOF [TIMESPAN] [PERIOD]
[TIMESPAN]	→	MOVEEARLIER [TIMESPAN] [PERIOD]
[TIMESPAN]	→	MOVELATER [TIMESPAN] [PERIOD]
[TIMESPAN]	→	WITHMODIFIER [TIMESPAN] modifier

Table 1: Rules allowed by the target time grammar. A "unit" is any `java.time.temporal.TemporalUnit`, e.g. SECONDS, WEEKS or DECADES. A "field" is any `java.time.temporal.TemporalField`, e.g. HOUROFAMPM, DAYOFMONTH or CENTURY. A "modifier" is any of the TIMEX3 "mod" values defined in TimeML.

from the source to the target. Each non-terminal thus corresponds to a synchronous grammar rule that describes how a source expression should be translated into the target time grammar. For example the root nodes correspond to an application of the following full synchronous rule:

[TIMESPAN] →
source: [UNIT] *of* [TIMESPAN]
target: FINDENCLOSING [TIMESPAN] [UNIT]

4 Parsing algorithm

Parsing with a synchronous context free grammar is much the same as parsing with just the source side of the grammar. Only a small amount of bookkeeping is necessary to allow the generation of the target parse once the source parse is complete. We can therefore apply standard parsing algorithms to this task.

However, we have some additional grammar requirements. As shown in Figure 1, we allow rules that expand into more than two terminals or non-terminals, the mixing of terminals and non-terminals in a production, a special [NIL] non-terminal for the ignoring of words, and a special [INT] non-terminal that can match ranges of integers and does not require all possible integers to be manually listed in the grammar. This means that we can't directly use CYK parsing or even CYK+ parsing (Chappelier and Rajman, 1998), which allows rules that expand into more than two terminals or non-terminals, but does not meet our other requirements.

Algorithm 1 shows our extended version of CYK+ parsing. As with standard CYK+ parsing, two charts are filled, one for rules that have been completed (C) and one for rules that have been only partially advanced (P). All parses covering 1 terminal are completed first, then these are used to complete parses covering 2 terminals, etc. until all parses covering all terminals are complete.

Our extensions to the standard CYK+ parsing are as follows. To handle integers, we modify the initialization to generate new rules on the fly for any numeric terminals that fit the range of an [INT:X-Y] non-terminal in the grammar (starts at line 5). To allow mixing of terminals and non-terminals, we extend the initialization step to also produce partial parses (line 17), and extend the parse advancement step to allow advancing rules with terminals (starting at line 23). Finally, to handle [NIL] rules, which consume tokens but are not included in the final parse, we add a step where rules are allowed to advance, unchanged, past a [NIL] rule (starting at line 35).

5 Parsing example

As an example, consider parsing *the week of March 6* with the following source side grammar:

[NIL] → *the*
[UNIT] → *week*
[MONTH] → *March*
[DAY] → [INT:1-31]
[FIELD] → [MONTH][DAY]
[TIMESPAN] → [FIELD]
[TIMESPAN] → [UNIT] *of* [TIMESPAN]

First the algorithm handles the numeric special case, completing an [INT] parse for the token *6* at index 4:

$C_{(1,4)} \cup= [\text{INT:1-31}] \rightarrow 6$

Then it completes parses based on just the terminals:

$C_{(1,0)} \cup= [\text{NIL}] \rightarrow \textit{the}$
$C_{(1,1)} \cup= [\text{UNIT}] \rightarrow \textit{week}$
$C_{(1,3)} \cup= [\text{MONTH}] \rightarrow \textit{March}$

Next, the algorithm starts working on parses that span 1 token. It can start two partial parses, using the [UNIT] at $C_{(1,1)}$, and using the [MONTH] at $C_{(1,3)}$:

$P_{(1,1)} \cup= [\text{TIMESPAN}] \rightarrow [\text{UNIT}] \bullet \textit{of}\ [\text{TIMESPAN}]$
$P_{(1,3)} \cup= [\text{FIELD}] \rightarrow [\text{MONTH}] \bullet [\text{DAY}]$

Algorithm 1 CYK+ parsing, extended for partially lexicalized rules, [Nil] rules and numbers

Require: G a set of rules, w a sequence of tokens

function PARSE(G, w)
  $C \leftarrow$ a new $|w|+1$ by $|w|$ matrix
  $P \leftarrow$ a new $|w|+1$ by $|w|$ matrix
  // Generate rules on the fly for numeric tokens
  for $i \leftarrow 0 \ldots (|w|-1)$ **do**
    if ISNUMBER(w_i) **then**
      for all [INT:x-y] $\in$ non-terminals of G **do**
        if $x \leq$ TONUMBER(w_i) $\leq y$ **then**
          $C_{(1,i)} \cup\!= [\text{INT:}x\text{-}y] \rightarrow w_i$
  // Start any rules that begin with terminals
  for $i \leftarrow 0 \ldots (|w|-1)$ **do**
    for all $\text{X} \rightarrow \alpha\beta \in G$ **do**
      if $\exists j \mid \alpha = w_{i:j} \wedge \neg$ISTERMINAL($\beta_0$) **then**
        if $\beta = \epsilon$ **then**
          $C_{(|w_{i:j}|,i)} \cup\!= \text{X} \rightarrow w_{i:j}\alpha$
        else
          $P_{(|w_{i:j}|,i)} \cup\!= (|w_{i:j}|, \text{X} \rightarrow w_{i:j}\alpha)$
  for $n \leftarrow 1 \ldots |w|; i \leftarrow 0 \ldots (|w|-n)$ **do**
    // Find all parses of size n starting at i
    for $m \leftarrow 1 \ldots n$ **do**
      for all $(p, \text{X} \rightarrow \alpha) \in P_{(m,i)}$ **do**
        // Advance partial parses using terminals
        if $w_{i+m:i+n} = \alpha_{p:p+n-m}$ **then**
          if $\alpha_{p+n-m:|\alpha|} = \epsilon$ **then**
            $C_{(n,i)} \cup\!= \text{X} \rightarrow \alpha$
          else
            $P_{(n,i)} \cup\!= (p+n-m, \text{X} \rightarrow \alpha)$
        // Advance partial parses using completes
        for all $\alpha_p \rightarrow \beta \in C_{(n-m,i+m)}$ **do**
          if $|\alpha| = p+1$ **then**
            $C_{(n,i)} \cup\!= \text{X} \rightarrow \alpha$
          else
            $P_{(n,i)} \cup\!= (p+1, \text{X} \rightarrow \alpha)$
      // Advance complete parses past [Nil] parses
      for all $\text{X} \rightarrow \alpha \in C_{(m,i)}$ **do**
        for all $\text{Y} \rightarrow \beta \in C_{(n-m,i+m)}$ **do**
          if $\text{X} \neq$ Nil $\wedge$ Y $=$ Nil **then**
            $C_{(n,i)} \cup\!= \text{X} \rightarrow \alpha$
          else if X $=$ Nil $\wedge$ $\text{Y} \neq$ Nil **then**
            $C_{(n,i)} \cup\!= \text{Y} \rightarrow \beta$
    // Start any rules that begin with a complete parse
    for all $\text{X} \rightarrow \alpha \in C_{(n,i)}$ **do**
      for all $\text{Y} \rightarrow \text{X}\alpha \in C_{(n,i)}$ **do**
        if $\alpha = \epsilon$ **then**
          $C_{(n,i)} \cup\!= \text{Y} \rightarrow \text{X}\alpha$
        else
          $P_{(n,i)} \cup\!= (1, \text{Y} \rightarrow \text{X}\alpha)$
  return $C_{(|w|,0)}$

(The • is the visual equivalent of the first element in the partial parse tuples of Algorithm 1, which marks parsing progress.) And given the [INT:1-31] at $C_{(1,4)}$ the algorithm can make a complete size 1 parse:

$C_{(1,4)} \cup\!=$ [DAY] $\rightarrow$ [INT:1-31]

The algorithm then moves on to create parses that span 2 tokens. The special handling of [NIL] allows the [UNIT] at $C_{(1,1)}$ to absorb the [NIL] at $C_{(1,0)}$:

$C_{(2,0)} \cup\!=$ [UNIT] $\rightarrow$ *week*

This [UNIT] then allows the start of a partial parse:

$P_{(2,0)} \cup\!=$ [TIMESPAN] $\rightarrow$ [UNIT] • *of* [TIMESPAN]

The partial parse at $P_{(1,1)}$ can be advanced using *of* at position 2, creating another 2 token partial parse:

$P_{(2,1)} \cup\!=$ [TIMESPAN] $\rightarrow$ [UNIT] *of* • [TIMESPAN])

The partial parse at $P_{(1,3)}$ can be advanced using the [DAY] at $C_{(1,4)}$, completing the 2 token parse:

$C_{(2,3)} \cup\!=$ [FIELD] $\rightarrow$ [MONTH][DAY]

This [FIELD] allows completion of a 2 token parse:

$C_{(2,3)} \cup\!=$ [TIMESPAN] $\rightarrow$ [FIELD]

The algorithm then moves on to 3 token parses. Only one is possible: the partial parse at $P_{(2,0)}$ can be advanced using the *of* at position 2, yielding:

$P_{(3,0)} \cup\!=$ [TIMESPAN] $\rightarrow$ [UNIT] *of* • [TIMESPAN]

The algorithm moves on to 4 token parses, finding that the partial parse at $P_{(2,1)}$ can be advanced using the [TIMESPAN] at $C_{(2,3)}$, completing the parse:

$C_{(4,1)} \cup\!=$ [TIMESPAN] $\rightarrow$ [UNIT] *of* [TIMESPAN]

Finally, the algorithm moves on to 5 token parses, where (1) the special handling of [NIL] allows the partial parse at $C_{(4,1)}$ to consume the [NIL] at $C_{(1,0)}$ and (2) the partial parse at $P_{(3,0)}$ can be advanced using the [TIMESPAN] at $C_{(2,3)}$. Both of these yield:

$C_{(5,0)} \cup\!=$ [TIMESPAN] $\rightarrow$ [UNIT] *of* [TIMESPAN]

The complete parses in $C_{(5,0)}$ are then deterministically translated into target side parses using the alignments in the rules of the synchronous grammar.

6 Evaluation

Using our synchronous grammar formalism for time normalization, we manually developed a grammar for English time expressions. Following the lead of TIMEN and HeidelTime, we developed our grammar by inspecting examples from the AQUAINT[4] and

[4] http://www.ldc.upenn.edu/Catalog/catalogEntry.jsp?catalogId=LDC2002T31

	N	TIMEN	HeidelTime	SCFG
AQUAINT	652	69.5	74.7	**76.5**
TimeBank	1426	67.7	80.9	**84.9**
Timen	214	**67.8**	49.1	56.5
TempEval2013	158	74.1	78.5	**81.6**

Table 2: Performance of TIMEN, HeidelTime and our synchronous context free grammar (SCFG) on each evaluation corpus. (N is the number of time expressions.)

TimeBank (Pustejovsky et al., 2003) corpora. The resulting grammar has 354 rules, 192 of which are only lexical, e.g., [UNIT] → (*seconds*, SECONDS).

Our grammar produces multiple parses when the input is ambiguous. For example, the expression *Monday* could mean either the previous Monday or the following Monday, and the expression *the day* could refer either to a period of one day, or to a specific day in time, e.g. 2013-04-14. For such expressions, our grammar produces both parses. To choose between the two, we employ a very simple set of heuristics: (1) prefer [TIMESPAN] to [PERIOD], (2) prefer an earlier [TIMESPAN] to a later one and (3) prefer a [TIMESPAN] with QUARTERS granularity if the anchor time is also in QUARTERS (this is a common rule in TimeBank annotations).

We evaluate on the AQUAINT corpus, the TimeBank corpus, the Timen corpus (Llorens et al., 2012) and the TempEval 2013 test set (UzZaman et al., 2013)[5]. We compare to two[6] state-of-the-art systems: TIMEN and HeidelTime. Table 2 shows the results. Our synchronous grammar approach outperformed HeidelTime on all corpora, both on the training corpora (AQUAINT and TimeBank) and on the test corpora (Timen and TempEval 2013). Both our model and HeidelTime outperformed TIMEN on all corpora except for the Timen corpus.

To better understand the issues in the Timen corpus, we manually inspected the 33 time expressions that TIMEN normalized correctly and our approach normalized incorrectly. 4 errors were places where our heuristic was wrong (e.g. we chose the earlier, not the later *Sept. 22*). 6 errors were coverage problems of our grammar, e.g. not handling *season*, *every time* or *long ago*. 2 errors were actually human annotation errors (*several years ago* was annotated as PASTREF and *daily* was annotated as XXXX-XX-XX, while the guidelines say these should be PXY and P1D respectively). The remaining 21 errors were from two new normalization forms not present at all in the training data: 19 instances of THH:MM:SS (times were always YYYY-MM-DDTHH:MM:SS in the training data) and 2 instances of BCYYYY (years were always YYYY in the training data).

7 Discussion

Our synchronous grammar approach to time normalization, which handles recursive structures better than existing string-to-string approaches and handles a wider variety of grammars than existing parsing approaches, outperforms the HeidelTime system on four evaluation corpora and outperforms the TIMEN system on three of the four corpora.

Our time normalization code and models are freely available. The source code and English grammar are hosted at `https://github.com/bethard/timenorm`, and official releases are published to Maven Central (group=`info.bethard`, artifact=`timenorm`).

In future work, we plan to replace the heuristic for selecting between ambiguous parses with a more principled approach. It would be a simple extension to support a probabilistic grammar, as in (Angeli et al., 2012). But given an expression like *Monday*, it would still be impossible to decide whether it refers to the future or the past, since the surrounding context, e.g. tense of the governing verb, is needed for such a judgment. A more promising approach would be to train a classifier that selects between the ambiguous parses based on features of the surrounding context.

Acknowledgements

The project described was supported in part by Grant Number R01LM010090 from the National Library Of Medicine. The content is solely the responsibility of the authors and does not necessarily represent the official views of the National Library of Medicine or the National Institutes of Health.

[5]We evaluate normalization accuracy over all time expressions, not the F1 of both finding and normalizing expressions, so the numbers here are not directly comparable to those reported by the TempEval 2013 evaluation.

[6]Though its performance was slightly lower than HeidelTime, we also intended to compare to the (Angeli et al., 2012) system. Its authors graciously helped us get the code running, but to date all models we were able to train performed substantially worse than their reported results, so we do not compare to them here.

Abstract

The rise of "Big Data" analytics over unstructured text has led to renewed interest in information extraction (IE). We surveyed the landscape of IE technologies and identified a major disconnect between industry and academia: while rule-based IE dominates the commercial world, it is widely regarded as dead-end technology by the academia. We believe the disconnect stems from the way in which the two communities measure the benefits and costs of IE, as well as academia's perception that rule-based IE is devoid of research challenges. We make a case for the importance of rule-based IE to industry practitioners. We then lay out a research agenda in advancing the state-of-the-art in rule-based IE systems which we believe has the potential to bridge the gap between academic research and industry practice.

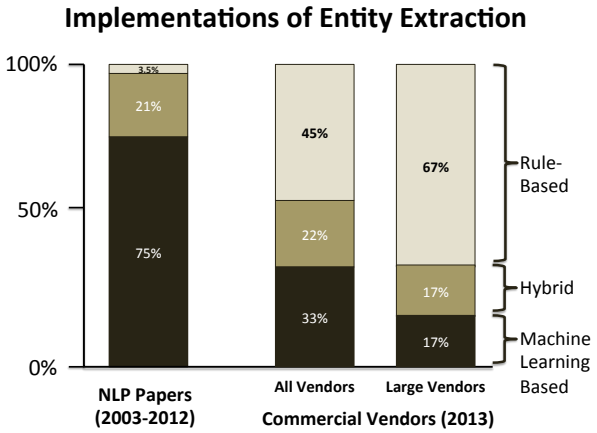

Figure 1: Fraction of NLP conference papers from EMNLP, ACL, and NAACL over 10 years that use machine learning versus rule-based techniques to perform entity extraction over text (left); the same breakdown for commercial entity extraction vendors one year after the end of this 10-year period (right). The rule-based approach, although largely ignored in the research community, dominates the commercial market.

1 Introduction

The recent growth of "Big Data" analytics over large quantities of unstructured text has led to increased interest in information extraction technologies from both academia and industry (Mendel, 2013).

Most recent academic research in this area starts from the assumption that statistical machine learning is the best approach to solving information extraction problems. Figure 1 shows empirical evidence of this trend drawn from a survey of recent published research papers. We examined the EMNLP, ACL, and NAACL conference proceedings from 2003 through 2012 and identified 177 different EMNLP research papers on the topic of entity extraction. We then classified these papers into three categories, based on the techniques used: purely rule-based, purely machine learning-based, or a hybrid of the two. We focus on entity extraction, as it is a classical IE task, and most industrial IE systems offer this feature.

The left side of the graph shows the breakdown of research papers according to this categorization. Only six papers relied solely on rules to perform the extraction tasks described. The remainder relied entirely or substantially on statistical techniques. As shown in Figure 2, these fractions were roughly constant across the 10-year period studied, indicating that attitudes regarding the relative importance of the different techniques have remained constant.

We found that distinguishing "hybrid" systems

Seattle, Washington, USA, 18-21 October 2013.

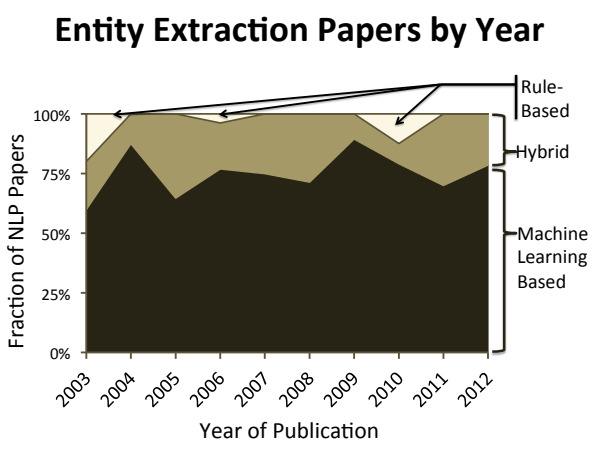

Figure 2: The conference paper data (left-hand bar) from Figure 1, broken down by year of publication. The relative fractions of the three different techniques have not changed significantly over time.

from pure machine learning systems was quite challenging. The papers that use a mixture of rule-based and machine learning techniques were generally written so as to obfuscate the use of rules, emphasizing the machine learning aspect of the work. Authors hid rules behind euphemisms such as "dependency restrictions" (Mausam et al., 2012), "entity type constraints" (Yao et al., 2011), or "seed dictionaries" (Putthividhya and Hu, 2011).

In the commercial world, the situation is largely reversed. The right side of Figure 1 shows the result of a parallel survey of commercial entity extraction products from 54 different vendors listed in (Yuen and Koehler-Kruener, 2012). We studied analyst reports and product literature, then classified each product according to the same three categories. Table 1 shows the 41 products considered in the study [1]. We conducted this industry survey in 2013, one year after the ten-year run of NLP papers we studied. One would expect the industrial landscape to reflect the research efforts of the previous 10 years, as mature technology moved from academia to industry. Instead, results of this second survey showed the opposite effect, with rule-based systems comprising the largest fraction of those surveyed. Only 1/3 of the vendors relied entirely on machine learning. Among public companies and private compa-

[1] Other products do not offer entity extraction, or we did not find sufficient evidence to classify the technology.

Table 2: Pros and Cons

	Pros	Cons
Rule-based	• Declarative • Easy to comprehend • Easy to maintain • Easy to incorporate domain knowledge • Easy to trace and fix the cause of errors	• Heuristic • Requires tedious manual labor
ML-based	• Trainable • Adaptable • Reduces manual effort	• Requires labeled data • Requires retraining for domain adaptation • Requires ML expertise to use or maintain • Opaque

nies with more than $100 million in revenue, the situation is even more skewed towards rule-based systems, with large vendors such as IBM, SAP, and Microsoft being completely rule-based.

2 Explaining the Disconnect

What is the source of this disconnect between research and industry? There does not appear to be a lack of interaction between the two communities. Indeed, many of the smaller companies we surveyed were founded by NLP researchers, and many of the larger vendors actively publish in the NLP literature. We believe that the disconnect arises from a difference in how the two communities measure the costs and benefits of information extraction.

Table 2 summarizes the pros and cons of machine learning (ML) and rule-based IE technologies (Atzmueller and Kluegl, 2008; Grimes, 2011; Leung et al., 2011; Feldman and Rosenfeld, 2006; Guo et al., 2006; Krishnan et al., 2005; Yakushiji et al., 2006; Kluegl et al., 2009). On the surface, both academia and commercial vendors acknowledge essentially the same pros and cons for the two approaches. However, the two communities weight the pros and cons significantly differently, leading to the drastic disconnect in Figure 1.

Evaluating the benefits of IE. Academic papers evaluate IE performance in terms of precision and recall over standard labeled data sets. This simple, clean, and objective measure is useful for judging competitions, but the reality of the business world is much more fluid and less well-defined.

In a business context, definitions of even basic entities like "product" and "revenue" vary widely from one company to another. Within any of these ill-defined categories, some entities are more important to get right than others. For example, in electronic legal discovery, correctly identifying names of executives is much more important than finding other types of person names.

In real-world applications, the output of extraction is often the input to a larger process, and it is the quality of the larger process that drives business value. This quality may derive from an aspect of extracted output that is only loosely correlated with overall precision and recall. For example, does extracted sentiment, when broken down and aggregated by product, produce an unbiased estimate of average sentiment polarity for each product?

To be useful in a business context, IE must function well with metrics that are ill-defined and subject to change. ML-based IE models, which require a careful up-front definition of the IE task, are poor fit for these metrics. The commercial world greatly values rule-based IE for its interpretability, which makes IE programs easier to adopt, understand, debug, and maintain in the face of changing requirements (Kluegl et al., 2009; Atzmueller and Kluegl, 2008). Furthermore, rule-based IE programs are valued for allowing one to easily incorporate domain knowledge, which is essential for targeting specific business problems (Grimes, 2011). As an example, an application may pose simple requirements to its entity recognition component to output only full person names, and not include salutation. With a rule-based system, such a requirement translates to removing a few rules. On the other hand, a ML-based approach requires a complete retrain.

Evaluating the costs of IE. In a business setting, the most significant costs of using information extraction are the *labor cost* of developing or adapting extractors for a particular business problem, and the *hardware cost* of compute resources required by the system.

NLP researchers generally have a well-developed sense of the labor cost of writing extraction rules, viewing this task as a "*tedious and time-consuming process*" that "*is not really practical*" (Yakushiji et al., 2006). These criticisms are valid, and, as we

point out in the next section, they motivate a research effort to build better languages and tools.

But there is a strong tendency in the NLP literature to ignore the complex and time-consuming tasks inherent in solving an extraction problem using machine learning. These tasks include: defining the business problem to be solved in strict mathematical terms; understanding the tradeoffs between different types of models in the context of the NLP task definition; performing feature engineering based on a solid working understanding of the chosen model; and gathering extensive labeled data — far more than is needed to measure precision and recall — often through clever automation.

All these steps are time-consuming; even highly-qualified workers with postgraduate degrees routinely fail to execute them effectively. Not surprisingly, in industry, ML-based systems are often deemed risky to adopt and difficult to understand and maintain, largely due to model opaqueness (Fry, 2011; Wagstaff, 2012; Malioutov and Varshney, 2013). The infeasibility of gathering labeled data in many real-world scenarios further increases the risk of committing to a ML-based solution.

A measure of the system's scalability and runtime efficiency, hardware costs are a function of two metrics: throughput and memory footprint. These figures, while extremely important for commercial vendors, are typically not reported in NLP literature. Nevertheless, our experience in practice suggests that ML-based approaches are much slower, and require more memory compared to rule-based approaches, whose throughput can be in the order of MB/second/core for complex extraction tasks like NER (Chiticariu et al., 2010).

The other explanation. Finally, we believe that the most notable reason behind the academic community's steering away from rule-based IE systems is the (false) perception of lack of research problems. The general attitude is one of *"What's the research in rule-based IE? Just go ahead and write the rules."* as indicated by anecdotal evidence and only implicitly stated in the literature, where any usage of rules is significantly underplayed as explained earlier. In the next section, we strive to debunk this perception.

3 Bridging the Gap

As NLP researchers who also work regularly with business customers, we have become increasingly worried about the gap in perception between information extraction research and industry. The recent growth of Big Data analytics has turned IE into big business (Mendel, 2013). If current trends continue, the business world will move ahead with unprincipled, ad-hoc solutions to customers' business problems, while researchers pursue ever more complex and impractical statistical approaches that become increasingly irrelevant. Eventually, the gap between research and practice will become insurmountable, an outcome in neither community's best interest.

The academic NLP community needs to stop treating rule-based IE as a dead-end technology. As discussed in Section 2, the domination of rule-based IE systems in the industry is well-justified. Even in their current form, with ad-hoc solutions built on techniques from the early 1980's, rule-based systems serve the industry needs better than the latest ML techniques. Nonetheless, there is an enormous untapped opportunity for researchers to make the rule-based approach more principled, effective, and efficient. In the remainder of this section, we lay out a research agenda centered around capturing this opportunity. Specifically, taking a systemic approach to rule-based IE, one can identify a set of research problems by separating rule development and deployment. In particular, we believe research should focus on: (a) data models and rule language, (b) systems research in rule evaluation and (c) machine learning research for learning problems in this richer target language.

Define standard IE rule language and data model. If research on rule-based IE is to move forward in a principled way, the community needs a standard way to express rules. We believe that the NLP community can replicate the success of the SQL language in connecting data management research and practice. SQL has been successful largely due to: (1) *expressivity*: the language provides all primitives required for performing basic manipulation of structured data, (2) *extensibility*: the language can be extended with new features without fundamental changes to the language, (3) *declarativity*: the language allows the specification of com-

putation logic without describing its control flow, thus allowing developers to code *what* the program should accomplish, rather than *how* to accomplish it.

An earlier attempt in late 1980's to formalize a rule language resulted in the Common Pattern Specification Language (CPSL) (Appelt and Onyshkevych, 1998). While CPSL did not succeed due to multiple drawbacks, including expressivity limitations, performance limitations, and its lack of support for core operations such as part of speech (Chiticariu et al., 2010), CPSL did gain some traction, e.g., it powers the JAPE language of the GATE open-source NLP system (Cunningham et al., 2011). Meanwhile, a number of declarative IE languages developed in the database community, including AQL (Chiticariu et al., 2010; Li et al., 2011), xLog (Shen et al., 2007), and SQL extensions (Wang et al., 2010; Jain et al., 2009), have shown that formalisms of rule-based IE systems are possible, as exemplified by (Fagin et al., 2013). However, they largely remain unknown in the NLP community.

We believe now is the right time to establish a standard IE rule language, drawing from existing proposals and experience over the past 30 years. Towards this goal, IE researchers need to answer the following questions: What is the right data model to capture text, annotations over text, and their properties? Can we establish a standard declarative extensible rule language for processing data in this model with a clear set of constructs that is sufficiently expressive to solve most IE tasks encountered so far?

Systems research based on standard IE rule language. Standard IE data model and language enables the development of systems implementing the standard. One may again wonder, *"Where is the research in that?"* As in the database community, initial research should focus on systemic issues such as data representation and speeding up rule evaluation via automatic performance optimization. Once baseline systems are established, system-related research would naturally diverge in several directions, such as extending the language with new primitives (and corresponding optimizations), and exploring modern hardware.

ML research based on standard IE rule language. A standard rule language and corresponding execution engine enables researchers to use the standard language as the expressivity of the output model, and define learning problems for this target language, including learning basic primitives such as regular expressions and dictionaries, or complete rule sets. (One need not worry about choosing the language, nor runtime efficiency.) With an expressive rule language, a major challenge is to prevent the system from generating arbitrarily complex rule sets, which would be difficult to understand or maintain. Some interesting research directions include devising proper measures for rule complexity, constraining the search space such that the learnt rules closely resemble those written by humans, active learning techniques to cope with scarcity of labeled data, and visualization tools to assist rule developers in exploring and choosing between different automatically generated rules. Finally, it is conceivable that some problems will not fit in the target language, and therefore will need alternative solutions. However, the community would have shown – objectively – that the problem is not learnable with the available set of constructs, thus motivating follow-on research on extending the standard with new primitives, if possible, or developing novel hybrid IE solutions by leveraging the standard IE rule language together with ML technology.

4 Conclusion

While rule-based IE dominates the commercial world, it is widely considered obsolete by the academia. We made a case for the importance of rule-based approaches to industry practitioners. Drawing inspiration from the success of SQL and the database community, we proposed directions for addressing the disconnect. Specifically, we call for the standardization of an IE rule language and outline an ambitious research agenda for NLP researchers who wish to tackle research problems of wide interest and value in the industry.

Improving Learning and Inference in a Large Knowledge-base using Latent Syntactic Cues

Matt Gardner, Partha Pratim Talukdar, Bryan Kisiel, and Tom Mitchell
Carnegie Mellon University
5000 Forbes Avenue
Pittsburgh, PA 15213, USA
{mg1,ppt,bkisiel,tom.mitchell}@cs.cmu.edu

Abstract

Automatically constructed Knowledge Bases (KBs) are often incomplete and there is a genuine need to improve their coverage. Path Ranking Algorithm (PRA) is a recently proposed method which aims to improve KB coverage by performing inference directly over the KB graph. For the first time, we demonstrate that addition of edges labeled with latent features mined from a large dependency parsed corpus of 500 million Web documents can significantly outperform previous PRA-based approaches on the KB inference task. We present extensive experimental results validating this finding. The resources presented in this paper are publicly available.

1 Introduction

Over the last few years, several large scale Knowledge Bases (KBs) such as Freebase (Bollacker et al., 2008), NELL (Carlson et al., 2010), and YAGO (Suchanek et al., 2007) have been developed. Each such KB consists of millions of facts (e.g., (*Tiger Woods*, *playsSport*, *Golf*)) spanning over multiple relations. Unfortunately, these KBs are often incomplete and there is a need to increase their coverage of facts to make them useful in practical applications.

A strategy to increase coverage might be to perform inference directly over the KB represented as a graph. For example, if the KB contained the following facts, (*Tiger Woods*, *participatesIn*, *PGA Tour*)) and (*Golf*, *sportOfTournament*, *PGA Tour*), then by putting these two facts together, we could potentially infer that (*Tiger Woods*, *playsSport*, *Golf*). The recently proposed Path Ranking Algorithm (PRA) (Lao and Cohen, 2010) performs such inference by automatically learning semantic inference rules over the KB (Lao et al., 2011). PRA uses features based off of sequences of edge types, e.g., ⟨*playsSport*, *sportOfTournament*⟩, to predict missing facts in the KB.

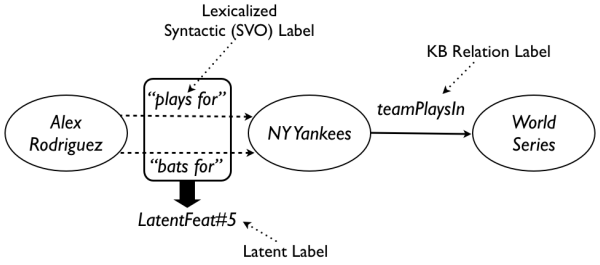

Figure 1: Example demonstrating how lexicalized syntactic edges can improve connectivity in the KB enabling PRA (Lao and Cohen, 2010) to discover relationships between *Alex Rodriguez* and *World Series*. Edges with latent labels can improve inference performance by reducing data sparsity. See Section 1.1 for details.

PRA was extended by (Lao et al., 2012) to perform inference over a KB augmented with dependency parsed sentences. While this opens up the possibility of learning syntactic-semantic inference rules, the set of syntactic edge labels used are just the *unlexicalized* dependency role labels (e.g., *nobj*, *dobj*, etc., without the corresponding words), thereby limiting overall expressitivity of the learned inference rules. To overcome this limitation, in this paper we augment the KB graph by adding edges with more expressive *lexicalized* syntactic labels (where the labels are words instead of dependen-

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 833–838,
Seattle, Washington, USA, 18-21 October 2013.

cies). These additional edges, e.g., (*Alex Rodriguez*, *"plays for"*, *NY Yankees*), are mined by extracting 600 million Subject-Verb-Object (SVO) triples from a large corpus of 500m dependency parsed documents, which would have been prohibitively expensive to add directly as in (Lao et al., 2012). In order to overcome the explosion of path features and data sparsity, we derive edge labels by learning latent embeddings of the lexicalized edges. Through extensive experiments on real world datasets, we demonstrate effectiveness of the proposed approach.

1.1 Motivating Example

In Figure 1, the KB graph (only solid edges) is disconnected, thereby making it impossible for PRA to discover any relationship between *Alex Rodriguez* and *World Series*. However, addition of the two edges with SVO-based lexicalized syntactic edges (e.g., (*Alex Rodriguez*, *plays for*, *NY Yankees*)) restores this inference possibility. For example, PRA might use the edge sequence $\langle$*"plays for"*, *teamPlaysIn*$\rangle$ as evidence for predicting the relation instance (*Alex Rodriguez*, *athleteWonChampionship*, *World Series*). Unfortunately, such naïve addition of lexicalized edges may result in significant data sparsity, which can be overcome by mapping lexicalized edge labels to some latent embedding (e.g., (*Alex Rodriguez*, *LatentFeat#5*, *NY Yankees*) and running PRA over this augmented graph. Using latent embeddings, PRA could then use the following edge sequence as a feature in its prediction models: $\langle$*LatentFeat#5*, *teamPlaysIn*$\rangle$. We find this strategy to be very effective as described in Section 4.

2 Related Work

There is a long history of methods using suface-level lexical patterns for extracting relational facts from text corpora (Hearst, 1992; Brin, 1999; Agichtein and Gravano, 2000; Ravichandran and Hovy, 2002; Etzioni et al., 2004). Syntactic information in the form of dependency paths have been explored in (Snow et al., 2006; Suchanek et al., 2006). A method of latent embedding of relation instances for sentence-level relation extraction was shown in (Wang et al., 2011). However, none of this prior work makes explicit use of the background KBs as we explore in this paper.

Path Ranking Algorithm (PRA) (Lao and Cohen, 2010) has been used previously to perform inference over graph-structured KBs (Lao et al., 2011), and to learn formation of online communities (Settles and Dow, 2013). In (Lao et al., 2012), PRA is extended to perform inference over a KB using syntactic information from parsed text. In contrast to these previous PRA-based approaches where all edge labels are either KB labels or at surface-level, in this paper we explore using latent edge labels in addition to surface-level labels in the graph over which PRA is applied. In particular, we focus on the problem of performing inference over a large KB and learn latent edge labels by mining dependency syntax statistics from a large text corpus.

Though we use Principal Components Analysis (PCA) for dimensionality reduction for the experiments in this paper, this is by no means the only choice. Various other dimensionality reduction techniques, and in particular, other verb clustering techniques (Korhonen et al., 2003), may also be used.

OpenIE systems such as Reverb (Etzioni et al., 2011) also extract verb-anchored dependency triples from large text corpus. In contrast to such approaches, we focus on how latent embedding of verbs in such triples can be combined with explicit background knowledge to improve coverage of existing KBs. This has the added capability of inferring facts which are not explicitly mentioned in text.

The recently proposed Universal Schema (Riedel et al., 2013) also demonstrates the benefit of using latent features for increasing coverage of KBs. Key differences between that approach and ours include our use of syntactic information as opposed to surface-level patterns in theirs, and also the ability of the proposed PRA-based method to generate useful inference rules which is beyond the capability of the matrix factorization approach in (Riedel et al., 2013).

3 Method

3.1 Path Ranking Algorithm (PRA)

In this section, we present a brief overview of the Path Ranking Algorithm (PRA) (Lao and Cohen, 2010), building on the notations in (Lao et al., 2012). Let $G = (V, E, T)$ be the graph, where V is the set of vertices, E is the set of edges, and T is the set of edge types. For each edge $(v_1, t, v_2) \in E$, we have

$v_1, v_2 \in V$ and $t \in T$. Let $R \subset T$ be the set of types predicted by PRA. R could in principal equal T, but in this paper we restrict prediction to KB relations, while T also includes types derived from surface text and latent embeddings. Let $\pi = \langle t_1, t_2, \ldots, t_w \rangle$ be a *path type* of length w over graph G, where $t_i \in T$ is the type of the i^{th} edge in the path. Each such path type is also a *feature* in the PRA model. For a given source and target node pair $s, t \in V$, let $P(s \rightarrow t; \pi)$ be the value of the feature π specifying the probability of reaching node t starting from node s and following a path constrained by path type π. We approximate these probabilities using random walks. A value of 0 indicates unreachability from s to t using path type π.

Let $B = \{\pi_1, \ldots, \pi_m\}$ be the set of all features (path types). The score that relation r holds between node s and node t is given by the following function:

$$\text{Score}_{\text{PRA}}(s, t, r) = \sum_{\pi \in B} P(s \rightarrow t; \pi)\, \theta_\pi^r$$

where θ_π^r is the weight of feature π in class $r \in R$.

Feature Selection: The set B of possible path types grows exponentially in the length of the paths that are considered. In order to have a manageable set of features to compute, we first perform a feature selection step. The goal of this step is to select for computation only those path types that commonly connect sources and targets of relation r. We perform this feature selection by doing length-bounded random walks from a given list of source and target nodes, keeping track of how frequently each path type leads from a source node to a target node. The most common m path types are selected for the set B.

Training: We perform standard logistic regression with L2 regularization to learn the weights θ_π^r. We follow the strategy in (Lao and Cohen, 2010) to generate positive and negative training instances.

3.2 $\text{PRA}_{\text{syntactic}}$

In this section, we shall extend the knowledge graph $G = (V, E, T)$ from the previous section with an augmented graph $G' = (V, E', T')$, where $E \subset E'$ and $T \subset T'$, with the set of vertices unchanged.

In order to get the edges in $E' - E$, we first collect a set of Subject-Verb-Object (SVO) triples $D = \{(s, v, o, c)\}$ from a large dependency parsed text corpus, with $c \in \mathbb{R}_+$ denoting the frequency of this triple in the corpus. The additional edge set is then defined as $E_{\text{syntactic}} = E' - E = \{(s, v, o) \mid \exists (s, v, o, c) \in D,\ s, o \in V\}$. We define $S = \{v \mid \exists (s, v, o) \in E_{\text{syntactic}}\}$ and set $T' = T \cup S$. In other words, for each pair of directly connected nodes in the KB graph G, we add an additional edge between those two nodes for each verb which takes the NPs represented by two nodes as subjects and objects (or vice versa) as observed in a text corpus. In Figure 1, (*Alex Rodriguez*, *"plays for"*, *NY Yankees*) is an example of such an edge.

PRA is then applied over this augmented graph G', over the same set of prediction types R as before. We shall refer to this version of PRA as $\text{PRA}_{\text{syntactic}}$. For the experiments in this paper, we collected $|D| = 600$ million SVO triples[1] from the entire ClueWeb corpus (Callan et al., 2009), parsed using the Malt parser (Nivre et al., 2007) by the Hazy project (Kumar et al., 2013).

3.3 $\text{PRA}_{\text{latent}}$

In this section we construct $G'' = (V, E'', T'')$, another syntactic-information-induced extension of the knowledge graph G, but instead of using the surface forms of verbs in S (see previous section) as edge types, we derive those edges types T'' based on latent embeddings of those verbs. We note that $E \subset E''$, and $T \subset T''$.

In order to learn the latent or low dimensional embeddings of the verbs in S, we first define $Q_S = \{(s, o) \mid \exists (s, v, o, c) \in D,\ v \in S\}$, the set of subject-object tuples in D which are connected by at least one verb in S. We now construct a matrix $X_{|S| \times |Q_S|}$ whose entry $X_{v,q} = c$, where $v \in S, q = (s, o) \in Q_S$, and $(s, v, o, c) \in D$. After row normalizing and centering matrix X, we apply PCA on this matrix. Let $A_{|S| \times d}$ with $d << |Q_S|$ be the low dimensional embeddings of the verbs in S as induced by PCA. We use two strategies to derive mappings for verbs from matrix A.

- $\text{PRA}_{\text{latent}_c}$: The verb is mapped to concatenation of the $\frac{k}{2}$ most positive columns in the row in A that corresponds to the verb. Similarly, for the most negative $\frac{k}{2}$ columns.

[1] This data and other resources from the paper are publicly available at http://rtw.ml.cmu.edu/emnlp2013_pra/.

	Precision	Recall	F1
PRA	0.800	0.331	0.468
$\text{PRA}_{\text{syntactic}}$	0.804	0.271	0.405
$\text{PRA}_{\text{latent}_c}$	**0.885**	0.334	0.485
$\text{PRA}_{\text{latent}_d}$	0.868	**0.424**	**0.570**

Table 1: Comparison of performance of different variants of PRA micro averaged across 15 NELL relations. We find that use of latent edge labels, in particular the proposed approach $\text{PRA}_{\text{latent}_d}$, significantly outperforms other approaches. This is our main result. (See Section 4)

- $\text{PRA}_{\text{latent}_d}$: The verb is mapped to disjunction of top-k most positive and negative columns in the row in A that corresponds to the verb.

4 Experiments

We compared the various methods using 15 NELL relations. For each relation, we split NELL's known relation instances into 90% training and 10% testing. For each method, we then selected 750 path features and trained the model, as described in Section 3, using GraphChi (Kyrola et al., 2012) to perform the random walk graph computations. To evaluate the model, we took all source nodes in the testing data and used the model to predict target nodes. We report the precision and recall (on the set of known target nodes) of the set of predictions for each model that are above a certain confidence threshold. Because we used strong regularization, we picked for our threshold a model score of 0.405, corresponding to 60% probability of the relation instance being true; values higher than this left many relations without any predictions. Table 1 contains the results.

As can be seen in the table, $\text{PRA}_{\text{syntactic}}$ on average performs slightly worse than PRA. While the extra syntactic features are very informative for some relations, they also introduce a lot of sparsity, which makes the model perform worse on other relations. When using latent factorization methods to reduce the sparsity of the syntactic features, we see a significant improvement in performance. $\text{PRA}_{\text{latent}_c}$ has a 45% reduction in precision errors vs. PRA while maintaining the same recall, and $\text{PRA}_{\text{latent}_d}$ reduces precision errors by 35% while improving recall by 27%. Section 4.1 contains some qualitative analysis of how sparsity is reduced with the latent methods. As a piece quantitative analysis, there were 908 possible path types found in the feature selection step with PRA on the relation *cityLiesOnRiver* (of which we then selected 750). For $\text{PRA}_{\text{syntactic}}$, there were 73,820, while $\text{PRA}_{\text{latent}_c}$ had 47,554 and $\text{PRA}_{\text{latent}_d}$ had 58,414.

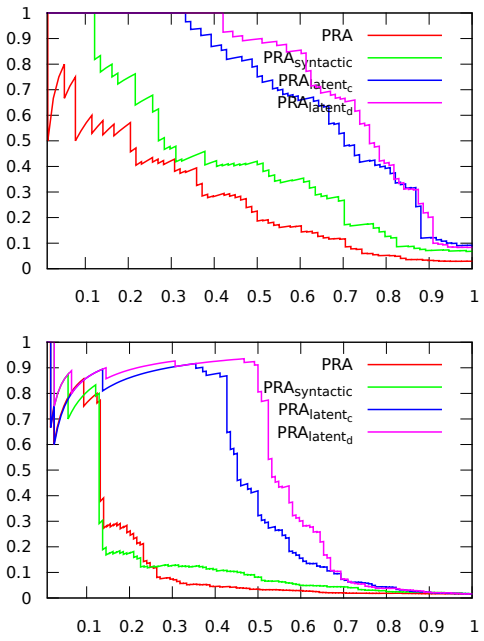

Figure 2: Precision (y axis) - Recall (x axis) plots for the relations *cityLiesOnRiver* (top) and *athletePlaysForTeam* (bottom). $\text{PRA}_{\text{latent}_d}$ (rightmost plot), the proposed approach which exploits latent edge labels, outperforms other alternatives.

Table 2 shows F1 scores for each model on each relation, and Figure 2 shows representative Precision-Recall plots for two NELL relations. In both cases, we find that $\text{PRA}_{\text{latent}_d}$ significantly outperforms other baselines.

4.1 Discussion

While examining the model weights for each of the methods, we saw a few occasions where surface relations and NELL relations combined to form interpretable path types. For example, in *athletePlaysForTeam*, some highly weighted features took the form of $\langle$*athletePlaysSport*, *"(sport) played by (team)"*$\rangle$. A high weight on this feature would bias the prediction towards teams that are known to play the same sport as the athlete.

For PRA, the top features for the best performing relations are path types that contain a single edge

Table 2: F1 performance of different variants of PRA for all 15 relations tested.

which is a supertype or subtype of the relation being predicted. For instance, for the relation *athletePlaysForTeam* (shown in Figure 2), the highest-weighted features in PRA are *athleteLedSportsTeam* (more specific than *athletePlaysForTeam*) and *personBelongsToOrganization* (more general than *athletePlaysForTeam*). For the same relation, $\text{PRA}_{\text{syntactic}}$ has features like *"scored for"*, *"signed"*, *"have"*, and *"led"*. When using a latent embedding of these verb phrases, *"signed"*, *"have"*, and *"led"* all have the same representation in the latent space, and so it seems clear that $\text{PRA}_{\text{latent}}$ gains a lot by reducing the sparsity inherent in using surface verb forms.

For *cityLiesOnRiver*, where PRA does not perform as well, there is no NELL relation that is an immediate supertype or subtype, and so PRA does not have as much evidence to use. It finds features that, e.g., are analogous to the statement "cities in the same state probably lie on the same river". Adding lexical labels gives the model edges to use like *"lies on"*, *"runs through"*, *"flows through"*, *"starts in"* and *"reaches"*, and these features give a significant boost in performance to $\text{PRA}_{\text{syntactic}}$. Once again, almost all of those verb phrases share the same latent embedding, and so $\text{PRA}_{\text{latent}}$ gains another significant boost in performance by combining them into a single feature.

5 Conclusion

In this paper, we introduced the use of latent lexical edge labels for PRA-based inference over knowledge bases. We obtained such latent edge labels by mining a large dependency parsed corpus of 500 million web documents and performing PCA on the result. Through extensive experiments on real datasets, we demonstrated that the proposed approach significantly outperforms previous state-of-the-art baselines.

Abstract

Most of the machine translation systems rely on a large set of translation rules. These rules are treated as discrete and independent events. In this short paper, we propose a novel method to model rules as observed generation output of a compact hidden model, which leads to better generalization capability. We present a preliminary generative model to test this idea. Experimental results show about one point improvement on TER-BLEU over a strong baseline in Chinese-to-English translation.

1 Introduction

Most of the modern Statistical Machine Translation (SMT) systems, for example (Koehn et al., 2003; Och and Ney, 2004; Chiang, 2005; Marcu et al., 2006; Shen et al., 2008), employ a large rule set that may contain tens of millions of translation rules or even more. In these systems, each translation rule has about 20 dense features, which represent key statistics collected from the training data, such as word translation probability, phrase translation probability etc. Except for these common features, there is no connection among the translation rules. The translation rules are treated as independent events.

The use of sparse features as in (Arun and Koehn, 2007; Watanabe et al., 2007; Chiang et al., 2009) to some extent mitigated this problem. In their work, there are as many as 10,000 features defined on the appearance of certain frequent words and Part of Speech (POS) tags in rules. They provide significant improvement in automatic evaluation metrics. However, these sparse features fire quite randomly and infrequently on each rule. Thus, there is still plenty of space to better model translation rules.

In this paper, we will explore the relationship among translation rules. We no longer view rules as discrete or unrelated events. Instead, we view rules, which are observed from training data, as random variables generated by a hidden model. This generative process itself is also hidden. All possible generative processes can be represented with factorized structures such as weighted hypergraphs and finite state machines. This approach leads to a compact model that has better generalization capability and allows translation rules not explicitly observed in training date.

This paper reports work-in-progress to exploit hidden relations among rules. Preliminary experiments show about one point improvement on TER-BLEU over a strong baseline in Chinese-to-English translation.

2 Hidden Models

Let $\mathcal{G} = \{(r, f)\}$ be a grammar observed from parallel training data, where f is the frequency of a bilingual translation rule r.

Let $\mathcal{M}$ be a hidden model that generates every translation rule r. For example, $\mathcal{M}$ could be modeled with a weighted hypergraph or finite state machine. For the sake of convenience, in this section we assume $\mathcal{M}$ is a meta-grammar $\mathcal{M} = \{m\}$, where each m represents a meta-rule. For each translation r, there exists a hypergraph H_r that represents all possible derivations $D_r = \{d\}$ that can generate rule r. Here, each derivation d is a hyperpath using meta-rules M_d, where $M_d \subseteq \mathcal{M}$. Thus, we can use hypergraph H_r to characterize r. Translation rules in $\mathcal{G}$

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 839–844,
Seattle, Washington, USA, 18-21 October 2013.

can share nodes and meta-rules in their hypergraphs, so that $\mathcal{M}$ is more compact model than $\mathcal{G}$.

In the rest of this section, we will introduce three methods to quantify H_r as features of rule r. It should be noted that there are more ways to exploit the compact model of $\mathcal{M}$ than these three.

2.1 Type 1 : A Generative Model

Let θ be the parameters of a statistical model $Pr(m;\theta)$ for meta-rules m in meta-grammar $\mathcal{M}$ estimated from the observed translation grammar $\mathcal{G}$. The probability of a translation rule r can be calculated as follows.

$$\begin{aligned} Pr(r;\theta) &\propto Pr(H_r;\theta) \\ &= \sum_{d \in D_r} Pr(d;\theta) \end{aligned} \quad (1)$$

By assuming separability,

$$Pr(d;\theta) = \prod_{m \in M_d} Pr(m;\theta) \quad (2)$$

we can further decompose rule probability $Pr(r;\theta)$ as below.

$$Pr(r;\theta) = \sum_{d \in D_r} \prod_{m \in M_d} Pr(m;\theta) \quad (3)$$

In practice, $Pr(r;\theta)$ in (3) can be calculated through bottom-up dynamic programming on hypergraph H_r. Hypergraphs of different rules can share nodes and meta-rules. This reveals the underlying relationship among translation rules.

As a by-product of this generative model, we use the log-likelihood of a translation rule, $\log Pr(r;\theta)$, as a new dense feature. We call it *Type 1* in experiments.

2.2 Type 2 : Meta-Rules as Sparse Features

As given in (3), likelihood of a translation rule is a function over $Pr(m;\theta)$, in which θ is estimated from the training data with a generative model. Previous work in (Chiang et al., 2009) showed the advantage of using a discriminative model to optimize individual weights for these factors towards a better automatic score.

Following this practice, we treat each meta-rule m as a sparse feature. Feature value $f(m) = 1$ if and only if m is used in hypergraph H_r. Otherwise, its default value is 0. We call these features *Type 2* in experiments. The Type 2 system contains the log-likelihood feature in Type 1.

2.3 Type 3 : Posterior as Feature Values

A natural question on the binary sparse features defined above is why all the active features have the same value of 1. We use these meta-rules to represent a translation rule in feature space. Intuitively, for meta-rules with closer connection to the translation rules, we hope to use relatively larger feature values to increase their effect.

We formalize this intuition with the posterior probability that a meta-rule m is used to generate r, as below.

$$\begin{aligned} f(m) &\equiv Pr(m|r;\theta) \\ &= \frac{Pr(m,r;\theta)}{Pr(r;\theta)} \\ &= \frac{\sum_{d \in D_r, m \in M_d} Pr(d;\theta)}{Pr(r;\theta)} \end{aligned} \quad (4)$$

The posterior in (4) could be too sharp. Following the common practice, we smooth the posterior features with a scaling factor α.

$$f(m) \equiv Pr(m|r)^{\alpha}$$

We use *Type 3*(α) to represent the posterior model with a scaling factor of α in experiments. The Type 3 systems also contain the log-likelihood feature in Type 1.

2.4 Parameter Estimation

Now we explain how to obtain parameter θ. With proper definition of the underlying model $\mathcal{M}$, we can estimate θ with the traditional EM algorithm or Bayesian methods.

In the next section, we will present an example of the hidden model. We will employ the EM algorithm to estimate the parameters in θ. Here, translation rules and their frequencies in $\mathcal{G}$ are observed data, and derivation d for each rule r is hidden. At the *Expectation* step, we search all derivations d in D_r of each rule r and calculate their probabilities according to equation (2). At the *Maximization* step, we re-estimate θ on all derivations in proportion to their posterior probability.

3 Case Study

In Section 2, we explored the use of meta-grammars as the underlying model $\mathcal{M}$ and developed three methods to define features. Similar techniques can be applied to finite state machines and other underlying models. Now, we introduce a POS-based underlying model to illustrate the generic model proposed in Section 2. We will show experimental results in Section 4.

3.1 Meta-rules on POS tags

Let $r \in \mathcal{G}$ be a translation rule composed of a pair of source and target word strings (F_w, E_w). Let F_p and E_p be the POS tags for the source and target sides respectively. For the sake of simplicity as the first attempt, we treat non-terminal as a special word X with POS tag X.

Suppose we have a Chinese-to-English translation rule as below.

$$yuehan\ qu\ zhijiage \Rightarrow john\ leaves\ for\ chicago$$

We call

$$NR\ VV\ NR \Rightarrow NNP\ VBZ\ IN\ NNP \quad (5)$$

a translation rule in POS tags.

We will propose an underlying model $\mathcal{M}$ to generate translation rules in POS tags instead of translation rules themselves. For the rest of this section, we take translation rules in POS tags as the target of our generative model. We define meta-rules on pairs of POS tag strings, e.g. $NR\ VV \Rightarrow NNP\ VBZ$.

We can decompose the probability of translation rule in (5) into a product on meta-rule probabilities via various derivations, such as

- $Pr(NR\ VV,\ NNP\ VBZ) \times Pr(NR,\ IN\ NNP)$, and
- $Pr(NR,\ NNP) \times Pr(VV,\ VBZ\ IN) \times Pr(NR,\ NNP)$.

3.2 The Underlying Model and Features

Now, we introduce a generative model M for translation rules in POS tags. We still use the example in (5) as shown in Figure 1, where the top box represents the source side and the bottom box represents the target side. Dotted lines represent word alignments on three pairs of words.

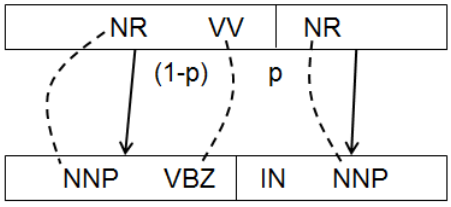

Figure 1: An example

We first generate the number of source tokens of a translation rule with a uniform distribution for up to, for example, 7 tokens.

Then we split the source side into chunks with a binomial distribution with a Bernoulli variable at the gap between each two continuous words, which splits the two words into two chunks with a probability of p. For example, the probability of obtaining two chunks *NR VV* and *NR* is $(1-p)p$, as shown in Figure 1.

Suppose we split the target side into two parts, *NNP VBZ* and *IN NNP*, which respects the word alignments. It generates two meta-rules *NR VV* $\Rightarrow$ *NNP VBZ* and *NR* $\Rightarrow$ *IN NNP*, as shown in Figure 1. The probability for the first meta-rule is

$$Pr(|E| = 2 \mid |F| = 2) \times$$

$$Pr(NR\ VV, NNP\ VBZ \mid |F| = 2, |E| = 2),$$

where $|F|$ represents the number of source tokens, and $|E|$ the number of target tokens. Similarly, the probability of the second one is as follows.

$$Pr(|E| = 2 \mid |F| = 1) \times$$

$$Pr(NR, IN\ NNP \mid |F| = 1, |E| = 2).$$

To sum up, the probability of a derivation d for a translation rule $r : F \Rightarrow E$ is

$$\begin{aligned} Pr(d) \approx\ & Pr_{\theta_1}(|F|) \\ & \times Pr_{\theta_2}(F_s) \\ & \times \prod_{m \in M_d} Pr_{\theta_3}(|E_m| \mid |F_m|) \\ & \times \prod_{m \in M_d} Pr_{\theta_4}(m \mid |F_m|, |E_m|) \end{aligned} \quad (6)$$

where F_m and E_m are source and target sides of a meta-rule m used in derivation d, and F_s is a splitting of the source side. As for the distributions, we

have

$$\begin{aligned}\theta_1 &\sim Uniform \\ \theta_2 &\sim Binomial \\ \theta_3 &\sim Categorical \\ \theta_4 &\sim Categorical\end{aligned}$$

where θ_1 and θ_2 have pre-selected hyperparameters, and θ_3 and θ_4 are estimated with the EM algorithm.

As for sparse features, we will obtain 7 meta-rule features as below.

- *NR* $\Rightarrow$ *NNP*
- *VV* $\Rightarrow$ *VBZ*
- *VV* $\Rightarrow$ *VBZ IN*
- *NR VV* $\Rightarrow$ *NNP VBZ*
- *NR VV* $\Rightarrow$ *NNP VBZ IN*
- *VV NR* $\Rightarrow$ *VBZ IN NNP*
- *NR VV NR* $\Rightarrow$ *NNP VBZ IN NNP*

All of them respect the word alignment, which means that

- there is no alignment that aligns one word in a meta-rule with the other out of the same meta-rule, and
- there is at least one alignment within a meta-rule.

3.3 Implementation Details

Even though the size of all possible meta-rules is much smaller than the space of translation rules, it is still too large to work with existing optimization methods for sparse features in MT, i.e. MIRA (Chiang et al., 2009) or L-BFGS (Matsoukas et al., 2009). In practice, we have to limit the feature space to around 20,000 dimensions.

For this purpose, we first use a frequency based method to filter meta-rule features. Specifically, we first divide all the meta-rules into 100 bins, $(|F|, |E|)$, where $|F|$ is the number of words on the source side, and $|E|$ the target side, $0 < |F|, |E| \leq 10$. For each bin, we keep the same top k-percentile of the meta-rules such that we obtain a total of 20,000 meta-rules as features.

System	BLEU%	TER%	T-B
Baseline	30.35	55.32	24.97
Type 1	30.74	55.48	24.74
Type 2	31.07	55.07	24.00
Type 3 (1)	30.93	55.34	24.41
Type 3 (0.1)	31.05	55.02	23.97
Type 3 (0.01)	31.09	54.96	23.87

Table 1: scores on test-1

A shortcoming of this filtering method is that all these features are positive indicators, while low-frequency negative indicators are discarded. In order to keep the features of various level of frequency, we define class features with a 3-tuple $C(|F|, |E|, q)$, where $|F|$ and $|E|$ are numbers of source and target words as defined above, and q is the integer part of the log_2 value of the feature frequency in the training data.

In this way, each meta-rule feature can be mapped to one of these classes. The value of a class feature equals the sum of the meta-rule features that mapped into this class. We have about 2,000 class features defined in this way. They are applied on both Type 2 and Type 3 features.

4 Experiments

We carry out our experiments on web genre of Chinese-to-English translation. The training set contains about 10 million parallel sentences available to Phase 1 of the DARPA BOLT MT task. The tune set contains 1275 sentences. Each has four references. There are two test sets. Test-1 is from a similar source of the tune set, and it contains 1239 sentences. Test-2 is the web part of the MT08 evaluation data.

Our baseline system is a home-made Hiero (Chiang, 2005) style system. The baseline rule set contains about 17 million rules. It contains about 40 dense features, including a 6-gram LM.

The sparse feature optimization algorithm is similar to the MIRA recipe described in (Chiang et al., 2009). We optimize on TER-BLEU (Snover et al., 2006; Papineni et al., 2001).

The BLEU, TER and T-B scores on the two tests are shown in Tables 1 and 2. It should be noted that, even though our metric of tuning is T-B, the baseline

System	BLEU%	TER%	T-B
Baseline	25.80	56.96	31.16
Type 1	26.18	57.09	30.91
Type 2	26.63	56.64	30.01
Type 3 (1)	26.30	57.00	30.70
Type 3 (0.1)	26.34	56.73	30.39
Type 3 (0.01)	26.50	56.73	30.23

Table 2: scores on test-2 (MT08-WB)

system already provides a very competitive BLEU score on MT08-WB as compared the best system in the evaluation[1], thanks to comprehensive features in the baseline system and more data in training.

All the three types of systems provide consistent improvement on both test sets in terms of T-B, our optimization metric. Type 1 gives marginal improvement of 0.2. This shows the limitation of the generative feature. When we use meta-rules as binary sparse features in Type 2, we obtain about one point improvement on T-B on both sets. This shows the advantage of tuning individual meta-rule weights over a generative model. Type 3 (0.01) and Type 2 are at the same level. Proper smoothing is important to Type 3.

5 Discussion

In the case study of Section 3, we use POS-based rules as hidden states. However, it should be noted that the hidden structures surely do not have to be POS tags. For example, an alternative could be unsupervised NT splitting similar to (Huang et al., 2010).

The meta-grammar based approach was also motivated by the insight acquired on mono-lingual linguistic grammar generation, especially in the TAG related research (Xia, 2001; Prolo, 2002). Meta-grammar was viewed as an effective way to remove redundancy in grammars.

The link between Tree Adjoining Grammar (TAG) (Joshi et al., 1975; Joshi and Schabes, 1997) and MT was first introduced in (Shieber and Schabes, 1990), a pioneer work in tree-to-tree translation. (DeNeefe and Knight, 2009) re-visited the use of adjoining operation in the context of Statistical MT, and reported encouraging results. On the other hand, (Dras, 1999) showed how a meta-level grammar could help in modeling parallel operations in (Shieber and Schabes, 1990). Our work is another effort of statistical modeling of well-recognized linguistic insight in NLP and MT.

6 Conclusions and Future Work

In this paper, we introduced a novel method to model translation rules as observed generation output of a compact hidden model. As a case study to capitalize this model, we presented three methods to enrich rule modeling with features defined on a hidden model. Preliminary experiments verified gain of one point on TER-BLEU over a strong baseline in Chinese-to-English translation.

As for future work, we plan to extend this work in the following aspects.

- To try other prior distributions to generate the number of source tokens.
- Unsupervised and semi-supervised learning of hidden models.
- To incorporate rich models into the generative process, e.g. reordering, non-terminals, structural information and lexical models.
- To improve the posterior model with better parameter estimation, e.g. Bayesian methods.
- To replace the exhaustive translation rule set with a compact meta grammar that can create and parameterize new translation rules dynamically, which is the ultimate goal of this line of work.

Abstract

Neural network language models, or continuous-space language models (CSLMs), have been shown to improve the performance of statistical machine translation (SMT) when they are used for reranking n-best translations. However, CSLMs have not been used in the first pass decoding of SMT, because using CSLMs in decoding takes a lot of time. In contrast, we propose a method for converting CSLMs into back-off n-gram language models (BNLMs) so that we can use converted CSLMs in decoding. We show that they outperform the original BNLMs and are comparable with the traditional use of CSLMs in reranking.

1 Introduction

Language models are important in natural language processing tasks such as speech recognition and statistical machine translation. Traditionally, back-off n-gram language models (BNLMs) (Chen and Goodman, 1996; Chen and Goodman, 1998; Stolcke, 2002) are being widely used for these tasks.

Recently, neural network language models, or continuous-space language models (CSLMs) (Bengio et al., 2003; Schwenk, 2007; Le et al., 2011) are being used in statistical machine translation (SMT) (Schwenk et al., 2006; Son et al., 2010; Schwenk et al., 2012; Son et al., 2012; Niehues and Waibel, 2012). These works have shown that CSLMs can improve the BLEU (Papineni et al., 2002) scores of SMT when compared with BNLMs, on the condition that the training data for language modeling are the same size. However, in practice, CSLMs have not been widely used in SMT.

One reason is that the computational costs of training and using CSLMs are very high. Various methods have been proposed to tackle the training cost issues (Son et al., 2010; Schwenk et al., 2012; Mikolov et al., 2011). However, there has been little work on reducing using costs. Since the using costs of CSLMs are very high, it is difficult to use CSLMs in decoding directly.

A common approach in SMT using CSLMs is the two pass approach, or n-best reranking. In this approach, the first pass uses a BNLM in decoding to produce an n-best list. Then, a CSLM is used to rerank those n-best translations in the second pass. (Schwenk et al., 2006; Son et al., 2010; Schwenk et al., 2012; Son et al., 2012)

Another approach is using restricted Boltzmann machines (RBMs) (Niehues and Waibel, 2012) instead of using multi-layer neural networks (Bengio et al., 2003; Schwenk, 2007; Le et al., 2011). Since probability in a RBM can be calculated very efficiently (Niehues and Waibel, 2012), they can use the RBM language model in SMT decoding. However, the RBM was just used in an adaptation of SMT, not in a large SMT task, because the training costs of RBMs are very high.

The last approach is using a BNLM to simulate a CSLM (Deoras et al., 2011; Arsoy et al., 2013). (Deoras et al., 2011) used a recurrent neural network language model (RNNLM) to generate a large amount of text, which was generated by sampling words from the probability distributions calculated by the RNNLM. Then, they trained the BNLM

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 845–850,
Seattle, Washington, USA, 18-21 October 2013.

from the text using the interpolated Kneser-Ney smoothing method. (Arsoy et al., 2013) converted neural network language models of increasing order to pruned back-off language models, using lower-order models to constrain the n-grams allowed in higher-order models.

Both of these methods were used in decoding for speech recognition. These methods were applied to not-so-large scale experiments (55 million (M) words for training their BNLMs) (Arsoy et al., 2013). In contrast, our method is applied to SMT and can be used to improve a BNLM created from 746 M words by using a CSLM trained from 42 M words.

Because BNLMs can be trained from much larger corpora than those that can be used for training CSLMs, improving a BNLM by using a CSLM trained from a smaller corpus is very important. Actually, a CSLM trained from a smaller corpus can improve the BLEU scores of SMT if it is used in the n-best reranking (Schwenk, 2010; Huang et al., 2013). In contrast, we will demonstrate that a BNLM simulating a CSLM can improve the BLEU scores of SMT in the first pass decoding.

Our approach is as follows: (1) First, we train a CSLM (Schwenk, 2007) from a corpus. (2) Second, we also train a BNLM from the same corpus or larger corpus. (3) Finally, we rewrite the probability of each n-gram of the BNLM with that probability calculated from the CSLM. We also re-normalize the probabilities of the BNLM, then use the re-written BNLM in SMT decoding.

In Section 2, we describe the BNLM and CSLM (Schwenk, 2010) used for re-writing BNLMs. In Section 3, we describe the method of converting a CSLM into a BNLM. In Sections 4 and 5, we evaluate our method and conclude.

2 Language Models

In this section, we will introduce the standard BNLM and CSLM structure and probability calculation.

2.1 Standard back-off ngram language model

A BNLM predicts the probability of a word w_i given its preceding $n-1$ words $h_i = w_{i-n+1}^{i-1}$. But it will suffer from data sparseness if the context, h_i, does not appear in the training data. So an estimation by "backing-off" to models with smaller histories is necessary. In the case of the modified Kneser-Ney smoothing (Chen and Goodman, 1998), the probability of w_i given h_i under a BNLM, $P_b(w_i|h_i)$, is:

$$P_b(w_i|h_i) = \hat{P}_b(w_i|h_i) + \gamma(h_i)P_b(w_i|w_{i-n+2}^{i-1}) \quad (1)$$

where $\hat{P}_b(w_i|h_i)$ is a discounted probability and $\gamma(h_i)$ is the back-off weight. A BNLM is used with a CSLM as shown below.

2.2 CSLM structure and probability calculation

The main structure of a CSLM using a multi-layer neural network contains four layers: the input layer projects all words in the context h_i onto the projection layer (the first hidden layer); the second hidden layer and the output layer achieve the non-liner probability estimation and calculate the language model probability $P(w_i|h_i)$ for the given context. (Schwenk, 2007).

The CSLM calculates the probabilities of all words in the vocabulary of the corpus given the context at once. However, because the computational complexity of calculating the probabilities of all words is quite high, the CSLM is only used to calculate the probabilities of a subset of the whole vocabulary. This subset is called a *short-list*, which consists of the most frequent words in the vocabulary. The CSLM also calculates the sum of the probabilities of all words not in the short-list by assigning a neuron for that purpose. The probabilities of other words not in the short-list are obtained from a BNLM (Schwenk, 2007; Schwenk, 2010).

Let w_i, h_i be the current word and history. The CSLM with a BNLM calculates the probability of w_i given h_i, $P(w_i|h_i)$, as follows:

$$P(w_i|h_i) = \begin{cases} \frac{P_c(w_i|h_i)}{1-P_c(o|h_i)} P_s(h_i) & \text{if } w_i \in \text{short-list} \\ P_b(w_i|h_i) & \text{otherwise} \end{cases} \quad (2)$$

where $P_c(\cdot)$ is the probability calculated by the CSLM, $P_c(o|h_i)$ is the probability of the neuron for the words not in the short-list, $P_b(\cdot)$ is the probability calculated by the BNLM as in Eq. 1, and

$$P_s(h_i) = \sum_{v \in \text{short-list}} P_b(v|h_i). \quad (3)$$

It can be considered that the CSLM redistributes the probability mass of all words in the short-list. This probability mass is calculated by using the BNLM.

3 Conversion of CSLM into BNLM

As described in the introduction, we first train a CSLM from a corpus. We also train a BNLM from the same corpus or a larger corpus. Then, we rewrite the probability of each ngram in the BNLM with the probability calculated from the CSLM.

First, we use the probabilities of 1-grams in the BNLM as they are. Next, we rewrite the probabilities of n-grams (n=2,3,4,5) in the BNLM with the probabilities calculated by using the n-gram CSLM, respectively. Note that the n-gram CSLM means that the length of its history is $n-1$. Note also that we only need to rewrite the probabilities of n-grams ending with a word in the short-list. Finally, we re-normalize the probabilities of the BNLM using the SRILM's '-renorm' option.

When we rewrite a BNLM trained from a larger corpus, the ngrams in the BNLM often contain unknown words for the CSLM. In that case, we use the probabilities in the BNLM as they are.

4 Experiments

4.1 Common settings

We used the patent data for the Chinese to English patent translation subtask from the NTCIR-9 patent translation task (Goto et al., 2011). The parallel training, development, and test data consisted of 1 M, 2,000, and 2,000 sentences, respectively.

We followed the settings of the NTCIR-9 Chinese to English translation baseline system (Goto et al., 2011) except that we used various language models to compare them. We used the MOSES phrase-based SMT system (Koehn et al., 2003), together with Giza++ (Och and Ney, 2003) for alignment and MERT (Och, 2003) for tuning on the development data. The translation performance was measured by the case-insensitive BLEU scores on the tokenized test data. We used `mteval-v13a.pl` for calculating BLEU scores.[1]

We used the 14 standard SMT features: five translation model scores, one word penalty score, seven distortion scores and one language model score. Each of the different language models was used to calculate the language model score.

As the baseline BNLM, we trained a 5-gram BNLM with modified Kneser-Ney smoothing using the English side of the 1 M sentences training data, which consisted of 42 M words. We did not discard any n-grams in training this model. That is, we did not use count cutoffs. We call this BNLM as *BNLM42*.

A 5-gram CSLM was trained on the same 1 M training sentences using the CSLM toolkit (Schwenk, 2010). The settings for the CSLM were: projection layer of dimension 256 for each word, hidden layer of dimension 384 and output layer (short-list) of dimension 8192, which were recommended in the CSLM toolkit. We call this CSLM *CSLM42*. CSLM42 used BNLM42 as the background BNLM.

We also trained a larger 5-gram BNLM with modified Kneser-Ney smoothing by adding sentences from the 2005 US patent data distributed in the NTCIR-8 patent translation task (Fujii et al., 2010) to the 42 M words. The data consisted of 746 M words. We call this BNLM *BNLM746*. We discarded 3,4,5-grams that occurred only once when we created BNLM746.

Next, we re-wrote BNLM42 with CSLM42 by using the method described in Section 3. This re-written BNLM was interpolated with BNLM42. The interpolation weight was determined by the grid search. That is, we changed the interpolation weight to 0.1, 0.3, 0.5, 0.7, 0.9 to create an interpolated BNLM. Then we used that BNLM in the SMT system to tune the weight parameters on the first half of the development data. Next, we selected the interpolation weight that obtained the highest BLEU score on the second half of the development data. After we selected the interpolation weight, we applied MERT again to the 2,000 sentence development data to tune the weight parameters.[2] We call this BNLM *CONV42*. We also obtained *CONV746* by re-writing BNLM746 with CSLM42

[1] It is available at `http://www.itl.nist.gov/iad/mig/tests/mt/2009/`

[2] We aware that the interpolation weight might be determined by minimizing the perplexity on the development data. However, we opted to directly maximize the BLEU score.

in the same way.

The vocabulary of these language models was the same, which was extracted from the 1 M training sentences.

4.2 Experimental results

Table 1 shows the percent BLEU scores on the test data. The figures in the "1st pass" column show the BLEU scores in the first pass decoding when we changed the language model. The figures in the "reranking" column show the BLEU scores when we applied CSLM42 to rerank the 100-best lists for the different language models. When we applied CSLM42 for reranking, we added the CSLM42 score as the additional 15th feature. The weight parameters were tuned by using Z-MERT (Zaidan, 2009).

LMs	1st pass	rerank
BNLM42	31.60	32.44
CONV42	32.58	32.98
BNLM746	32.83	33.36
CONV746	33.22	33.54

Table 1: Comparison of BLEU scores

We also performed the paired bootstrap resampling test (Koehn, 2004).[3] We sampled 2000 samples for each significance test.

Table 2 shows the results of a statistical significance test, in which the "1st" is short for the "1st pass". The marks indicate whether the LM to the left of a mark is significantly better than that above the mark at a certain level. ("$\gg$": significantly better at $\alpha = 0.01$, "$>$": $\alpha = 0.05$, "$-$": not significantly better at $\alpha = 0.05$)

First, as shown in the tables, the reranking by applying CSLM42 increased the BLEU scores for all language models. This observation is in accordance with those of previous work (Schwenk, 2010; Huang et al., 2013).

Second, the reranking results of BNLM42 (32.44) were not better than those of the first pass of BNLM746 (32.83). This indicates that if the underlying BNLM is made from a small corpus, the reranking using CSLM can not compensate for it.

[3]We used the code available at `http://www.ark.cs.cmu.edu/MT/`.

	BNLM746 (rerank)	CONV746 (1st)	CONV42 (rerank)	BNLM746 (1st)	CONV42 (1st)	BNLM42 (rerank)	BNLM42 (1st)
CONV746 (rerank)	$-$	$\gg$	$\gg$	$\gg$	$\gg$	$\gg$	$\gg$
BNLM746 (rerank)		$-$	$\gg$	$>$	$\gg$	$\gg$	$\gg$
CONV746 (1st)			$\gg$	$-$	$\gg$	$\gg$	$\gg$
CONV42 (rerank)				$-$	$\gg$	$\gg$	$\gg$
BNLM746 (1st)					$-$	$\gg$	$\gg$
CONV42 (1st)						$-$	$\gg$
BNLM42 (rerank)							$\gg$

Table 2: Significance tests for systems with different LMs

Third, CONV42 was better than BNLM42 for both first-pass and reranking. This also holds in the case of CONV746 and BNLM746. This indicated that our conversion method improved the BNLMs, even if the underlying BNLM was trained on a larger corpus than that used for training the CSLM. As described in the introduction, this is very important because BNLMs can be trained from much larger corpora than those that can be used for training CSLMs. This observation has not been found in the previous work.

In addition, the first-pass of CONV42 and CONV746 (32.58 and 33.22) were comparable with those of the reranking results of BNLM42 and BNLM746 (32.44 and 33.36), respectively. That is, there were no significant differences between these results. This indicates that our conversion method preserves the performance of the reranking using CSLM.

5 Conclusion

We have proposed a method for converting CSLMs into BNLMs. The method can be used to improve a BNLM by using a CSLM trained from a smaller corpus than that used for training the BNLM. We have also shown that BNLMs created by our method performs as good as the reranking using CSLMs.

Our future work is to compare our conversion method with that of (Arsoy et al., 2013).[4]

[4]We aware that (Arsoy et al., 2013) compared their method with the one that is identical with our method. However, the experiments were conducted on a speech recognition task and the scale of the experiment was not so large. Since we noticed their work just before the submission of our paper, we did not have time to compare their method with our method in SMT.

Acknowledgments

We appreciate the helpful discussion with Andrew Finch and Paul Dixon, and three anonymous reviewers for many invaluable comments and suggestions to improve our paper. Abstract

MIRA based tuning methods have been widely used in statistical machine translation (SMT) system with a large number of features. Since the corpus-level BLEU is not decomposable, these MIRA approaches usually define a variety of heuristic-driven sentence-level BLEUs in their model losses. Instead, we present a new MIRA method, which employs an exact corpus-level BLEU to compute the model loss. Our method is simpler in implementation. Experiments on Chinese-to-English translation show its effectiveness over two state-of-the-art MIRA implementations.

1 Introduction

Margin infused relaxed algorithm (MIRA) has been widely adopted for the parameter optimization in SMT with a large feature size (Watanabe et al., 2007; Chiang et al., 2008; Chiang et al., 2009; Chiang, 2012; Eidelman, 2012; Cherry and Foster, 2012). Since BLEU is defined on the corpus, and not decomposed into sentences, most MIRA approaches consider a variety of sentence-level BLEUs for the model losses, many of which are heuristic-driven (Watanabe et al., 2007; Chiang et al., 2008; Chiang et al., 2009; Chiang, 2012; Cherry and Foster, 2012). The sentence-level BLEU appearing in the objective is generally based on a pseudo-document, which may not precisely reflect the corpus-level BLEU. We believe that this mismatch could potentially harm the performance. To avoid the sentence BLEU, the work in (Haddow et al., 2011) proposed to process sentences in small batches. The authors adopted a Gibbs sampling (Arun et al., 2009) technique to search the *hope* and *fear* hypotheses, and they did not compare with MIRA. Watanabe (2012) also tuned the parameters with small batches of sentences and optimized a hinge loss not explicitly related to BLEU using stochastic gradient descent. Both approaches introduced additional complexities over baseline MIRA approaches.

In contrast, we propose a remarkably simple but efficient batch MIRA approach which exploits the exact corpus-level BLEU to compute model losses. We search for a *hope* and a *fear* hypotheses for the corpus with a straightforward approach and minimize the structured hinge loss defined on them. The experiments show that our method consistently outperforms two state-of-the-art MIRAs in Chinese-to-English translation tasks with a moderate margin.

2 Margin Infused Relaxed Algorithm

We optimize the model parameters based on *N*-best lists. Our development (*dev*) set is a set of triples $\{(f_i, \mathbf{e}_i, \mathbf{r}_i)\}_{i=1}^{M}$, where f_i is a source-language sentence, corresponded by a list of target-language hypotheses $\mathbf{e}_i = \{e_{ij}\}_{j=1}^{N(f_i)}$, with a number of references $\mathbf{r}_i$. $\mathbf{h}(e_{ij})$ is a feature vector. Generally, most decoders return a top-1 candidate as the translation result, such that $\bar{e}_i(\mathbf{w}) = \arg\max_j \mathbf{w} \cdot \mathbf{h}(e_{ij})$, where $\mathbf{w}$ are the model parameters. In this paper, we aim at optimizing the BLEU score (Papineni et al., 2002).

MIRA is an instance of online learning which assumes an overlap of the decoding procedure and the parameter optimization procedure. For example in (Crammer et al., 2006; Chiang et al., 2008), MIRA

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 851–856,
Seattle, Washington, USA, 18-21 October 2013.

is performed after an input sentence are decoded, and the next sentence is decoded with the updated parameters. The objective for each sentence i is,

$$\min_{\mathbf{w}} \quad \frac{1}{2}||\mathbf{w}-\mathbf{w}'||^2 + C \cdot l_i(\mathbf{w}) \tag{1}$$

$$l_i(\mathbf{w}) = \max_{e_{ij}} \{\mathrm{b}(e_i^*) - \mathrm{b}(e_{ij}) - \mathbf{w}\cdot[\mathbf{h}(e_i^*) - \mathbf{h}(e_{ij})]\} \tag{2}$$

where $e_i^* \in \mathbf{e_i}$ is a *hope* candidate, $\mathbf{w}'$ is the parameter vector from the last sentence. Since MIRA defines its objective only based on the current sentence, $\mathrm{b}(\cdot)$ is a sentence-level BLEU.

Most MIRA algorithms need a deliberate definition of $\mathrm{b}(\cdot)$, since BLEU cannot be decomposed into sentences. The types of the sentence BLEU calculation includes: (a) a smoothed version of BLEU for e_{ij} (Liang et al., 2006), (b) fit e_{ij} into a pseudo-document considering the history (Chiang et al., 2008; Chiang, 2012), (c) use e_{ij} to replace the corresponding hypothesis in the oracles (Watanabe et al., 2007). The sentence-level BLEU sometimes perplexes the algorithms and results in a mismatch with the corpus-level BLEU.

3 Corpus-level MIRA

3.1 Algorithm

We propose a batch tuning strategy, corpus-level MIRA (c-MIRA), in which an objective is not built upon a hinge loss of a single sentence, but upon that of the entire corpus.

The online MIRAs are difficult to parallelize. Therefore, similar to the batch MIRA in (Cherry and Foster, 2012), we conduct the batch tuning by repeating the following steps: (a) Decode source sentences (in parallel) and obtain $\{\mathbf{e_i}\}_{i=1}^M$, (b) Merge $\{\mathbf{e_i}\}_{i=1}^M$ with the one from the previous iteration, (c) Invoke Algorithm 1.

We define $\mathcal{E} = (e_{\mathcal{E},1}, e_{\mathcal{E},2}, ..., e_{\mathcal{E},M})$ as a corpus hypothesis, with $\mathbf{H}(\mathcal{E}) = \frac{1}{M}\sum_{i=1}^{M}\mathbf{h}(e_{\mathcal{E},i})$. $e_{\mathcal{E},i}$ is the hypothesis of the source sentence f_i covered by $\mathcal{E}$. $\mathcal{E}$ is corresponded to a corpus-level BLEU, which we ultimately want to optimize. Following MIRA formulated in (Crammer et al., 2006; Chiang et al., 2008), c-MIRA repeatedly optimizes,

$$\min_{\mathbf{w}} \quad \frac{1}{2}||\mathbf{w}-\mathbf{w}'||^2 + C \cdot l_{corpus}(\mathbf{w}) \tag{3}$$

$$l_{corpus}(\mathbf{w}) = \max_{\mathcal{E}} \{\mathrm{B}(\mathcal{E}^*) - \mathrm{B}(\mathcal{E}) - \mathbf{w}\cdot[\mathbf{H}(\mathcal{E}^*) - \mathbf{H}(\mathcal{E})]\} \tag{4}$$

where $\mathrm{B}(\cdot)$ is a corpus-level BLEU. $\mathcal{E}^*$ is a *hope* hypothesis. $\mathcal{E} \in \mathcal{L}$, where $\mathcal{L}$ is the hypothesis space of the entire corpus, and $|\mathcal{L}| = |\mathbf{e_1}|\cdots|\mathbf{e_M}|$.

Algorithm 1 Corpus-Level MIRA

Require: $\{(f_i, \mathbf{e}_i, \mathbf{r}_i)\}_{i=1}^M$, $\mathbf{w_0}$, C

for $t = 1 \cdots T$ **do**
  $\mathcal{E}^* = \{\}$,$\mathcal{E}' = \{\}$ ▷ Initialize the *hope* and *fear*
  for $i = 1 \cdots M$ **do**
    $e_{\mathcal{E}^*,i} = \arg\max_{e_{ij}} [\mathbf{w_{t-1}} \cdot \mathbf{h}(e_{ij}) + \mathrm{b}'(e_{ij})]$
    $e_{\mathcal{E}',i} = \arg\max_{e_{ij}} [\mathbf{w_{t-1}} \cdot \mathbf{h}(e_{ij}) - \mathrm{b}'(e_{ij})]$
    $\mathcal{E}^* \leftarrow \mathcal{E}^* + \{e_{\mathcal{E}^*,i}\}$ ▷ Build the *hope*
    $\mathcal{E}' \leftarrow \mathcal{E}' + \{e_{\mathcal{E}',i}\}$ ▷ Build the *fear*
  end for
  $\triangle_{\mathrm{B}} = \mathrm{B}(\mathcal{E}^*) - \mathrm{B}(\mathcal{E}')$ ▷ the BLEU difference
  $\triangle_{\mathbf{H}} = \mathbf{H}(\mathcal{E}') - \mathbf{H}(\mathcal{E}^*)$ ▷ the feature difference
  $\alpha = \min\left[C, \frac{\triangle_{\mathrm{B}} + \mathbf{w_{t-1}}\cdot\triangle_{\mathbf{H}}}{||\triangle_{\mathbf{H}}||^2}\right]$
  $\mathbf{w_t} = \mathbf{w_{t-1}} - \alpha \cdot \triangle_{\mathbf{H}}$
  $\bar{\mathbf{w}}_t = \frac{1}{t+1}\sum_{t=0}^{t}\mathbf{w}_t$
end for
return $\bar{\mathbf{w}}_t$ with the optimal BLEU on the *dev* set.

c-MIRA can be regarded as a standard MIRA, in which there is only one single triple $(\mathcal{F}, \mathcal{L}, \mathcal{R})$, where $\mathcal{F}$ and $\mathcal{R}$ are the source and reference of the corpus respectively. Eq. 3 is equivalent to a quadratic programming with $|\mathcal{L}|$ constraints. Crammer et al. (2006) show that a single constraint with one *hope* $\mathcal{E}^*$ and one *fear* $\mathcal{E}'$ admits a closed-form update and performs well. We denote one execution of the outer loop as an *epoch*. The *hope* and *fear* are updated in each *epoch*. Similar to (Chiang et al., 2008), the *hope* and *fear* hypotheses are defined as following,

$$\mathcal{E}^* = \max_{\mathcal{E}}[\mathbf{w}\cdot\mathbf{H}(\mathcal{E}) + \mathrm{B}(\mathcal{E})] \tag{5}$$

$$\mathcal{E}' = \max_{\mathcal{E}}[\mathbf{w}\cdot\mathbf{H}(\mathcal{E}) - \mathrm{B}(\mathcal{E})] \tag{6}$$

Eq. 5 and 6 find the hypotheses with the best and worse BLEU that the decoder can easily achieve. It is unnecessary to search the entire space of $\mathcal{L}$ for precise solution $\mathcal{E}^*$and $\mathcal{E}'$, because MIRA only at-

tempts to separate the *hope* from the *fear* by a margin proportional to their BLEU differentials (Cherry and Foster, 2012). We just construct $\mathcal{E}^*$and $\mathcal{E}'$ respectively by,

$$e_{\mathcal{E}^*,i} = \max_{e_{i,j}}[\mathbf{w}\cdot\mathbf{h}(e_{i,j}) + \mathrm{b}'(e_{i,j})]$$
$$e_{\mathcal{E}',i} = \max_{e_{i,j}}[\mathbf{w}\cdot\mathbf{h}(e_{i,j}) - \mathrm{b}'(e_{i,j})]$$

where b' is simply a BLEU with add one smoothing (Lin and Och, 2004). A smoothed BLEU is good enough to pick up a "satisfying" pair of *hope* and *fear*. However, the updating step (Line 11) uses the corpus-level BLEU.

3.2 Justification

c-MIRA treats a corpus as one sentence for decoding, while conventional decoders process sentences one by one. We show the optimal solutions from the two methods are equivalent theoretically.

We follow the notations in (Och and Ney, 2002). We search a hypothesis on corpus $\mathcal{E} = \{e_{1,k_1}, e_{2,k_2}, ..., e_{M,k_M}\}$ with the highest probability given the source corpus $\mathcal{F} = \{\mathrm{f}_1, \mathrm{f}_2, ..., \mathrm{f}_\mathrm{M}\}$,

$$\begin{aligned}\overline{\mathcal{E}} &= \arg\max_{\mathcal{E}} \log P(\mathcal{E}|\mathcal{F}) \\ &= \arg\max_{\mathcal{E}} \left(\mathbf{w}\cdot\sum_{i=1}^{M}\mathbf{h}(e_{i,k_i}) - \sum_{\mathrm{i}=1}^{\mathrm{M}}\log(\mathrm{Z_i})\right) \quad (7) \\ &= \{\arg\max_{e_{i,k_i}} \mathbf{w}\cdot\mathbf{h}(e_{i,k_i})\}_{i=1}^{M} \quad (8)\end{aligned}$$

where $Z_i = \sum_{j=1}^{N(f_i)}\exp(\mathbf{w}\cdot\mathbf{h}(e_{i,j}))$, which is a constant with respective to $\mathcal{E}$. Eq. 7 shows that the feature vector of $\mathcal{E}$ is determined by the sum of each candidate's feature vectors. Also, the model score can be decomposed into each sentence in Eq. 8, which shows that decoding all sentences together equals to decoding one by one.

We also show that if the metric is decomposable, the loss in c-MIRA is actually the sum of the hinge loss $l_i(\mathbf{w})$ in structural SVM (Tsochantaridis et al., 2004; Cherry and Foster, 2012). We assume $B(e_{ij})$ to be the metric of a sentence hypothesis, then the loss of c-MIRA in Eq. 4 is,

$$\begin{aligned}l_{corpus}(\mathbf{w}) &\propto \max_{\mathcal{E}'}\sum_{i=1}^{M}[B(e_{i,k_{\mathcal{E}^*}}) - B(e_{i,k_{\mathcal{E}'}}) \\ &\quad -\mathbf{w}\cdot\mathbf{h}(e_{i,k_{\mathcal{E}^*}}) + \mathbf{w}\cdot\mathbf{h}(e_{i,k_{\mathcal{E}'}})] \\ &= \sum_{i=1}^{M}\max_{e_{ij}}[B(e_{i,k_{\mathcal{E}^*}}) - B(e_{ij}) \\ &\quad -\mathbf{w}\cdot\mathbf{h}(e_{i,k_{\mathcal{E}^*}}) + \mathbf{w}\cdot\mathbf{h}(e_{ij})] = \sum_{i=1}^{M} l_i(\mathbf{w})\end{aligned}$$

Instead of adopting a cutting-plane algorithm (Tsochantaridis et al., 2004), we optimize the same loss with a MIRA pattern in a simpler way. However, since BLEU is not decomposable, the structural SVM (Cherry and Foster, 2012) uses an interpolated sentence BLEU (Liang et al., 2006). Although Algorithm 1 has an outlook similar to the batch-MIRA algorithm in (Cherry and Foster, 2012), their loss definitions differ fundamentally. Batch MIRA basically uses a sentence-level loss, and they also follow the sentence-by-sentence tuning pattern. In the future work, we will compare structural SVM and c-MIRA under decomposable metrics like WER or SSER (Och and Ney, 2002).

4 Experiments and Analysis

We first evaluate c-MIRA in a iterative batch tuning procedure in a Chinese-to-English machine translation system with 228 features. Second, we show c-MIRA is also effective in the re-ranking task with more than 50,000 features.

In both experiments, we compare c-MIRA and three baselines: (1) MERT (Och, 2003), (2) Chiang et al.'s MIRA (MIRA_1) in (Chiang et al., 2008). (3) batch-MIRA (MIRA_2) in (Cherry and Foster, 2012). Here, we roughly choose C with the best BLEU on *dev* set, from $\{0.1, 0.01, 0.001, 0.0001, 0.00001\}$. We convert Chiang et al.'s MIRA to the batch mode described in section 3.1. So the only difference between MIRA_1 and MIRA_2 is: MIRA_1 obtains multiple constraints before optimization, while MIRA_2 only uses one constraint. We implement MERT and MIRA_1, and directly use MIRA_2 from Moses (Koehn et al., 2007). We conduct experiments in a server of 8-cores with 2.5GHz Opteron. We set the maximum number of *epochs* as we generally do not observe an obvious increase on the *dev* set BLEU.

		MERT	MIRA_1	MIRA_2	c-MIRA
	C		0.0001	0.001	0.0001
8	*dev*	**34.80**	34.70	34.73	34.70
feat.	04	**31.92**	31.81	31.73	31.83
	05	28.85	**28.94**	28.71	28.92
	C		0.001	0.001	0.001
all	*dev*	34.61	35.24	35.14	**35.56**
feat.	04	31.76	32.25	32.04	**32.57+**
	05	28.85	**29.43**	29.37	29.41
	06news	30.91	31.43	31.24	**31.82+**
	06others	27.43	28.01	28.13	**28.45**
	08news	25.62	26.11	26.03	**26.40**
	08others	16.22	16.66	16.46	**17.10+**

Table 1: BLEUs (%) on the *dev* and *test* sets with 8 dense features only and all features. The significant symbols (+ at 0.05 level) are compared with MIRA_2

The *epoch* size for MIRA_1 and MIRA_2 is 40, while the one for c-MIRA is 400. c-MIRA runs more *epochs*, because we update the parameters by much fewer times. However, we can implement Line 3$\sim$8 in Algorithm 1 in multi-thread (we use eight threads in the following experiments), which makes our algorithm much faster. Also, we increase the *epoch* sizes of MIRA_1 and MIRA_2 to 400, and find there is no improvement on their performance.

4.1 Iterative Batch Training

In this experiment, we conduct the batch tuning procedure shown in section 3. We align the FBIS data including about 230K sentence pairs with GIZA++ for extracting grammar, and train a 4-gram language model on the Xinhua portion of Gigaword corpus. A hierarchical phrase-based model (Chiang, 2007) is tuned on NIST MT 2002, which has 878 sentences, and tested on MT 2004, 2005, 2006, and 2008. All features used here, besides eight basic ones in (Chiang, 2007), consists of an extra 220 group features. We design such feature templates to group grammar by the length of source side and target side, $(feat\_type, a \leq src\_side \leq b, c \leq tgt\_side \leq d)$, where $feat\_type$ denotes any of relative frequency, reversed relative frequency, lexical probability and reversed lexical probability, and $[a, b]$, $[c, d]$ enumerate all possible subranges of $[1, 10]$, as the maximum length on each side of a hierarchical grammar is limited to 10. There are 4×55 extra group features. We also set the size of *N*-best list per sentence before merge as 200.

	MERT	MIRA_1	MIRA_2	c-MIRA
R. T.	25.8min	16.0min	7.3min	7.8min

Table 2: Running time.

All methods use 30 decoding iterations. We select the iteration with the best BLEU of the *dev* set for testing. We present the BLEU scores in Table 1 on two feature settings: (1) 8 basic features only, and (2) all 228 features. In the first case, due to the small feature size, MERT can get a better BLEU of the *dev* set, and all MIRA algorithms fails to generally beat MERT on the *test* set. However, as the feature size increase to 228, MERT degrades on the *dev*-set BLEU, and also become worse on *test* sets, while MIRA algorithms improve on the *dev* set expectedly. MIRA_1 performs better than MIRA_2, probably because of more constraints. c-MIRA can moderately improve BLEU by 0.2$\sim$0.4 from MIRA_1 and 0.2$\sim$0.6 from MIRA_2. This might indicate that a loss defined on corpus is more accurate than the one defined on sentence. Table 2 lists the running time. Only MIRA_2 is fairly faster than c-MIRA because of more *epochs* in c-MIRA.

4.2 Re-ranking Experiments

The baseline system is a state-of-the-art hierarchical phrase-based system, and trained on six million parallel sentences corpora available to the DARPA BOLT Chinese-English task. This system includes 51 dense features (including translation probabilities, provenance features, etc.) and about 50k sparse features (mostly lexical and fertility-based). The language model is a six-gram model trained on a 10 billion words monolingual corpus, including the English side of our parallel corpora plus other corpora such as Gigaword (LDC2011T07) and Google News. We use 1275 sentences for tuning and 1239 sentences for testing from the LDC2010E30 corpus respectively. There are four reference translations for each input sentence in both tuning and testing datasets.

We use a N-best list which is an intermediate out-

		MIRA_1	MIRA_2	c-MIRA

only	test	30.89	30.89	**31.07**
dense	dev	32.29	32.20	**32.49**
+sparse	test	31.12	31.00	**31.39**

Table 3: BLEUs (%) on re-ranking experiments.

MIRA_1	MIRA_2	c-MIRA
about 1,966,720	35,120	400

Table 4: Times of updating model parameters.

put of the baseline system optimized on TER-BLEU instead of BLEU. Before the re-ranking task, the initial BLEUs of the top-1 hypotheses on the tuning and testing set are 31.45 and 30.56. The average numbers of hypotheses per sentence are about 200 and 500, respectively for the tuning and testing sets. Again, we use the best *epoch* on the tuning set for testing. The BLEUs on *dev* and *test* sets are reported in Table 3. We observe that the effectiveness of c-MIRA is not harmed as the feature size is scaled up.

4.3 Analysis

To examine the simple search for *hopes* and *fears* (Line 3∼8 in Alg. 1), we use two *hope/fear* building strategies to get $\mathcal{E}^*$ and $\mathcal{E}'$: (1) simply connect each e_i^* and e_i' in Line 4∼5 of Algorithm 1, (2) conduct a slow beam search among the N-best lists of all foreign sentences from $\mathbf{e_1}$ to $\mathbf{e_M}$ and use Eq. 5 and 6 to prune the stack. The stack size is 10. We observe that there is no significant difference between the two strategies on the BLEU of the *dev* set. But the second strategy is about 10 times slower.

We also consider more constraints in Eq. 3. By beam search, we obtain one corpus-level oracle and 29 other hypotheses similar to (Chiang et al., 2008), and optimize with SMO (Platt, 1998). Unfortunately, experiments show that more constraints lead to an overfitting and no improved performance.

As shown in Table 4, in one execution, our method updates the parameters by only 400 times; MIRA_2 updates by $40 \times 878 = 35120$ times; and MIRA_1 updates much more (about 1,966,720 times) due to the SMO procedure. We are surprised to find c-MIRA gets a higher training BLEU with such few parameter updates. This probably suggests that there is a gap between sentence-level BLEU and corpus-level BLEU, so standard MIRAs need to update the parameters more often.

Regarding simplicity, MIRA_1 uses a strongly-heuristic definition of a sentence BLEU, and MIRA_2 needs a pseudo-document with a decay rate of $\gamma = 0.9$. In comparison, c-MIRA avoids both the sentence level BLEU and the pseudo-document, thus needs fewer variables.

5 Conclusion

We present a simple and effective MIRA batch tuning algorithm without the heuristic-driven calculation of sentence-level BLEU, due to the indecomposability of a corpus-level BLEU. Our optimization objective is directly defined on the corpus-level hypotheses. This work simplifies the tuning process, and avoid the mismatch between the sentence-level BLEU and the corpus-level BLEU. This strategy can be potentially applied to other optimization paradigms, such as the structural SVM (Cherry and Foster, 2012), SGD and AROW (Chiang, 2012), and other forms of samples, such as forests (Chiang, 2012) and lattice (Cherry and Foster, 2012).

Abstract

Multilingual speakers switch between languages in online and spoken communication. Analyses of large scale multilingual data require automatic language identification at the word level. For our experiments with multilingual online discussions, we first tag the language of individual words using language models and dictionaries. Secondly, we incorporate context to improve the performance. We achieve an accuracy of 98%. Besides word level accuracy, we use two new metrics to evaluate this task.

1 Introduction

There are more multilingual speakers in the world than monolingual speakers (Auer and Wei, 2007). Multilingual speakers switch across languages in daily communication (Auer, 1999). With the increasing use of social media, multilingual speakers also communicate with each other in online environments (Paolillo, 2011). Data from such resources can be used to study code switching patterns and language preferences in online multilingual conversations. Although most studies on multilingual online communication rely on manual identification of languages in relatively small datasets (Danet and Herring, 2007; Androutsopoulos, 2007), there is a growing demand for automatic language identification in larger datasets. Such a system would also be useful for selecting the right parsers to process multilingual documents and to build language resources for minority languages (King and Abney, 2013).

In this paper, we identify Dutch (NL) en Turkish (TR) at the word level in a large online forum for Turkish-Dutch speakers living in the Netherlands. The users in the forum frequently switch languages within posts, for example:

<TR> *Sariyi ver* </TR>
<NL> *Wel mooi doelpunt* </NL>

So far, language identification has mostly been modeled as a document classification problem. Most approaches rely on character or byte n-grams, by comparing n-gram profiles (Cavnar and Trenkle, 1994), or using various machine learning classifiers. While McNamee (2005) argues that language identification is a solved problem, classification on a more fine-grained level (instead of document level) remains a challenge (Hughes et al., 2006). Furthermore, language identification is more difficult for short texts (Baldwin and Lui, 2010; Vatanen et al., 2010), such as queries and tweets (Bergsma et al., 2012; Carter et al., 2012; Ceylan and Kim, 2009). Tagging individual words (without context) has been done using dictionaries, affix statistics and classifiers using character n-grams (Hammarström, 2007; Gottron and Lipka, 2010). Although Yamaguchi and Tanaka-Ishii (2012) segmented text by language, their data was artificially created by randomly sampling and concatenating text segments (40-160 characters) from monolingual texts. Therefore, the language switches do not reflect realistic switches as they occur in natural texts. Most related to ours is the work by King and Abney (2013) who labeled languages of words in multilingual web pages, but evaluated the task only using word level accuracy.

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 857–862,
Seattle, Washington, USA, 18-21 October 2013.

Our paper makes the following contributions: 1) We explore two new ways to evaluate the task for analyzing multilingual communication and show that only word accuracy gives a limited view 2) We are the first to apply this task on a conversational and larger dataset 3) We show that features using the context improve the performance 4) We present a new public dataset to support research on language identification.

In the rest of the paper, we first discuss the related work and describe our dataset. Secondly, we present our experiments. We finally conclude with a summary and suggestions for future work.

2 Corpus

Our data[1] comes from one of the largest online communities in The Netherlands for Turkish-Dutch speakers. All posts from May 2006 until October 2012 were crawled. Although Dutch and Turkish dominate the forum, English fixed phrases (e.g. *no comment, come on*) are also occasionally observed. Users switch between languages within and across posts. Examples 1 and 2 illustrate switches between Dutch and Turkish within the same post. Example 1 is a switch at sentence level, example 2 is a switch at word level.

Example 1:
<NL>Mijn dag kan niet stuk :) </NL>
<TR> Cok guzel bir haber aldim </TR>
Translation: <NL> This made my day:)
</NL><TR> I received good news
</TR>

Example 2:
<TR>kahvalti</TR><NL>met
vriendinnen by my thuis </NL>
Translation: <TR>breakfast </TR>
<NL> with my girlfriends at my home
</NL>

The data is highly informal with misspellings, lengthening of characters (e.g. *hotttt*), replacement of Turkish characters (*kahvalti* instead of *kahvaltı*) and spelling variations (*tankyu* instead of *thank you*). Dutch and Turkish sometimes share common spellings (e.g. *ben* is *am* in Dutch and *I* in Turkish), making this a challenging task.

Annotation
For this research, we classify words as either Turkish or Dutch. Since Dutch and English are typologically more similar to each other than Turkish, the English phrases (less than 1%) are classified as Dutch. Posts were randomly sampled and annotated by a native Turkish speaker who is also fluent in Dutch. A native Dutch speaker annotated a random set of 100 posts (Cohen's kappa = 0.98). The following tokens were ignored for language identification:

- Smileys (as part of the forum markup, as well as textual smileys such as ":)").
- Numeric tokens and punctuation.
- Forum tags (e.g. *[u]* to underline text).
- Links, images, embedded videos etc.
- Turkish and Dutch first names and place names[2].
- Usernames when indicated with special forum markup.
- Chat words, such as *hahaha*, *ooooh* and *lol* recognized using regular expressions.

Posts for which all tokens are ignored, are not included in the corpus.

Statistics
The dataset was randomly divided into a training, development and test set. The statistics are listed in Table 1. The statistics show that Dutch is the majority language, although the difference between Turkish and Dutch is not large. We also find that the documents (i.e. posts) are short, with on average 18 tokens per document. The data represents realistic texts found in online multilingual communication. Compared to previously used datasets (Yamaguchi and Tanaka-Ishii, 2012; King and Abney, 2013), the data is noisier and the documents are much shorter.

	#NL tokens	**#TR tokens**	**#Posts/(BL%)**
Train	14900 (54%)	12737 (46%)	1603 (15%)
Dev	8590 (51%)	8140 (49%)	728 (19%)
Test	5895 (53%)	5293 (47%)	735 (17%)

Table 1: Number of tokens and posts for Dutch (NL) and Turkish (TR), including % of bilingual (BL) posts

[2]Based on online name lists and Wikipedia pages

3 Experimental Setup

3.1 Training Corpora

We used the following corpora to extract dictionaries and language models.

- *GenCor*: Turkish web pages (Sak et al., 2008).
- *NLCOW2012*: Dutch web pages (Schäfer and Bildhauer, 2012).
- *Blog authorship corpus*: English blogs (Schler et al., 2006).

Each corpus was chunked into large segments which were then selected randomly until 5M tokens were obtained for each language. We tokenized the text and kept the punctuation.

3.2 Baselines

As baselines, we use *langid.py*[3] (Lui and Baldwin, 2012) and van Noord's *TextCat* implementation[4] of the algorithm by Cavnar and Trenkle (1994). TextCat is based on the comparison of n-gram profiles and langid.py on Naive Bayes with n-gram features. For both baselines, words were entered individually to each program. Words for which no language could be determined were assigned to Dutch. These models were developed to identify the languages of the documents instead of words and we did not retrain them. Therefore, these models are not expected to perform well on this task.

3.3 Models

We start with models that assign languages based on only the current word. Next, we explore models and features that can exploit the context (the other words in the post). Words with the highest probability for English were assigned to Dutch for evaluation.

Dictionary lookup (`DICT`)
We extract dictionaries with word frequencies from the training corpora. This approach looks up the words in the dictionaries and chooses the language for which the word has the highest probability. If the word does not occur in the dictionaries, Dutch is chosen as the language.

Language model (`LM`)
We build a character n-gram language model for each language (max. n-gram length is 5). We use Witten-Bell smoothing and include word boundaries for calculating the probabilities.

Dictionary + Language model (`DICT+LM`)
We first use the dictionary lookup approach (`DICT`). If the word does not occur in dictionaries, a decision is made using the language models (`LM`).

Logistic Regression (`LR`)
We use a logistic regression model that incorporates context with the following features:

- (Individual word) Label assigned by the `DICT+LM` model.
- (Context) The results of the `LM` model based on previous + current token, and current token + next token (e.g. the sequence "*ben thuis*" (*am home*) as a whole if *ben* is the current token). This gives the language model more context for estimation. We compare the use of the assigned labels (`LAB`) with the use of the log probability values (`PROB`) as feature values.

Conditional Random Fields (`CRF`)
We treat the task as a sequence labeling problem and experiment with linear-chain Conditional Random Fields (Lafferty et al., 2001) in three settings:

- (Individual word) A CRF with only the tags assigned by the `DICT+LM` to the individual tokens as a feature (`BASE`).
- (Context). CRFs using the `LAB` or `PROB` as additional features (same features as in the logistic regression model) to capture additional context.

3.4 Implementation

Language identification was not performed for texts within quotes. To handle the alphabetical lengthening (e.g. *lollll*), words are normalized by trimming same character sequences of three characters or more. We use the Lingpipe[5] and Scikit-learn (Pedregosa et al., 2011) toolkits for our experiments.

Table 2: Results of language identification experiments.

3.5 Evaluation

The assigned labels can be used for computational analysis of multilingual data in different ways. For example, these labels can be used to analyze language preferences in multilingual communication or the direction of the switches (from Turkish to Dutch or the other way around). Therefore, we evaluate the methods from different perspectives.

The evaluation at word and post levels is done with the following metrics:

- *Word classification* precision (P), recall (R) and accuracy. Although this is the most straightforward approach to evaluate the task, it ignores the document boundaries.
- *Fraction of language in a post*: Pearson's correlation (ρ) and Mean Absolute Error (MAE) of proportion of Turkish in a post. This evaluates the measured proportion of languages in a post when the actual tags for individual words are not needed. For example, such information is useful for analyzing the language preferences of users in the online forum. Besides reporting the MAE over all posts, we also separate the performance over monolingual and bilingual posts (BL).
- *Post classification*: Durham (2003) analyzed the switch between languages in terms of the amount of monolingual and bilingual posts. Our posts are classified as NL, TR or bilingual (BL) if all words are tagged in the particular language or both. We report F_1 and accuracy.

4 Results

The results are presented in Table 2. Significance tests were done by comparing the results of the word and post classification measures using McNemar's test, and comparing the MAEs using paired t-tests. All runs were significantly different from each other based on these tests ($p < 0.05$), except the MAEs of the `DICT+LM` and `LR+LAB` runs and the MAEs and post classification metrics between the CRFs runs.

The difficulty of the task is illustrated by examining the coverage of the tokens by the dictionaries. 24.6% of the tokens (dev + test set) appear in both dictionaries, 31.1% only in the Turkish dictionary, 30.5% only in the Dutch dictionary and 13.9% in none of the dictionaries.

The baselines do not perform well. This confirms that language identification at the word level needs different approaches than identification at the document level. Using language models result in a better performance than dictionaries. They can handle unseen words and are more robust against the noisy spellings. The combination of language models and dictionaries is more effective than the individual models. The results improve when context was added using a logistic regression model, especially with the probability values as feature values.

CRFs improve the results but the improvement on the correlation and MAE is less. More specifically, CRFs improve the performance on monolingual posts, especially when a single word is tagged in the wrong language. However, when the influence of the context is too high, CRFs reduce the performance in bilingual posts.

This is also illustrated with the results of the post classification. The LR+PROB run has a high recall (0.905), but a low precision (0.559) for bilingual posts, while the CRF+PROB approach has a low recall (0.611) and a high precision (0.828).

The fraction of Dutch and Turkish in posts varies widely, providing additional challenges to the use of CRFs for this task. Classifying posts first as monolingual/bilingual and tagging individual words afterwards for bilingual posts might improve the performance.

The evaluation metrics highlight different aspects of the task whereas word level accuracy gives a limited view. We suggest using multiple metrics to evaluate this task for future research.

Dictionaries versus Language Models

The results reported in Table 2 were obtained by sampling 5M tokens of each language. To study the effect of the number of tokens on the performance of the DICT and LM runs, we vary the amount of data. The performance of both methods increases consistently with more data (Figure 1). We also find that language models achieve good performance with only a limited amount of data, and consistently outperform the approach using dictionaries. This is probably due to the highly informal and noisy nature of our data.

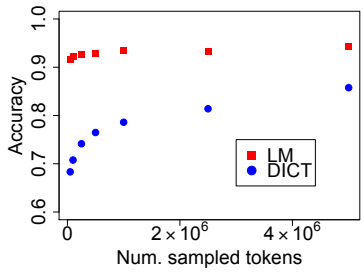

Figure 1: Effect of sampling size

Post classification

We experimented with classifying posts into TR, NL and bilingual using the results of the word level language identification (Table 2: post classification). Posts were classified as a particular language if all words were tagged as belonging to that language, and bilingual otherwise. Runs using CRFs achieved the best performance.

We now experiment with allowing a margin (e.g. a margin of 0.10 classifies posts as TR if at least 90% of the words are classified as TR). Allowing a small margin already increases the results of simpler approaches (such as the LR-PROB run, Table 3) by making it more robust against errors. However, allowing a margin reduces the performance of the CRF runs.

Margin	0.0	0.05	0.10	0.15	0.20
Accuracy	0.849	0.873	0.876	0.878	0.865

Table 3: Effect of margin on post classification (LR-PROB run)

Error analysis

The manual analysis of the results revealed three main challenges: 1) Our data is highly informal with many spelling variations (e.g. *moimoimoi*, *gooooooooooollllll*) and noise (e.g. *asdfghjfgshahaha*) 2) Words sharing spelling in Dutch and Turkish are difficult to identify especially when there is no context available (e.g. a post with only one word). These words are annotated based on their context. For example, the word *super* in *"Seyma, super"* is annotated as Turkish since *Seyma* is also a Turkish word. 3) Named entity recognition is necessary to improve the performance of the system and decrease the noise in evaluation. Based on precompiled lists, our system ignores named entities. However, some names still remain undetected (e.g. usernames).

5 Conclusion

We presented experiments on identifying the language of individual words in multilingual conversational data. Our results reveal that language models are more robust than dictionaries and adding context improves the performance. We evaluate our methods from different perspectives based on how language identification at word level can be used to analyze multilingual data. The highly informal spelling in online environments and the occurrences of named entities pose challenges.

Future work could focus on cases with more than two languages, and languages that are typologically less distinct from each other or dialects (Trieschnigg et al., 2012).

Abstract

Linking name mentions in microblog posts to a knowledge base, namely microblog entity linking, is useful for text mining tasks on microblog. Entity linking in long text has been well studied in previous works. However few work has focused on short text such as microblog post. Microblog posts are short and noisy. Previous method can extract few features from the post context. In this paper we propose to use extra posts for the microblog entity linking task. Experimental results show that our proposed method significantly improves the linking accuracy over traditional methods by 8.3% and 7.5% respectively.

1 Introduction

Microblogging services (e.g. Twitter) are attracting millions of users to share and exchange their ideas and opinions. Millions of new microblog posts are generated on such open broadcasting platforms every day [1]. Microblog provides a fruitful and instant channel of global information publication and acquisition.

A necessary step for the information acquisition on microblog is to identify which entities a post is about. Such identification can be challenging because the entity mention may be ambiguous. Let's begin with a real post from Twitter.

(1) No excuse for floods tax, says Abbott URL

This post is about an Australia political leader, `Tony Abbot`, and his opinion on flood tax policy. To understand that this post mentions Tony Abbot is not trivial because the name Abbot can refer to many people and organizations. In the Wikipedia page of *Abbott*, there lists more than 20 *Abbott*s, such as baseball player `Jim Abbott`, actor `Bud Abbott` and company `Abbott Laboratories`, etc..

Given a knowledge base (KB) (e.g. Wikipedia), entity linking is the task to identify the referent KB entity of a target name mention in plain text. Most current entity linking techniques are designed for long text such as news/blog articles (Mihalcea and Csomai, 2007; Cucerzan, 2007; Milne and Witten, 2008; Han and Sun, 2011; Zhang et al., 2011; Shen et al., 2012; Kulkarni et al., 2009; Ratinov et al., 2011). Entity linking for microblog posts has not been well studied.

Comparing with news/blog articles, microblog posts are:

short each post contains no more than 140 characters;

fresh the new entity-related content may have not been included in the knowledge base;

informal acronyms and spoken language writing style are common.

Due to these properties, few feature can be extracted from a post. Without enough features, previous entity linking methods may fail. In order to overcome the feature sparseness, we turn to another property of microblog:

*Corresponding author

[1] See http://blog.twitter.com/2011/06/ 200-million-tweets-per-day.html.

Seattle, Washington, USA, 18-21 October 2013.

redundancy For each day, over 340M short messages are posted in twitter. Similar information may be posted in different expressions.

For example, we find the following post,

> *(2) Julia Gillard and Tony Abbott on the flood levy just after 8.30am on @612brisbane!*

The content of post (2) is highly related to post (1). In contrast to the confusing post (1), the text in post (2) explicitly indicates that the *Abbott* here refers to the Australian political leader. This inspires us to bridge the confusing post and the knowledge base with other posts.

In this paper, we approach the microblog entity linking by leveraging extra posts. A straightforward method is to expand the post context with similar posts, which we call Context-Expansion-based Microblog Entity Linking (CEMEL). In this method, we first construct a query with the given post and then search for it in a collection of posts. From the search result, we select the most similar posts for the context expansion. The disambiguation will benefit from the extra posts if, hopefully, they are related to the given post in content and include explicit features for the disambiguation.

Furthermore, we propose a Graph-based Microblog Entity Linking (GMEL) method. In contrast to CEMEL, the extra posts in GMEL are not directly added into the context. Instead, they are represented as nodes in a graph, and weighted by their similarity with the target post. We use an iterative algorithm in this graph to propagate the entity weights through the edges between the post nodes.

We conduct experiments on real microblog data which we harvested from Twitter. Current entity linking corpus, such as the TAC-KBP data (McNamee and Dang, 2009), mainly focuses on long text. And few microblog entity linking corpus is publicly available. In this work, we manually annotated a microblog entity linking corpus. This corpus inherit the target names from TAC-KBP2009. So it is comparable with the TAC-KBP2009 corpus.

Experimental results show that the performance of previous methods drops on microblog posts comparing with on long text. Both of CEMEL and GMEL can significantly improve the performance over baselines, which means that entity linking system on microblog can be improved by leveraging extra posts. The results also show that GMEL outperforms CEMEL significantly.

We summarize our contributions as follows.

- We propose a context-expansion-based and a graph-based method for microblog entity linking by leveraging extra posts.
- We annotate a microblog entity linking corpus which is comparable to an existing long text corpus.
- We show the inefficiency of previous method on the microblog corpus and our method can significantly improve the results.

2 Task defination

The microblog entity linking task is that, for a name mention in a microblog post, the system is to find the referent entity of the name in a knowledge base, or return a NIL mark if the entity is absence from the knowledge base. This definition is close to the entity linking task in the TAC-KBP evaluation (Ji and Grishman, 2011) except for the context of the target name is microblog post whereas in TAC-KBP the context is news article or web log.

Several related tasks have been studied on microblog posts. In Meij et al. (2012)'s work, they link a post, rather than a name mention in the post, to relevant Wikipedia concepts. Guo et al. (2013a) and Liu et al. (2013) define entity linking as to first detect all the mentions in a post and then link the mentions to the knowledge base. In contrast, our definition (as well as the TAC-KBP definition) focuses on a concerned name mention across different posts/documents.

3 Method

A typical entity linking system can be broken down into two steps:

candidate generation This step narrows down the candidate entity range from any entity in the world to a limited set.

candidate ranking This step ranks the candidates and output the top ranked entity as the result.

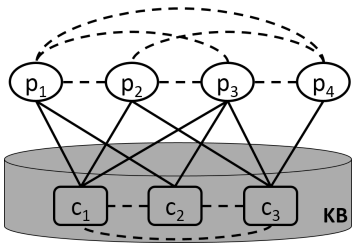

Figure 1: An example of the GMEL graph. $p_1 \dots p_4$ are post nodes and $c_1 \dots c_3$ are candidate entity nodes. Each post node is connected to the corresponding candidate nodes from the knowledge base. The edges between the nodes are weighted by the similarity between them.

In this paper, we use the candidate generation method described in Guo et al.(2013). For the candidate ranking, we use a Vector Space Model (VSM) and a Learning to Rank (LTR) as baselines. VSM is an unsupervised method and LTR is a supervised method. Both of them have achieved the state-of-the-art performances in the TAC-KBP evaluations.

The major challenge in microblog entity linking is the lack of context in the post. An ideal solution is to expand the context with the posts which contain the same entity. However, automatically judging whether a name mention in two documents refers to the same entity, namely cross document co-reference, is not trivial. Here our solution is to rank the posts by their possibility of co-reference to the target one and select the most possible co-referent posts for the expansion.

CEMEL is based on the assumption that, given a name and two posts where the name is mentioned, the higher similarity between the posts the higher possibility of their co-reference and that the co-referent posts may contains useful features for the disambiguation. However, two literally similar posts may not be co-referent. If such non co-referent post is expanded to the context, noises may be included.

Take the following post as an example.

(3) AG Abbott says that bullets have crossed the border from Mexico to Texas at least four times. URL

This post is similar to post (1) because they both contains "says" and "URL". But the Abbott in post (3) refers to the Texas Attorney General Greg Abbott. In this mean, the expanded context in post (3) could mislead the disambiguation for post (1). Such noise can be controlled by setting a strict number of posts to expand the context or weighting the contribution of this post to the target one.

Our CEMEL method consists of the following steps: First we construct a query with the terms from the target post. Second we search for the query in a microblog post collection using a common information retrieval model such as the vector space model. Note that here we limit the searched posts must contain the target name mention. Then we expand the target post with top N similar posts and use a typical entity linking method (such as VSM and LTR) with the expanded context.

Figure 1 illustrates the graph of GMEL. Each node of this graph represents an candidate entity (e.g. $c_1 \dots c_3$) or a post of the given target name (e.g. $p_1 \dots p_4$) In this graph, each node represents an entity or a post of the given target name. Between each pair of post nodes, each pair of entity nodes and each post node and its candidate entity nodes, there is an edge. The edge is weighted by the similarity between the two linked nodes. Entity nodes are labeled by themselves and candidate nodes are initialized as unlabeled nodes. For the edges between post node pairs and entity node pairs, we use cosine similarity. For the edges between a post node and its candidate entity nodes, we use the score given by traditional entity linking methods. We use an iterative algorithm on this graph to propagate the labels from the entity nodes to the post nodes. We adapt Label Propagation (LP) (Zhu and Ghahramani, 2002) and Modified Adsorption (MAD) (Talukdar and Pereira, 2010) for the iteration over the graph.

4 Experiment

4.1 Data Annotation

Till now, few microblog entity linking data is publicly available. In this work, we manually annotate a data set on microblog posts[2]. We collect 15.6 million microblog posts in Twitter dated from January 23 to February 8, 2011. In order to compare with existing entity linking on long text, we select a subset of target names from TAC-KBP2009 and inherit the knowledge base in the TAC-KBP evaluation. The

[2]We published this data so that researchers can reproduce our results.

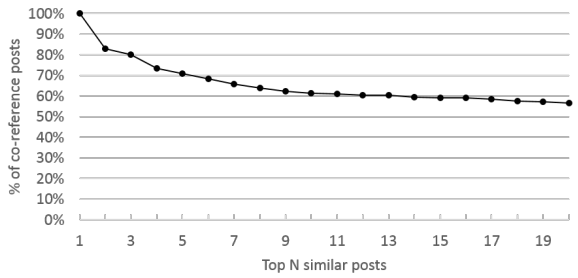

Figure 2: Percentage of the co-reference posts in the top N similar posts

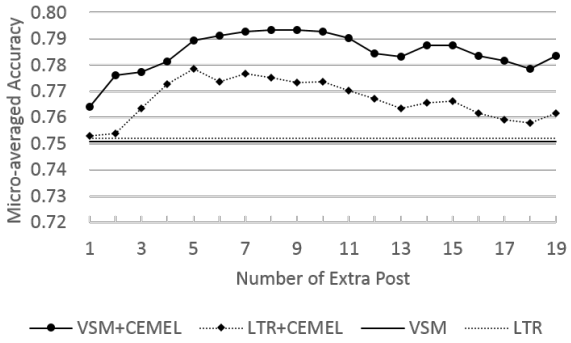

Figure 3: Impact of expansion post number in CEMEL

TAC-KBP2009 data set includes 513 target names. We search for all the target names in the post collection and get 26,643 matches. We randomly sample 120 posts for each of the top 30 most frequently matched target names and filter out non-English and overly short (i.e. less than 3 words) posts. Then we get 2,258 posts for 25 target names and manually link the target name mentions in the posts to the TAC-KBP knowledge base.

In order to evaluate the assumption in CEMEL: similar posts tend to co-reference, we randomly select 10 posts for 5 target names respectively and search for the posts in the post collection. From the search result of each of the 50 posts, we select the top 20 posts and manually annotate if they co-reference with the query post.

4.2 Settings

We generate candidates with the method described in (Guo et al., 2013b) and use Vector Space Model (VSM) (Varma et al., 2009) and Learning to Rank (LTR) (Zheng et al., 2010) as the ranking model. We

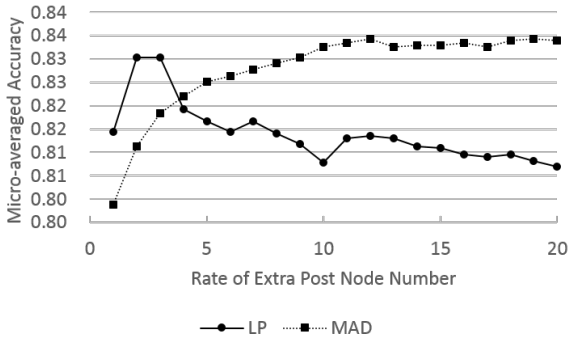

Figure 4: Accuracy of GMEL with different rate of extra post nodes

use Lucene and ListNet with default settings for the VSM and LTR implementation respectively. We use bigram feature for VSM and the feature set of (Chen et al., 2011) for LTR. LTR is evaluated with 10-fold cross validation. Given a target name, the GMEL graph includes all the evaluation posts as well as a set of extra post nodes searched from the post collection with the query of the target name. We filter out determiners, interjections, punctuations, emoticons, discourse markers and URLs in the posts with a twitter part-of-speech tagger (Owoputi et al., 2013). The similarity between a post and its candidate entities is set with the score given by VSM or LTR and the similarity between other nodes is set with the corresponding cosine similarity. We employ junto[3] with default settings for the iterative algorithm implementation .

4.3 Results

Figure 2 shows the relationship between similarity and co-reference. From this figure we can see that the percentage decreases with the growth of N. When the N is up to 10, about 60% of the similar posts co-reference with the query post and the decrease speed slows down. The Pearson correlation coefficient between the percentage and the number of top N is -0.843, which shows a significant correlation between the two variables (with p-value 0.01 under t-test).

Figure 3 shows the impact of the extra post number for the context expansion in CEMEL. We can see that the accuracies of VSM and LTR are improved

[3]See https://github.com/parthatalukdar/junto

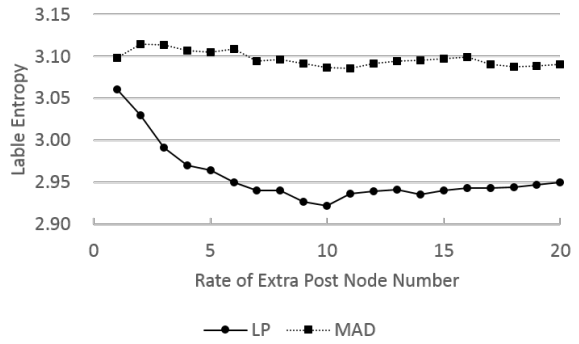

Figure 5: Label entropy of GMEL with different rate of extra post nodes

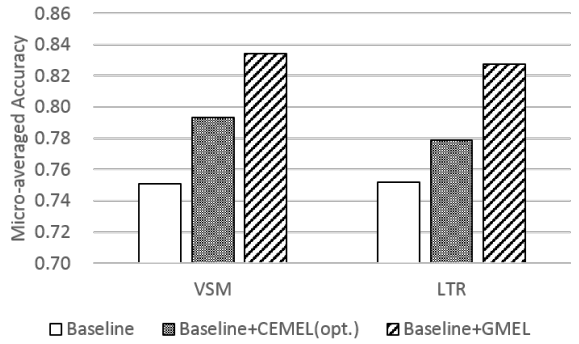

Figure 6: Accuracy of the systems

by CEMEL. The improvements peak with 5-10 extra posts. Then more extra posts will pull down the accuracy.

Figure 4 shows the accuracy of GMEL. The x-axis is the rate of the extra post number over the evaluation post number. We can see that the accuracy of MAD increases with the number of extra post nodes at first and then turns to be stable. The accuracy of LP increases at first and drops when more extra posts are added into the graph.

Figure 5 shows the information entropy of the labels in LP and MAD. The curves show that the prediction of LP tends to converge into a small number of labels. This is because LP prefers smoothing labelings over the graph (Talukdar and Pereira, 2010).

We also evaluate our baselines on TAC-KBP2009 data set (LTR is trained on TAC-KBP2010 data set). The accuracy of VSM and LTR are 0.8338 and 0.8372 respectively, which are comparable with the state-of-the-art result (Hachey et al., 2013).

Figure 6 shows the performances of the systems on the microblog data. We set the optimal expansion post number of CEMEL and use MAD algorithm for GMEL with all searched extra post nodes. From this figure we can see that the results of VSM and LTR baselines are comparable and both of them are significantly lower than that on TAC-KBP2009 data. CEMEL improves the VSM and LTR baselines by 4.3% and 2.7% respectively. GMEL improves VSM and LTR by 8.3% and 7.5% respectively. The results of GMEL are also significantly better than CEMEL. All of the improvements are significant under Z-test with $p < 0.05$.

5 Conclusion

In this paper we approach microblog entity linking by leveraging extra posts. We propose a context-expansion-based and a graph-based method. Experimental results on our data set show that the performance of traditional method drops on the microblog data. The graph-based method outperforms the context-expansion-based method and both of them significantly improve the accuracy of traditional methods. In the graph-based method the modified adsorption algorithm performs better than the label propagation algorithm.

Abstract

Multi-Domain learning (MDL) assumes that the domain labels in the dataset are known. However, when there are multiple metadata attributes available, it is not always straightforward to select a single best attribute for domain partition, and it is possible that combining more than one metadata attributes (including continuous attributes) can lead to better MDL performance. In this work, we propose an automatic domain partitioning approach that aims at providing better domain identities for MDL. We use a supervised clustering approach that learns the domain distance between data instances , and then cluster the data into better domains for MDL. Our experiment on real multi-domain datasets shows that using our automatically generated domain partition improves over popular MDL methods.

1 Introduction

Instead of assuming data are *i.i.d*, Multi-domain learning (MDL) methods assumes that data come from several domains and make use of domain labels to improve modeling performance (Daumé III, 2007). The motivation of using MDL is that datasets from different domains could be different, in two ways. First, the feature distribution $p(x)$ could be domain specific, meaning that the importance of each feature is different across domains. Second, the distribution of label Y given X, $p(y|x)$, of different domains could be different. These differences could create problems for traditional machine learning methods: models learned from one domain might not be generalizable to other domains (Ben-David et al., 2006; Ben-David et al., 2010).

One common assumption of MDL methods is that the domain identities are pre-defined. For example, in the multi-domain Amazon product review dataset (Finkel and Manning, 2009), the product categories are typically used as the domain identities. However, a question raised by Joshi et al. (2012) is that, in real-world data sets, there could be many ways to split data into domains, and it is hard to decide which one to use. Consider the Amazon product reviews, where we have multiple attributes attached to each review: for example, product category, reviewer location, price, and number of feedback. Which attribute is the most informative domain label? Or we should use all of these meta-data and partition the data into many small domains?

In this paper, we investigate the problem of automatic domain partitioning. We propose an empirical domain difference testing method to examine whether two groups of data are *i.i.d*, or generated from different distributions, and how different they are. Using this approach, we generate data pairs that belong to the same distribution, and data pairs that should be partitioned into different domains. These pairs are then used as training data for a supervised clustering algorithm, which automatically partitions the dataset into several domains. In the evaluation, we show that our automatically-partitioned domains improve the performances of two popular MDL methods on real sentiment analysis data sets.

Note that Joshi et al. (2013) proposed a Multi-Attribute Multi-Domain learning (MAMD) method, which also exploited multiple dimensions of meta-

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 869–873,
Seattle, Washington, USA, 18-21 October 2013.

data and provided extensions to two traditional MDL methods. However, extensions to the MAMD setting may not be trivial for every MDL algorithm, while our method serves as a pre-processing step and can be easily used for all MDL approaches. In addition to this, MAMD only works with categorical metadata, and can not fully utilize information in the form of continuous metadata values.

2 Automatic Domain Partitioning

In this section, we introduce the Automatic Domain Partitioning (ADP) problem: given data X, metadata M and label Y, find a function $g : M \mapsto I$ such that the common MDL methods perform better with data X and domain identity I in the prediction of Y. For example, on Amazon sentiment analysis data, X is the feature matrix extracted from reviews, Y is the positive or negative label vector, and M is the metadata matrix associated with reviews (e.g. product price and category).

Our approach works as follows: in training, we first use an empirical domain difference testing method to detect whether two groups of data should be considered as different domains; after that we apply supervised clustering to learn the distance metric between two data points, i.e. how different thay are in MDL view, from training data generated by our domain difference test method; finally, based on the distance metric learned, we cluster our data into several clusters, and train MDL models with those clusters as domain labels; in testing, we assign data instance to its nearest cluster and use that cluster as its domain identity, and then apply the trained MDL models for prediction.

2.1 Empirical Domain Difference Test

The key motivation of MDL is that a model fits for one domain may not fit well for other domains. Following the same motivation, we propose an empirical method for domain difference test called Domain Model Loss (DML) that provides us the domain difference score $d(G_1, G_2)$ between two groups of data $G_1 = \{X_1, Y_1\}$ and $G_2 = \{X_2, Y_2\}$.

Domain Model Loss If the mapping functions $f_1 : X_1 \mapsto Y_1$ and $f_2 : X_2 \mapsto Y_2$ are different for two data groups, we could directly use the disagreement of f_1 and f_2 as domain difference score. More specifically, if we train two classifiers $\hat{f}_1 : X_1 \mapsto Y_1, \hat{f}_2 : X_2 \mapsto Y_2$ individually on G_1 and G_2, we could have the K-fold empirical loss:

$$\hat{l}(f_1, G_1) = \frac{1}{K} \sum_i \text{Error of } f_1 \text{ on i-th fold of } G_1,$$

$$\hat{l}(f_2, G_2) = \frac{1}{K} \sum_i \text{Error of } f_2 \text{ on i-th fold of } G_2.$$

And we could also apply the trained model f_1 on G_2, and f_2 on G_1 to get:

$$\hat{l}(f_1, G_2) = \text{Error of } f_1 \text{ on } G_2,$$
$$\hat{l}(f_2, G_1) = \text{Error of } f_2 \text{ on } G_1.$$

Then, if G_1 and G_2 are actually the same with each other, then both models will have same empirical loss on either data set, but if they are not, we will have a positive DML score:

$$DML(G_1, G_2) = \frac{1}{2}(\hat{L}(f_1, G_2) + \hat{L}(f_2, G_1)),$$

where:

$$\hat{L}(f_1, G_2) = \frac{\hat{l}(f_1, G_2) - \hat{l}(f_1, G_1)}{\hat{l}(f_1, G_1)},$$
$$\hat{L}(f_2, G_1) = \frac{\hat{l}(f_2, G_1) - \hat{l}(f_2, G_2)}{\hat{l}(f_2, G_2)}.$$

2.2 Supervised Clustering for Domain Partitioning

Our domain difference test method calculates the distance between two partitioned data groups. However, to directly use it for domain partitioning, we must go through all possible combinations of domain assignments in exponential time, which is infeasible. Our solution is to use a polynomial-time supervised clustering method developed by Xing et al. (2002) to learn a distance function that calculates the distance between any two data points. Formally, given a set of data pairs D, which belong to different domains, and a set of data pairs S, which belong to the same domain, it learns a distance metric A by:

$$\begin{aligned} \max_A g(A) &= \sum_{(i,j)\in D} \sqrt{(m_i - m_j)^T A (m_i - m_j)} \\ s.t. f(A) &= \sum_{(i,j)\in S} (m_i - m_j)^T A (m_i - m_j) \le 1 \\ A &\succeq 0, \end{aligned}$$

where m_i, m_j are meta data of i and j.

The metadata M are preprocessed as follows: 1) Each categorical attribute was converted to several binary questions, one per category, and each binary question was considered as one metadata dimension in ADP method. For example, if categorical attribute "Product Type" has two values "Music" and "Electronics", then there will be two dimensions of metadata corresponding to "Product Type" in ADP. Two metadata dimensions correspond to binary questions: "Is Product Type Music" and "Is Product Type Electronics". 2) Each continuous attribute was normalized by scaling between 0 and 1.

The training data S, D for metric learning are generated as follows:

1. For each dimension M_k of M, split data at value 0.5, sample two equally sized groups, apply our domain difference testing method and find the difference between these data groups.
2. Assign distance to each pair of instances by the average distance of all partitions that partitions the pair into different groups.
3. Select top n similar pairs as S and top n different pairs as D.

The learned distance metric A now conveys the domain difference information obtained from our domain distance test results: which meta attributes are important for domain partitioning and which are not as important. Following Xing et al. (2002), we transfer the instance's metadata feature M by MB^T, where $B^TB = A$. Then we use a clustering method on MB^T, and the output is our domain partitioning result.

3 Experiment Methodology

Datasets To evaluate our methods, we used two subsets of Amazon review corpus (Jindal and Liu, 2008), which originally contain 5.8 million reviews with a variety of metadata about products and users. The first subset (`BOOK`) contains 20,000 reviews on books published by eleven most popular publishers, while the second (`PROD`) is reviews about products within seven most common product categories. We randomly split each dataset into training and testing sets with equal size. The task is to predict a positive or negative label for each review. Case insensitive unigrams excluding stop words are used as features, and all features appear less than 500 times are removed for efficient experiment processing. Reviews of 4 or 5 stars are considered positive and 1 or 2 stars are considered negative, while 3 stars reviews are excluded. Each review has multiple metadata such as book's publisher, product's type, user's state location, product price, review year, and number of other user feedback. Reviews with missing metadata are filtered out.

MDL Methods Our first MDL algorithm is the Frustratingly Easy Domain Adaptation (**FEDA**) (Daumé III, 2007) which is easy to implement and achieved competitive performance on many applications. It creates an augmented feature space as the Cartesian product of the input features and the original domains plus a shared domain. Then it uses a SVM classifier over the augmented feature space to obtain classification result. Specifically, our FEDA methods use L_2-regularized SVM with linear kernel by LIBLINEAR package[1]. The parameters C = 0.01 was selected using five-fold cross-validation on training set.

Our second MDL algorithm is Multi-Domain Regularization (**MDR**) (Dredze and Crammer, 2008), which is a classifier combination approach based on Confidence-Weighted (CW) learning (Dredze et al., 2008). The CW learning is an online update method that maintains probabilistic confidence for each parameter by keeping track of its variance. In our experiments, we use the CW implementation provided by its authors and choose the best performing configurations described in (Dredze and Crammer, 2008).

Domain Partition Methods We evaluated the domain partition results provided by our ADP on the two MDL methods (FEDA & MDR). For simplicity and efficiency, we use Naive Bayes as our base prediction model f_1 and f_2 to generate the domain model loss score, described in section 2.1. In training data generation, we choose top 10% similar pairs as S and top 10% different pairs as D. And given the learnt distance metric A, we use K-means to do the clustering. The number of clusters is selected by five-fold cross-validation on training set.

[1] http://www.csie.ntu.edu.tw/∼cjlin/liblinear

We compare our domain partition quality with three other methods: 1) **1-Best** chooses best performing categorical metadata on a validation set as domain indicators, where the original training set was splitted equally to train and validate the performance of each categorical attribute; 2) **Random** partition that assigns domain identities to instances randomly with same number of domains as 1-Best. We run each random partition ten times and took the average; 3) **MAMD** proposed by Joshi et al. (2013). However, the original version of MAMD does not support continuous attribute such as price. So we made an extension that sorts these values to ten bins and then treats them as categorical values.

4 Results and Discussions

Partition + MDL	PROD	BOOK
ADP + FEDA	82.02 $*$	86.22 ‡$*$
MAMD + FEDA	81.04	86.08
1-Best + FEDA	82.00	85.85
Random + FEDA	79.36	84.72
ADP + MDR	82.10 ♯ ‡ $*$	86.62 ♯ ‡ $*$
MAMD + MDR	80.17	84.37
1-Best + MDR	79.79	83.68
Random + MDR	74.65	81.16

Table 1: Overall accuracies on PROD and BOOK datasets. ADP results that are statistically significantly better than MAMD are marked with ♯, and better than 1-Best and Random are indicated by ‡ and $*$ respectively, using a paired t-test, with $p < 0.05$.

Table 1 shows the overall experimental results of four domain partition methods with two MDL methods on PROD and BOOK datasets. One could see that when using MDR method, ADP could significantly outperform all baselines on both data sets, with relatively more than 2% gains. For FEDA, on PROD data, ADP performs the same with MAMD and 1-Best; on BOOK data, ADP outperforms 1-Best significantly, but is just slightly better than MAMD. One possible reason is that the best numbers of cluster selected by cross-validation are around 150. With such large number of none-perfect domains, FEDA will generate huge dimension of features and perhaps require more training data to provide better performances. Another possible reason is that FEDA and the SVM underlying FEDA are very robust against bad domain partition results. This might be the reason of high FEDA baselines. In general, our ADP method helps existing MDL approaches achieve better performance, while bad (Random) partitioning does hurt.

Figure 1(a) and 1(b) shows the performances of applying FEDA on different domain partitioning methods on PROD and BOOK, while Figure 1(c) and 1(d) shows experiment results with MDR. The x-axis is the size of the output domains (the K in our K-means clustering), and y-axis is the accuracy of models. With our domain partitioning approach, MDR can perform consistently higher than all the three baselines on both dataset when $k > 50$. As we discussed for Table 1, FEDA might be less sensitive to domain partition results, which causes high baseline performance and high ADP+FEDA performance with small K. Since the performance trends to increase along with k until 50 in three figures (1(b), 1(c) and 1(d)), we believe that the ground-truth domain size is likely larger than 50. These results clearly indicate ADP does provide more desirable domain assignments for MDL. The domain selected by 1-Best such as publishers has only 11 domains, which limits the ability of 1-Best to completely express domain information. And our generated domains integrate multiple metadata attributes, lead to more detailed domain partitions, and enhance the ability of MDL methods to capture the difference between different groups of data. Although accuracies are growing with k in general, we also see that there are fluctuations on curves especially when curves are zoomed to a small range. To get smoother results, we can sample more data to calculate domain similarity and repeat the K-means clustering with more different initializations.

5 Conclusions

In this paper, we propose an Automatic Domain Partition (ADP) method that provides better domain identities for multi-domain learning methods. We first propose a new approach to identify whether two data groups should be considered as different domains, by comparing the differences using Domain Model Loss. We use a supervised clustering approach to train our model with labels generated by domain difference tests, and cluster the re-weighted

metadata as our domain partition by K-means. Experiments on real world multi-domain data show that the domain identities generated by our method can improve the performance of MDL models.

Decipherment with a Million Random Restarts

Taylor Berg-Kirkpatrick **Dan Klein**

University of California, Berkeley
{tberg,klein}@cs.berkeley.edu

Abstract

This paper investigates the utility and effect of running numerous random restarts when using EM to attack decipherment problems. We find that simple decipherment models are able to crack homophonic substitution ciphers with high accuracy if a large number of random restarts are used but almost completely fail with only a few random restarts. For particularly difficult homophonic ciphers, we find that big gains in accuracy are to be had by running upwards of 100K random restarts, which we accomplish efficiently using a GPU-based parallel implementation. We run a series of experiments using millions of random restarts in order to investigate other empirical properties of decipherment problems, including the famously uncracked Zodiac 340.

1 Introduction

What can a million restarts do for decipherment? EM frequently gets stuck in local optima, so running between ten and a hundred random restarts is common practice (Knight et al., 2006; Ravi and Knight, 2011; Berg-Kirkpatrick and Klein, 2011). But, how important are random restarts and how many random restarts does it take to saturate gains in accuracy?

We find that the answer depends on the cipher. We look at both Zodiac 408, a famous homophonic substitution cipher, and a more difficult homophonic cipher constructed to match properties of the famously unsolved Zodiac 340. Gains in accuracy saturate after only a hundred random restarts for Zodiac 408, but for the constructed cipher we see large gains in accuracy even as we scale the number of random restarts up into the hundred thousands. In both cases the difference between few and many random restarts is the difference between almost complete failure and successful decipherment.

We also find that millions of random restarts can be helpful for performing exploratory analysis. We look at some empirical properties of decipherment problems, visualizing the distribution of local optima encountered by EM both in a successful decipherment of a homophonic cipher and in an unsuccessful attempt to decipher Zodiac 340. Finally, we attack a series of ciphers generated to match properties of Zodiac 340 and use the results to argue that Zodiac 340 is likely not a homophonic cipher under the commonly assumed linearization order.

2 Decipherment Model

Various types of ciphers have been tackled by the NLP community with great success (Knight et al., 2006; Snyder et al., 2010; Ravi and Knight, 2011). Many of these approaches learn an encryption key by maximizing the score of the decrypted message under a language model. We focus on homophonic substitution ciphers, where the encryption key is a 1-to-many mapping from a plaintext alphabet to a cipher alphabet. We use a simple method introduced by Knight et al. (2006): the EM algorithm (Dempster et al., 1977) is used to learn the emission parameters of an HMM that has a character trigram language model as a backbone and the ciphertext as the observed sequence of emissions. This means that we learn a multinomial over cipher symbols for each plaintext character, but do not learn transition

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 874–878,
Seattle, Washington, USA, 18-21 October 2013.

parameters, which are fixed by the language model. We predict the deciphered text using posterior decoding in the learned HMM.

2.1 Implementation

Running multiple random restarts means running EM to convergence multiple times, which can be computationally intensive; luckily, restarts can be run in parallel. This kind of parallelism is a good fit for the Same Instruction Multiple Thread (SIMT) hardware paradigm implemented by modern GPUs. We implemented EM with parallel random restarts using the CUDA API (Nickolls et al., 2008). With a GPU workstation,[1] we can complete a million random restarts roughly a thousand times more quickly than we can complete the same computation with a serial implementation on a CPU.

3 Experiments

We ran experiments on several homophonic substitution ciphers: some produced by the infamous Zodiac killer and others that were automatically generated to be similar to the Zodiac ciphers. In each of these experiments, we ran numerous random restarts; and in all cases we chose the random restart that attained the highest model score in order to produce the final decode.

3.1 Experimental Setup

The specifics of how random restarts are produced is usually considered a detail; however, in this work it is important to describe the process precisely. In order to generate random restarts, we sampled emission parameters by drawing uniformly at random from the interval $[0, 1]$ and then normalizing. The corresponding distribution on the multinomial emission parameters is mildly concentrated at the center of the simplex.[2]

For each random restart, we ran EM for 200 iterations.[3] We found that smoothing EM was important for good performance. We added a smoothing constant of 0.1 to the expected emission counts before each M-step. We tuned this value on a small held out set of automatically generated ciphers.

In all experiments we used a trigram character language model that was linearly interpolated from character unigram, bigram, and trigram counts extracted from both the Google N-gram dataset (Brants and Franz, 2006) and a small corpus (about 2K words) of plaintext messages authored by the Zodiac killer.[4]

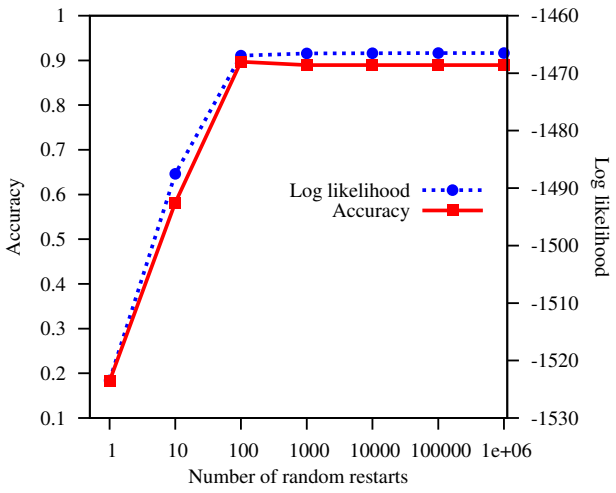

Figure 1: Zodiac 408 cipher. Accuracy by best model score and best model score vs. number of random restarts. Bootstrapped from 1M random restarts.

3.2 An Easy Cipher: Zodiac 408

Zodiac 408 is a homophonic cipher that is 408 characters long and contains 54 different cipher symbols. Produced by the Zodiac killer, this cipher was solved, manually, by two amateur code-breakers a week after its release to the public in 1969. Ravi and Knight (2011) were the first to crack Zodiac 408 using completely automatic methods.

In our first experiment, we compare a decode of Zodiac 408 using one random restart to a decode using 100 random restarts. Random restarts have high

[1] We used a single workstation with three NVIDIA GTX 580 GPUs. These are consumer graphics cards introduced in 2011.

[2] We also ran experiments where emission parameters were drawn from Dirichlet distributions with various concentration parameter settings. We noticed little effect so long as the distribution did not favor the corners of the simplex. If the distribution did favor the corners of the simplex, decipherment results deteriorated sharply.

[3] While this does not guarantee convergence, in practice 200 iterations seems to be sufficient for the problems we looked at.

[4] The interpolation between n-gram orders is uniform, and the interpolation between corpora favors the Zodiac corpus with weight 0.9.

variance, so when we present the accuracy corresponding to a given number of restarts we present an average over many bootstrap samples, drawn from a set of one million random restarts. If we attack Zodiac 408 with a single random restart, on average we achieve an accuracy of 18%. If we instead use 100 random restarts we achieve a much better average accuracy of 90%. The accuracies for various numbers of random restarts are plotted in Figure 1. Based on these results, we expect accuracy to increase by about 72% when using 100 random restarts instead of a single random restart; however, using more than 100 random restarts for this particular cipher does not appear to be useful.

Also in Figure 1, we plot a related graph, this time showing the effect that random restarts have on the achieved model score. By construction, the (maximum) model score must increase as we increase the number of random restarts. We see that it quickly saturates in the same way that accuracy did.

This raises the question: have we actually achieved the globally optimal model score or have we only saturated the usefulness of random restarts? We can't prove that we have achieved the global optimum,[5] but we can at least check that we have surpassed the model score achieved by EM when it is initialized with the gold encryption key. On Zodiac 408, if we initialize with the gold key, EM finds a local optimum with a model score of -1467.4. The best model score over 1M random restarts is -1466.5, which means we have surpassed the gold initialization.

The accuracy after gold initialization was 92%, while the accuracy of the best local optimum was only 89%. This suggests that the global optimum may not be worth finding if we haven't already found it. From Figure 1, it appears that large increases in likelihood are correlated with increases in accuracy, but small improvements to high likelihoods (e.g. the best local optimum versus the gold initialization) may not to be.

[5]ILP solvers can be used to globally optimize objectives corresponding to short 1-to-1 substitution ciphers (Ravi and Knight, 2008) (though these objectives are slightly different from the likelihood objectives faced by EM), but we find that ILP encodings for even the shortest homophonic ciphers cannot be optimized in any reasonable amount of time.

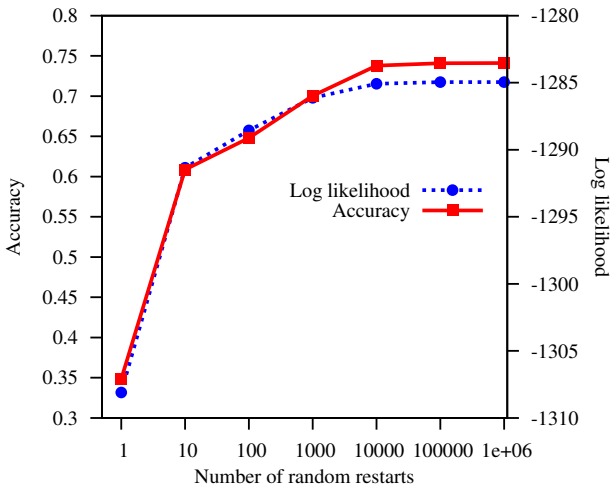

Figure 2: Synth 340 cipher. Accuracy by best model score and best model score vs. number of random restarts. Bootstrapped from 1M random restarts.

3.3 A Hard Cipher: Synth 340

What do these graphs look like for a harder cipher? Zodiac 340 is the second cipher released by the Zodiac killer, and it remains unsolved to this day. However, it is unknown whether Zodiac 340 is actually a homophonic cipher. If it were a homophonic cipher we would certainly expect it to be harder than Zodiac 408 because Zodiac 340 is shorter (only 340 characters long) and at the same time has *more* cipher symbols: 63. For our next experiment we generate a cipher, which we call Synth 340, to match properties of Zodiac 340; later we will generate multiple such ciphers.

We sample a random consecutive sequence of 340 characters from our small Zodiac corpus and use this as our message (and, of course, remove this sequence from our language model training data). We then generate an encryption key by assigning each of 63 cipher symbols to a single plain text character so that the number of cipher symbols mapped to each plaintext character is proportional to the frequency of that character in the message (this balancing makes the cipher more difficult). Finally, we generate the actual ciphertext by randomly sampling a cipher token for each plain text token uniformly at random from the cipher symbols allowed for that token under our generated key.

In Figure 2, we display the same type of plot, this time for Synth 340. For this cipher, there is an abso-

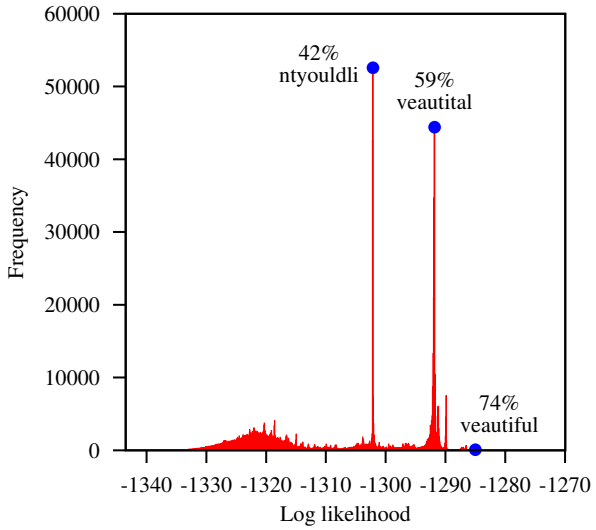

Figure 3: Synth 340 cipher. Histogram of the likelihoods of the local optima encountered by EM across 1M random restarts. Several peaks are labeled with their average accuracy and a snippet of a decode. The gold snippet is "beautiful."

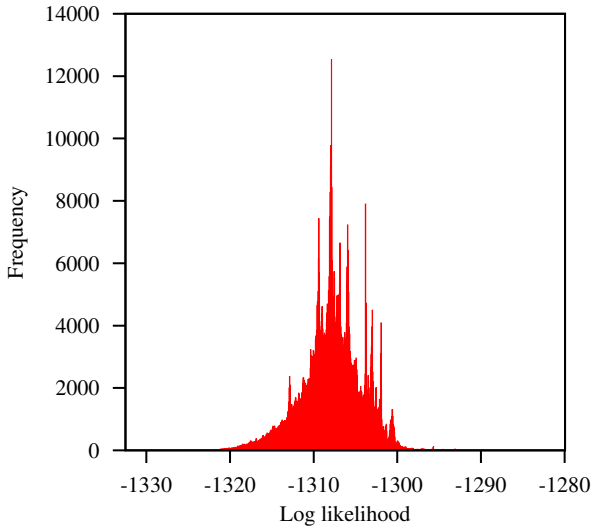

Figure 4: Zodiac 340 cipher. Histogram of the likelihoods of the local optima encountered by EM across 1M random restarts.

lute gain in accuracy of about 9% between 100 random restarts and 100K random restarts. A similarly large gain is seen for model score as we scale up the number of restarts. This means that, even after tens of thousands of random restarts, EM is still finding new local optima with better likelihoods. It also appears that, even for a short cipher like Synth 340, likelihood and accuracy are reasonably coupled.

We can visualize the distribution of local optima encountered by EM across 1M random restarts by plotting a histogram. Figure 3 shows, for each range of likelihood, the number of random restarts that led to a local optimum with a model score in that range. It is quickly visible that a few model scores are substantially more likely than all the rest. This kind of sparsity might be expected if there were a small number of local optima that EM was extremely likely to find. We can check whether the peaks of this histogram each correspond to a single local optimum or whether each is composed of multiple local optima that happen to have the same likelihood. For the histogram bucket corresponding to a particular peak, we compute the average relative difference between each multinomial parameter and its mean. The average relative difference for the highest peak in Figure 3 is 0.8%, and for the second highest peak is 0.3%. These values are much smaller than the average relative difference between the means of these two peaks, 40%, indicating that the peaks do correspond to single local optima or collections of extremely similar local optima.

There are several very small peaks that have the highest model scores (the peak with the highest model score has a frequency of 90 which is too small to be visible in Figure 3). The fact that these model scores are both high and rare is the reason we continue to see improvements to both accuracy and model score as we run numerous random restarts. The two tallest peaks and the peak with highest model score are labeled with their average accuracy and a small snippet of a decode in Figure 3. The gold snippet is the word "beautiful."

3.4 An Unsolved Cipher: Zodiac 340

In a final experiment, we look at the Zodiac 340 cipher. As mentioned, this cipher has never been cracked and may not be a homphonic cipher or even a valid cipher of any kind. The reading order of the cipher, which consists of a grid of symbols, is unknown. We make two arguments supporting the claim that Zodiac 340 is not a homophonic cipher with row-major reading order: the first is statistical, based on the success rate of attempts to crack similar synthetic ciphers; the second is qualitative, comparing distributions of local optimum likelihoods.

If Zodiac 340 is a homophonic cipher should we

expect to crack it? In order to answer this question we generate 100 more ciphers in the same way we generated Synth 340. We use 10K random restarts to attack each cipher, and compute accuracies by best model score. The average accuracy across these 100 ciphers was 75% and the minimum accuracy was 36%. All but two of the ciphers were deciphered with more than 51% accuracy, which is usually sufficient for a human to identify a decode as partially correct.

We attempted to crack Zodiac 340 using a row-major reading order and 1M random restarts, but the decode with best model score was nonsensical. This outcome would be unlikely if Zodiac 340 were like our synthetic ciphers, so Zodiac 340 is probably not a homophonic cipher with a row-major order. Of course, it could be a homophonic cipher with a different reading order. It could also be the case that a large number of salt tokens were inserted, or that some other assumption is incorrect.

In Figure 4, we show the histogram of model scores for the attempt to crack Zodiac 340. We note that this histogram is strikingly different from the histogram for Synth 340. Zodiac 340's histogram is not as sparse, and the range of model scores is much smaller. The sparsity of Synth 340's histogram (but not Zodiac 340's histogram) is typical of histograms corresponding to our set of 100 generated ciphers.

4 Conclusion

Random restarts, often considered a footnote of experimental design, can indeed be useful on scales beyond that generally used in past work. In particular, we found that the initializations that lead to the local optima with highest likelihoods are sometimes very rare, but finding them can be worthwhile; for the problems we looked at, local optima with high likelihoods also achieved high accuracies. While the present experiments are on a very specific unsupervised learning problem, it is certainly reasonable to think that large-scale random restarts have potential more broadly.

In addition to improving search, large-scale restarts can also provide a novel perspective when performing exploratory analysis, here letting us argue in support for the hypothesis that Zodiac 340 is not a row-major homophonic cipher.

Russian Stress Prediction using Maximum Entropy Ranking

Keith Hall **Richard Sproat**
Google, Inc
New York, NY, USA
{kbhall,rws}@google.com

Abstract

We explore a model of stress prediction in Russian using a combination of local contextual features and linguistically-motivated features associated with the word's stem and suffix. We frame this as a ranking problem, where the objective is to rank the pronunciation with the correct stress above those with incorrect stress. We train our models using a simple Maximum Entropy ranking framework allowing for efficient prediction. An empirical evaluation shows that a model combining the local contextual features and the linguistically-motivated non-local features performs best in identifying both primary and secondary stress.

1 Introduction

In many languages, one component of accurate word pronunciation prediction is predicting the placement of lexical stress. While in some languages (e.g. Spanish) the lexical stress system is relatively simple, in others (e.g. English, Russian) stress prediction is quite complicated. Much as with other work on pronunciation prediction, previous work on stress assignment has fallen into two camps, namely systems based on linguistically motivated rules (Church, 1985, for example) and more recently data-driven techniques where the models are derived directly from labeled training data (Dou et al., 2009). In this work, we present a machine-learned system for predicting Russian stress which incorporates both data-driven contextual features as well as linguistically-motivated word features.

2 Previous Work on Stress Prediction

Pronunciation prediction, of which stress prediction is a part, is important for many speech applications including automatic speech recognition, text-to-speech synthesis, and transliteration for, say, machine translation. While there is by now a sizable literature on pronunciation prediction from spelling (often termed "grapheme-to-phoneme" conversion), work that specifically focuses on stress prediction is more limited. One of the best-known early pieces of work is (Church, 1985), which uses morphological rules and stress pattern templates to predict stress in novel words. Another early piece of work is (Williams, 1987).

The work we present here is closer in spirit to data-driven approaches such as (Webster, 2004; Pearson et al., 2000) and particularly (Dou et al., 2009), whose features we use in the work described below.

3 Russian Stress Patterns

Russian stress preserves many features of Indo-European accenting patterns (Halle, 1997). In order to know the stress of a morphologically complex word consisting of a stem plus a suffix, one needs to know if the stem has an accent, and if so on what syllable; and similarly for the suffix. For words where the stem is accented,

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 879–883,
Seattle, Washington, USA, 18-21 October 2013.

	acc	unacc	postacc
Dat Sg	гор'оху	г'ороду	корол'ю
	gor'oxu	g'orodu	korolj'u
Dat Pl	гор'охам	город'ам	корол'ям
	gor'oxam	gorod'am	korolj'am
	'pea'	'town'	'king'

Table 1: Examples of accented, unaccented and postaccented nouns in Russian, for dative singular and plural forms.

this accent overrides any accent that may occur on the suffix. With unaccented stems, if the suffix has an accent, then stress for the whole word will be on the suffix; if there is also no stress on the suffix, then a default rule places stress on the first syllable of the word. In addition to these patterns, there are also postaccented words, where accent is placed uniformly on the first syllable of the suffix — an innovation of East and South Slavic languages (Halle, 1997). These latter cases can be handled by assigning an accent to the stem, indicating that it is associated with the syllable *after* the stem. Some examples of each of these classes, from (Halle, 1997, example 11), are given in Table 1. According to Halle (1997), considering just nouns, 91.6% are accented (on the stem), 6.6% are postaccented and 0.8% are unaccented, with about 1.0% falling into other patterns.

Stress placement in Russian is important for speech applications since over and above the phonetic effects of stress itself (prominence, duration, etc.), the position of stress strongly influences vowel quality. To take an example of the lexically unaccented noun город *gorod* 'city', the genitive singular г'орода *g'oroda* /gˈɔrədə/ contrasts with the nominative plural город'а *gorod'a* /gərʌdˈa/. All non-stressed /a/ are reduced to schwa — or by most accounts if before the stressed syllable to /ʌ/; see (Wade, 1992).

The stress patterns of Russian suggest that useful features for predicting stress might include (string) prefix and suffix features of the word in order to capture properties of the stem, since some stems are (un)accented, or of the suffix, since some suffixes are accented.

4 Maximum Entropy Rankers

Similarly to Dou et al. (2009), we frame the stress prediction problem as a ranking problem. For each word, we identify stressable vowels and generate a set of alternatives, each representing a different primary stress placement. Some words also have secondary stress which, if it occurs, always occurs before the primary stressed syllable. For each primary stress alternative, we generate all possible secondary stressed alternatives, including an alternative that has no secondary stress. (In the experiments reported below we actually consider two conditions: one where we ignore secondary stress in training and evaluation; and one where we include it.)

Formally, we model the problem using a Maximum Entropy ranking framework similar to that presented in Collins and Koo (2005). For each example, x_i, we generate the set of possible stress patterns $\mathcal{Y}_i$. Our goal is to rank the items in $\mathcal{Y}_i$ such that all of the valid stress patterns $\mathcal{Y}_i^*$ are above all of the invalid stress patterns. Our objective function is the likelihood, $\mathcal{L}$ of this conditional distribution:

$$\mathcal{L} = \prod_i p(\mathcal{Y}_i^* | \mathcal{Y}_i, x_i) \quad (1)$$

$$\log \mathcal{L} = \sum_i \log p(\mathcal{Y}_i^* | \mathcal{Y}_i, x_i) \quad (2)$$

$$= \sum_i \log \frac{\sum_{y' \in \mathcal{Y}_i^*} e^{\sum_k \theta_k f_k(y', x)}}{Z} \quad (3)$$

Z is defined as the sum of the conditional likelihood over all hypothesized stress predictions for example x_i:

$$Z = \sum_{y'' \in \mathcal{Y}_i} e^{\sum_k \theta_k f_k(y'', x)} \quad (4)$$

The objective function in Equation 3 can be optimized using a gradient-based optimization. In our case, we use a variety of stochastic gradient descent (SGD) which can be parallelized for efficient training.

During training, we provide all plausibly correct primary stress patterns as the *positive* set

$\mathcal{Y}_i^*$. At prediction-time, we evaluate all possible stress predictions and pick the one with the highest score under the trained model Θ:

$$\arg\max_{y' \in \mathcal{Y}_i} p(y'|\mathcal{Y}_i) = \arg\max_{y' \in \mathcal{Y}_i} \sum_k \theta_k f_k(y', x) \quad (5)$$

The primary motivation for using Maximum Entropy rather the ranking-SVM is for efficient training and inference. Under the above Maximum Entropy model, we apply a linear model to each hypothesis (i.e., we compute the dot-product) and sort according to this score. This makes inference (prediction) fast in comparison to the ranking SVM-based approach proposed in Dou et al. (2009).

All experiments presented in this paper used the Iterative Parameter Mixtures distributed SGD training optimizer (Hall et al., 2010). Under this training approach, per-iteration averaging has a regularization-like effect for sparse feature spaces. We also experimented with L1-regularization, but it offered no additional improvements.

5 Features

The features used in (Dou et al., 2009) are based on trigrams consisting of a vowel letter, the preceding consonant letter (if any) and the following consonant letter (if any). Attached to each trigram is the stress level of the trigram's vowel — 1, 2 or 0 (for no stress). For the English word *overdo* with the stress pattern 2-0-1, the basic features would be *ov:2*, *ver:0*, and *do:1*. Notating these pairs as $s_i : t_i$, where s_i is the triple, t_i is the stress pattern and i is the position in the word, the complete feature set is given in Table 2, where the stress pattern for the whole word is given in the last row as $t_1 t_2 ... t_N$. Dou and colleagues use an SVM-based ranking approach, so they generated features for all possible stress assignments for each word, assigning the highest rank to the correct assignment. The ranker was then trained to associate feature combinations to the correct ranking of alternative stress possibilities.

Given the discussion in Section 3, plausible additional features are all prefixes and suffixes of the word, which might be expected to better capture some of the properties of Russian stress patterns discussed above, than the much more local features from (Dou et al., 2009). In this case for all stress variants of the word we collect prefixes of length 1 through the length of the word, and similarly for suffixes, except that for the stress symbol we treat that together with the vowel it marks as a single symbol. Thus for the word *gorod'a*, all prefixes of the word would be *g*, *go*, *gor*, *goro*, *gorod*, *gorod'a*.

In addition, we include prefixes and suffixes of an "abstract" version of the word where most consonants and vowels have been replaced by a phonetic class. The mappings for these are shown in Table 3.

Note that in Russian the vowel ё /jɔ/ is *always* stressed, but is rarely written in text: it is usually spelled as е, whose stressed pronunciation is /(j)ɛ/. Since written е is in general ambiguous between е and ё, when we compute stress variants of a word for the purpose of rank-

Substring	s_i, t_i
	s_i, i, t_i
Context	s_{i1}, t_i
	$s_{i1}s_i, t_i$
	s_{i+1}, t_i
	$s_i s_{i+1}, t_i$
	$s_{i1}s_i s_{i+1}, ti$
Stress Pattern	$t_1 t_2 ... t_N$

ing, we include both variants that have е and ё.

6 Data

Our data were 2,004,044 fully inflected words with assigned stress expanded from Zaliznyak's *Grammatical Dictionary of the Russian Language* (Zaliznyak, 1977). These were split randomly into 1,904,044 training examples and 100,000 test examples. The 100,000 test examples obviously contain no *forms* that were found in the training data, but most of them are word forms that derive from lemmata from which some training data forms are also derived. Given the fact that Russian stress is lexically determined as outlined in Section 3, this is perfectly reasonable: in order to know how to stress a form, it is often necessary to have seen other words that share the same lemma. Nonetheless, it is also of interest to know how well the system works on words that do not share any lemmata with words in the training data. To that end, we collected a set of 248 forms that shared no lemmata with the training data. The two sets will be referred to in the next section as the "shared lemmata" and "no shared lemmata" sets.

7 Results

Table 4 gives word accuracy results for the different feature combinations, as follows: Dou et al's features (Dou et al., 2009); our affix features; our affix features plus affix features based on the abstract phonetic class versions of words; Dou et al's features plus our affix features; Dou et al's features plus our affix features plus the abstract affix features.

When we consider only primary stress (column 2 in Table 4, for the shared-lemmata test data, Dou et al's features performed the worst at 97.2% accuracy, with all feature combinations that include the affix features performing at the same level, 98.7%. For the no-shared-lemmata test data, using Dou et al's features alone achieved an accuracy of 80.6%. The affix features alone performed worse, at 79.8%, presumably because it is harder for them to generalize to unseen cases, but using the abstract affix features increased the performance to 81.0%, better than that of using Dou et al's features alone. As can be seen combining Dou et al's features with various combinations of the affix features improved the performance further.

Features	1 stress	1+2 stress
shared lemmata		
Dou et al	0.972	0.965
Aff	0.987	0.985
Aff+Abstr Aff	0.987	0.985
Dou et al+Aff	0.987	0.986
Dou et al+Aff+Abstr Aff	0.987	0.986
no shared lemmata		
Dou et al	0.806	0.798
Aff	0.798	0.782
Aff+Abstr	0.810	0.790
Dou et al+Aff	0.823	0.810
Dou et al+Aff+Abstr Aff	0.839	0.815

Table 4: Word accuracies for various feature combinations for both shared lemmata and no-shared lemmata conditions. The second column reports results where we consider only primary stress, the third column results where we also predict secondary stress.

For primary *and* secondary stress prediction (column 3 in the table), the results are overall degraded for most conditions but otherwise very similar in terms of ranking of the features to what we find with primary stress alone. Note though that for the shared-lemmata condition the results with affix features are almost as good as for the primary-stress-only case, whereas there is a significant drop in performance for the Dou et al. features. For the no-shared-lemmata condition, Dou et al.'s features fare rather better compared to the affix features. On the other hand there is a substantial benefit to combining the features, as the results for "Dou et al+Aff" and "Dou et al+Aff+Abstr Aff" show. Note that in the no-shared-lemmata condition, there is only one word that is marked with a secondary stress, and that stress is actually correctly predicted by all methods. Much of the difference between the Dou et al. features and the affix condition can be accounted for by three cases involving the same root, which the affix condition misas-

signs secondary stress to.

For the shared-lemmata task however there were a substantial number of differences, as one might expect given the nature of the features. Comparing just the Dou et al. features and the all-features condition, systematic benefit for the all-features condition was found for secondary stress assignment for productive prefixes where secondary stress is typically found. For example, the prefix аэро ('aero-') as in а`эродина'мика ('aerodynamics') typically has secondary stress. This is usually missed by the Dou et al. features, but is uniformly correct for the all-features condition.

Since the no-shared-lemmata data set is small, we tested significance using two permutation tests. The first computed a distribution of scores for the test data where successive single test examples were removed. The second randomly permuted the test data 248 times, after each random permutation, removing the first ten examples, and computing the score. Pairwise t-tests between all conditions for the primary-stress-only and for the primary plus secondary stress predictions, were highly significant in all cases.

We also experimented with a postaccent feature to model the postaccented class of nouns described in Section 3. For each *prefix* of the word, we record whether the following vowel is stressed or unstressed. This feature yielded only very slight improvements, and we do not report these results here.

8 Discussion

In this paper we have presented a Maximum Entropy ranking-based approach to Russian stress prediction. The approach is similar in spirit to the SVM-based ranking approach presented in (Dou et al., 2009), but incorporates additional affix-based features, which are motivated by linguistic analyses of the problem. We have shown that these additional features generalize better than the Dou et al. features in cases where we have seen a related form of the test word, and that combing the additional features with the Dou et al. features always yields an improvement.

Scaling to Large^3 Data: An efficient and effective method to compute Distributional Thesauri

Martin Riedl and **Chris Biemann**

Abstract

We introduce a new highly scalable approach for computing Distributional Thesauri (DTs). By employing pruning techniques and a distributed framework, we make the computation for very large corpora feasible on comparably small computational resources. We demonstrate this by releasing a DT for the whole vocabulary of Google Books syntactic n-grams. Evaluating against lexical resources using two measures, we show that our approach produces higher quality DTs than previous approaches, and is thus preferable in terms of speed and quality for large corpora.

1 Introduction

Using larger data to estimate models for machine learning applications as well as for applications of Natural Language Processing (NLP) has repeatedly shown to be advantageous, see e.g. (Banko and Brill, 2001; Brants et al., 2007). In this work, we tackle the influence of corpus size for building a distributional thesaurus (Lin, 1998). Especially, we shed light on the interaction of similarity measures and corpus size, as well as aspects of scalability.

We shortly introduce the JoBimText framework for distributional semantics and show its scalability for large corpora. For the computation of the data we follow the MapReduce (Dean and Ghemawat, 2004) paradigm. The computation of similarities between terms becomes challenging on large corpora, as both the numbers of terms to be compared and the number of context features increases. This makes standard similarity calculations as proposed in (Lin, 1998; Curran, 2002; Lund and Burgess, 1996; Weeds et al., 2004) computationally infeasible. These approaches first calculate an information measure between each word and the according context and then calculate the similarity between all words, based on the information measure for all shared contexts.

2 Related Work

A variety of approaches to compute DTs have been proposed to tackle issues regarding size and runtime. The reduction of the feature space seems to be one possibility, but still requires the computation of such reduction cf. (Blei et al., 2003; Golub and Kahan, 1965). Other approaches use randomised indexing for storing counts or hashing functions to approximate counts and measures (Gorman and Curran, 2006; Goyal et al., 2010; Sahlgren, 2006). Another possibility is the usage of distributed processing like MapReduce. In (Pantel et al., 2009; Agirre et al., 2009) a DT is computed using MapReduce on 200 quad core nodes (for 5.2 billion sentences) respectively 2000 cores (1.6 Terawords), an amount of hardware only available to commercial search engines. Whereas Agirre uses a χ^2 test to measure the information between terms and context, Pantel uses the Pointwise Mutual Information (PMI). Then, both approaches use the cosine similarity to calculate the similarity between terms. Furthermore, Pantel describes an optimization for the calculation of the cosine similarity. Whereas Pantel and Lin (2002) describe a method for sense clustering, they also use a method to calculate similarities between terms. Here, they propose a pruning scheme similar to ours, but do not explicitly evaluate its effect.

The evaluation of DTs has been performed in extrinsic and intrinsic manner. Extrinsic evaluations have been performed using e.g. DTs for automatic

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 884–890,
Seattle, Washington, USA, 18-21 October 2013.

set expansion (Pantel et al., 2009) or phrase polarity identification (Goyal and Daumé, 2011). In this work we will concentrate on intrinsic evaluations: Lin (1997; 1998) introduced two measures using WordNet (Miller, 1995) and Roget's Thesaurus. Using WordNet, he defines context features (synsets a word occurs in Wordnet or subsets when using Roget's Thesaurus) and then builds a gold standard thesaurus using a similarity measure. Then he evaluates his generated Distributional Thesaurus (DT) with respect to the gold standard thesauri. Weeds et al. (2004) evaluate various similarity measures based on 1000 frequent and 1000 infrequent words. Curran (2004) created a gold standard thesaurus by manually extracting entries from several English thesauri for 70 words. His automatically generated DTs are evaluated against this gold standard thesaurus using several measures. We will report on his measure and additionally propose a measure based on WordNet paths.

3 Building a Distributional Thesaurus

Here we present our scalable DT algorithm using the MapReduce paradigm, which is divided into two parts: The holing system and a computational method to calculate distributional similarities. A more detailed description, especially for the MapReduce steps, can be found in (Biemann and Riedl, 2013).

3.1 Holing System

The holing operation splits an observation (e.g. a dependency relation) into a pair of two parts: a term and a context feature. This captures their first-order relationship. These pairs are subsequently used for the computation of the similarities between terms, leading to a second-order relation. The representation can be formalized by the pair <x,y> where x is the term and y represents the context feature. The position of x in y is denoted by the hole symbol '@'. As an example the dependency relation *(nsub;gave$_2$;I$_1$)* could be transferred to *<gave$_2$,(nsub;@;I$_1$)>* and *<I$_1$,(nsub;gave$_2$;@)>*. This representation scheme is more generic then the schemes introduced in (Lin, 1998; Curran, 2002), as it allows to characterise pairs by several holes, which could be used to learn analogies, cf. (Turney and Littman, 2005).

3.2 Distributional Similarity

First, we count the frequency for each first-order relation and remove all features that occur with more than w terms, as these context features tend to be too general to characterise the similarity between other words (Rychlý and Kilgarriff, 2007; Goyal et al., 2010, cmp.). From this. we calculate a significance score for all first-order relations. For this work, we implemented two different significance measures: Pointwise Mutual Information (PMI): $PMI(term, feature) = \log_2(\frac{f(term,feature)}{f(term)f(feature)})$ (Church and Hanks, 1990) and Lexicographer's Mutual Information (LMI): $LMI(term, feature) = f(term, feature)\log_2(\frac{f(term,feature)}{f(term)f(feature)})$ (Evert, 2005).

We then prune all negatively correlated pairs ($s<0$). The maximum number of context features per term are defined with p, as we argue that it is sufficient to keep only the p most salient (ordered descending by their significance score) context features per term. Features of low saliency generally should not contribute much to the similarity of terms and also could lead to spurious similarity scores. Afterwards, all terms are aggregated by their features, which allows us to compute similarity scores between all terms that share at least one such feature.

Whereas the method introduced by (Pantel and Lin, 2002) is very similar to the one proposed in this paper (the similarity between terms is calculated solely by the number of features two terms share), they use PMI to rank features and do not use pruning to scale to large corpora, as they use a rather small corpus. Additionally, they do not evaluate the effect of such pruning.

In contrast to the best measures proposed by Lin (1998; Curran (2002; Pantel et al. (2009; Goyal et al. (2010) we do not calculate any information measure using frequencies of features and terms (we use significance ranking instead), as shown in Table 1.

Additionally, we avoid any similarity measurement using the information measure, as also done in these approaches, to calculate the similarity over the feature counts of each term: we merely count how many salient features two terms share. All these constraints makes this approach more scalable to larger corpora, as we do not need to know the full list of

Information Measures	
Lin's formula	$I(term, feature) = lin(term, feature) = \log \frac{f(term,feature)*f(relation(feature))}{\sum(f(word,relation(feature))f(word)}$
Curran's TTest	$I(term, feature) = ttest(term, feature) = \frac{p(term,feature)-p(feature)*p(term)}{\sqrt{p(feature)*p(term)}}$
Similarity Measures	
Lin's formula	$sim(t_1, t_2) = \frac{\sum_{f \in features(t_1) \cap features(t_2)}(I(t_1,f)+I(t_2,f))}{\sum_{f \in features(t_1)} I(t_1,f)+\sum_{f \in features(w_2)} I(w_2,f)}$
Curran's Dice	$sim(t_1, t_2) = \frac{\sum_{f \in features(t_1) \cap features(t_2)} min(I(t_1,f),I(t_2,f))}{\sum_{f \in features(t_1) \cap features(t_2)}(I(t_1,f)+I(t_2,f))}$ with $I(t, f) > 0$
Our Measure	$sim(t_1, t_2) = \sum_{f \in features(t_1) \cap features(t_2)} 1$ with $s > 0$

Table 1: Similarity measures used for computing the distributional similarity between terms.

features for a term pair at any time. While our computations might seem simplistic, we demonstrate its adequacy for large corpora in Section 5.

4 Evaluation

The evaluation is performed using a recent dump of English Wikipedia, containing 36 million sentences and a newspaper corpus, compiled from 120 million sentences (about 2 Gigawords) from Leipzig Corpora Collection (Richter et al., 2006) and the Gigaword corpus (Parker et al., 2011). The DTs are based on collapsed dependencies from the Stanford Parser (Marneffe et al., 2006) in the holing operation. For all DTs we use the pruning parameters s=0, p=1000 and w=1000. In a final evaluation, we use the syntactic n-grams built from Google Books (Goldberg and Orwant, 2013).

To show the impact of corpus size, we downsampled our corpora to 10 million, 1 million and 100,000 sentences. We compare our results against DTs calculated using Lin's (Lin, 1998) measure and the best measure proposed by Curran (2002) (see Table 1).

Our evaluation is performed using the same 1000 frequent and 1000 infrequent nouns as previously employed by Weeds et al. (2004). We create a gold standard, by extracting reasonable entries of these 2000 nouns using Roget's 1911 thesaurus, Moby Thesaurus, Merriam Webster's Thesaurus, the Big Huge Thesaurus and the OpenOffice Thesaurus and employ the inverse ranking measure (Curran, 2002) to evaluate the DTs.

Furthermore, we introduce a WordNet-based method. To calculate the similarity between two terms, we use the WordNet::Similarity path (Pedersen et al., 2004) measure. While its absolute scores are hard to interpret due to inhomogenity in the granularity of WordNet, they are well-suited for relative comparison. The score between two terms is inversely proportional to the shortest path between all the synsets of both terms. The highest possible score is one, if two terms share a synset. We compare the average score of the top five (or ten) entries in the DT for each of the 2000 selected words for our comparison.

5 Results

First, we inspect the results of Curran's measure using the Wikipedia and newspaper corpus for the frequent nouns, shown in Figure 1.

Both graphs show the inverse ranking score against the size of the corpus. Our method scores consistently higher when using LMI instead of PMI for ranking the features per term. The PMI measure declines when the corpus becomes larger. This can be attributed to the fact that PMI favors term-context pairs involving rare contexts (Bordag, 2008). Computing similarities between terms should not be performed on the basis of rare contexts, as these do not generalize well because of their sparseness.

All other measures improve with larger corpora. It is surprising that recent works use PMI to calculate similarities between terms (Goyal et al., 2010; Pantel et al., 2009), who, however evaluate their approach only with respect to their own implementation or extrinsically, and do not prune on saliency. Apart from the PMI measure, Curran's measure leads to the weakest results. We could not confirm that his measure outperforms Lin's measure as stated in (Curran, 2002)[1]. An explanation for this results

[1]Regarding Curran's Dice formula, it is not clear whether to use the intersection or the union of the features. We use an intersection, as it is unclear how to interpret the minimum function otherwise, and the alternatives performed worse.

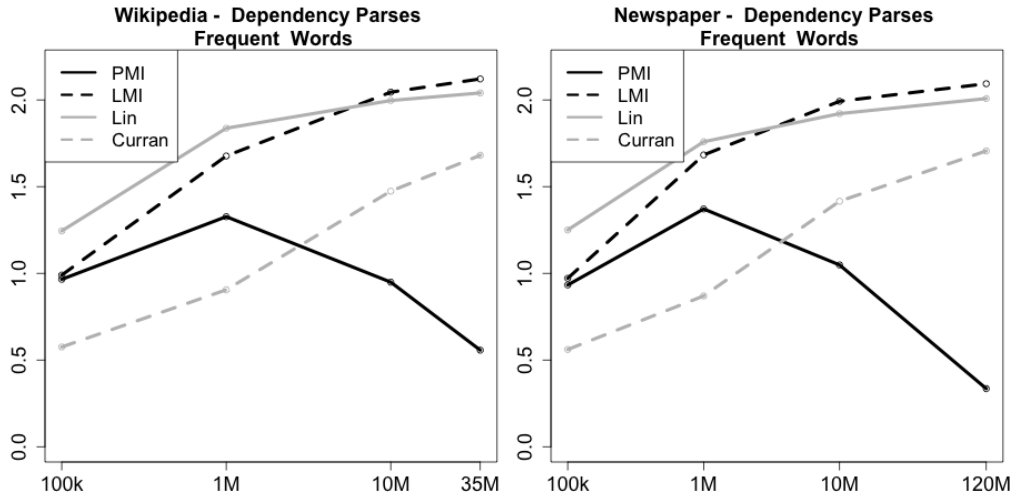

Figure 1: Inverse ranking for 1000 frequent nouns (Wikipedia left, Newspaper right) for different sized corpora. The 4 lines represent the scores of following DTs: our method using LMI (dashed black line) and the PMI significance measure (solid black line) and Curran's (dash bray line) and Lin's measure (solid tray line).

might be the use of a different parser, very few test words and also a different gold standard thesaurus in his evaluation. Comparing our method using LMI to Lin's method, we achieve lower scores with our method using small corpora, but surpass Lin's measure from 10 million sentences onwards.

Next, we show the results of the WordNet evaluation measure in Figure 2. Comparing the top 10 (upper) to the top 5 words (lower) used for the evaluation, we can observe higher scores for the top 5 words, which validates the ranking. These results are highly correlated to the results achieved with the inverse ranking measure. This is a positive result, as the WordNet measure can be performed automatically using a single public resource[2]. In Figure 3, we show results for the 1000 infrequent nouns using the inverse ranking (upper) and the WordNet measure (lower).

We can see that our method using PMI does not decline for larger corpora, as the limit on first-order features is not reached and frequent features are still being used. Comparing our LMI DT is en par with Lin's measure for 10 million sentences, and makes better use of large data when using the complete dataset. Again, the inverse ranking and the WordNet Path measure are highly correlated.

[2]Building a gold standard thesaurus following Curran (2002) needs access to all the used thesauri. Whereas for some, programming interfaces exist, often with limited access and licence restrictions, others have to be extracted manually.

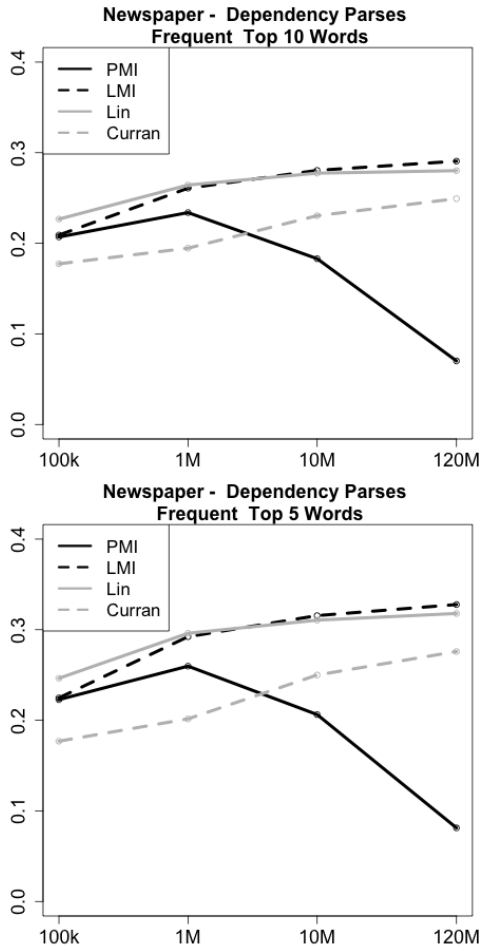

Figure 2: Results, using the WordNet:Path measure for frequent nouns using the newspaper corpus.

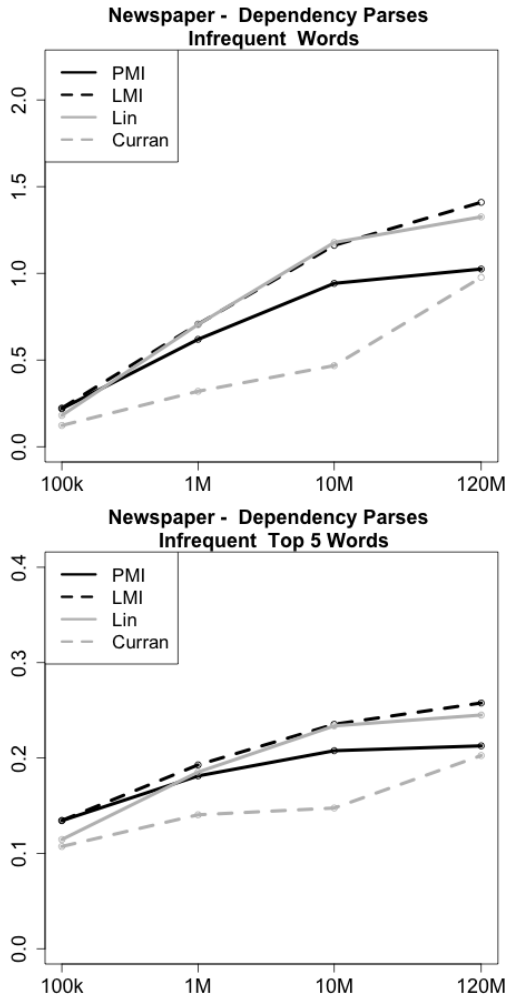

Figure 3: WordNet::Path results for 1000 infrequent nouns

The results shown here validate our pruning approach. Whereas Lin and Curran propose approaches to filter features that have low word feature scores, they do not remove features that occur with too many words, which is done in this work. Using these pruning steps, a simplistic similarity measure does not only lead to reduced computation times, but also to better results, when using larger corpora.

5.1 Using a large[3] corpus

We demonstrate the scalability of our method using the very large Google Books dataset (Goldberg and Orwant, 2013), consisting of dependencies extracted from 17.6 billion sentences. The evaluation results, using different measures, are given in Table 2.

Comparing the results for the Google Books DT to the ones achieved using Wikipedia and the newspaper, we can observe a boost in the performance, both for the inverse ranking and the WordNet measures. Additionally, we show results for the P@1 measure, which indicates the percentage of entries, whose first entry is in the gold standard thesaurus. Remarkably, we get a P@1 against our gold standard thesaurus of 76% for frequent and 64% for infrequent nouns using the Google Books DT.

	Corpus	Inv.	P@1	Path@5	Path@10
frequent nouns	Newspaper	2.0935	0.709	0.3277	0.2906
	Wikipedia	2.1213	0.703	0.3365	0.2968
	Google Books	2.3171	0.764	0.3712	0.3217
infrequent nouns	Newspaper	1.4097	0.516	0.2577	0.2269
	Wikipedia	1.3832	0.514	0.2565	0.2265
	Google Books	1.8125	0.641	0.2989	0.2565

Table 2: Comparing results for different corpora.

The most computation time was needed for the dependency parsing and took two weeks on a small cluster (64 cores on 8 nodes) for the 120 million Newspaper sentences. The DT for the Google Books was calculated in under 30 hours on a Hadoop cluster (192 cores on 16 nodes) and could be calculated within 10 hours for the Newspaper corpus. The computation of a DT using this huge corpus would be intractable with standard vector-based measurements. Even computing Lin's and Curran's vector-based similarity measure for the whole vocabulary of the newspaper corpus was not possible with our Hadoop cluster, as too much memory would have been required and thus we computed similarities only for the 2000 test nouns on a server with 92GB of main memory.

6 Conclusion

We have introduced a highly scalable approach to DT computation and showed its adequacy for very large corpora. Evaluating against thesauri and WordNet, we demonstrated that our similarity measure yields better-quality DTs and scales to corpora of billions of sentences, even on comparably small compute clusters. We achieve this by a number of pruning operations, and distributed processing. The framework and the DTs for Google Books, Newspaper and Wikipedia are available online[3] under the ASL 2.0 licence.

Abstract

Matrix and tensor factorization have been applied to a number of semantic relatedness tasks, including paraphrase identification. The key idea is that similarity in the latent space implies semantic relatedness. We describe three ways in which labeled data can improve the accuracy of these approaches on paraphrase classification. First, we design a new discriminative term-weighting metric called TF-KLD, which outperforms TF-IDF. Next, we show that using the latent representation from matrix factorization as features in a classification algorithm substantially improves accuracy. Finally, we combine latent features with fine-grained n-gram overlap features, yielding performance that is 3% more accurate than the prior state-of-the-art.

1 Introduction

Measuring the semantic similarity of short units of text is fundamental to many natural language processing tasks, from evaluating machine translation (Kauchak and Barzilay, 2006) to grouping redundant event mentions in social media (Petrović et al., 2010). The task is challenging because of the infinitely diverse set of possible linguistic realizations for any idea (Bhagat and Hovy, 2013), and because of the short length of individual sentences, which means that standard bag-of-words representations will be hopelessly sparse.

Distributional methods address this problem by transforming the high-dimensional bag-of-words representation into a lower-dimensional latent space. This can be accomplished by factoring a matrix or tensor of term-context counts (Turney and Pantel, 2010); proximity in the induced latent space has been shown to correlate with semantic similarity (Mihalcea et al., 2006). However, factoring the term-context matrix means throwing away a considerable amount of information, as the original matrix of size $M \times N$ (number of instances by number of features) is factored into two smaller matrices of size $M \times K$ and $N \times K$, with $K \ll M, N$. If the factorization does not take into account labeled data about semantic similarity, important information can be lost.

In this paper, we show how labeled data can considerably improve distributional methods for measuring semantic similarity. First, we develop a new discriminative term-weighting metric called TF-KLD, which is applied to the term-context matrix *before* factorization. On a standard paraphrase identification task (Dolan et al., 2004), this method improves on both traditional TF-IDF and Weighted Textual Matrix Factorization (WTMF; Guo and Diab, 2012). Next, we convert the latent representations of each sentence pair into a feature vector, which is used as input to a linear SVM classifier. This yields further improvements and substantially outperforms the current state-of-the-art on paraphrase classification. We then add "fine-grained" features about the lexical similarity of the sentence pair. The combination of latent and fine-grained features yields further improvements in accuracy, demonstrating that these feature sets provide complementary information on semantic similarity.

Seattle, Washington, USA, 18-21 October 2013.

2 Related Work

Without attempting to do justice to the entire literature on paraphrase identification, we note three high-level approaches: (1) string similarity metrics such as n-gram overlap and BLEU score (Wan et al., 2006; Madnani et al., 2012), as well as string kernels (Bu et al., 2012); (2) syntactic operations on the parse structure (Wu, 2005; Das and Smith, 2009); and (3) distributional methods, such as latent semantic analysis (LSA; Landauer et al., 1998), which are most relevant to our work. One application of distributional techniques is to replace individual words with distributionally similar alternatives (Kauchak and Barzilay, 2006). Alternatively, Blacoe and Lapata (2012) show that latent word representations can be combined with simple element-wise operations to identify the semantic similarity of larger units of text. Socher et al. (2011) propose a syntactically-informed approach to combine word representations, using a recursive auto-encoder to propagate meaning through the parse tree.

We take a different approach: rather than representing the meanings of individual words, we directly obtain a distributional representation for the entire sentence. This is inspired by Mihalcea et al. (2006) and Guo and Diab (2012), who treat sentences as pseudo-documents in an LSA framework, and identify paraphrases using similarity in the latent space. We show that the performance of such techniques can be improved dramatically by using supervised information to (1) reweight the individual distributional features and (2) learn the importance of each latent dimension.

3 Discriminative feature weighting

Distributional representations (Turney and Pantel, 2010) can be induced from a co-occurrence matrix $\mathbf{W} \in \mathbb{R}^{M \times N}$, where M is the number of instances and N is the number of distributional features. For paraphrase identification, each instance is a sentence; features may be unigrams, or may include higher-order n-grams or dependency pairs. By decomposing the matrix $\mathbf{W}$, we hope to obtain a latent representation in which semantically-related sentences are similar. Singular value decomposition (SVD) is traditionally used to perform this factorization. However, recent work has demonstrated the robustness of nonnegative matrix factorization (NMF; Lee and Seung, 2001) for text mining tasks (Xu et al., 2003; Arora et al., 2012); the difference from SVD is the addition of a non-negativity constraint in the latent representation based on non-orthogonal basis.

While $\mathbf{W}$ may simply contain counts of distributional features, prior work has demonstrated the utility of reweighting these counts (Turney and Pantel, 2010). TF-IDF is a standard approach, as the inverse document frequency (IDF) term increases the importance of rare words, which may be more discriminative. Guo and Diab (2012) show that applying a special weight to unseen words can further improvement performance on paraphrase identification.

We present a new weighting scheme, TF-KLD, based on supervised information. The key idea is to increase the weights of distributional features that are discriminative, and to decrease the weights of features that are not. Conceptually, this is similar to Linear Discriminant Analysis, a supervised feature weighting scheme for continuous data (Murphy, 2012).

More formally, we assume labeled sentence pairs of the form $\langle \vec{w}_i^{(1)}, \vec{w}_i^{(2)}, r_i \rangle$, where $\vec{w}_i^{(1)}$ is the binarized vector of distributional features for the first sentence, $\vec{w}_i^{(2)}$ is the binarized vector of distributional features for the second sentence, and $r_i \in \{0, 1\}$ indicates whether they are labeled as a paraphrase pair. Assuming the order of the sentences within the pair is irrelevant, then for k-th distributional feature, we define two Bernoulli distributions:

- $p_k = P(w_{ik}^{(1)} | w_{ik}^{(2)} = 1, r_i = 1)$. This is the probability that sentence $w_i^{(1)}$ contains feature k, given that k appears in $w_i^{(2)}$ and the two sentences are labeled as paraphrases, $r_i = 1$.

- $q_k = P(w_{ik}^{(1)} | w_{ik}^{(2)} = 1, r_i = 0)$. This is the probability that sentence $w_i^{(1)}$ contains feature k, given that k appears in $w_i^{(2)}$ and the two sentences are labeled as not paraphrases, $r_i = 0$.

The Kullback-Leibler divergence $KL(p_k || q_k) = \sum_x p_k(x) \log \frac{p_k(x)}{q_k(x)}$ is then a measure of the discriminability of feature k, and is guaranteed to be non-

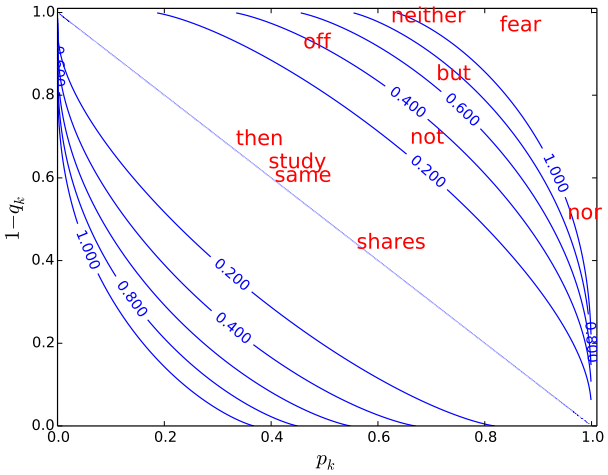

Figure 1: Conditional probabilities for a few hand-selected unigram features, with lines showing contours with identical KL-divergence. The probabilities are estimated based on the MSRPC training set (Dolan et al., 2004).

negative.[1] We use this divergence to reweight the features in $\mathbf{W}$ before performing the matrix factorization. This has the effect of increasing the weights of features whose likelihood of appearing in a pair of sentences is strongly influenced by the paraphrase relationship between the two sentences. On the other hand, if $p_k = q_k$, then the KL-divergence will be zero, and the feature will be ignored in the matrix factorization. We name this weighting scheme TF-KLD, since it includes the term frequency and the KL-divergence.

Taking the unigram feature *not* as an example, we have $p_k = [0.66, 0.34]$ and $q_k = [0.31, 0.69]$, for a KL-divergence of 0.25: the likelihood of this word being shared between two sentence is strongly dependent on whether the sentences are paraphrases. In contrast, the feature *then* has $p_k = [0.33, 0.67]$ and $q_k = [0.32, 0.68]$, for a KL-divergence of 3.9×10^{-4}. Figure 1 shows the distributions of these and other unigram features with respect to p_k and $1 - q_k$. The diagonal line running through the middle of the plot indicates zero KL-divergence, so features on this line will be ignored.

[1] We obtain very similar results with the opposite divergence $KL(q_k||p_k)$. However, the symmetric Jensen-Shannon divergence performs poorly.

4 Supervised classification

While previous work has performed paraphrase classification using distance or similarity in the latent space (Guo and Diab, 2012; Socher et al., 2011), more direct supervision can be applied. Specifically, we convert the latent representations of a pair of sentences $\vec{v}_1$ and $\vec{v}_2$ into a sample vector,

$$\vec{s}(\vec{v}_1, \vec{v}_2) = \left[\vec{v}_1 + \vec{v}_2, |\vec{v}_1 - \vec{v}_2|\right], \qquad (1)$$

concatenating the element-wise sum $\vec{v}_1 + \vec{v}_2$ and absolute difference $|\vec{v}_1 - \vec{v}_2|$. Note that $\vec{s}(\cdot, \cdot)$ is symmetric, since $\vec{s}(\vec{v}_1, \vec{v}_2) = \vec{s}(\vec{v}_2, \vec{v}_1)$. Given this representation, we can use any supervised classification algorithm.

A further advantage of treating paraphrase as a supervised classification problem is that we can apply additional features besides the latent representation. We consider a subset of features identified by Wan et al. (2006), listed in Table 1. These features mainly capture fine-grained similarity between sentences, for example by counting specific unigram and bigram overlap.

5 Experiments

Our experiments test the utility of the TF-KLD weighting towards paraphrase classification, using the Microsoft Research Paraphrase Corpus (Dolan et al., 2004). The training set contains 2753 true paraphrase pairs and 1323 false paraphrase pairs; the test set contains 1147 and 578 pairs, respectively.

The TF-KLD weights are constructed from only the training set, while matrix factorizations are per-

formed on the entire corpus. Matrix factorization on both training and (unlabeled) test data can be viewed as a form of *transductive learning* (Gammerman et al., 1998), where we assume access to unlabeled test set instances.[2] We also consider an inductive setting, where we construct the basis of the latent space from only the training set, and then project the test set onto this basis to find the corresponding latent representation. The performance differences between the transductive and inductive settings were generally between 0.5% and 1%, as noted in detail below. We reiterate that the TF-KLD weights are never computed from test set data.

Prior work on this dataset is described in section 2. To our knowledge, the current state-of-the-art is a supervised system that combines several machine translation metrics (Madnani et al., 2012), but we also compare with state-of-the-art unsupervised matrix factorization work (Guo and Diab, 2012).

5.1 Similarity-based classification

In the first experiment, we predict whether a pair of sentences is a paraphrase by measuring their cosine similarity in latent space, using a threshold for the classification boundary. As in prior work (Guo and Diab, 2012), the threshold is tuned on held-out training data. We consider two distributional feature sets: **FEAT**$_1$, which includes unigrams; and **FEAT**$_2$, which also includes bigrams and unlabeled dependency pairs obtained from MaltParser (Nivre et al., 2007). To compare with Guo and Diab (2012), we set the latent dimensionality to $K = 100$, which was the same in their paper. Both SVD and NMF factorization are evaluated; in both cases, we minimize the Frobenius norm of the reconstruction error.

Table 2 compares the accuracy of a number of different configurations. The transductive TF-KLD weighting yields the best overall accuracy, achieving 72.75% when combined with non-negative matrix factorization. While NMF performs slightly better than SVD in both comparisons, the major difference is the performance of discriminative TF-KLD weighting, which outperforms TF-IDF regardless of the factorization technique. When we perform the matrix factorization on only the training data, the accuracy on the test set is 73.58%, with F1 score 80.55%.

[2]Another example of transductive learning in NLP is when Turian et al. (2010) induced word representations from a corpus that included both training and test data for their downstream named entity recognition task.

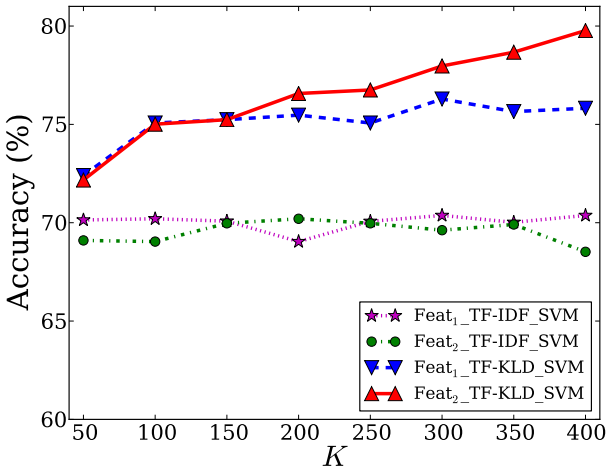

Figure 2: Accuracy of feature and weighting combinations in the classification framework.

5.2 Supervised classification

Next, we apply supervised classification, constructing sample vectors from the latent representation as shown in Equation 1. For classification, we choose a Support Vector Machine with a linear kernel (Fan et al., 2008), leaving a thorough comparison of classifiers for future work. The classifier parameter C is tuned on a development set comprising 20% of the original training set.

Figure 2 presents results for a range of latent dimensionalities. Supervised learning identifies the important dimensions in the latent space, yielding significantly better performance that the similarity-based classification from the previous experiment. In Table 3, we compare against prior published work, using the held-out development set to select the best value of K (again, $K = 400$). The best result is from TF-KLD, with distributional features FEAT$_2$, achieving 79.76% accuracy and 85.87% F1. This is well beyond all known prior results on this task. When we induce the latent basis from only the training data, we get 78.55% on accuracy and 84.59% F1, also better than the previous state-of-art.

Finally, we augment the distributional representation, concatenating the ten "fine-grained" features in Table 1 to the sample vectors described in Equation 1. As shown in Table 3, the accu-

Factorization	Feature set	Weighting	K	Measure	Accuracy (%)	F1

racy now improves to 80.41%, with an F1 score of 85.96%. When the latent representation is induced from only the training data, the corresponding results are 79.94% on accuracy and 85.36% F1, again better than the previous state-of-the-art. These results show that the information captured by the distributional representation can still be augmented by more fine-grained traditional features.

6 Conclusion

We have presented three ways in which labeled data can improve distributional measures of semantic similarity at the sentence level. The main innovation is TF-KLD, which discriminatively reweights the distributional features *before* factorization, so that discriminability impacts the induction of the latent representation. We then transform the latent representation into a sample vector for supervised learning, obtaining results that strongly outperform the prior state-of-the-art; adding fine-grained lexical features further increases performance. These ideas may have applicability in other semantic similarity tasks, and we are also eager to apply them to new, large-scale automatically-induced paraphrase corpora (Ganitkevitch et al., 2013).

Is Twitter A Better Corpus for Measuring Sentiment Similarity?

Abstract

Extensive experiments have validated the effectiveness of the corpus-based method for classifying the word's sentiment polarity. However, no work is done for comparing different corpora in the polarity classification task. Nowadays, Twitter has aggregated huge amount of data that are full of people's sentiments. In this paper, we empirically evaluate the performance of different corpora in sentiment similarity measurement, which is the fundamental task for word polarity classification. Experiment results show that the Twitter data can achieve a much better performance than the Google, Web1T and Wikipedia based methods.

1 Introduction

Measuring semantic similarity for words and short texts has long been a fundamental problem for many applications such as word sense disambiguation, query expansion, search advertising and so on.

Determining the word's polarity plays a critical role in opinion mining and sentiment analysis task. Usually we can detect the word's polarity by measuring it's semantic similarity with a positive seed word se_p and a negative seed word se_n respectively, as shown in Formula (1):

$$SO(w) = sim(w, se_p) - sim(w, se_n) \quad (1)$$

where $sim(w_i, w_j)$ is the semantic similarity measurement method for the given word w_i and w_j. A lot of papers have been published for designing appropriate similarity measurements. One direction is to learn similarity from the knowledge base or concept taxonomy (Lin, 1998; Resnik, 1999). Another direction is to learn semantic similarity with the help of large corpus such as Web or Wikipedia data (Sahami and Heilman, 2006; Yih and Meek, 2007; Bollegala et al., 2011; Gabrilovich and Markovitch, 2007). The basic assumption of this kind of methods is that the word with similar semantic meanings often co-occur in the given corpus. Extensive experiments have validated the effectiveness of the corpus-based method in polarity classification task (Turney, 2002; Kaji and Kitsuregawa, 2007; Velikovich et al., 2010). For example, PMI is a well-known similarity measurement (Turney, 2002), which makes use of the whole Web as the corpus, and utilizes the search engine hits number to estimate the co-occurrence probability of the give word pairs. The PMI based method has achieved promising results. However, according to Kanayama's investigation, only 60% co-occurrences in the same window in Web pages reflect the same sentiment orientation (Kanayama and Nasukawa, 2006). Therefore, we may ask the question whether the choosing of corpus can change the performance of sim and is there any better corpus than the Web page data for measuring the sentiment similarity?

Everyday, enormous numbers of tweets that contain people's rich sentiments are published in Twitter. The Twitter may be a good source for measuring the sentiment similarity. Compared with the Web page data, the tweets have a higher rate of subjective text posts. The length limitation can guarantee the polarity consistency of each tweet. Moreover, the tweets contain graphical emoticons, which can be

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 897–902,
Seattle, Washington, USA, 18-21 October 2013.

considered as natural sentiment labels for the corresponding tweets in Twitter. In this paper, we attempt to empirically evaluate the performance of different corpora in sentiment similarity measurement task. As far as we know, no work is done on this topic.

2 The Characteristics of Twitter Data

As the world's second largest SNS website, at the end of 2012 Twitter had aggregated more than 500 million registered users, among which 200 million were active users . More than 400 million tweets are posted every day.

Several examples of typical posts from Twitter are shown below.

(1) *She had a headache and feeling light headed with no energy.* :(

(2) *@username Nice work! Looks like you had a fun day. I'm headed there Sat or Sun.* :)

(3) *I seen the movie on Direc Tv. I ordered it and I really liked it. I can't wait to get it for blu ray! Excellent work Rob!*

We observe that comparing with the other corpus, the Twitter data has several advantages in measuring the sentiment similarity.

Large. Users like to record their personal feelings and talk about the trend topics in Twitter (Java et al., 2007; Kwak et al., 2010). So there are huge amount of subjective texts with various topics generated in the millions of tweets everyday. Further more, the flexible Twitter API makes these data easy to access and collect.

Length Limitation. Twitter has a length limitation of 140 characters. Users have limited space to express their feelings. So the sentiments in tweets are usually concise, straightforward and polarity consistent.

Emoticons. Users tend to utilize emoticons to emphasize their sentiment feelings. According to the statistics, about 8.1% tweets contain at least one emoticon (Yang and Leskovec, 2011). Since the tweets have the length limitation, the sentiments expressed in these short texts are usually consistent with the embedded emoticons, such as the word *fun* and *headache* in above examples.

In addition to the above advantages, there are also some disadvantages for measuring sentiment similarity using Twitter data. The spam tweets that caused by advertisements may add noise and bias during the similarity measurement. The short length may also bring in lower co-occurrence probability of words. Some words may not co-occur with each other when the corpus is small. These disadvantages set obstacles for measuring sentiment similarity by using Twitter data as corpus. In the experiment section, we will see if we can overcome these drawbacks and get benefit from the advantages of Twitter data.

3 The Corpus-based Sentiment Similarity Measurements

The intuition behind the corpus-based semantic similarity measuring method is that the words with similar meanings tend to co-occur in the corpus. Given the word w_i, w_j, we use the notation $P(w_i)$ to denote the occurrence counts of word w_i in the corpus $\mathcal{C}$. $P(w_i, w_j)$ denotes the co-occurrence counts of word w_i and w_j in $\mathcal{C}$. In this paper we employ the corpus-based version of the three well-known similarity measurements: Jaccard, Dice and PMI.

$$CorpusJaccard(w_i, w_j) = \frac{P(w_i,w_j)}{P(w_i)+P(w_j)-P(w_i,w_j)} \quad (2)$$

$$CorpusDice(w_i, w_j) = \frac{2 \times P(w_i, w_j)}{P(w_i) + P(w_j)} \quad (3)$$

$$CorpusPMI(w_i, w_j) = \log_2\left(\frac{\frac{P(w_i,w_j)}{N}}{\frac{P(w_i)}{N}\frac{P(w_j)}{N}}\right) \quad (4)$$

In Formula (4), N is the number of documents in the corpus $\mathcal{C}$. The above similarity measurements may have their own strengths and weaknesses. In this paper, we utilize these classical measurements to evaluate the quality of the corpus in polarity classification task.

Google is the world's largest search engine, which has indexed a huge number of Web pages. Using the extreme large indexed Web pages as corpus, Cilibrasi and Vitanyi (2007) presented a method for measuring similarity between words and phrases based on information distance and Kolmogorov complexity. The search result page counts of Google were utilized to estimate the occurrence frequencies of the words in the corpus. Suppose w_i, w_j represent the candidate words, the Normalized Google

Distance is defined as:

$$NGD(w_i, w_j) = \frac{\max\{\log P(w_i), \log P(w_j)\} - \log P(w_i, w_j)}{\log N - \min\{\log P(w_i), \log P(w_j)\}} \quad (5)$$

where $P(w_i)$ denotes page counts returned by Google using w_i as keyword; $P(w_i, w_j)$ denotes the page counts by using w_i and w_j as joint keywords; N is the number of Web pages indexed by Google. Cilibrasi and Vitanyi have validated the effectiveness of Google distance in measuring the semantic similarity between concept words.

Based on the above formulas, we compare the Twitter data with the Web and Wikipedia data as the similarity measurement corpus. Given a candidate word w, we firstly measure its sentiment similarity with a positive seed word and a negative seed word respectively in Formula (1), and the difference of sim is used to further detect the polarity of w. The above four similarity measurements serve as sim with Web, Wikipedia and Twitter data as corpus. Turney (2002) chose *excellent* and *poor* as seed words. However, using isolated seed words may cause the bias problem. Therefore, we further select two groups of seed words that are lack of sensitivity to context and form a positive seed set PS and a negative seed set NS (Turney, 2003). The Formula (1) can be rewritten as:

$$\overline{SO}(w) = \sum_{se_p \in PS} sim(w, se_p) - \sum_{se_n \in NS} sim(w, se_n) \quad (6)$$

Based on the Formula(6) and the sentiment seed words, we can measure the sentiment polarity of the given candidate words.

4 Experiment

4.1 Experiment Setup

Corpus Preparing. The Twitter corpus corresponds to the *476 million Twitter tweets* (Yang and Leskovec, 2011), which includes over 476 million Twitter posts from 20 million users, covering a 7 month period from June 1, 2009 to December 31, 2009. We filter out the non-English tweets and the spam tweets that have only few words with URLs. The tweets that contain three or more trending topics are also removed. Finally, we construct the Twitter corpus that consists of 266.8 million English tweets. For calculating page counts in Web data, the candidate words were launched to Google from February 2013 to April 2013. We also conduct the experiments on the Google Web 1T data that consists of Google n-gram counts (frequency of occurrence of each n-gram) for $1 \leq n \leq 5$ (Brants and Franz, 2006). The Web 1T data provides a nice approximation to the word co-occurrence statistics in Web pages in a predefined window size ($1 \leq n \leq 5$). For example, the 5 gram Web1T data means the co-occurrence window size is 5. The English Wikipedia dump [1] we used was extracted at the end of March 2013, which contained more than 13 million articles. We extracted the plain texts of the Wikipedia data as the training corpus for the Formula (6).

Evaluation Method. Two well-know sentiment lexicons are utilized as gold standard for polarity classification task. The statistics of Liu's sentiment lexicon (Liu et al., 2005) and MPQA subjectivity lexicon (Wilson et al., 2005) are shown in Table 1. For each word w in the lexicons, we employ the Formula (6) to calculate the word's polarity using different corpora. If $\overline{SO}(w) > 0$, the word w is classified into the positive category. Otherwise if $\overline{SO}(w) < 0$, it is classified into the negative category. The accuracy of the classification result is used to measure the quality of the corpus.

Table 3: Polarity classification accuracies using the seed word groups

natural window size (140 characters) have a positive impact on determining the word's polarity. The Google based method gets a lower accuracy, this may be due to the length of Web documents which can not usually guarantee the semantic consistency in the returned data. Even though two words appear in one page (returned by Google), they might not be semantically related. Furthermore, the Google based method is time-consuming, because we have to periodically send queries in order to avoid being blocked by Google. The Web1T based method gets a much worse accuracy. After detailed analysis, we find that although the small window size (4 or 5) can guarantee the semantic consistency, the short length also brings in lower co-occurrence probability. Statistics show that about 38% $\overline{SO}$ values are zero when using Web1T corpus. Due to the short length, the Twitter data also suffers from the low co-occurrence problem.

To tackle the low co-occurrence problem, the seed word sets are selected as Turney's (2003) settings. The positive word set *PS*={*good, nice, excellent, positive, fortunate, correct, superior*} and negative word set *NS* = {*bad, nasty, poor, negative, unfortunate, wrong, inferior*} for the Formula (6). These seed words have been verified to be effective in Turney's paper for polarity classification. The experiment results are shown in Table 3.

Table 3 shows that the performance of Twitter corpus is much improved since the multiple seed words alleviate the problem of low co-occurrence probability in tweets. Generally, when using the seed word groups the Twitter can achieve a much better performance than all the other corpora. The improvements are statistically significant (p-value < 0.05). We further add the emoticons ':)' and ':(' into the seed word groups, denoted by Twitter$^+$ in Table 3. The emoticons are natural sentiment labels. We can see that the performances are further improved by considering emoticons as seed words. The above experiment results have validated the effectiveness of Twitter data as a better corpus for measuring the sentiment similarity. The results also reveal the potential usefulness of Twitter corpus in semantic similarity measurement.

5 Related Work

Detecting the polarity of words is the fundamental problem for most of sentiment analysis tasks (Hatzivassiloglou and McKeown, 1997; Pang and Lee, 2007; Feldman, 2013).

Many methods have been proposed to measure the words' or short texts similarity based on large corpus (Sahami and Heilman, 2006; Yih and Meek, 2007; Gabrilovich and Markovitch, 2007). Bollegala *et al*. (2011) submitted the word to the search engine, and the related result pages were employed to represent the meaning of the original word. Mihalcea *et al*. (2006) proposed a method to measure the semantic similarity of words or short texts, considering both corpus-based and knowledge-based information. Although the previous algorithms have achieved promising results, there are no work done on evaluating the quality of different corpora.

Mohtarami *et al*. (2012; 2013a; 2013b) introduced the concept of sentiment similarity, which was considered as different from the traditional semantic similarity, and more focused on revealing the underlying sentiment relations between words. Mo-

htarami *et al*. (2013b) proposed a hidden emotional model to calculating the sentiment similarity of word pairs. However, the impact of the different corpora is not considered for this task.

Mohammad *et al*. (2013) generated word-sentiment association lexicons from Tweets with the help of hashtags and emoticons. Pak and Paroubek (2010) collected tweets with happy and sad emoticons as training corpus, and built sentiment classifier based on traditional machine learning methods. Brody and Diakopoulos (2011) showed that lengthening was strongly associated with subjectivity and sentiment in tweets. Davidov *et al*. (2010) treated 50 Twitter tags and 15 smileys as sentiment labels and a supervised sentiment classification framework was proposed to classify the tweets. The previous literatures have showed that the emoticons can be treated as natural sentiment labels of the tweets.

6 Conclusion and Future Work

The quality of corpus may affect the performance of sentiment similarity measurement. In this paper, we compare the Twitter data with the Google, Web1T and Wikipedia data in polarity classification task. The experiment results validate that when using the seed word groups the Twitter can achieve a much better performance than the other corpora and adding emoticons as seed words can further improve the performance. It is observed that the twitter corpus is a potential good source for measuring sentiment similarity between words. In future work, we intend to design new similarity measurements that can make best of the advantages of Twitter data.

Abstract

Implicit feature detection, also known as implicit feature identification, is an essential aspect of feature-specific opinion mining but previous works have often ignored it. We think, based on the explicit sentences, several Support Vector Machine (SVM) classifiers can be established to do this task. Nevertheless, we believe it is possible to do better by using a constrained topic model instead of traditional attribute selection methods. Experiments show that this method outperforms the traditional attribute selection methods by a large margin and the detection task can be completed better.

1 Introduction

Feature-specific opinion mining has been well defined by Ding and Liu(2008). Example 1 is a cell phone review in which two features are mentioned.

Example 1 *This cell phone is fashion in appearance, and it is also very cheap.*

If a feature appears in a review directly, it is called an *explicit feature*. If a feature is only implied, it is called an *implicit feature*. In Example 1, *appearance* is an explicit feature while *price* is an implicit feature, which is implied by *cheap*. Furthermore, an *explicit sentence* is defined as a sentence containing at least one explicit feature, and an *implicit sentence* is the sentence only containing implicit features. Thus, the first sentence is an explicit sentence, while the second is an implicit one.

This paper proposes an approach for implicit feature detection based on SVM and Topic Model(TM). The Topic Model, which incorporated into constraints based on the pre-defined product feature, is established to extract the training attributes for SVM. In the end, several SVM classifiers are constructed to train the selected attributes and utilized to detect the implicit features.

2 Related Work

The definition of implicit feature comes from Liu et al. (2005)'s work. Su et al. (2006) used Pointwise Mutual Information (PMI) based semantic association analysis to identify implicit features, but no quantitative experimental results were provided. Hai et al. (2011) used co-occurrence association rule mining to identify implicit features. However, they only dealt with opinion words and neglected the facts. Therefore, in this paper, both the opinions and facts will be taken into account.

Blei et al. (2003) proposed the original LDA using EM estimation. Griffiths and Steyvers (2004) applied Gibbs sampling to estimate LDA's parameters. Since the inception of these works, many variations have been proposed. For example, LDA has previously been used to construct attributes for classification; it often acts to reduce data dimension(Blei and Jordan, 2003; Fei-Fei and Perona, 2005; Quelhas et al., 2005). Here, we modify LDA and adopt it to select the training attributes for SVM.

3 Model Design

3.1 Introduction to LDA

We briefly introduce LDA, following the notation of Griffiths(Griffiths and Steyvers, 2004). Given D

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 903–907,
Seattle, Washington, USA, 18-21 October 2013.

documents expressed over *W* unique words and *T* topics, LDA outputs the document-topic distribution θ and topic-word distribution φ, both of which can be obtained with Gibbs Sampling. For this scheme, the core process is the topic updating for each word in each document according to Equation 1.

$$P(z_i = j|\mathbf{z}_{-i}, \mathbf{w}, \alpha, \beta) = \\ (\frac{n_{-i,j}^{(w_i)} + \beta}{\sum_{w'}^{W} n_{-i,j}^{(w')} + W\beta})(\frac{n_{-i,j}^{(d_i)} + \alpha}{\sum_{j}^{T} n_{-i,j}^{(d_i)} + T\alpha}) \quad (1)$$

where $z_i = j$ represents the assignment of the i^{th} word in a document to topic j, z_{-i} represents all the topic assignments excluding the i^{th} word. $n_j^{(w')}$ is the number of instances of word w' assigned to topic j and $n_j^{(d_i)}$ is the number of words from document d_i assigned to topic j, the $-i$ notation signifies that the counts are taken omitting the value of z_i. Furthermore, α and β are hyper-parameters for the document-topic and topic-word Dirichlet distributions, respectively. After N iterations of Gibbs sampling for all words in all documents, the distribution θ and φ are finally estimated using Equations 2 and 3.

$$\phi_j^{(w_i)} = \frac{n_j^{(w_i)} + \beta}{\sum_{w'}^{W} n_j^{(w')} + W\beta} \quad (2)$$

$$\theta_j^{(d_i)} = \frac{n_j^{(d_i)} + \alpha}{\sum_{j}^{T} n_j^{(d_i)} + T\alpha} \quad (3)$$

3.2 Framework

Algorithm 1 summarizes the main steps. When a specific product and the reviews are provided, the explicit sentences and corresponding features are extracted(Line 1) by word segmentation, part-of-speech(POS) tagging and synonyms feature clustering. Then the prior knowledge are drawn from the explicit sentences automatically and integrated into the constrained topic model((Line 3 - Line 5). The word clusters are chosen as the training attributes(Line 6). Finally, several SVM classifiers are generated and applied to detect implicit features(Line 7 - Line 12).

Algorithm 1 Implicit Feature Detection

1: $ES \leftarrow$ extract explicit sentence set
2: $NES \leftarrow$ non-explicit sentence set
3: $CS \leftarrow$ constraint set from ES
4: $CPK \leftarrow$ correlation prior knowledge from ES
5: $ETM \leftarrow$ ConstrainedTopicModel(T,ES,CS,CPK)
6: $TA \leftarrow$ select training attributes from ETM
7: **for** each f_i in feature clusters **do**
8: $TD_i \leftarrow$ GenerateTrainingData(TA_i,ES)
9: $C_i \leftarrow$ BuildClassificationModelBySVM(TD_i)
10: $PR_i \leftarrow$ positive result of Classify(C_i,NES)
11: the feature of sentence in $PR_i \leftarrow f_i$
12: **end for**

3.3 Prior Knowledge Extraction and Incorporation

It is obvious that the pre-existing knowledge can assist to produce better and more significant clusters. In our work, we use a constrained topic model to select attributes for each product features. Each topic is first pre-defined a product feature. Then two types of prior knowledge, which are derived from the pre-defined product features, are extracted automatically and incorporated: must-link/cannot-link and correlation prior knowledge.

3.3.1 Must-link and Cannot-link

Must-link: It specifies that two data instances must be in the same cluster. Here is the must-link from an observation: as "*cheap*" to "*price*", some words must be associated with a feature. In order to mine these words, we compute the co-occurrence degree by *frequency*PMI(f,w)*, whose formula is as following: $P_{f\&w} * \log_2 \frac{P_{f\&w}}{P_f P_w}$, where P is the probability of subscript occurrence in explicit sentences, f is the feature, w is the word, and $f\&w$ means the co-occurrence of f and w. A higher value of *frequency*PMI* signifies that w often indicates f. For a feature f_i, the top five words and f_i constitute must-links. For example, the co-occurrence of "*price*" and "*cheap*" is very high, then the must-link between "*price*" and "*cheap*" can be identified.

Cannot-link: It specifies that two data instances cannot be in the same cluster. If a word and a feature never co-occur in our corpus, we assume them to form a cannot-link. For example, the word *low-cost* has never co-occurred with the product feature *screen*, so they constitute a cannot-link in our cor-

pus.

In this paper, the pre-defined process, must-link, and cannot-link are derived from Andrzejewski and Zhu (2009)'s work, all must-links and cannot-links are incorporated our constrained topic model. We multiply an indicator function $\delta(w_i, z_j)$, which represents a hard constraint, to the Equation 1 as the final probability for topic updating (see Equation 4).

$$P(z_i = j|\mathbf{z}_{-i}, \mathbf{w}, \alpha, \beta) = \delta(w_i, z_j)(\frac{n_{-i,j}^{(w_i)} + \beta}{\sum_{w'}^{W} n_{-i,j}^{(w')} + W\beta})(\frac{n_{-i,j}^{(d_i)} + \alpha}{\sum_{j}^{T} n_{-i,j}^{(d_i)} + T\alpha}) \quad (4)$$

As illustrated by Equations 1 and 4, $\delta(w_i, z_j)$, which represents intervention or help from pre-existing knowledge of must-links and cannot-links, plays a key role in this study. In the topic updating for each word in each document, we assume that the current word is w_i and its linked feature topic set is $Z^{(w_i)}$, then for the current topic z_j, $\delta(w_i, z_j)$ is calculated as follows:

1. If w_i is constrained by must-links and the linked feature belongs to $Z^{(w_i)}$, $\delta(w_i, z_j|z_j \in Z^{(w_i)}) = 1$ and $\delta(w_i, z_j|z_j \notin Z^{(w_i)}) = 0$.

2. If w_i is constrained by cannot-links and the linked feature belongs to $Z^{(w_i)}$, $\delta(w_i, z_j|z_j \in Z^{(w_i)}) = 0$ and $\delta(w_i, z_j|z_j \notin Z^{(w_i)}) = 1$.

3. In other cases, $\delta(w_i, z_j|j = 1, \ldots, T) = 1$.

3.3.2 Correlation Prior Knowledge

In view of the explicit product feature of each topic, the association of the word and the feature to topic-word distribution should be taken into account. Therefore, Equation 2 is revised as the following:

$$\phi_j^{(w_i)} = \frac{(1 + C_{w_i,j})(n_j^{(w_i)}) + \beta}{\sum_{w'}^{W}(1 + C_{w',j})(n_j^{(w')}) + W\beta} \quad (5)$$

where $C_{w',j}$ reflects the correlation of w' with the topic j, which is centered on the product feature f_{z_j}. The basic idea is to determine the association of w' and f_{z_j}, if they have the high relevance, $C_{w',j}$ should be set as a positive number. Otherwise, if we can determine w' and f_{z_j} are irrelevant, $C_{w',j}$ should be set as a positive number. In this paper, we attempt to using PMI or dependency relation to judge the relevance. For word w' and feature f_{z_j}:

1. Dependency relation judgement: If w' as parent node in the syntax tree mainly co-occurs with f_{z_j}, $C_{w',j}$ will be set positive. If w' mainly co-occurs with several features including f_{z_j}, $C_{w',j}$ will be set negative. Otherwise, $C_{w',j}$ will be set 0.

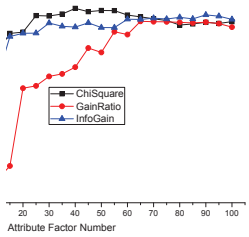
2. PMI judgement: If w' mainly co-occurs with f_{z_j} and $PMI(w', f_{z_j})$ is greater than the given value, $C_{w',j}$ will be set positive. Otherwise, $C_{w',j}$ will be set negative.

3.4 Attribute Selection

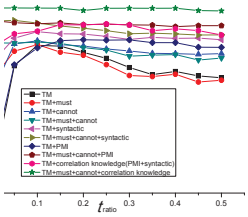
Some words, such as "*good*", can modify several product features and should be removed. In the result of run once, if a word appears in the topics which relates to different features, it is defined as a **conflicting word**. If a term is thought to describe several features or indicate no features, it is defined as a **noise word** .

When each topic has been pre-allocated, we run the explicit topic model 100 times. If a word turns into a conflicting word T_{cw} times(T_{cw} is set to 20), we assume that it is a noise word. Then the noise word collection is obtained and applied to filter the explicit sentences. Actually, here 100 is just an estimated number. And for T_{cw}, when it is between 15 and 25, the result is same, and when it exceeds 25, the result does not change a lot. The most important part to filter noise words is the correlation computation. So the experiment can work well with only estimated parameters.

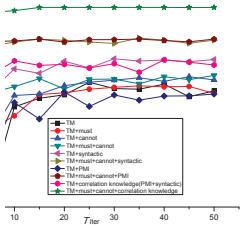
Next, By integrating pre-existing knowledge, the explicit topic model, which runs T_{iter} times, severs as attribute selection for SVM. In every result for each topic cluster, we remove the least four probable of word groups and merge the results by the pre-defined product feature. For a feature, if a word appears in its topic words more than $T_{iter} * t_{ratio}$ times, it is selected as one of the training attributes for the feature. In the end, if an attribute associates with different features, it is deleted.



(a) SVM based on traditional attribute selection method



(b) our constrained topic model by different t_{ratio} ($T_{iter} = 20$)



(c) our constrained topic model by different T_{iter} ($t_{ratio} = 0.1$)

Figure 1: Performance of different cases

3.5 Implicit Feature Detection via SVM

After completing attribute selection, vector space model(VSM) is applied to the selected attributes on the explicit sentences. For each feature f_i, a SVM classifier C_i is adopted. In train-set, the positive cases are the explicit sentences of f_i, and the negative cases are the other explicit sentences. For a non-explicit sentence, if the classification result of C_i is positive, it is an implicit sentence which implies f_i.

4 Evaluation of Experimental Results

4.1 Data Sets

There has no standard data set yet, we crawled the experiment data, which included reviews about a cellphone, from a famous Chinese shopping website[1]. The data contains 14218 sentences. The feature of each sentence was manually annotated by two research assistants. A handful of sentences which were annotated inconsistently were deleted. Table 1 depicts the data set which is evaluated. Other features were ignored because of their rare appearance.

Here are some explanations: (1)The sentences containing several explicit features were not added to the train-set. (2) A tiny number of sentences contain both explicit and implicit features, and they can only be regarded as explicit sentences. (3) The training set contains 3140 explicit sentences, the test set contains 7043 non-explicit sentences and more than 5500 sentences have no feature. (4) According to the ratio among the explicit sentences(6:1:2:3:1:2), it is reasonable that the most suitable number of topics should be 14. For example, the ratio of the product feature *screen* is 6, so we can assign the feature to topic 0,1,2,3,4,5. In our experiment, the performance of algorithm 1 is evaluated using F-measure. (5) Although the size of dataset is limited, out proposed is based on the constraint-based topic model, which has been widely used in different NLP fields. So, our approach can generalize well in different datasets. Of course, more high quality data will be collected to do the experiment in the future.

Table 1: Experiment data

Features	Explicit	Implicit	Total
screen	1165	244	1409
quality	199	83	282
battery	456	205	661
price	627	561	1188
appearance	224	167	391
software	469	129	598

4.2 Experimental Results

Figure 1a depicts the performance of using traditional attribute selection methods on SVM. Using χ^2 *test* on SVM can achieve the best performance, which is about 66.7%. In our constrained topic model, we use different T_{iter} and t_{ratio}. We conducted experiments by incorporating different types prior knowledge. From Figure 1b and 1c, we conclude that: (1)All these methods perform much better than the traditional feature selection methods, the improvements are more than 6%. (2)The reason for the little improvement of must-links is that the topic clusters have already obtained these linked word-

s. (3)All the pre-existing knowledge performs best and shows 3% improvement over non prior knowledge. (4)Different types of prior knowledge have different impact on the stabilities of different parameters. (5)As we have expected, by combing all prior knowledge, the best performance can reach 77.78%. Furthermore, as t_{ratio} or T_{iter} changes, our constrained topic model incorporating all prior knowledge look like very stable.

5 Conclusions

In this paper, we adopt a constrained topic model incorporating prior knowledge to select attribute for SVM classifiers to detect implicit features. Experiments show this method outperforms the attribute feature selection methods and detect implicit features better.

Abstract

Online learning algorithms like the perceptron are widely used for structured prediction tasks. For sequential search problems, like left-to-right tagging and parsing, beam search has been successfully combined with perceptron variants that accommodate search errors (Collins and Roark, 2004; Huang et al., 2012). However, perceptron training with inexact search is less studied for bottom-up parsing and, more generally, inference over hypergraphs. In this paper, we generalize the violation-fixing perceptron of Huang et al. (2012) to hypergraphs and apply it to the cube-pruning parser of Zhang and McDonald (2012). This results in the highest reported scores on WSJ evaluation set (UAS 93.50% and LAS 92.41% respectively) without the aid of additional resources.

1 Introduction

Structured prediction problems generally deal with exponentially many outputs, often making exact search infeasible. For sequential search problems, such as tagging and incremental parsing, beam search coupled with perceptron algorithms that account for potential search errors have been shown to be a powerful combination (Collins and Roark, 2004; Daumé and Marcu, 2005; Zhang and Clark, 2008; Huang et al., 2012). However, sequential search algorithms, and in particular left-to-right beam search (Collins and Roark, 2004; Zhang and Clark, 2008), squeeze inference into a very narrow space. To address this, Huang (2008) formulated constituency parsing as approximate bottom-up inference in order to compactly represent an exponential number of outputs while scoring features of arbitrary scope. This idea was adapted to graph-based dependency parsers by Zhang and McDonald (2012) and shown to outperform left-to-right beam search.

Both these examples, bottom-up approximate dependency and constituency parsing, can be viewed as specific instances of inexact hypergraph search. Typically, the approximation is accomplished by cube-pruning throughout the hypergraph (Chiang, 2007). Unfortunately, as the scope of features at each node increases, the inexactness of search and its negative impact on learning can potentially be exacerbated. Unlike sequential search, the impact on learning of approximate hypergraph search – as well as methods to mitigate any ill effects – has not been studied. Motivated by this, we develop online learning algorithms for inexact hypergraph search by generalizing the violation-fixing percepron of Huang et al. (2012). We empirically validate the benefit of this approach within the cube-pruning dependency parser of Zhang and McDonald (2012).

2 Structured Perceptron for Inexact Hypergraph Search

The structured perceptron algorithm (Collins, 2002) is a general learning algorithm. Given training instances $(x, \hat{y})$, the algorithm first solves the decoding problem $y' = \mathbf{argmax}_{y \in \mathcal{Y}(x)} \mathbf{w} \cdot \mathbf{f}(x, y)$ given the weight vector $\mathbf{w}$ for the high-dimensional feature representation $\mathbf{f}$ of the mapping (x, y), where y' is the prediction under the current model, $\hat{y}$ is the gold output and $\mathcal{Y}(x)$ is the space of all valid outputs for input x. The perceptron update rule is simply: $\mathbf{w}' = \mathbf{w} + \mathbf{f}(x, \hat{y}) - \mathbf{f}(x, y')$.

The convergence of original perceptron algorithm relies on the $\mathbf{argmax}$ function being exact so that the condition $\mathbf{w} \cdot \mathbf{f}(x, y') > \mathbf{w} \cdot \mathbf{f}(x, \hat{y})$ (modulo ties) always holds. This condition is called a *violation* because the prediction y' scores higher than the correct label $\hat{y}$. Each perceptron update moves weights

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 908–913,
Seattle, Washington, USA, 18-21 October 2013.

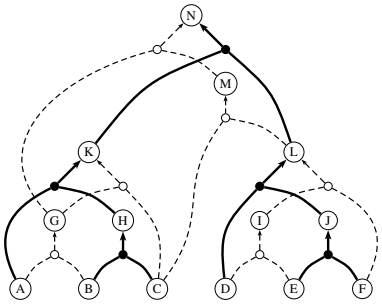

Figure 1: A hypergraph showing the union of the gold and Viterbi subtrees. The hyperedges in bold and dashed are from the gold and Viterbi trees, respectively.

away from y' and towards $\hat{y}$ to fix such violations. But when search is inexact, y' could be suboptimal so that sometimes $\mathbf{w} \cdot \mathbf{f}(x, y') < \mathbf{w} \cdot \mathbf{f}(x, \hat{y})$. Huang et al. (2012) named such instances *non-violations* and showed that perceptron model updates for non-violations nullify guarantees of convergence. To account for this, they generalized the original update rule to select an output y' within the pruned search space that scores higher than $\hat{y}$, but is not necessarily the highest among all possibilities, which represents a true violation of the model on that training instance. This *violation fixing perceptron* thus relaxes the $\mathbf{argmax}$ function to accommodate inexact search and becomes provably convergent as a result.

In the sequential cases where $\hat{y}$ has a linear structure such as tagging and incremental parsing, the violation fixing perceptron boils down to finding and updating along a certain prefix of $\hat{y}$. Collins and Roark (2004) locate the earliest position in a chain structure where $\hat{y}_{\text{pref}}$ is worse than y'_{pref} by a margin large enough to cause $\hat{y}$ to be dropped from the beam. Huang et al. (2012) locate the position where the violation is largest among all prefixes of $\hat{y}$, where size of a violation is defined as $\mathbf{w} \cdot \mathbf{f}(x, y'_{\text{pref}}) - \mathbf{w} \cdot \mathbf{f}(x, \hat{y}_{\text{pref}})$.

For hypergraphs, the notion of prefix must be generalized to subtrees. Figure 1 shows the packed-forest representation of the union of gold subtrees and highest-scoring (Viterbi) subtrees at every gold node for an input. At each gold node, there are two incoming hyperedges: one for the gold subtree and the other for the Viterbi subtree. After bottom-up parsing, we can compute the scores for the gold subtrees as well as extract the corresponding Viterbi subtrees by following backpointers. These Viterbi subtrees need not necessarily to belong to the full Viterbi path (i.e., the Viterbi tree rooted at node (N)). An update strategy must choose a subtree or a set of subtrees at gold nodes. This is to ensure that the model is updating its weights relative to the intersection of the search space and the gold path.

Our first update strategy is called *single-node max-violation (s-max)*. Given a gold tree $\hat{y}$, it traverses the gold tree and finds the node n on which the violation between the Viterbi subtree and the gold subtree is the largest over all gold nodes. The violation is guaranteed to be greater than or equal to zero because the lower bound for the max-violation on any hypergraph is 0 which happens at the leaf nodes. Then we choose the subtree pair $(\hat{y}_n, y'_n)$ and do the update similar to the prefix update for the sequential case. For example, in Figure 1, suppose the max-violation happens at node (K), which covers the left half of the input x, then the perceptron update would move parameters to the subtree represented by nodes (B), (C), (H) and (K) and away from (A), (B), (G) and (K).

Our second update strategy is called *parallel max-violation (p-max)*. It is based on the observation that violations on non-overlapping nodes can be fixed in parallel. We define a set of *frontiers* as a set of nodes that are non-overlapping and the union of which covers the entire input string x. The frontier set can include up to $|x|$ nodes, in the case where the frontier is equivalent to the set of leaves. We traverse $\hat{y}$ bottom-up to compute the set of frontiers such that each has the max-violation in the span it covers. Concretely, for each node n, the max-violation frontier set can be defined recursively,

$$\text{ft}(n) = \begin{cases} n, & \text{if } n = \text{maxv}(n) \\ \bigcup_{n_i \in \text{children}(n)} \text{ft}(n_i), & \text{otherwise} \end{cases}$$

where $\text{maxv}(n)$ is the function that returns the node with the absolute maximum violation in the subtree rooted at n and can easily be computed recursively over the hypergraph. To make a perceptron update, we generate the max-violation frontier set for the entire hypergraph and use it to choose subtree pairs $\bigcup_{n \in \text{ft}(\text{root}(x))} (\hat{y}_n, y'_n)$, where $\text{root}(x)$ is the root of the hypergraph for input x. For example, in Figure 1, if the union of (K) and (L) satisfies the definition of ft, then the perceptron update would move feature

weights away from the union of the two Viterbi subtrees and towards their gold counterparts.

In our experiments, we compare the performance of the two violation-fixing update strategies against two baselines. The first baseline is the *standard* update, where updates always happen at the root node of a gold tree, even if the Viterbi tree at the root node leads to a non-violation update. The second baseline is the *skip* update, which also always updates at the root nodes but skips any non-violations. This is the strategy used by Zhang and McDonald (2012).

3 Experiments

We ran a number of experiments on the cube-pruning dependency parser of Zhang and McDonald (2012), whose search space can be represented as a hypergraph in which the nodes are the complete and incomplete states and the hyperedges are the instantiations of the two parsing rules in the Eisner algorithm (Eisner, 1996).

The feature templates we used are a superset of Zhang and McDonald (2012). These features include first-, second-, and third-order features and their labeled counterparts, as well as valency features. In addition, we also included a feature template from Bohnet and Kuhn (2012). This template examines the leftmost child and the rightmost child of a modifier simultaneously. All other high-order features of Zhang and McDonald (2012) only look at arcs on the same side of their head. We trained the parser with hamming-loss-augmented MIRA (Crammer et al., 2006), following Martins et al. (2010). Based on results on the English validation data, in all the experiments, we trained MIRA with 8 epochs and used a beam of size 6 per node.

To speed up the parser, we used an unlabeled first-order model to prune unlikely dependency arcs at both training and testing time (Koo and Collins, 2010; Martins et al., 2013). We followed Rush and Petrov (2012) to train the first-order model to minimize filter loss with respect to max-marginal filtering. On the English validation corpus, the filtering model pruned 80% of arcs while keeping the oracle unlabeled attachment score above 99.50%. During training only, we insert the gold tree into the hypergraph if it was mistakenly pruned. This ensures that the gold nodes are always available, which is required for model updates.

3.1 English and Chinese Results

We report dependency parsing results on the Penn WSJ Treebank and the Chinese CTB-5 Treebank. Both treebanks are constituency treebanks. We generated two versions of dependency treebanks by applying commonly-used conversion procedures. For the first English version (PTB-YM), we used the Penn2Malt[1] software to apply the head rules of Yamada and Matsumoto and the Malt label set. For the second English version (PTB-S), we used the Stanford dependency framework (De Marneffe et al., 2006) by applying version 2.0.5 of the Stanford parser. We split the data in the standard way: sections 2-21 for training; section 22 for validation; and section 23 for evaluation. We utilized a linear chain CRF tagger which has an accuracy of 96.9% on the validation data and 97.3% on the evaluation data[2]. For Chinese, we use the Chinese Penn Treebank converted to dependencies and split into train/-validation/evaluation according to Zhang and Nivre (2011). We report both unlabeled attachment scores (UAS) and labeled attachment scores (LAS), ignoring punctuations (Buchholz and Marsi, 2006).

Table 1 displays the results. Our improved cube-pruned parser represents a significant improvement over the feature-rich transition-based parser of Zhang and Nivre (2011) with a large beam size. It also improves over the baseline cube-pruning parser without max-violation update strategies (Zhang and McDonald, 2012), showing the importance of update strategies in inexact hypergraph search. The UAS score on Penn-YM is slightly higher than the best result known in the literature which was reported by the fourth-order unlabeled dependency parser of Ma and Zhao (2012), although we did not utilize fourth-order features. The LAS score on Penn-YM is on par with the best reported by Bohnet and Kuhn (2012). On Penn-S, there are not many existing results to compare with, due to the tradition of reporting results on Penn-YM in the past. Nevertheless, our result is higher than the second best by a large margin. Our Chinese parsing scores are the highest reported results.

Table 1: Parsing results on test sets of the Penn Treebank and CTB-5. UAS and LAS are measured on all tokens except punctuations. We also include the tokens per second numbers for different parsers whenever available, although the numbers from other papers were obtained on different machines. Speed numbers marked with † were converted from sentences per second.

The speed of our parser is around 200-300 tokens per second for English. This is faster than the parser of Bohnet and Kuhn (2012) which has roughly the same level of accuracy, but is slower than the parser of Martins et al. (2013) and Rush and Petrov (2012), both of which only do unlabeled dependency parsing and are less accurate. Given that predicting labels on arcs can slow down a parser by a constant factor proportional to the size of the label set, the speed of our parser is competitive. We also tried to prune away arc labels based on observed labels for each POS tag pair in the training data. By doing so, we could speed up our parser to 500-600 tokens per second with less than a 0.2% drop in both UAS and LAS.

3.2 Importance of Update Strategies

The lower portion of Table 1 compares cube-pruning parsing with different online update strategies in order to show the importance of choosing an update strategy that accommodates search errors. The max-violation update strategies (s-max and p-max) improved results on both versions of the Penn Treebank as well as the CTB-5 Chinese treebank. It made a larger difference on Penn-S relative to Penn-YM, improving as much as 0.93% in LAS against the skip update strategy. Additionally, we measured the percentage of non-violation updates at root nodes. In the last epoch of training, on Penn-YM, there was 24% non-violations if we used the skip update strategy; on Penn-S, there was 36% non-violations. The portion of non-violations indicates the inexactness of the underlying search. Search is harder on Penn-S due to the larger label set. Thus, as expected, max-violation update strategies improve most where the search is the hardest and least exact.

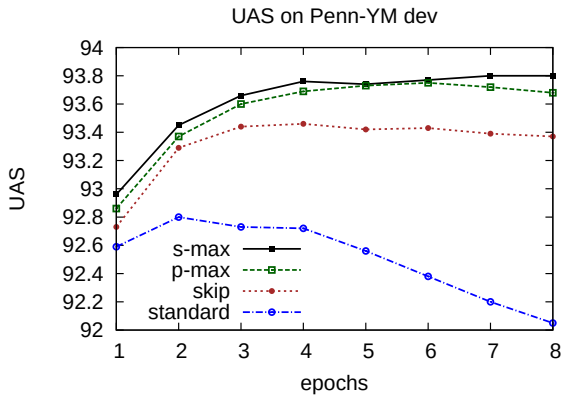

Figure 2: Constrast of different update strategies on the validation data set of Penn-YM. The x-axis is the number of training epochs. The y-axis is the UAS score. s-max stands for single-node max-violation. p-max stands for parallel max-violation.

Figure 2 shows accuracy per training epoch on the validation data. It can be seen that bad update strategies are not simply slow learners. More iterations of training cannot close the gap between strategies. Forcing invalid updates on non-violations (standard update) or simply ignoring them (skip update) produces less accurate models overall.

Table 2: Parsing Results for languages from CoNLL 2006/2007 shared tasks. When a language is in both years, we use the 2006 data set. The best results with † are the maximum in the following papers: Buchholz and Marsi (2006), Nivre et al. (2007), Zhang and McDonald (2012), Bohnet and Kuhn (2012), and Martins et al. (2013), For consistency, we scored the CoNLL 2007 best systems with the CoNLL 2006 evaluation script. ZN 2011 (reimpl.) is our reimplementation of Zhang and Nivre (2011), with a beam of 64. Results in bold are the best among ZN 2011 reimplementation and different update strategies from this paper.

3.3 CoNLL Results

We also report parsing results for 17 languages from the CoNLL 2006/2007 shared-task (Buchholz and Marsi, 2006; Nivre et al., 2007). The parser in our experiments can only produce projective dependency trees as it uses an Eisner algorithm backbone to generate the hypergraph (Eisner, 1996). So, at training time, we convert non-projective trees – of which there are many in the CoNLL data – to projective ones through flattening, i.e., attaching words to the lowest ancestor that results in projective trees. At testing time, our parser can only predict projective trees, though we evaluate on the true non-projective trees.

Table 2 shows the full results. We sort the languages according to the percentage of non-projective trees in increasing order. The Spanish treebank is 98% projective, while the Dutch treebank is only 64% projective. With respect to the Zhang and Nivre (2011) baseline, we improved UAS in 16 languages and LAS in 15 languages. The improvements are stronger for the projective languages in the top rows. We achieved the best published UAS results for 7 languages: Spanish, Catalan, Bulgarain, Italian, Swedish, Danish, and Greek. As these languages are typically from the more projective data sets, we speculate that extending the parser used in this study to handle non-projectivity will lead to state-of-the-art models for the majority of languages.

4 Conclusions

We proposed perceptron update strategies for inexact hypergraph search and experimented with a cube-pruning dependency parser. Both single-node max-violation and parallel max-violation update strategies signficantly improved parsing results over the strategy that ignores any invalid udpates caused by inexactness of search. The update strategies are applicable to any bottom-up parsing problems such as constituent parsing (Huang, 2008) and syntax-based machine translation with online learning (Chiang et al., 2008).

Abstract

We present a classification model that predicts the presence or omission of a lexical connective between two clauses, based upon linguistic features of the clauses and the type of discourse relation holding between them. The model is trained on a set of high frequency relations extracted from the Penn Discourse Treebank and achieves an accuracy of 86.6%. Analysis of the results reveals that the most informative features relate to the discourse dependencies between sequences of coherence relations in the text. We also present results of an experiment that provides insight into the nature and difficulty of the task.

1 Introduction

A central goal of natural language generation and summarization systems is to produce interpretable, coherent text that rivals material a human would produce. Doing so requires that systems not only have the ability to generate clauses that are grammatical and easy for people to process, but also the ability to employ the appropriate discourse structuring devices needed to yield fluid transitions between these clauses. This is a tricky issue in that it requires that a balance be achieved between the opposing goals of communicative expressiveness and economy. On the one hand, insufficient cueing of inter-clausal relationships can lead to a discourse that is at best difficult to process, and at worst misunderstood. On the other hand, too much explicit marking can result in a clunky and even redundant sounding discourse.

Here we consider the question of when to explicitly mark the COHERENCE RELATIONS in discourse, that is, the inter-clausal relationships that the language producer intends the interpreter to infer between the meanings of clauses (Hobbs, 1979; Mann and Thompson, 1988; Kehler, 2002; Asher and Lascarides, 2003). Consider, for example, the EXPLANATION coherence relation that holds in (1), in which the second clause provides a cause or reason for the eventuality described in the first:

(1) a. Max will visit Australia this summer **because** his father is turning 65.
    b. Max will visit Australia this summer. His father is turning 65.

As example (1) shows, coherence relations can be marked explicitly—by using lexical connectives such as coordinating or subordinating conjunctions (e.g., *because* in 1a) or certain types of prepositional or adverbial phrases—or left implicit as in (1b). Either way, establishing the relation itself requires the reader to go through a complex inferential process necessitating that a variety of assumptions be made, typically supported by context and/or world knowledge, that are not explicitly asserted by the actual linguistic material. In (1), for instance, such inferences would include that Max intends to see his father when he travels to Australia, that his father resides in that country, and that the birthday will taking place during the time of the visit. Importantly, the role of the connective in (1a) is therefore not to *establish* that an EXPLANATION relation holds. Instead, connectives serve the function of directing the addressee's inference processes toward a smaller set of coherence relations than might otherwise be available, among other possible roles.

The fact that both (1a) and (1b) are felicitous may lead us to believe that the choice to insert a connective between clauses is simply optional. This is not

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 914–923,
Seattle, Washington, USA, 18-21 October 2013.

always the case, however. Sometimes the use of a connective is required, since omitting it would likely result in incorrect inferences being drawn by the addressee. For example, the use of *when* in (2a) implies a backward temporal ordering of events, which is reversed if the connective is left out, as in (2b).

(2) a. Maggie fell over in shock **when** Saul offered to help her.
    b. Maggie fell over in shock. Saul offered to help her.

On the other hand, a connective can seem unnecessary if the relation between the two clauses is sufficiently implied by other cues in the text. For instance, since the act of throwing a vase against a concrete wall would normally be expected to cause the vase to break, the adverbial phrase *as a result* in (3a), while felicitous, seems overly verbose and perhaps even redundant.

(3) a. Susan threw the fragile vase against the concrete wall. **As a result**, it broke.
    b. Susan threw the fragile vase against the concrete wall. It broke.

The foregoing examples suggest that the appropriateness of including an explicit connective is inherently gradient, and is in fact correlated with ease of inference: the more difficult recovering the correct relation would be without a connective, the more necessary it is to include one. This characterization in turn suggests that predicting whether a connective should be included might be a difficult problem for an NLP system to address, since current-day systems lack the requisite world knowledge and capacity for inference that would be necessary to evaluate the ease with which coherence relations can be established on arbitrary examples. However, it is also possible that the decision to include a connective depends in part on stylistic and other types of factors as well, such that there might be predictive information in the kinds of shallow linguistic and textual features that systems *do* have access to. This is the question taken up in this work: Given two adjacent clauses in a text, the type of coherence relation holding between them and a candidate connective that could be used to signal the relation, we ask how well a system can predict whether or not that connective was used by the author of the text. This capability would be useful to generation systems as a post-cursor to discourse-level message planning and sentence realization processes, as well as summarization systems that take existing sentences and have to reconsider connective placement upon reassembling them.

To our knowledge, there is no work in the literature that addresses this issue directly. There is a growing body of research (Sporleder and Lascarides, 2008; Pitler et al., 2009; Lin et al., 2009; Zhou et al., 2010) that focuses on building supervised models for classifying implicit relations using a variety of contextual features, such as the polarity of clauses, the semantic class and tense/aspect of verbs, and information from syntactic parses. With respect to explicit relations, Elhadad and McKeown (1990) sketch a procedure to select an appropriate connective to link two propositions as part of a larger text generation system, using linguistic features derived from the sentences. The procedure selects the best connective from a given set of candidates, but does not allow for the option of leaving the relation implicit. More recently, Asr and Demberg (2012a) look at both explicit and implicit relations, and make the observation that certain relation types are more likely to be realized explicitly than others. Relatedly, Asr and Demberg (2012b) discuss which connectives are the strongest predictors of which relation types. However, there is no work of which we are aware that specifically predicts whether connectives should be used or omitted.

2 Classification Model

Our model is a binary classifier trained on data extracted from the Penn Discourse Treebank (PDTB; Prasad et al. (2008)), a large-scale corpus of annotated discourse coherence relations covering the one-million-word Wall Street Journal corpus of the Penn Treebank (Marcus et al., 1993).

2.1 Data

For every relation in the PDTB, the following components are annotated: (i) the connective used to signal the relation; (ii) the textual spans of the two clausal arguments that constitute the relation; (iii) the semantic sense of the relation, according to a hierarchical tagset of senses; and (iv) the attribution of the assertions and beliefs expressed in the text to the

relevant individuals. Crucially for our purposes, for the implicit relations the corpus indicates the most suitable connective if the relation were instead signaled explicitly. For example, the annotators decided that the best connective to signal the REASON relation in (4) would be *because*, rather than other plausible candidates, such as *as* or *since*.

(4) It's a shame their meeting never took place. [IMPLICIT=*because*] Mr. Katzenstein certainly would have learned something. (WSJ0037)

In total, there are 18,459 explicit and 16,053 implicit relations annotated in the PDTB. We excluded a subset of these cases in training our model based on two criteria. First, whereas explicit relations in the PDTB can hold between spans of text that either are or are not adjacent, we excluded the non-adjacent cases. This was done to ensure consistency in discourse structure between the relations considered in the model, since only the implicit relations between adjacent clauses were annotated. Second, we excluded relations that have lower frequency semantic senses or use low frequency connectives. As a result, the model considers only the eight most common semantic senses of relations, which in total account for just less than 90% of the relations in the corpus.[1] Further, for each relation, we only consider the connectives that account for more than 5% of the instances of that relation. After applying these filters, the resulting corpus comprised 10,039 explicit and 11,690 implicit relations.

Table 1 shows the eight relations that were modeled. The majority of these relations exist at the middle layer of the three-level hierarchy of semantic senses annotated in the PDTB.[2] Relations at the highest level – representing the four major semantic categories COMPARISON, CONTINGENCY, EXPANSION and TEMPORAL – were deemed too broad to be of practical use in a generation system, whereas the lowest-level senses were considered either unnecessarily fine-grained or have too few tokens in the corpus to allow for meaningful statistical modeling. Two exceptions were made for REASON and RESULT relations, which do appear at the lowest level in the PDTB hierarchy (beneath the CAUSE category). These were included because they are both attested frequently in the corpus and are undeniably contrastive: with REASON, the second clause provides an explanation for the proposition expressed in the first clause, whereas with RESULT, the second clause describes a consequence of the first. It is reasonable to want these relations to be modeled separately.

Sections 2-22 of the corpus were used as the training set, and sections 23 and 24 were used as the test set. Sections 0 and 1 of the corpus were set aside as a development set for feature design and parameter optimization. The training set comprised 18,218 tokens, distributed as shown in Table 1.

Relation Type	**Explicit**		**Implicit**	
Asynchronous	1,120	(70%)	469	(30%)
Conjunction	2,940	(61%)	1,906	(39%)
Contrast	2,044	(66%)	1,054	(34%)
Instantiation	203	(16%)	1,093	(84%)
Reason	771	(28%)	1,938	(72%)
Restatement	76	(4%)	2,081	(96%)
Result	354	(21%)	1,295	(79%)
Synchronous	748	(86%)	126	(14%)
Total	**8,256**	(45%)	**9,962**	(55%)

Table 1: Distribution of Training Set

As Table 1 shows, the preference for an overt connective varies significantly according to the type of relation. The ASYNCHRONOUS, CONJUNCTION, CONTRAST and SYNCHRONOUS relations are realized explicitly the majority of the time, whereas INSTANTIATION, REASON, RESTATEMENT and RESULT relations are more often left implicit. We can also see that some relation types (such as RESTATEMENT, INSTANTIATION and SYNCHRONOUS) exhibit a strong preference to be realized in a particular form, whereas other types show more variability in whether they are realized explicitly or implicitly.

The distribution of tokens in Table 1 can be used to determine a baseline accuracy against which the performance of our model is evaluated. A naive model that uses the semantic type of the coherence relation as the sole predictive feature makes a binary classification based simply on the majority category for that relation type. A baseline model using this methodology results in classification accuracy of 77.0% over the held-out test set.

[1] The next most common relation type, CONDITION, was excluded because it is always marked explicitly in the corpus.

[2] For more details of the PDTB sense hierarchy, see Prasad et al. (2008).

2.2 Model

We built a composite model containing binary logistic regression classifiers for each coherence relation, trained on a set of linguistic features extracted from each token in the training set. Logistic regression was chosen because it produces a model with high performance and results that are easily interpretable. The features included in the model fall into the following three broad classes: relation-level, argument-level, and discourse-level.

Relation-level features

In addition to the semantic type of the relation, we include as a feature the connective used to signal the relation in the text (or, for the implicit relations, the connective indicated by the annotators as most appropriate). This feature (*Connect*) is included based upon the observation that connectives vary as to their rates of being realized explicitly—even for connectives that signal relations with the same semantic sense. Consequently, given a relation of a particular semantic type, an indication of the best fitting connective may be a consistent predictor of whether or not this relation is realized explicitly.

We also include a feature reflecting the attribution of the relation. As mentioned above, the PDTB is annotated to describe the attribution of the propositions expressed within a relation to individuals or entities in the text. For example, in the relation shown in (5), the first clause contains a direct quotation, clearly attributing the proposition expressed to the individual *Rep. Stark*. However, the second clause contains no such indication of attribution to an entity in the text, and so the proposition is instead assumed to be asserted by the writer of the article.

(5) "No magic bullet will be discovered next year, an election year," says Rep. Stark. **But** 1991 could be a window for action. (WSJ0314)

Inspection of the corpus data suggests that when one argument of a relation contains a proposition that is attributable to an individual in the text (either by direct or indirect quotation) but the other is assumed by default to be attributed to the author, this relation is more likely to be realized explicitly. This may well have an explanation based on sentence processing: the intervening attribution phrase *'says Rep. Stark'* may serve as a distraction, with the result that the intended coherence relation is harder to infer without a connective. Consequently, we include a factor (*AttMismatch*) indicating if the two arguments are not attributed to the perspective of the same individual.

Finally, in any particular genre there may be formulaic prose whose systematic features can be exploited by a system tasked with generating text within that same genre. In this case, the genre represented by the corpus data comprises copy-edited articles from the Wall Street Journal, many of which refer to company earnings reports or other financial events, and are written in a highly prescribed style. Accordingly, we may suspect that there is a greater prevalence of implicit relations in these cases, since the reader is assumed to be habituated to the way in which the information in this type of article is presented. Consequently, for the domain at hand we include a binary feature (*Financial*) indicating whether the relation pertains to financial information. This feature takes the value 1 if the textual spans of both arguments in the relation contain percentage amounts or dollar figures.

Argument-level features

For each relation, the model includes features capturing the size or complexity of each of its two arguments. The arguments were identified by the annotators according to a principle of minimality, whereby the annotations indicate the shortest text spans necessary for the appropriate coherence relation to be interpreted. However, the annotators also indicated other text that is in some way relevant to the interpretation of the arguments. This supplementary material can include unrestricted relative clauses, appositives, or other parenthetical information. Our observation of the data indicates that relations which have supplementary material annotated alongside one or both of their arguments are more often than not realized explicitly with connectives. As a result, we include binary features (*Supp1*, *Supp2*) indicating whether the first and second arguments of the relation include such supplementary information. We also include features (*Length1*, *Length2*) reflecting a simple measure of the length of each argument, calculated as the log transformed count of the number of words in the arguments' minimal text spans.

One measure of the complexity of an argument

is the number of clauses it contains. It might be thought that the greater the syntactic complexity of an argument, the more likely it is that the relation containing it is marked explicitly, so as to give the reader more help in drawing the correct intended inference between the arguments. As a proxy for the number of clauses in each argument, we include features (*NPSbj1*, *NPSbj2*) equal to the total number of main, subordinate, or complement clause subjects included within the textual spans of the respective arguments, determined using the syntactic parses available in the corpus data.

We also consider whether the underlying richness of the informational content expressed by the argument may influence the presence or omission of a connective. Considering the way in which readers process text in real time, it would intuitively be more difficult to infer the intended relation between two clauses without the aid of a connective if the arguments themselves had greater processing demands owing to increased lexical retrieval, reference and anaphor resolution requirements, and so forth. Given this intuition, we may expect that arguments with higher density of information are correlated with the increased use of connectives as a means of facilitating the inference of the relation type and thereby easing the overall processing burden. Consequently, our model includes features (*ContDensity1*, *ContDensity2*) calculated as the ratio of the count of words in each argument that are content words (i.e. ignoring articles, prepositions and pronouns), divided by the total number of words, as well as features (*PronDensity1*, *PronDensity2*) calculated as the ratio of pronouns in each argument to the number of noun phrases.

Finally, the accessibility of the subject of the second argument in a relation may play a role in determining whether the relation is explicitly marked. Specifically, informal observation of the data suggests that there is a tendency for the second argument of an implicit relation to begin with a longer, contentful noun phrase, rather than a pronoun. Consequently, our model includes a binary feature (*FirstA2Pron*) indicating whether the first word in the second argument is a pronoun.

Discourse-level features

The final class of features takes account of the way in which a relation fits into the broader discourse structure in the text. In their work on implicit relation classification, Pitler et al. (2008) identified various dependencies between bigram sequences of explicitly- and implicitly-realized relations of different semantic types. These results suggest that the semantic type and the presence of a connective in one relation may be predictive of whether or not the following relation in the text is marked with a connective. Consequently, we include features indicating the semantic type of the relation occurring immediately prior in the text (*PrevSemType*), and whether this relation was marked implicitly or explicitly (*PrevForm*).

The other discourse-level features take account of the dependencies between the relation in question and its neighboring relations in the text. As part of a supervised learning model developed to classify the semantic class of implicit relations in the PDTB, Lin et al. (2009) found features based on the two main types of discourse dependency pattern in the corpus ('shared' and 'fully embedded' arguments) to be highly predictive. We speculatively include similar features in our model to see if they are helpful in predicting the presence of connectives.

The first type of dependency between adjacent relations is one where the second argument of one relation is also the first argument of the following relation, as in Figure 1. Accordingly, we include two binary features indicating whether an argument is shared with the preceding relation (*Arg1isPrevArg2*) or the following relation (*Arg2isNextArg1*) in the corpus.

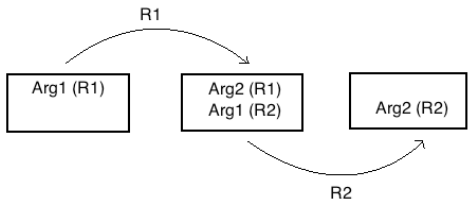

Figure 1: Shared argument

The other main type of discourse dependency, a 'fully embedded' dependency, is one where an entire relation (including both of its arguments) is completely embedded within one argument of an adjacent relation in the text, as in Figure 2. To capture

this type of dependency structure, we include two binary features (*EmbedNext*, *EmbedPrev*) indicating whether the current relation is embedded within either one of its adjacent relations. We also include two binary features (*Arg1Embed*, *Arg2Embed*) to indicate whether either argument of the current relation completely contains an embedded relation.

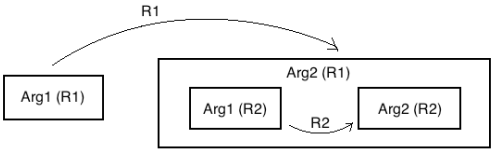

Figure 2: Fully embedded argument

The two relations in (6) exemplify a typical instantiation of this embedded dependency structure.

(6) It is an overwhelming job. [IMPLICIT= *because*] There are so many possible proportions **when** you consider how many things are made out of eggs and butter and milk. (WSJ0261)

In this example, there is an implicit REASON relation holding between the two complete sentences, and an explicit SYNCHRONOUS relation signaled by the connective *when* holding between the two clauses of the second sentence. Since the REASON relation fully embeds another relation within its second argument, the feature *Arg2Embed* for this relation takes the value 1. For the SYNCHRONOUS relation, the feature *EmbedPrev* takes the value 1 since the entire relation is fully contained within the second argument of the preceding relation in the text.

3 Results and Evaluation

3.1 Classification accuracy

The model was evaluated by assessing the accuracy of its predictions against the unseen test set. The model achieved an overall accuracy of 86.6%, an improvement of 9.6% above baseline.[3] Table 2 shows the model accuracy for each relation type, together with the baseline performance based on the majority category for that type.

[3]During the preparation of the final version of this paper, a model was trained with an SVM using the same set of features, which resulted in a modest improvement in performance (87.3%). The ensuing discussion of results, however, will continue to pertain to the regression model.

Relation Type	Accuracy	Baseline
Asynchronous	91.7%	79.7%
Conjunction	84.5%	78.2%
Contrast	81.1%	65.0%
Instantiation	83.3%	82.5%
Reason	88.2%	68.3%

Total	**86.6%**	**77.0%**

Table 2: Classification Accuracy by Relation Type

The model achieved an improvement in accuracy across all relation types but one: RESTATEMENT relations, for which the baseline accuracy was already close to 100%. The greatest improvement in accuracy was seen for REASON relations, for which the model accuracy was 19.9% above baseline. We now discuss which of the factors in each of the feature classes turned out to be the most predictive.

3.2 Significant predictors

We trained the model on subsets of the features to investigate the predictive power of the different feature classes. The accuracy assessed against the test set is shown in Table 3.

Feature Class	# Features	Accuracy
Relation Level	4	80.4%
Argument Level	11	77.2%
Discourse Level	8	80.9%
Rel + Arg Levels	15	82.8%
Rel + Disc Levels	12	85.1%
Arg + Disc Levels	19	82.4%
All Features	23	86.6%

Table 3: Classification Accuracy by Feature Class

The classes of Relation-level and Discourse-level features each separately yielded significantly better performance over baseline (one-sided tests of proportion, z=2.50 and z=2.92, respectively; $p<0.01$ for both), whereas the Argument-level features alone performed only marginally better than baseline. However, all three classes of features are needed to attain the highest model performance.

Across all relation types, we found that the features relating to the discourse dependencies between a relation and its neighbors were the strongest and

most consistent predictors of whether that relation is explicit or implicit. A relation that is fully embedded within a single argument of an adjacent relation in the text (indicated by the features *EmbedPrev* and *EmbedNext*) has a much higher likelihood of being signaled explicitly. Conversely, a relation that fully contains another relation within one of its arguments (indicated by *Arg1Embed* and *Arg2Embed*) has a significantly higher likelihood of being implicit. The result is consistent with the embedded discourse dependency shown in (6), in which the implicit REASON relation fully contains an explicit SYNCHRONOUS relation within its second argument.

The model also found that the features which indicate whether a relation has shared arguments with either the preceding or following relations in the text (*Arg1isPrevArg2*, *Arg2isNextArg1*) are both predictors of an implicit outcome. In other words, if a clause in the text serves as the argument for two adjacent relations, then both of these relations are more likely to be realized implicitly.

The next most predictive feature was the connective used to signal the relation (*Connect*). This feature was a significant predictor for every relation type. Eliminating this feature from the final model reduces the overall accuracy by 2.5%. The other features in the model were less significantly predictive, and generally worked in the expected direction. Longer arguments (*Length1, Length2*) and the indication of a financial genre (*Financial*) were generally associated with predicted implicit outcomes, whereas the presence of supplementary material (*Supp1, Supp2*), a mismatch of attribution (*AttMismatch*), more 'content rich' arguments (*ContDensity1, ContDensity2*), and a pronoun appearing as the first word of the second argument (*FirstA2Pron*) all tended to increase the odds in favor of a predicted explicit outcome.

The features indexing syntactic complexity (*NPSbj1* and *NPSbj2*) were found to be marginally predictive of an explicit outcome for most relation types, but the overall effect in the model was relatively small—resulting in only a 0.2% improvement—meaning that the level of performance reported on this task depends very little on the model having access to full syntactic parses. Somewhat unexpectedly, the factors indicating the semantic type of the previous relation in the text (*PrevSemType*) and whether or not this relation was explicitly signaled by a connective (*PrevForm*) were found not to be significant predictors. Our analysis of the training data confirmed the findings of Pitler et al. (2008) in that certain bigrams of coherence relation types are significantly more prevalent than others. However, the differences in the frequencies were evidently not sufficiently correlated with the explicit/implicit distinction as to make the type or form of the previous relation a significant feature in the model.

3.3 Error analysis

We analyzed a sample of cases incorrectly predicted by the model to see if there were any consistent traits. We focus our attention here on the CONTRAST relations, which is the type with the lowest model accuracy. The majority of these errors were cases where the model predicted that the relation would be explicit—the most likely outcome for a CONTRAST relation—whereas in the corpus the intended relation was signaled by linguistic cues other than an overt connective. For instance, the strong syntactic parallelism of the two arguments in (7), and the opposite polarity of the lexical items *delight* and *detriment*, combine to induce a contrastive relationship without the need for a connective.

(7) To the delight of some doctors, the bill dropped a plan passed by the Finance Committee. [IMPLICIT=*but*] To the detriment of many low-income people, efforts to boost Medicaid funding were also stricken. (WSJ2372)

Other ways that the contrast relation is signaled implicitly include contrasting temporal modifiers (*It wasn't so long ago X. Now, Y*), repetition of the predicate in the argument (*. . . it could only happen once. . . . it's happening again*), or even by the use of punctuation such as a semicolon. Previous work (Sporleder and Lascarides, 2008; Lin et al., 2009) has sought to make use of such cues to identify and classify implicit relations in the text. The results of this brief error analysis suggest that such indirect cues could also be useful factors in determining whether to choose to use a connective for a given relation type when generating text.

4 Judgment Study

The system described in the last section outperformed a baseline majority-category classifier on the task of deciding whether a relation should be made explicit or left implicit. This result might be considered surprising, for two reasons that we have previously discussed. First, the system was able to make this improvement using relatively shallow features extracted from the text, without access to the richer types of contextual information and world knowledge required for establishing coherence relations during actual discourse comprehension. Second, the data suggest that the appropriateness of including a connective is not as cut-and-dried as a binary classification task may suggest, but is instead gradient, with many cases for which the inclusion of a connective appears to be optional. Obviously, the PDTB does not avail us of the opportunity to evaluate this gradience directly (or even use a 3-way required/optional/redundant distinction), since the producer of the actual text samples in the corpus had to ultimately decide whether or not to use a connective. The apparent optionality of many examples thus puts limits on how well we can expect a system to perform, since there is no way to reliably predict cases in which the decision is made arbitrarily.

This observation leads us to ask how well humans perform on this same task. Do they make highly accurate predictions, or does optionality limit their performance? In order to shed light on this question, we carried out an experiment to see how consistently humans choose to use lexical connectives to signal intended coherence relations between clauses.

4.1 Methodology

We selected a balanced sample of 100 clause-pair tokens from the test set, reflecting the distribution of the different major relation types (six relations were represented in the sample). This sample comprised 44 explicit and 56 implicit tokens, consistent with the distribution in the overall corpus. The experimental stimulus for each item consisted of two versions of the same clause pair, one including a connective between the clauses, and the other without. For relations that were realized explicitly in the corpus, as in (8a), the alternative implicit stimulus omitted the connective and showed the second argument as a separate sentence, as in (8b).

(8) a. Mr. Nesbit also said the FDA has asked Bolar Pharmaceutical Co. to recall at the retail level its urinary tract antibiotic, **but** so far the company hasn't complied with that request.

b. Mr. Nesbit also said the FDA has asked Bolar Pharmaceutical Co. to recall at the retail level its urinary tract antibiotic. So far the company hasn't complied with that request.

For the implicit relations, the alternative explicit stimulus for the experiment used the connective annotated in the PDTB as the one being most appropriate. For each item, a short passage was created including the preceding and following sentences in the text to serve as context. The relative ordering of the presentation of the explicit and implicit forms was randomized, without regard to the actual corpus outcome for that stimulus.

Using Amazon's Mechanical Turk, judges were presented with the two passages for each item. They were told to assume that the passages had the same intended meaning, and were asked to judge which of the two sounded more natural. We collected 30 responses for each item.[4]

4.2 Results

We classified each experimental item as either explicit or implicit, based on the majority response of the judges. Using this classification, the judges' responses matched the actual outcomes in 68 of the 100 cases.[5] The distribution of correctly-judged items across relation types is shown in Table 4. The judgments for REASON relations most closely matched the corpus outcomes, with 9 out of the 12 explicit tokens and all 6 implicit tokens in the cor-

[4]The data from a small number of judges were discarded due to an unreasonably fast response time or because their judgments showed a unanimous preference across every experimental item. This left a total of 2,925 judgments over the 100 experimental items, from 113 different judges.

[5]Using the majority response of judges for each item to measure classification accuracy is consistent with the statistical model, whereby probabilities are rounded up or down to arrive at a binary classification. If accuracy is instead calculated in terms of average correctness over the individual responses, performance drops to 60.4%.

pus correctly identified by the judges. The lowest scoring relation type was CONTRAST, for which 9 of the 10 explicit tokens were judged correctly but only 4 out of the 11 implicit tokens were correctly identified.

Relation Type	Items	Correct	Accuracy
Conjunction	22	15	68.2%
Contrast	21	13	61.9%
Instantiation	9	6	66.7%
Reason	18	15	83.3%
Restatement	16	9	62.5%
Result	14	10	64.2%
Total	100	68	68.0%

Table 4: Results of Mechanical Turk study

There were hence 32 experimental items for which the majority response by the judges did not match the actual corpus outcome. In two-thirds (21) of these cases, the judges indicated a preference for a connective when the relation in the corpus was implicit. These mismatches occurred across the range of relation types. This suggests that the judges tended to err on the side on inserting a connective, even when it may not have been strictly necessary. While the reason for this is not clear, one possibility is that the texts reflected the genre and the highly-prescribed editing guidelines for the newspaper articles that comprise the corpus, under which unnecessary or redundant words are excised. Without such pressures to edit the copy down to a minimal form, the judges may have preferred to see the relations signaled explicitly in cases in which either decision would result in a felicitous passage.

In the remaining 11 cases, for which the relations in the corpus were explicitly signaled with a connective, the judges on average indicated a preference to leave the relation implicit. Interestingly, all of these cases were either CONJUNCTION or CONTRAST relations, semantic types which are usually signaled explicitly with a connective. We inspected these cases to ascertain why judges may have preferred an outcome opposite to that actually seen in the text. We found that all 7 of the CONTRAST mismatches were instances where the second argument of the relation in the corpus was a sentence beginning with the coordinating conjunction *but*, as in (9).

(9) At those levels stocks are set up to be hammered by index arbitragers. **But** nobody knows at what level the futures and stocks will open today. (WSJ2300)

Similarly, three of the mismatched CONJUNCTION relations had a sentential second argument beginning with the conjunction *and*. The responses of the judges to these cases may simply reflect a dispreference for sentence-initial conjunctions, a practice which is frowned upon in prescriptive grammar books, but apparently allowed by the Wall Street Journal style sheet.

For this sample of 100 relations, the model achieves a classification accuracy of 84%. This may seem at first blush to be an odd result, since it appears that the model is surpassing human performance. As we have suggested, however, this could be the result of our experimental judges having different preferences than the writers and editors at the Wall Street Journal for cases in which connective placement is truly optional. We therefore sought to evaluate the effect of optionality on these results.

If inaccurate predictions are associated with optionality of connective use, we might expect that both human judges and the classification model would be less certain about their categorizations of these examples than for the cases that were correctly classified. This was indeed the case. First, there was a significant difference in the variability of judges' responses between items that were incorrectly classified and those that were correct (66% vs. 73%, respectively; two-sample t test: t=2.60, df=73, $p<0.02$). Thus, as a group the judges were less sure of themselves in those cases in which they incorrectly decided to use or omit the connective, suggesting that either option may have been acceptable. Second, we analyzed the levels of confidence our model had for its judgments on correctly and incorrectly categorized cases, measured in terms of the probability of the predicted outcome assigned by the model. The analysis revealed that the average model confidence for the relations that were incorrectly classified was significantly lower than the average model confidence for the correctly-classified items (71% vs. 88%, respectively; t=5.65, df=25, $p<0.001$). Taken together, these results are consistent with the idea that, at least for a significant portion of the data, the incorrect judgments made by

both the judges and the model may have occurred on passages for which either including or omitting the connective would have been acceptable.

5 Conclusion

We have presented a model that predicts whether the coherence relation holding between two clauses is marked explicitly with a lexical connective or left implicit. Whereas there is reason to think that an author's decision to use a connective is in part influenced by properties of the extra-linguistic context that are inaccessible to NLP systems (such as semantics and world knowledge), we find that relatively simple linguistic features derivable from the clauses and from local discourse dependencies can be exploited to reach a level of performance significantly greater than that achieved by a baseline. The variability in the judgments of native speakers when presented with these data suggests that the use of a connective is in many cases simply optional; in such cases the decision may reflect lower-level stylistic choices on the part of the author. This in turn indicates that there may be an inherent upper bound to the performance of computational systems on this task.

Acknowledgments

Japanese Zero Reference Resolution Considering Exophora and Author/Reader Mentions

Abstract

In Japanese, zero references often occur and many of them are categorized into zero exophora, in which a referent is not mentioned in the document. However, previous studies have focused on only zero endophora, in which a referent explicitly appears. We present a zero reference resolution model considering zero exophora and author/reader of a document. To deal with zero exophora, our model adds pseudo entities corresponding to zero exophora to candidate referents of zero pronouns. In addition, we automatically detect mentions that refer to the author and reader of a document by using lexico-syntactic patterns. We represent their particular behavior in a discourse as a feature vector of a machine learning model. The experimental results demonstrate the effectiveness of our model for not only zero exophora but also zero endophora.

1 Introduction

Zero reference resolution is the task of detecting and identifying omitted arguments of a predicate. Since the arguments are often omitted in Japanese, zero reference resolution is essential in a wide range of Japanese natural language processing (NLP) applications such as information retrieval and machine translation.

(1) パスタが 好きで 毎日 (ϕ ガ)
pasta-NOM like everyday (ϕ-NOM)
(ϕ ヲ) 食べます。
(ϕ-ACC) eat
(Liking pasta, (ϕ) eats (ϕ) every day)

For example, in example (1) , the accusative argument of the predicate “食べます” (eat) is omitted .[1] The omitted argument is called a zero pronoun. In this example, the zero pronoun refers to “パスタ” (pasta).

Zero reference resolution is divided into two subtasks: zero pronoun detection and referent identification. Zero pronoun detection is the task that detects omitted zero pronouns from a document. In example (1), this task detects that there are the zero pronouns in the accusative and nominative cases of “食べます” (eat) and there is no zero pronoun in the dative case of “食べます”. Referent identification is the task that identifies the referent of a zero pronoun. In example (1), this task identifies that the referent of the zero pronoun in the accusative case of “食べます” is “パスタ” (pasta). These two subtasks are often resolved simultaneously and our proposed model is a unified model.

Many previous studies (Imamura et al., 2009; Sasano et al., 2008; Sasano and Kurohashi, 2011) have treated only **zero endophora**, which is a phenomenon that a referent is mentioned in a document, such as “パスタ” (pasta) in example (1). However, **zero exophora**, which is a phenomenon that a referent does not appear in a document, often occurs in Japanese when a referent is an author or reader of a document or an indefinite pronoun. For example, in example (1), the referent of the zero pronoun of the nominative case of “食べます” (eat) is the author of

[1] In this paper, we use the following abbreviations: NOM (nominative), ABL(ablative), ACC (accusative), DAT (dative), ALL (allative), GEN (genitive), CMI (comitative), CNJ (conjunction), INS(instrumental) and TOP (topic marker).

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 924–934,
Seattle, Washington, USA, 18-21 October 2013.

	Zero pronoun	Referent in the document	Example
Zero endophora	Exist	Exist	僕はカフェが好きで毎日 (カフェ ニ)通っている。 (I like cafes and go (to a cafe) everyday.)
Zero exophora	Exist	Not exist	私がメリットを ([*reader*] ニ) 説明させていただきます。 (I would like to explain the advantage (to [*reader*]).)
No zero reference	Not exist	Not exist	あなたはリラックスタイムが (×ニ)過ごせる。 (You can have a relaxing time.) *There is no dative case.

Table 1: Examples of zero endophora, zero exophora and no zero reference.

the document, but the author is not mentioned explicitly.

(2) 最近は パソコンで 動画を
recently PC-INS movie-ACC
([*unspecified:person*] ガ) 見れる。
([*unspecified:person*]-NOM) can see
(Recently, (people) can see movies by a PC.)

Similarly, in example (2), the referent of the zero pronoun of the nominative case of "見れる" (can see) is an unspecified person.[2]

Most previous studies have neglected zero exophora, as though a zero pronoun does not exist in a sentence. However, such a rough approximation has impeded the zero reference resolution research. In Table 1, in "zero exophora," the dative case of the predicate has the zero pronoun, but in "no zero reference," the dative case of the predicate does not have a zero pronoun. Treating them with no distinction causes a decrease in accuracy of machine learning-based zero pronoun detection due to a gap between the valency of a predicate and observed arguments of the predicate. In this work, to deal with zero exophora explicitly, we provide pseudo entities such as [*author*], [*reader*] and [*unspecified:person*] as candidate referents of zero pronouns.

In the referent identification, selectional preferences of a predicate (Sasano et al., 2008; Sasano and Kurohashi, 2011) and contextual information (Iida et al., 2006) have been widely used. The author and reader (A/R) of a document have not been used for contextual clues because the A/R rarely appear in the discourse in corpora based on newspaper articles, which are main targets of the previous studies. However, in other domain documents such as blog articles and shopping sites, the A/R often appear in the discourse. The A/R tend to be omitted and there are many clues for the referent identification about the A/R such as honorific expressions and modality expressions. Therefore, it is important to deal with the A/R of a document explicitly for the referent identification.

The A/R appear as not only the exophora but also the endophora.

(3) 僕 $_{author}$ は 京都に (僕ガ)
I-TOP Kyoto-DAT (I-NOM)
行こうと 思っています。
will go have thought
(I have thought (I) will go to Kyoto.)

皆さん $_{reader}$ は どこに 行きたいか
you all-TOP where-DAT want to go
(皆さんガ) (僕ニ) 教えてください。
(you all-NOM) (I-DAT) let me know

(Please let (me) know where do you want to go.)

In example (3), "僕" (I), which is explicitly mentioned in the document, is the author of the document and "皆さん" (you all) is the reader. In this paper, we call these expressions, which refer to the author and reader, **author mention** and **reader mention**. We treat them explicitly to improve the performance of zero reference resolution. Since the A/R are mentioned as various expressions besides personal pronouns in Japanese, it is difficult to detect the A/R mentions based merely on lexical information. In this work, we automatically detect the A/R mentions by using a learning-to-rank algorithm(Herbrich et al., 1998; Joachims, 2002) that uses lexico-syntactic patterns as features.

Once the A/R mentions can be detected, their information is useful for the referent identification.

[2] In the following examples, omitted arguments are put in parentheses and exophoric referents are put in square brackets.

The A/R mentions have both a property of the discourse element mentioned in a document and a property of the zero exophoric A/R. In the first sentence of example (3), it can be estimated that the referent of the zero pronoun of the nominative case of “行こう” (will go) from a contextual clue that “僕” (I) is the topic of this sentence and a syntactic clues that “僕” (I) depends on “思っています” (have thought) over the predicate “行こう” (will go).[3] Such contextual clues can be available only for the discourse entities that are mentioned explicitly. On the other hand, in the second sentence, since “教えてください” (let me know) is a request form, it can be assumed that the referent of the zero pronoun of the nominative case is “僕” (I), which is the author, and the one of the dative case is “皆様” (you all), which is the reader. The clues such as request forms, honorific expressions and modality expressions are available for the author and reader. In this work, to represent such aspect of the A/R mentions, both the endophora and exophora features are given to them.

In this paper, we propose a zero reference resolution model considering the zero exophora and the author/reader mentions, which resolves the zero reference as a part of a predicate-argument structure analysis.

2 Related Work

Several approaches to Japanese zero reference resolution have been proposed.

Iida et al. (2006) proposed a zero reference resolution model that uses the syntactic relations between a zero pronoun and a candidate referent as a feature. They deal with zero exophora by judging that a zero pronoun does not have anaphoricity. However, the information of zero pronoun existences is given and thus they did not address zero pronoun detection.

Zero reference resolution has been tackled as a part of predicate-argument structure analysis. Imamura et al. (2009) proposed a predicate-argument structure analysis model based on a log-linear model that simultaneously conducts zero endophora resolution. They assumed a particular candidate referent, NULL, and when the analyzer selected this referent, the analyzer outputs “zero exophora or no zero pronoun,” in which they are treated without distinction. Sasano et al. (2008) proposed a probabilistic predicate-argument structure analysis model including zero endophora resolution by using wide-coverage case frames constructed from a web corpus. Sasano and Kurohashi (2011) extended the Sasano et al. (2008)’s model by focusing on zero endophora. Their model is based on a log-linear model that uses case frame information and the location of a candidate referent as features. In their work, zero exophora is not treated and they assumed that a zero pronoun is absent when there is no referent in a document.

For languages other than Japanese, zero pronoun resolution methods have been proposed for Chinese, Portuguese, Spanish and other languages. In Chinese, Kong and Zhou (2010) proposed tree-kernel based models for three subtasks: zero pronoun detection, anaphoricity decision and referent selection. In Portuguese and Spanish, only a subject word is omitted and zero pronoun resolution has been tackled as a part of coreference resolution. Poesio et al. (2010) and Rello et al. (2012) detected omitted subjects and made a decision whether the omitted subject has anaphoricity or not as preprocessing of coreference resolution systems.

3 Baseline Model

In this section, we describe a baseline zero reference resolution system. In our model, the zero reference resolution is conducted as a part of predicate-argument structure (PAS) analysis. The PAS consists of a case frame and an alignment between case slots and referents. The case frames are constructed for each meaning of a predicate. Each case frame describes surface cases that each predicate has (case slot) and words that can fill each case slot (example). In this study, the case frames are constructed from 6.9 billion Web sentences by using Kawahara and Kurohashi (2006a)’s method.

The baseline model does not treat zero exophora as the previous studies. The baseline model analyzes a document in the following procedure in the same way as the previous study (Sasano and Kurohashi, 2011).[4]

[3] Since “僕” (I) depends on “思っています” (have thought), the relation between “僕” (I) and “行こう” (will go) is the zero reference.

[4] For learning, the previous study used a log-linear model, but we use a learning-to-rank model. In our preliminary exper-

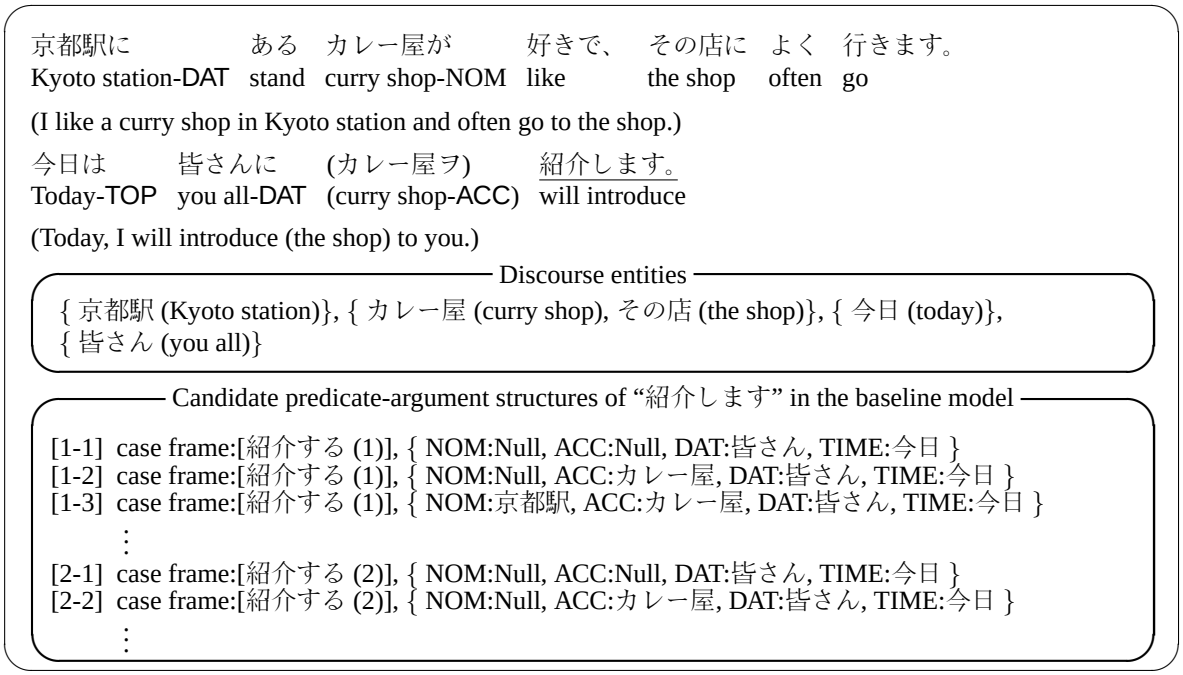

Figure 1: Examples of discourse entities and predicate-argument structures

1. Parse the input document and recognize named entities.
2. Resolve coreferential relations and set discourse entities.
3. Analyze the predicate-argument structure for each predicate using the following steps:
   (a) Generate candidate predicate-argument structures.
   (b) Calculate the score of each predicate-argument structure and select the one with the highest score.

We illustrate the details of the above procedure. First, we describe how to set the discourse entities in step 2. In our model, we treat referents of a zero pronoun using a unit called **discourse entity**, which is what mentions in a coreference chain are bound into. In Figure 1, we treat "カレー屋" (curry shop) and "その店" (the shop), which are in a coreference chain, as one discourse entity. In Figure 1, the discourse entity { カレー屋, その店 } is selected for the referent of the accusative case of the predicate "紹介します" (will introduce).

Next, we illustrate the PAS analysis in step 3. In step 3a, possible combinations of the case frame (cf) and the alignment (a) between case slots and discourse entities are listed. First, one case frame is selected from case frames for the predicate. Next, overt arguments, which have dependency relations with the predicate, are aligned to a case slot of the case frame. Finally, each of zero pronouns of remaining case slots is assigned to a discourse entity or is not assigned to any discourse entities. The case slot whose zero pronoun is not assigned to any discourse entities corresponds to the case that does not have a zero pronoun. In Figure 1, we show the examples of candidate PASs. In these examples, [紹介する (1)] and [紹介する (2)] are case frames corresponding to each meaning of "紹介する". Referents of each case slot are actually selected from discourse entities but are explained as a representative word for illustration. "Null" indicates that a case slot is not assigned to any discourse entities. Since alignments between case slots and discourse entities of the PAS [1-2] and [2-2] are the same but their case frames are different, we deal with them as discrete PASs. In this case, however, the results of zero reference resolution are the same.

We represent each PAS as a feature vector, which is described in section 3.1, and calculate a score of each PAS with the learned weights. Finally, the system outputs the PAS with the highest score.

iment of the baseline model, there is little difference between the results of these methods.

Type	Value	Description
Case frame	Log	Probabilities that {words, categories and named entity types} of e is assigned to c of cf
	Log	Generative probabilities of {words, categories and named entity types} of e
	Log	PMIs between {words, categories and named entity types} of e and c of cf
	Log	Max of PMIs between {words, categories and named entity types} of e and c of cf
	Log	Probability that c of cf is assigned to any words
	Log	Ratio of examples of c to ones of cf
	Binary	c of cf is {adjacent and obligate} case
Predicate	Binary	Modality types of p
	Binary	Honorific expressions of p
	Binary	Tenses of p
	Binary	p is potential form
	Binary	Modifier of p (predicate, noun and end of sentence)
	Binary	p is {dynamic and stative} verb
Context	Binary	Named entity types of e
	Integer	Number of mentions about e in t
	Integer	Number of mentions about e {before and after} p in t
	Binary	e is mentioned with post position "は" in a target sentence
	Binary	Sentence distances between e and p
	Binary	Location categories of e (Sasano and Kurohashi, 2011)
	Binary	e is mentioned at head of a target sentence
	Binary	e is mentioned with post position {"は" and "が" } at head of a target sentence
	Binary	e is mentioned at head of the first sentence
	Binary	e is mentioned with post position "は" at head of the first sentence

	Binary	e is mentioned with copula at end of the first sentence
	Binary	e is mentioned with noun phrase stop at end of the first sentence
	Binary	Salience score of e is larger than 1 (Sasano and Kurohashi, 2011)
other	Binary	c is assigned

Table 2: The features of $\phi_{assigned}(cf, c \leftarrow e, p, t)$

3.1 Feature Representation of Predicate-Argument Structure

When text t and target predicate p are given and PAS (cf, a) is chosen, we represent a feature vector of the PAS as $\phi(cf, a, p, t)$. $\phi(cf, a, p, t)$ consists of a feature vector $\phi_{overt\text{-}PAS}(cf, a, p, t)$ and feature vectors $\phi(cf, c/e, p, t)$. Where $\phi_{overt\text{-}PAS}(cf, a, p, t)$ corresponds to alignment between case slots and overt (not omitted) arguments and $\phi(cf, c/e, p, t)$ represents that a case slot c is assigned to a discourse entity e. If a case slot is assigned to an overt entity, $\phi(cf, c/e, p, t)$ is set to a zero vector.

Each feature vector $\phi(cf, c/e, p, t)$ consists of $\phi_A(cf, c/e, p, t)$ and $\phi_{NA}(cf, c/Null, p, t)$. $\phi_A(cf, c/e, p, t)$ becomes active when the case slot c is assigned to the discourse entity e and $\phi_{NA}(cf, c/Null, p, t)$ becomes active when the case slot c is not assigned to any discourse entities. For example, the PAS [1-2] in Figure 1 is represented as:
($\phi_{overt\text{-}PAS}$(紹介する (1), {NOM:Null, ACC:Null, NOM:皆さん, TIME:今日 }), $\mathbf{0}_{\phi_A}$,
ϕ_{NA}(紹介する (1), NOM/$Null$),
ϕ_A(紹介する (1), ACC/カレー屋),
$\mathbf{0}_{\phi_{NA}}, \mathbf{0}_{\phi_A}, \mathbf{0}_{\phi_{NA}}$). [5]
In our feature representation, the second and third terms correspond to the nominative case, the forth and fifth ones correspond to the accusative and the sixth and seventh ones correspond to the dative case.

We present the details of $\phi_{overt\text{-}PAS}(cf, a, p, t)$, $\phi_A(cf, c/e, p, t)$ and $\phi_{NA}(cf, c/Null, p, t)$. We use a score of the probabilistic PAS analysis (Kawahara and Kurohashi, 2006b) to $\phi_{overt\text{-}PAS}(cf, a, p, t)$. We list the features of $\phi_A(cf, c/e, p, t)$ in Table 2 and the features of $\phi_{NA}(cf, c/Null, p, t)$ in Table

[5] In the following example, p and t are sometimes omitted and $\mathbf{0}_\phi$ is 0 vector that has the same dimension as ϕ.

Type	Value	Description
Case frame	Log	Probability that c of cf is not assigned
	Log	Ratio of number of examples of c to ones of cf
	Binary	c of cf is {adjacent and obligate} case

Table 3: The features of $\phi_{NA}(cf, c/Null, p, t)$

3.

3.2 Weight Learning

In the previous section, we defined the feature vector $\phi(cf, a, p, t)$, which represents a PAS. In this section, we illustrate the learning method of the weight vector corresponding to the feature vector. The weight vector is learned by using a learning-to-rank algorithm.

In a corpus, gold-standard alignments a^* are manually annotated but case frames are not annotated. Since the case frames are constructed for each meaning, some of them are unsuitable for a usage of a prdicate in a context. If training data includes PASs (cf, a^*) whose cf is such case a frame as correct instances, these are harmful for training. Hence, we treat a case frame cf^* which is selected by a heuristic method as a correct case frame and remove (cf, a^*) which has other cf.

In particular, we make ranking data for the learning for each target predicate p in the following steps.

1. List possible PASs (cf, a) for predicate p.
2. Calculate a probabilistic zero reference resolution score for each (cf, a^*) and define the one with highest score as (cf^*, a^*).
3. Remove (cf, a^*) except (cf^*, a^*) from the learning instance.
4. Make ranking data that (cf^*, a^*) has a higher rank than other (cf, a).

In the above steps, we make ranking data for each predicate and use the ranking data collected from all target predicates as training data.

4 Corpus

In this work, we use Diverse Document Leads Corpus (DDLC) (Hangyo et al., 2012) for experiments. In DDLC, documents collected from the web are annotated with morpheme, syntax, named entity, coreference, PAS and A/R mention. Morpheme, syntax, named entity, coreference and PAS are annotated on the basis of Kyoto University Text Corpus (Kawahara et al., 2002). The PAS annotation includes zero reference information and the exophora referents are defined as five elements, [*author*], [*reader*], [*US(unspecified):person*], [*US:matter*] and [*US:situation*]. The A/R mentions are annotated to head phrases of compound nouns when the A/R mentions consist of compound nouns. If the A/R is mentioned by multiple expressions, only one of them is annotated with the A/R mention tag and all of these mentions are linked by a coreference chain. In other words, the A/R mentions are annotated to discourse entities. In the web site of an organization such as a company, the site administrator often writes the document on behalf of the organization. In such a case, the organization is annotated as the author.

5 Author/Reader Mention Detection

A/R mentions, which refer to A/R of a document, have different properties from other discourse entities. The A/R are mentioned as very various expressions such as personal pronouns, proper expressions and role expressions.

(4) こんにちは、 企画チームの
Hello project team-GEN
梅辻 $_{author}$ です。
am Umetsuji
(Hello, I'm Umetsuji on the project team.)

(5) 問題が あれば 管理人 $_{author}$ まで
problem-NOM exist to moderator
お知らせください。
let me know
(Please let me know if there are any problems.)

In example (4), the author is mentioned as "梅辻" (Umetsuji), which is the name of the author, and in example (5), the author is mentioned as "管理人" (moderator), which expresses the status of the author. Likewise, the reader is sometimes mentioned as "お客様" (customer) and others. However, since such expressions often refer to someone other than the A/R, whether an expression indicates the A/R of a document depends on the context of the document.

In English and other languages, the A/R mentions can be detected from coreference information because it can be assumed that the expression that has

a coreference relation with first or second personal pronoun is the A/R mention. However, since the A/R tend to be omitted and personal pronouns are rarely used in Japanese, it is difficult to detect the A/R mentions from coreference information. Because of these reasons, it is difficult to detect which discourse entity is the A/R mention from lexical information of the entities. In this study, the A/R mentions are detected from lexico-syntactic (LS) patterns in the document. We use a learning-to-rank algorithm to detect A/R mentions by using the LS patterns as features.

5.1 Author/Reader Detection Model

We use a learning-to-rank method for detecting A/R mentions. This method learns the ranking that entities of the A/R mentions have a higher rank than other discourse entities. Here, it is an important point that there are no A/R mentions in some documents. The documents in which the A/R mentions do not appear are classified into two types. The first type is a document that the A/R do not appear in the discourse of the document such as newspaper articles and novels. The second type is a document that the A/R appear in the discourse but all of their mentions are omitted. For example, in Figure 1, the author appears in the discourse (e.g. the nominative argument of "like") but is not mentioned explicitly. We introduce two pseudo entities corresponding to these types. The first pseudo entity "no A/R mention (discourse)" represents the document that the A/R do not appear in the discourse. It is considered that the document that the A/R do not appear have characteristics of writing style such that honorific expressions and request expressions are rarely used. This pseudo entity is represented as a document vector that consists of LS pattern features of the whole document, which reflect a writing style of a document. The second pseudo entity "no A/R mention (omitted)" represents the document in which all mentions of the A/R are omitted and this pseudo entity is represented as 0 vector. Since a decision score of this pseudo entity is allways 0, discourse entities whose score is lower than the score of this pseudo entity can be treated as a negative example in a binary classification.

When there are A/R mentions in a document, we make ranking data where the discourse entity of the A/R mention has a higher rank than other discourse entities and "no A/R mention" pseudo entities. When the A/R do not appear in the discourse, we make ranking data where "no A/R mention (discourse)" has a higher rank than all discourse entities and "no A/R mention (omitted)". When the A/R appear in the discourse but all mentions are omitted, we make ranking data where "no A/R mention (omitted)" has a higher rank than all discourse entities and "no A/R mention (discourse)". We judge that the A/R appear in the discourse if the A/R appear as a referent of zero reference in gold-standard PASs and this judgment is used only in the training phase. After making the ranking data for each document, all of the ranking data are merged and the merged data is fed into the learning-to-rank model.

For the A/R mention detection, we calculate the score of all discourse entities and the pseudo entities and select the discourse entity with the highest score to the A/R mention. If any "no A/R mention" have the highest score, we decide that there are no A/R mentions in the document.

5.2 Lexico-Syntactic Patterns

For each discourse entity, phrases of the discourse entity, its parent and their dependency relations are used to make LS patterns that represent the discourse entity. When a discourse entity is mentioned multiple times, the phrases of all mentions are used to make the LS patterns. LS patterns of phrases are made by generalizing these phrases on various levels (types). LS patterns of dependencies are made from combining the LS patterns of phrases.

Table 4 lists generalization types. On the *word* type, we make a phrase LS pattern by generalizing each content word and jointing them. For example, a LS pattern of the phrase "ぼくは" generalized on the <representative form> is "僕は". The *word+* type is the same as *word* except all content words are generalized on the <part of speech and conjugation>. For example, a LS pattern of the dependency relation "太郎は → 走った" generalized on the <named entity> is "NE:PERSON+は → verb:past". We also use the LS patterns of generalized individual morphemes. On the *phrase* type, each phrase is generalized according to the information assigned to the phrase and all content words are generalized on the <part of speech and conjugation> if the information

Unit	Type	Example (original phrase)
word	<no generalization>	僕は (僕は)
	<original form>	走った (走る)
	<representative form>	僕は (ぼくは)
	<part of speech and conjugation>	verb:past (走った)
word+	<category>	Category:PERSON+は (僕は)
	<named entity>	NE:PERSON+は (太郎は)
	<first person pronoun>	FirstPersonPronoun+は (僕は)
	<second person pronoun>	SecondPersonPronoun+に (あなたに)
phrase	<modality>	modality:request (お問い合わせください)
	<honorific expression>	honorific:modest (お送りします)
	<attached words>	ください (お問い合わせください)

Table 4: Generalization types of the LS patterns

is not assigned to the phrase.

For "no A/R mention (discourse)" instance, the above features of all mentions, including verbs and adjectives, and their dependencies in the document are gathered and used as the features representing the instance.

6 Zero Reference Resolution Considering Exophora and Author/Reader Mentions

In this section, we describe the zero reference resolution system that considers the zero exophora and the A/R mentions. The proposed model resolves zero reference as a part of the PAS analysis based on the baseline model.

The proposed model analyzes the PASs in the following steps:

1. Parse the input document and recognize named entities.
2. Resolve coreferential relations and set discourse entities.
3. Detect the A/R mentions of the document.
4. Set pseudo entities from the estimated A/R mentions.
5. Analyze the PAS for each predicate using the same procedure as the baseline model.

The differences form baseline model are the estimation of the A/R mentions in step 3 and the setting of pseudo entities in step 4.

6.1 Pseudo Entities and Author/Reader Mentions for Zero Exophora

In the baseline model, referents of zero pronouns are selected form discourse entities. The proposed model adds pseudo entities([*author*], [*reader*], [*US:person*] (unspecified:person) and [*US:others*] (unspecified:others)[6]) to deal with zero exophora.

When the A/R mentions appear in a document, the A/R pseudo entities raise an issue. The zero endophora are given priority to zero exophora. In other words, the A/R mentions are selected to the referents in preference to pseudo entities when there are A/R mentions. Therefore, when the system estimates that A/R mentions appear, the A/R pseudo entities are not created.

In the PAS analysis, referents are selected from discourse entities and the pseudo entities. A zero reference is the zero exophora when a case slot is assigned to pseudo entities. Candidate PASs of "紹介します" in Figure 1 are shown in Figure 2.

6.2 Feature Representation of Predicate Argument Structure

In the same way as the baseline model, the proposed model represents a PAS as a feature vector that consists of the feature vector $\phi_{overt\text{-}PAS}(cf, a, p, t)$ and the feature vectors $\phi(cf, c/e, p, t)$. The difference from the baseline model is a composition of $\phi_A(cf, c/e, p, t)$. In the proposed model, each $\phi_A(cf, c/e)$ is composed of vectors, $\phi_{discourse}(cf, c/e)$, $\phi_{[author]}(cf, c/e)$, $\phi_{[reader]}(cf, c/e)$, $\phi_{[US:person]}(cf, c/e)$, $\phi_{[US:others]}(cf, c/e)$ and $\phi_{max}(cf, c/e)$. Their contents and dimensions are the same and similar to $\phi_A(cf, c/e)$ of the baseline model the except for the

[6]We merge [*US:matter*] and [*US:situation*] because of the small amount of [*US:situation*] in the corpus.

[1-1] case frame:[紹介する (1)], { NOM:[*author*], ACC:Null, DAT:皆さん $_{reader}$, TIME:今日 }
[1-2] case frame:[紹介する (1)], { NOM:[*US:person*], ACC:Null, DAT:皆さん $_{reader}$, TIME:今日 }
[1-3] case frame:[紹介する (1)], { NOM:[*author*], ACC:カレー屋, DAT:皆さん $_{reader}$, TIME:今日 }
[1-4] case frame:[紹介する (1)], { NOM:京都駅, ACC:カレー屋, DAT:皆さん $_{reader}$, TIME:今日 }
[1-5] case frame:[紹介する (1)], { NOM:[*author*], ACC:[*US:others*], DAT:皆さん $_{reader}$, TIME:今日 }
⋮
[2-1] case frame:[紹介する (2)], { NOM:[*author*], ACC:Null, DAT:皆さん $_{reader}$, TIME:今日 }
[2-2] case frame:[紹介する (2)], { NOM:[*US:person*], ACC:Null, DAT:皆さん $_{reader}$, TIME:今日 }
⋮

Figure 2: Candidate predicate-argument structures of "紹介します" in the proposed model

	Expressions	Categories
author	私 (I), 我々 (we), 俺 (I), 僕 (I), 当社 (our company), 弊社 (our company), 当店 (our shop)	PERSON, ORGANIZATION
reader	あなた (you), 客 (customer), 君 (you), 皆様 (you all), 皆さん (you all), 方 (person), 方々 (people)	PERSON
US:person	人 (person), 人々 (people)	PERSON
US:others	もの (thing), 状況 (situation)	all categories except PERSON and ORGANIZATION

Table 5: Expressions and categories for pseudo entities

addition of a few features described in section 6.3.

$\phi_{discourse}$ corresponds to the discourse entities, which are mentioned explicitly and becomes active when e is a discourse entity including the A/R mentions. $\phi_{discourse}$ is the same as ϕ_A of the baseline model and the difference is explained in section 6.3. $\phi_{[author]}$ and $\phi_{[reader]}$ become active when e is [*author*]/[*reader*] or the discourse entity corresponding to the A/R mention. In particular, when e is the discourse entity corresponding to the A/R mention, both $\phi_{discourse}$ and $\phi_{[author]}$/$\phi_{[reader]}$ become active. This representation gives the A/R mentions the properties of the discourse entity and the A/R. $\phi_{[US:person]}$ and $\phi_{[US:others]}$ become active when e is [*US:person*] and [*US:others*].

Because $\phi_{[author]}$, $\phi_{[reader]}$, $\phi_{[US:person]}$ and $\phi_{[US:others]}$ correspond to the pseudo entities, which are not mentioned explicitly, we cannot use word information such as expressions and categories. We assume that the pseudo entities have expressions and categories shown in Table 5 and use these to calculate case frame features. Finally, ϕ_{max} consists of the highest value of correspondent feature of the above feature vectors.

6.3 Author/Reader Mention Score

We add A/R mention score features to the feature vector $\phi_A(cf, c/e, p, t)$ described in Table 2. The A/R mention scores are the discriminant function scores of the A/R mention detection. When e is the A/R mention, we set the A/R mention score to the feature.

7 Experiments

7.1 Experimental Settings

We used 1,000 documents from DDLC and performed 5-fold cross-validation. 1,440 zero endophora and 1,935 zero exophora are annotated in these documents. 258 documens are annotated with author mentions and 105 documens are annotated with reader mentions. We used gold-standard (manually annotated) morphemes, named entities, dependency structures and coreference relations to focus on the A/R detection and the zero reference resolution. We used SVM^{rank}[7] for the learning-to-rank method of the A/R detection and the PAS analysis. The categories of words are given by the morphological analyzer JUMAN[8]. Named entities and predicate features (e.g., honorific expressions, modality)

[7] http://www.cs.cornell.edu/people/tj/svm_light/svm_rank.html
[8] http://nlp.ist.i.kyoto-u.ac.jp/EN/index.php?JUMAN

		System output		
		Exist		None
		Correct	Wrong	
Gold -standard	Exist	140	6	112
	None	-	38	704

Table 6: Result of the author mention detection

		System output		
		Exist		None
		Correct	Wrong	
Gold -standard	Exist	56	2	47
	None	-	23	872

Table 7: Result of the reader mention detection

are given by the syntactic parser KNP.[9]

7.2 Results of Author/Reader Mention Detection

We show the results of the author and reader mention detection in Table 6 and Table 7. In these tables, "exist" indicates numbers of documents in which the A/R mentions are manually annotated or our system estimated that some discourse entities are A/R mentions. From these results, the A/R mentions including "none" can be predicted to accuracies of approximately 80%. On the other hand, the recalls are not particularly high: the recall of author is 140/258 and the recall of reader is 56/105. This is because the documents in which the A/R do not appear are more than the ones in which the A/R appear and the system prefers to output "no author/reader mention" as the result of training.

7.3 Results of Zero Reference Resolution

We show the results of zero reference resolution in Table 8 and Table 9. The difference between the baseline and the proposed model is statistically significant ($p < 0.05$) from the McNemar's test. In Table 8, we evaluate only the zero endophora for comparison to the baseline model, which deals with only the zero endophora. "Proposed model (estimate)" shows the result of the proposed model which estimated the A/R mentions and "Proposed model (gold-standard)" shows the result of the proposed model which is given the A/R mentions of gold-standard from the corpus.

From Table 8, considering the zero exophora and the A/R mentions improves accuracy of zero endophora resolution as well as zero reference resolution including zero exophora.

[9] http://nlp.ist.i.kyoto-u.ac.jp/EN/index.php?KNP

	Recall	Precision	F1
Baseline	0.269	0.377	0.314
Proposed model (estimate)	0.282	0.448	0.346
Proposed model (gold-standard)	0.388	0.522	0.445

Table 8: Results of zero endophora resolution

	Recall	Precision	F1
Baseline	0.115	0.377	0.176
Proposed model (estimate)	0.317	0.411	0.358
Proposed model (gold-standard)	0.377	0.485	0.424

Table 9: Results of zero reference resolution

From Table 8 and Table 9, the proposed model given the gold-standard A/R mentions achieves extraordinarily high accuracies. This result indicates that improvement of the A/R mention detection improves the accuracy of zero reference resolution in the proposed model.

8 Conclusion

This paper presented a zero reference resolution model considering exophora and author/reader mentions. In the experiments, our proposed model achieves higher accuracy than the baseline model. As future work, we plan to improve the author/reader detection model to improve the zero reference resolution.

Abstract

Natural language conversation is widely regarded as a highly difficult problem, which is usually attacked with either rule-based or learning-based models. In this paper we propose a retrieval-based automatic response model for short-text conversation, to exploit the vast amount of short conversation instances available on social media. For this purpose we introduce a dataset of short-text conversation based on the real-world instances from Sina Weibo (a popular Chinese microblog service), which will be soon released to public. This dataset provides rich collection of instances for the research on finding natural and relevant short responses to a given short text, and useful for both training and testing of conversation models. This dataset consists of both naturally formed conversations, manually labeled data, and a large repository of candidate responses. Our preliminary experiments demonstrate that the simple retrieval-based conversation model performs reasonably well when combined with the rich instances in our dataset.

1 Introduction

Natural language conversation is one of the holy grail of artificial intelligence, and has been taken as the original form of the celebrated Turing test. Previous effort in this direction has largely focused on analyzing the text and modeling the state of the conversation through dialogue models, while in this paper we take one step back and focus on a much easier task of finding the response for a given short text. This task is in clear contrast with previous effort in dialogue modeling in the following two aspects

- we do not consider the context or history of conversations, and assume that the given short text is self-contained;
- we only require the response to be natural, relevant, and human-like, and do not require it to contain particular opinion, content, or to be of particular style.

This task is much simpler than modeling a complete dialogue session (e.g., as proposed in Turing test), and probably not enough for real conversation scenario which requires often several rounds of interactions (e.g., automatic question answering system as in (Litman et al., 2000)). However it can shed important light on understanding the complicated mechanism of the interaction between an utterance and its response. The research in this direction will not only instantly help the applications of short session dialogue such as automatic message replying on mobile phone and the chatbot employed in voice assistant like Siri[1], but also it will eventually benefit the modeling of dialogues in a more general setting.

Previous effort in modeling lengthy dialogues focused either on rule-based or learning-based models (Carpenter, 1997; Litman et al., 2000; Williams and Young, 2007; Schatzmann et al., 2006; Misu et al., 2012). This category of approaches require relatively less data (e.g. reinforcement learning based) for

*The work is done when the first author worked as intern at Noah's Ark Lab, Huawei Techologies.

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 935–945,
Seattle, Washington, USA, 18-21 October 2013.

training or no training at all, but much manual effort in designing the rules or the particular learning algorithms. In this paper, we propose to attack this problem using an alternative approach, by leveraging the vast amount of training data available from the social media. Similar ideas have appeared in (Jafarpour and Burges, 2010; Leuski and Traum, 2011) as an initial step for training a chatbot.

With the emergence of social media, especially microblogs such as Twitter, in the past decade, they have become an important form of communication for many people. As the result, it has collected conversation history with volume previously unthinkable, which brings opportunity for attacking the conversation problem from a whole new angle. More specifically, instead of generating a response to an utterance, we pick a massive suitable one from the candidate set. The hope is, with a reasonable retrieval model and a *large enough* candidate set, the system can produce fairly natural and appropriate responses.

This retrieval-based model is somewhat like non-parametric model in machine learning communities, which performs well only when we have abundant data. In our model, it needs only a relatively small *labeled* dataset for training the retrieval model, but requires a rather large *unlabeled* set (e.g., one million instances) for candidate responses. To further promote the research in similar direction, we create a dataset for training and testing the retrieval model, with a candidate responses set of reasonable size. Sina Weibo is the most popular Twitter-like microblog service in China, hosting over 500 million registered users and generating over 100 million messages per day [2]. As almost all microblog services, Sina Weibo allows users to comment on a published post[3], which forms a natural one-round conversation. Due to the great abundance of those (post, response) pairs, it provides an ideal data source and test bed for one-round conversation. We will make this dataset publicly available in the near future.

[2] http://en.wikipedia.org/wiki/Sina_Weibo

[3] Actually it also allows users to comment on other users' comments, but we will not consider that in the dataset.

2 The Dialogues on Sina Weibo

Sina Weibo is a Twitter-like microblog service, on which a user can publish short messages (will be referred to as *post* in the remainder of the paper) visible to public or a group specified by the user. Similar to Twitter, Sina Weibo has the word limit of 140 Chinese characters. Other users can comment on a published post, with the same length limit, as shown in the real example given in Figure 6 (in Chinese). Those comments will be referred to as *responses* in the remainder of the paper.

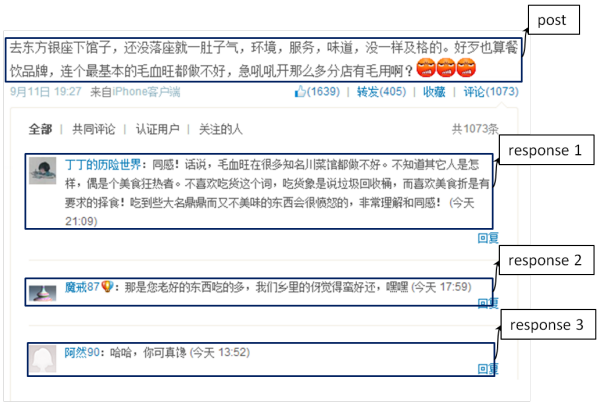

Figure 1: An example of Sina Weibo post and the comments it received.

We argue that the (post, response) pairs on Sina Weibo provide rather valuable resource for studying *one round* dialogue between users. The comments to a post can be of rather flexible forms and diverse topics, as illustrated in the example in Table 1. With a post stating the user's status (traveling to Hawaii), the comments can be of quite different styles and contents, but apparently all appropriate.

In many cases, the (post, response) pair is self-contained, which means one does not need any background and contextual information to get the main point of the conversation (Examples of that include the responses from **B, D, G** and **H**). In some cases, one may need extra knowledge to understand the conversation. For example, the response from user **E** will be fairly elusive if taken out of the context that **A**'s Hawaii trip is for an international conference and he is going to give a talk there. We argue that the number of self-contained (post, response) pairs is vast, and therefore the extracted (post, re-

Post	
User A:	*The first day at Hawaii. Watching sunset at the balcony with a big glass of wine in hand.*
Responses	
User B:	*Enjoy it & don't forget to share your photos!*
User C:	*Please take me with you next time!*
User D:	*How long are you going to stay there?*
User E:	*When will be your talk?*
User F:	*Haha, I am doing the same thing right now. Which hotel are you staying in?*
User G:	*Stop showing-off, buddy. We are still coding crazily right now in the lab.*
User H:	*Lucky you! Our flight to Honolulu is delayed and I am stuck in the airport. Chewing French fries in MacDonald's right now.*

Table 1: A typical example of Sina Weibo post and the comments it received. The original text is in Chinese, and we translated it into English for easy access of readers. We did the same thing for all the examples throughout this paper.

sponse) pairs can serve as a rich resource for exploring rather sophisticated patterns and structures in natural language conversation.

3 Content of the Dataset

The dataset consists of three parts, as illustrated in Figure 2. Part 1 contains the original (post, response) pairs, indicated by the dark-grey section in Figure 2. Part 2, indicated by the light-gray section in Figure 2, consists labeled (post, response) pairs for some Weibo posts, including positive and negative examples. Part 3 collects all the responses, including but not limited to the responses in Part 1 and 2. Some of the basic statistics are summarized in Table 2.

# posts	# responses	vocab.	# labeled pairs
4,6345	1,534,874	105,732	12,427

Table 2: Some statistics of the dataset

Original (Post, Response) Pairs This part of dataset gives (post, response) pairs naturally presented in the microblog service. In other words, we create a (post, response) pair there when the response is actually given to the post in Sina Weibo. The part of data is noisy since the responses given to a Weibo post could still be inappropriate for different reasons, for example, they could be spams or targeting some responses given earlier. We have $628,833$ pairs.

Labeled Pairs This part of data contains the (post, response) pairs that are labeled by human. Note that 1) the labeling is only on a small subset of posts, and 2) for each selected post, the labeled responses are not originally given to it. The labeling is done in an active manner (see Section 4 for more details), so the obtained labels are much more informative than the those on randomly selected pairs (over 98% of which are negative). This part of data can be directly used for training and testing of retrieval-based response models. We have labeled 422 posts and for each of them, about 30 candidate responses.

Responses This part of dataset contains only responses, but they are not necessarily for a certain post. These extra responses are mainly filtered out by our data cleaning strategy (see Section 4.2) for original (post, response) pairs, including those from filtered-out Weibo posts and those addressing other responses. Nevertheless, those responses are still valid candidate for responses. We have about 1.5 million responses in the dataset.

3.1 Using the Dataset for Retrieval-based Response Models

Our data can be used for training and testing of retrieval-based response model, or just as a bank of responses. More specifically, it can be used in at least the following three ways.

Training Low-level Matching Features The rather abundant original (post, response) pairs provide rather rich supervision signal for learning different matching patterns between a post and a response. These matching patterns could be of dif-

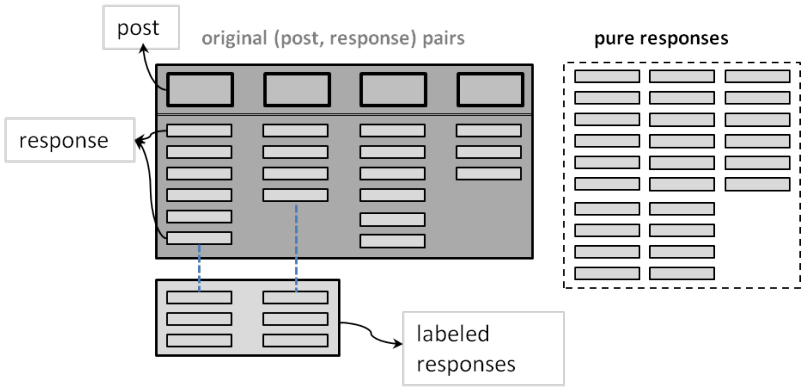

Figure 2: Content of the dataset.

ferent levels. For example, one may discover from the data that when the word "Hawaii" occurs in the post, the response are more likely to contain words like "trip", "flight", or "Honolulu". On a slightly more abstract level, one may learn that when an entity name is mentioned in the post, it tends to be mentioned again in the response. More complicated matching pattern could also be learned. For example, the response to a post asking "how to" is statistically longer than average responses. As a particular case, Ritter et al. (2011) applied translation model (Brown et al., 1993) on similar parallel data extracted from Twitter in order to extract the word-to-word correlation. Please note that with more sophisticated natural language processing, we can go beyond bag-of-words for more complicated correspondence between post and response.

Training Automatic Response Models Although the original (post, response) pairs are rather abundant, they are not enough for discriminative training and testing of retrieval models, for the following reasons. In the labeled pairs, both positive and negative ones are ranked high by some baseline models, and hence more difficult to tell apart. This supervision will naturally tune the model parameters to find the real good responses from the seemingly good ones. Please note that without the labeled negative pairs, we need to generate negative pairs with randomly chosen responses, which in most of the cases are too easy to differentiate by the ranking model and cannot fully tune the model parameters. This intuition has been empirically verified by our experiments.

Testing Automatic Response Models In testing a retrieval-based system, although we can simply use the original responses associated with the query post as positive and treat all the others as negative, this strategy suffers from the problem of spurious negative examples. In other words, with a reasonably good model, the retrieved responses are often good even if they are not the original ones, which brings significant bias to the evaluation. With the labeled pairs, this problem can be solved if we limit the testing only in the small pool of labeled responses.

3.2 Using the Dataset for Other Purposes

Our dataset can also be used for other researches related to short-text conversations, namely anaphora resolution, sentiment analysis, and speech act analysis, based on the large collection of original (post, response) pairs. For example, to determine the sentiment of a response, one needs to consider both the original post as well as the observed interaction between the two. In Figure 3, if we want to understand user's sentiment towards the "invited talk" mentioned in the post, the two responses should be taken as positive, although the sentiment in the mere responses is either negative or neutral.

4 Creation of the Dataset

The (post, comment) pairs are sampled from the Sina Weibo posts published by users in a loosely connected community and the comments they received (may not be from this community). This community is mainly posed of professors, researchers, and students of natural language processing (NLP) and related areas in China, and the users

Query Post:	十点半主楼有XXX博士的关于深度学习的讲座，有兴趣的同学不要错过！ *There is a talk on deep learning given by Dr. XXX on deep learning in the main building. Come if you are interested*
Response1:	太悲催了，我十点钟有节课 *Damn it! I have a class at 10 am*
Response2:	到底主楼哪个房间啊？ *Come on, which room in the main building?*

Figure 3: An example (original Chinese and the English translation) on the difficulty of sentiment analysis on responses.

commonly followed them.

The creation process of the dataset, as illustrated in Figure 4, consists of three consecutive steps: 1) crawling the community of users, 2) crawling their Weibo posts and their responses, 3) cleaning the data, with more details described in the remainder of this section.

4.1 Sampling Strategy

We take the following sampling strategy for collecting the (post, response) pairs to make the topic relatively focused. We first locate 3,200 users from a loosely connected community of Natural Language Processing (NLP) and Machine Learning (ML) in China. This is done through crawling followees[4] of ten manually selected seed users who are NLP researchers active on Sina Weibo (with no less than 2 posts per day on average) and popular enough (with no less than 100 followers).

We crawl the posts and the responses they received (not necessarily from the crawled community) for two months (from April 5th, 2013, to June 5th, 2013). The topics are relatively limited due to our choice of the users, with the most saliently ones being:

- **Research:** discussion on research ideas, papers, books, tutorials, conferences, and researchers in NLP and machine learning, etc;
- **General Arts and Science:** mathematics, physics, biology, music, painting, etc;
- **IT Technology:** Mobile phones, IT companies, jobs opportunities, etc;
- **Life:** traveling (both touring or conference trips), food, photography, etc.

[4]When user A follows user B, A is called B's follower, and B is called A's followee.

4.2 Processing, Filtering, and Data Cleaning

On the crawled posts and responses, we first perform a four-step filtering on the post and responses

- We first remove the Weibo posts and their responses if the length of post is less than 10 Chinese characters or the length of the response is less than 5 characters. The reason for that is two-fold: 1) if the text is too short, it can barely contain information that can be reliably captured, e.g. the following example

P:	*Three down, two to go.*

  and 2) some of the posts or responses are too general to be interesting for other cases, e.g. the response in the example below,

P:	*Nice restaurant. I'd strong recommend it. Everything here is good except the long waiting line*
R:	*wow.*

- In the remained posts, we only keep the first 100 responses in the original (post, response) pairs, since we observe that after the first 100 responses there will be a non-negligible proportion of responses addressing things other than the original Weibo post (e.g., the responses given earlier). We however will still keep the responses in the bank of responses.
- The last step is to filter out the potential advertisements. We will find the long responses that have been posted more than twice on different posts and scrub them out of both original (post, response) pairs and the response repository.

For the remained posts and responses, we remove the punctuation marks and emoticons, and use ICTCLAS (Zhang et al., 2003) for Chinese word segmentation.

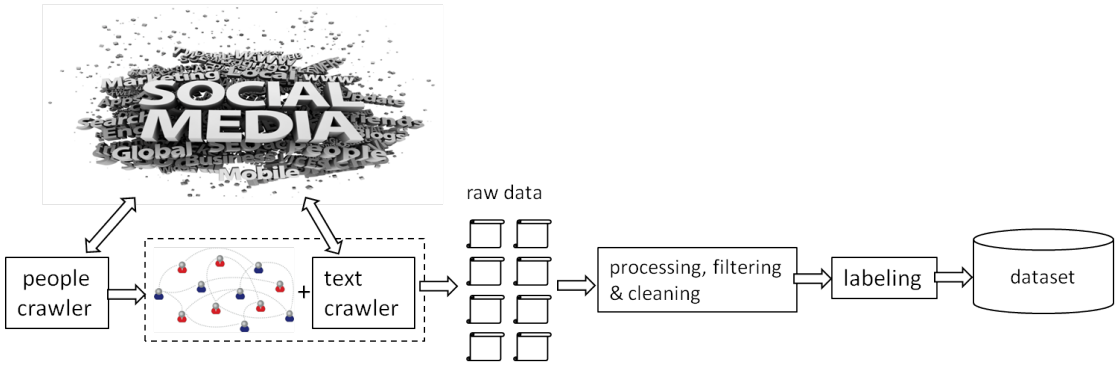

Figure 4: Diagram of the process for creating the dataset.

4.3 Labeling

We employ a pooling strategy widely used in information retrieval for getting the instance to label (Voorhees, 2002). More specifically, for a given post, we use three baseline retrieval models to each select 10 responses (see Section 5 for the description of the baselines), and merge them to form a much reduced candidate set with size ≤ 30. Then we label the reduced candidate set into "suitable" and "unsuitable" categories. Basically we consider a response suitable for a given post if we cannot tell whether it is an original response. More specifically the suitability of a response is judged based on the following three criteria[5]:

Semantic Relevance: This requires the content of the response to be semantically relevant to the post. As shown in the example right below, the post **P** is about soccer, and so is response **R1** (hence semantically relevant), whereas response **R2** is about food (hence semantically irrelevant).

P:	*There are always 8 English players in their own penalty area. Unbelievable!*
R1:	*Haha, it is still 0:0, no goal so far.*
R2:	*The food in England is horrible.*

Another important aspect of semantic relevance is the entity association. This requires the entities in the response to be correctly aligned with those in the post. In other words, if the post is about entity A, while the response is about entity B, they are very likely to be mismatched. As shown in the following example, where the original post is about Paris, and the response **R2** talks about London:

P:	*It is my last day in Paris. So hard to say goodbye.*
R1:	*Enjoy your time in Paris.*
R2:	*Man, I wish I am in London right now.*

This is however not absolute, since a response containing a different entity could still be sound, as demonstrated by the following two responses to the post above

R1:	*Enjoy your time in France.*
R2:	*The fall of London is nice too.*

Logic Consistency: This requires the content of the response to be logically consistent with the post. For example, in the table right below, post **P** states that the Huawei mobile phone "Honor" is already in the market of mainland China. Response **R1** talks about a personal preference over the same phone model (hence logically consistent), whereas **R2** asks the question the answer to which is already clear from **P** (hence logically inconsistent).

P:	*HUAWEI's mobile phone, Honor, sells well in Chinese Mainland.*
R1:	*HUAWEI Honor is my favorite phone*
R2:	*When will HUAWEI Honor get to the market in mainland China?*

Speech Act Alignment: Another important factor in determining the suitability of a response is the

[5]Note that although our criteria in general favor short and general answers like "Well said!" or "Nice", most of these general answers have already been filtered out due to their length (see Section 4.2).

speech act. For example, when a question is posed in the Weibo post, a certain act (e.g., answering or forwarding it) is expected. In the example below, post **P** asks a special question about location. Response **R1** and **R2** either forwards or answers the question, whereas **R3** is a negative sentence and therefore does not align well in speech act.

P:	*Any one knows where KDD will be held the year after next?*
R1:	*co-ask. Hopefully Europe*
R2:	*New York, as I heard*
R3:	*No, it is still in New York City*

5 Retrieval-based Response Model

In a retrieval-based response model, for a given post x we pick from the candidate set the response with the highest ranking score, where the score is the ensemble of several individual matching features

$$\mathsf{score}(x, y) = \sum_{i \in \Omega} w_i \Phi_i(x, y). \quad (1)$$

with y stands for a candidate response.

We perform a two-stage retrieval to handle the scalability associated with the massive candidate set, as illustrated in Figure 5. In **Stage I**, the system employs several fast baseline matching models to retrieve a number of candidate responses for the given post x, forming a much reduced candidate set $\mathcal{C}_{\mathbf{x}}^{(reduced)}$. In **Stage II**, the system uses a ranking function with more and sophisticated features to further evaluate all the responses in $\mathcal{C}_{\mathbf{x}}^{(reduced)}$, returning a matching score for each response. Our response model then decides whether to respond and which candidate response to choose.

In **Stage II**, we use the linear score function defined in Equation 1 with 15 features, trained with RankSVM (Joachims, 2002). The training and testing are both performed on the 422 labeled posts, with about 12,000 labeled (post, response) pairs. We use a 5-fold cross validation with a fixed penalty parameter for slack variable. [6]

5.1 Baseline Matching Models

We use the following matching models as the baseline model for **Stage I** fast retrieval. Moreover, the matching features used in the ranking function in **Stage II** are generated, directly or indirectly, from the those matching models:

POST-RESPONSE SEMANTIC MATCHING: This particular matching function relies on a learned mapping from the original sparse representation for text to a low-dimensional but dense representation for both Weibo posts and responses. The level of matching score between a post and a response can be measured as the inner product between their images in the low-dimensional space

$$\mathsf{SemMatch}(x, y) = \mathbf{x}^\top L_{\mathcal{X}} L_{\mathcal{Y}}^\top \mathbf{y}. \quad (2)$$

where $\mathbf{x}$ and $\mathbf{y}$ are respectively the 1-in-N representations of x and y. This is to capture the semantic matching between a Weibo post and a response, which may not be well captured by a word-by-word matching. More specifically, we find $L_{\mathcal{X}}$ and $L_{\mathcal{Y}}$ through a large margin variant of (Wu et al., 2013)

$$\begin{aligned} \arg\min_{L_{\mathcal{X}}, L_{\mathcal{Y}}} \quad & \sum_i \max(1 - \sum_i \mathbf{x}_i^\top L_{\mathcal{X}} L_{\mathcal{Y}}^\top \mathbf{y}_i, 0) \\ s.t. \quad & \|L_{n,\mathcal{X}}\|_1 \le \mu_1,\ n = 1, 2, \cdots, N_x \\ & \|L_{m,\mathcal{Y}}\|_1 \le \mu_1,\ m = 1, 2, \cdots, N_y \\ & \|L_{n,\mathcal{X}}\|_2 = \mu_2,\ n = 1, 2, \cdots, N_x \\ & \|L_{m,\mathcal{Y}}\|_2 = \mu_2\, m = 1, 2, \cdots, N_y. \end{aligned}$$

where i indices the original (post, response) pairs. Our experiments (Section 6) indicate that this simple linear model can learn meaningful patterns, due to the massive training set. For example, the image of the word "Italy" in the post in the latent space matches well word "Sicily", "Mediterranean sea" and "travel". Once the mapping $L_{\mathcal{X}}$ and $L_{\mathcal{Y}}$ are learned, the semantic matching score $\mathbf{x}^\top L_{\mathcal{X}} L_{\mathcal{Y}}^\top \mathbf{y}$ will be treated as a feature for modeling the overall suitability of y as a response to post x.

POST-RESPONSE SIMILARITY: Here we use a simple vector-space model for measuring the similarity between a post and a response

$$\mathsf{sim}_{PR}(\mathbf{x}, \mathbf{y}) = \frac{\mathbf{x}^\top \mathbf{y}}{\|\mathbf{x}\| \|\mathbf{y}\|}. \quad (3)$$

Although it is not necessarily true that a good response has many common words as the post, but this measurement is often helpful in finding relevant responses. For example, when the post and response

[6] The performance is fairly insensitive to the choice of the penalty, so we only report the result with a typical choice of it.

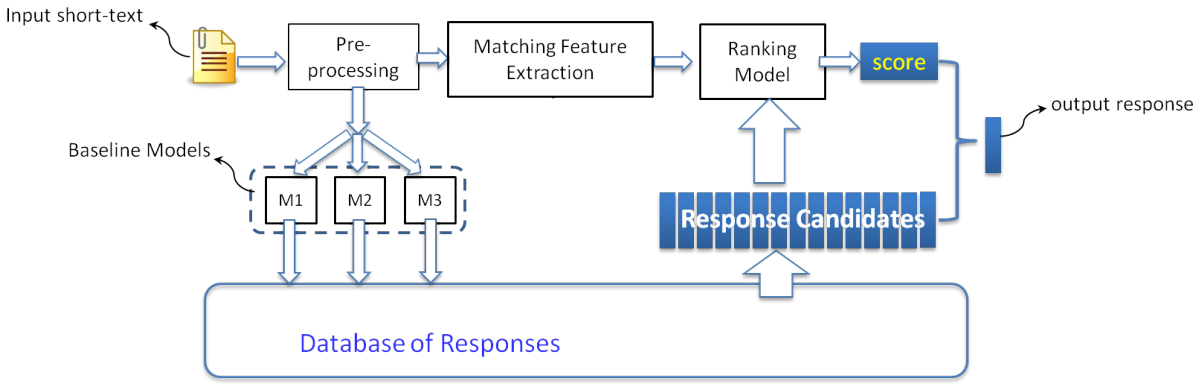

Figure 5: Diagram of the retrieval-based automatic response system.

both have "National Palace Museum in Taipei", it is a strong signal that they are about similar topics. Unlike the semantic matching feature, this simple similarity requires no learning and works on infrequent words. Our empirical results show that it can often capture the Post-Response relation failed with semantic matching feature.

POST-POST SIMILARITY: The basic idea here is to find posts similar to x and use their responses as the candidates. Again we use the vector space model for measuring the post-post similarity

$$\mathsf{sim}_{PP}(x, x') = \frac{\mathbf{x}^\top \mathbf{x}'}{\|\mathbf{x}\|\|\mathbf{x}'\|}. \quad (4)$$

The intuition here is that if a post x' is similar to x its responses might be appropriate for x. It however often fails, especially when a response to x' addresses parts of x not contained by x, which fortunately can be alleviated when combined with other measures.

5.2 Learning to Rank with Labeled Data

With all the matching features, we can learn a ranking model with the labeled (post, response) pairs, e.g., through off-the-shelf ranking algorithms. From the labeled data, we can extract triples (x, y^+, y^-) to ensure that $\mathsf{score}(x, y^+) > \mathsf{score}(x, y^-)$. Apparently y^+ can be selected from labeled positive response of x, while y^- can be sampled either from labeled negative negative or randomly selected ones. Since the manually labeled negative instances are top-ranked candidates according to some individual retrieval model (see Section 5.1) and therefore generally yield slightly better results.

The matching features are mostly constructed by combining the individual matching models, for example the following two

- $\Phi_7(x, y)$: this feature measures the length of the longest common string in the post and the response;
- $\Phi_{12}(x, y)$: this feature considers both semantic matching score between query post x and candidate response $\mathbf{y}$, as well as the similarity between x and y's *original* post x':

$$\Phi_{12}(x, y) = \mathsf{SemMatch}(x, y)\mathsf{sim}_{PP}(x, x').$$

In addition to the matching features, we also have simple features describing responses only, such as the length of it.

6 Experimental Evaluation

We perform experiments on the proposed dataset to test our retrieval-based model as an algorithm for automatically generating response.

6.1 Performance of Models

We evaluate the retrieved models based on the following two metrics:

MAP This one measures the mean average precision (MAP)(Manning et al., 2008) associated with the ranked list on $\mathcal{C}_{\mathbf{x}}^{(reduced)}$.

P@1 This one simply measures the precision of the top one response in the ranked list:

$$P@1 = \frac{\#\text{good top-1 responses}}{\#\text{posts}}$$

We perform a 5-fold cross-validation on the 422 labeled posts, with the results reported in Table 1. As it shows, the semantic matching helps slightly improve the overall performance on P@1.

Model	MAP	P@1
P2R	0.565	0.489
P2R + P2P	0.621	0.567
P2R + MATCH	0.575	0.513
P2R + P2P + MATCH	0.621	0.574

Table 3: Comparison of different choices of features, where P2R stands for the features based on post-response similarity, P2P stands for the features based on post-post similarity, and MATCH stands for the semantic match feature.

To mimic a more realistic scenario on automatic response model on Sina Weibo, we allow the system to choose which post to respond to. Here we simply set the response algorithm to respond only when the highest score of the candidate response passes a certain threshold. Our experiments show that when we choose to respond only to 50% of the posts, the P@1 increases to 0.76, while if the system only respond to 25% of the posts, P@1 keeps increasing to 81%.

6.2 Case Study

Although our preliminary retrieval model does not consider more complicated syntax, it is still able to capture some useful coupling structure between the appropriate (post, response) pairs, as well as the similar (post, post) pairs.

Query Post:	创新工场三年庆, 在 我们的智慧树会议室
	Today is the 3-year anniversary of Innovation Works. We are in the meeting rooms named Tree of Wisdom
Response:	嗯, 中午去的, 新环境不错, 很宽敞
	Yeah, I came in the noon. Nice environment, quite spacious

Figure 6: An actual instance (the original Chinese text and its English translation) of response returned by our retrieval-based system.

Case study shows that our retrieval is fairly effective at capturing the semantic relevance (Section 6.2.1), but relative weak on modeling the logic consistency (Section 6.2.2). Also it is clear that the semantic matching feature (described in Section 5.1) helps find matched responses that do not share any words with the post (Section 6.2.3).

6.2.1 On Semantic Relevance

The features employed in our retrieval model are mostly vector-space based, which are fairly good at capturing the semantic relevance, as illustrated by Example 1 & 2.

EXAMPLE 1:

P:	*It is a small town on an Spanish with 500 population, and guess what, they even have a casino!*
R:	*If you travel to Spain, you need to spend some time there.*

EXAMPLE 2:

P:	*One quote from Benjamin Franklin: "We are all born ignorant, but one must work hard to remain stupid."*
R:	*Benjamin Franklin is a wise man, and one of the founding fathers of USA.*

However our retrieval model also makes bad choice, especially when either the query post or the response is long, as shown in Example 3. Here the response is picked up because 1) the correspondence between the word "IT" in the post and the word "mobile phone" in the candidate, and 2) the Chinese word for "lay off" in the post and the word for "outdated" in the response are the same.

EXAMPLE 3:

P:	*As to the laying-off, I haven't heard anything about it. "Elimination of the least competent" is kind-off conventional in IT, but the ratio is actually quite small.*
R:	*Please don't speak that way, otherwise you can get outdated. Mobile phones are very expensive when they were just out, but now they are fairly cheap. Look forward, or you will be outdated.*

The entity association is only partially addressed with features like post-response cosine similarity, treating entity name just as a word, which is apparently not enough for preventing the following type

of mistakes (see Example 4 & 5) when the post and response match well on other parts

EXAMPLE 4:

P:	*Professor Wang will give a curse on natural language processing, starting next semester.*
R:	*Jealous.. I wish I can attend Prof. Li's course too some time in the future.*

EXAMPLE 5:

P:	*The fine China from Exhibition at the National Palace Museum in Taipei*
R:	*This drawing looks so nice. National Palace Museum in Taipei is full of national treasures*

6.2.2 On Logic Consistency

Our current model does not explicitly maintain the logic consistency between the response and the post, since Logic consistency requires a deeper analysis of the text, and therefore hard to capture with just a vector space model. Below are two examples which are semantically relevant, and correct with respect to speech act, but logically inappropriate.

EXAMPLE 1:

P:	*I checked. Wang Fengyi is not my great grandfather, although they've done similar deeds and both were called "Wang the Well-doer".*
R:	*wow, Wang Fengyi is your great grand-father*

EXAMPLE 2:

P:	*We are looking for summer interns. We provide books and lunch. If you are in Wu Han and interested, drop us an email. Sorry we don't take any students outside Wu Han.*
R:	*Are you looking for summer intern?*

6.2.3 The Effect of Semantic Matching

The experiments also show that we may find interesting and appropriate responses that have no common words as the post, as shown in the example below. Our bi-linear semantic matching model however performs relatively poorly on long posts, where the topics of the sentence cannot be well captured by the sum of the latent vectors associated with each word.

P:	*Eight England players stand in the penalty area.*
R1:	*What a classic match*
R2:	*Haha, it is still 0:0, no goal so far*

7 Summary

In this paper we propose a retrieval-based response model for short-text based conversation, to leverage the massive instances collected from social media. For research in similar directions, we create a dataset based on the posts and comments from Sina Weibo. Our preliminary experiments show that our retrieval-based response model, when combined with a large candidate set, can achieve fairly good performance. This dataset will be valuable for both training and testing automatic response models for short texts.

Discourse Level Explanatory Relation Extraction from Product Reviews Using First-order Logic

Qi Zhang, Jin Qian, Huan Chen, Jihua Kang, Xuanjing Huang
School of Computer Science
Fudan University
Shanghai, P.R. China
{qz, 12110240030, 12210240054, 12210240059, xjhuang}@fudan.edu.cn

Abstract

Explanatory sentences are employed to clarify reasons, details, facts, and so on. High quality online product reviews usually include not only positive or negative opinions, but also a variety of explanations of why these opinions were given. These explanations can help readers get easily comprehensible information of the discussed products and aspects. Moreover, explanatory relations can also benefit sentiment analysis applications. In this work, we focus on the task of identifying subjective text segments and extracting their corresponding explanations from product reviews in discourse level. We propose a novel joint extraction method using first-order logic to model rich linguistic features and long distance constraints. Experimental results demonstrate the effectiveness of the proposed method.

1 Introduction

Through analyzing product reviews with high helpfulness ratings assigned by readers, we find that a large number of explanatory sentences are used to clarify the causes, details, or consequences of opinions. According to the statistic based on the dataset we crawled from a popular product review website, more than 56.1% opinion expressions are further explained by other sentences. Since most consumers are not experts, these explanations would bring lots of helpful and easy comprehension information for them. Suggestions about writing a product review also advise authors to include not only whether they like or dislike a product, but also why.[1]

For example, let us consider the following snippets extracted from online reviews:

> **Example 1**: *TVs with lower refresh rates may suffer from motion blur. If you're watching a fast-paced football game, for example, you may notice a bit of blurring as the players run around the field.*

> **Example 2**: *The LED screen is highly reflective. The reflection of my own face makes it very hard to see the subject I am trying to shoot.*

The first sentence of example 1 expresses negative opinion about refresh rate, which is one of the most important attributes of TV. The second sentence describes the consequence of it through an example. In example 2, detail descriptions are used to explain the reflection problem of the camera screen.

Although, explanations provide valuable information, to the best of our knowledge, there is no existing work that deals with explanation extraction for opinions in discourse level. We think that if explanatory relations can be automatically identified from reviews, sentiment analysis applications may benefit from it. Existing opinion mining approaches mainly focus on subjective text. They try to determine the subjectivity and polarity of fragments of documents (e.g. a paragraph, a sentence, a phrase and a word) (Pang et al., 2002; Riloff et al., 2003; Takamura et al., 2005; Mihalcea et al., 2007; Dasgupta and Ng, ; Hassan and Radev, 2010; Meng et al., 2012; Dragut et al., 2012). Fine-grained methods were also introduced to extract opinion holder, opinion expression, opinion target, and other opinion elements (Kobayashi et al., 2007; Wu et al.,

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 946–957,
Seattle, Washington, USA, 18-21 October 2013.

2011; Xu et al., 2013; Yang and Cardie, 2013). Major research directions and challenges of sentiment analysis can also be found in surveys (Pang and Lee, 2008; Liu, 2012).

In this work, we aim to identify subjective text segments and extract their corresponding explanations from product reviews in discourse level. We propose to use Markov Logic Networks (MLN) (Richardson and Domingos, 2006) to learn the joint model for subjective classification and explanatory relation extraction. MLN has been applied in several natural language processing tasks (Singla and Domingos, 2006; Poon and Domingos, 2008; Yoshikawa et al., 2009; Andrzejewski et al., 2011; Song et al., 2012) and demonstrated its advantages. It can easily incorporate rich linguistic features and global constraints by designing various logic formulas, which can also be viewed as templates or rules. Logic formulas are combined in a probabilistic framework to model soft constraints. Hence, the proposed approach can benefit a lot from this framework.

To evaluate the proposed method, we crawled a large number of product reviews and constructed a labeled corpus through Amazon's Mechanical Turk. Two tasks were deployed for labeling the corpus. We compared the proposed method with state-of-the-art methods on the dataset. Experimental results demonstrate that the proposed approach can achieve better performance than state-of-the-art methods.

The remaining part of this paper is organized as follows: In Section 2, we define the problem and give some examples to show the challenges of this task. Section 3 describes the proposed MLN based method. Dataset construction, experimental results and analyses are given in Section 4. In Section 5, we present the related work and Section 6 concludes the paper.

2 Problem Statement

Motivated by the argument structure of discourse relations used in Penn Discourse Treebank (Rashmi Prasad and Webber, 2008), in this work, we adopt the clause unit-based definition. It means that clauses are treated as the basic units of opinion expressions and explanations. Let $d = \{c_1, c_2, ...c_n\}$ be the clauses of document d. Directed graph $G = (V, E)$ is used to represent the subjectivity of clauses and explanatory relationships between them. In the graph, vertices represent clauses, whose categories are specified by the vertex attributes. Directed edges describe the explanatory relationships between them, of which the heads are explanatory clauses. If clause c_a describes a set of facts which clarify the causes, context, situation, or consequences of another clause c_b, $c_a \longrightarrow c_b$ is used to indicate that clause c_a *explains* c_b.

Adopting clause unit-based definition is based on the following reasons: 1) clause is normally considered as the smallest grammatical unit which can express a complete proposition (Kroeger, 2005); 2) from analyzing online reviews, we observe that a clause can express a complete opinion about one aspect in most of cases; 3) in Penn Discourse Treebank, the basic unit of discourse relations (with a few exceptions) is also taken to be a clause (Rashmi Prasad and Webber, 2008).

Figure 1(a) illustrates a sample document. Figure 1(b) is the corresponding output of the given document. In the graph, vertices whose color are black stand for subjective clauses. The other clauses are represented by white vertices. Edges describe the explanatory relationships between them, of which the heads are explanatory clauses.

Although the explanatory relation extraction task has been studied from the view of linguistic and discourse representation by existing works (Carston, 1993; Lascarides and Asher, 1993), the automatic extraction task is still an open question. Consider the following examples extracting from online reviews:

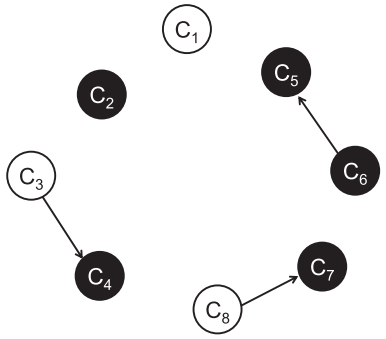
Example 3: *It takes great pictures. Color renditions, skin tones, exposure levels are all first rate.* From the example, we can observe that the second sentence explains the first one. However, the second sentence itself also expresses opinion on various opinion targets. In other words, both subjective and objective sentences can be used as explanations.

Example 4: *When we called their service center they made us wait for them the whole day and no one turned up. This level of service is simply not acceptable.* The first sentence in example 4 explains the second one. Hence, the feature of relative location between two sentences does not always work well in all cases.

Example 5: *This backpack is great! its very big*

(c1) I have both the Panasonic LX3 and the Canon S90. ***(c2)*** Both cameras are quite different but truly excellent. ***(c3)*** The S90 is a true pocket camera. ***(c4)*** It is very compact. ***(c5)*** The build quality is also top notch. ***(c6)*** It feels solid and it is easy to grip. ***(c7)*** It is so small and convenient, ***(c8)*** you will find that you will always carry it with you.

(a) Example Review



(b) Directed Graph Representation

Figure 1: Directed graph representation of a sample document.

and fits more than enough stuff. Many sentences, which express explanatory relation, do not contain any connectives (e.g. "*because*", "*the reason is*", and so on). Lin et al.(2009) generalized four challenges (include ambiguity, inference, context, and world knowledge) to automated implicit discourse relation recognition. In this task, we also need to address those challenges.

From the these examples, we can observe that extracting explanatory relations from product reviews is a challenging task. Both linguistic and global constraints should be carefully studied.

3 The Proposed Approach

In this section, we present our method for jointly classifying the subjectivity of text segments and extracting explanatory relations. Firstly, we briefly describe the framework of Markov Logic Networks. Then, we introduce the clause extraction method based on the definition described in the Section 2. Finally, we present the first-order logic formulas including local formulas and global formulas used for joint modeling in this work.

3.1 Markov Logic Networks

A MLN consists of a set of logic formulas that describe first-order knowledge base. Each formula consists of a set of first-order predicates, logical connectors and variables. Different with first-order logic, these hard logic formulas are softened and can be violated with some penalty (the weight of formula) in MLN.

We use $\mathcal{M}$ to represent a MLN and $\{(\phi_i, w_i)\}$ to represent formula ϕ_i and its weight w_i. These weighted formulas define a probability distribution over sets of possible worlds. Let y denote a possible world, the $p(y)$ is defined as follows (Richardson and Domingos, 2006):

$$p(y) = \frac{1}{Z} exp\left(\sum_{(\phi_i, w_i)\in\mathcal{M}} w_i \sum_{c\in C^{n_{\phi_i}}} f_c^{\phi_i}(y)\right),$$

where each c is a binding of free variable in ϕ_i to constraints; $f_c^{\phi_i}(y)$ is a binary feature function that returns 1 if the true value is obtained in the ground formula we get by replacing the free variables in ϕ_i with the constants in c under the given possible world y, and 0 otherwise; $C^{n_{\phi_i}}$ is all possible bindings of variables to constants, and Z is a normalization constant.

Many methods have been proposed to learn the weights of MLN using both generative and discriminative approaches (Richardson and Domingos, 2006; Singla and Domingos, 2006). There are also several MLN learning packages available online such as thebeast[2], Tuffy[3], PyMLNs[4], Alchemy[5], and so on.

Describing the attributes of words	
$subjLexicon(w)$	The word w belongs to the subjective lexicon (Baccianella et al., 2010).
$relationLexicon(w)$	The word w belongs to the lexicon of explanation relation connectives (Pitler and Nenkova, 2009).
Describing the attributes of the clause c_i	
$word(i, w)$	The clause c_i has word w.
$firstWord(i, w)$	The first word of clause c_i is word w.
$pos(i, w, t)$	The POS tag of word w is t in clause c_i.
$dep(i, h, m)$	Word m and h are governor and dependent of a dependency relation in clause c_i.
Describing the attributes of relations between clause c_i and clause c_j	
$clauseDistance(i, j, m)$	Distance between clause c_i and clause c_j in clauses is m.
$sentenceDistance(i, j, n)$	Distance between clause c_i and clause c_j in sentences is n.

Table 1: Descriptions of observed predicates.

3.2 Clause Identification

We model the clause boundary identification problem through sequence labeling and use Conditional Random Fields (CRFs) to identify clause boundaries. Words and part-of-speech (POS) tags are used as feature sets. Since we do not allow embedded segments, the performance of our method is promising, which achieves the F1 score of 92.8%. The result is comparable with the best results obtained during the CoNLL-2001 campaign (Tjong et al., 2001).

3.3 Formulas

In this work, we propose to use predicate $subj(i)$ to indicate that the ith clause is subjective and $explain(i, j)$ to indicate that the jth clause explains the ith clause. Both $subj$ and $explain$ are hidden predicates and jointly modeled by MLN. We use local and global formulas to model rich linguistic features and long distance constraints.

3.3.1 Local Formulas

The local formulas relate one or more observed predicates to exactly one hidden predicate. In this work, we define a list of observed predicates to describe the properties of individual clauses and attributes of relations between two clauses. The observed predicates and descriptions are shown in Table 1. The observed predicates can be categorized into 3 groups: words, clauses, and relations between clauses. We use two lexicons to capture background knowledge of words. Lexical, part-of-speech tag, and dependency relation are used to describe a single clause. We also propose two predicates to model distance between clauses.

Table 2 lists the local formulas used in this work. The "+" notation in the formulas indicates that each constant of the logic variable should be weighted separately. For subjective classification and relation extraction, we construct a number of formulas respectively.

For subjective classification, the first two formulas model the influence of lexical and POS tag. It is similar as the bag-of-words model, which is a simplifying representation and has been successfully used for various natural language processing tasks. Since words which provide positive or negative opinions may provide important information for subjectivity classification, we combine predicates of words and lexicon of opinion words. Bigrams are also proved to be useful for textual classification in several NLP tasks. Hence, we also combine predicates about individual word and POS tag to capture this kind of information. Word-level relations are explicitly presented at the dependency trees, we

Table 2: Descriptions of local formulas.

also construct local formulas based on predicates extracted from dependency trees of clauses.

For explanatory relation extraction, we firstly use formulas to capture lexical and syntactic information from both of the clauses. Since distances between clauses are helpful in determining the relation, we incorporate two kinds of distance features with lexical and syntactic predicates. Connective words such as *for example*, *since*, explicitly signal the presence of the explanation relation. Although some connective words are ambiguous in terms of relation they mark (Pitler and Nenkova, 2009), they may still be useful for explanation relation extraction. Hence, we construct local formulas with relation lexicon and other predicates.

3.3.2 Global Formulas

Local formulas are designed to deal with subjective classification of a single clause or relation determination of a single pair of clauses. Global formulas are designed to handle global constraints of multiple clauses. From the definition of explanatory relation and corpus statistics, we observe the following properties:

Property 1: One clause can only serve as the explanation of one subjective clause.

Property 2: Explanatory clauses occur immediately before or after their corresponding subjective clauses.

Property 3: The positions of explanatory clauses are consecutive. In other words, if clause c_k and c_{k+2} explain clause c_j, the clause c_{k+1} would also be explanatory clause of c_j.

For property 1, we use the following global formula to make sure that one clause only explains at most one another clause.

$$explain(i,j) \Rightarrow \neg explain(k,j) \quad \forall k \neq i,j \quad (1)$$

Based on the property 2 and 3, explanatory clauses are consecutive and immediately before or after their corresponding subjective clauses. We use the following formulas to guarantee the property:

$$explain(i,i+k) \Rightarrow explain(i,i+m), \quad 1 \leq m \leq k-1 \quad (2)$$

$$explain(i,i-k) \Rightarrow explain(i,i-m), \quad 1 \leq m \leq k-1 \quad (3)$$

Since our aim is to extract explanatory for subjective clauses, we also use the following formulas to make sure that the clauses which are explained are subjective ones.

$$explain(i,j) \Rightarrow subj(i) \quad (4)$$

4 Experiments

4.1 Data Set

We crawled a number of reviews about digital cameras from Buzzillions[6], which is a product review site and contains more than 16 million reviews. We randomly select 100 reviews whose usefulness ratings are 5 on a 5-point scale. They contain 1137 sentences, which are composed by 1665 clauses. Amazon's Mechanical Turk is used to deploy two tasks for labeling the corpus. 694 clauses are labeled subjective and 478 clauses explain other ones. More than 56.1% opinion expressions are explained by their corresponding explanatory sentences.

The two projects we deployed on Amazon's Mechanical Turk are: 1) Determine whether a clause contains opinion expressions or not; 2) Determine whether a clause clarifies causes, reasons, or consequences of another given clause. In order to control the labeling quality, we configured parameters of the project to make sure that all the tasks should be judged by at least 20 annotators. Most of the annotators can complete a task within 25 seconds. Figure 2 shows the screenshots of the two projects.

Over all, 127 workers participated in the project. About 72% of them submitted more than 5 tasks. Although we listed several examples on the project descriptions, different people may have their own understanding and criteria for those tasks. In order to measure the quality of the labeling task, we use perplexity to evaluate each task. If the perplexity of a task is below 0.51, which means that more than 80% of the workers submitted the same decision, the result of the task will be used as training or testing data. From the statistic of the corpus, we observe that only 6.2% of the clauses' subjectiveness and 15.6% of explanation relations can not be certainly decided. For the first project, we treated those clauses as objective one. And, those clause pairs in the second project were not considered as explanation relations.

[6] www.buzzillions.com

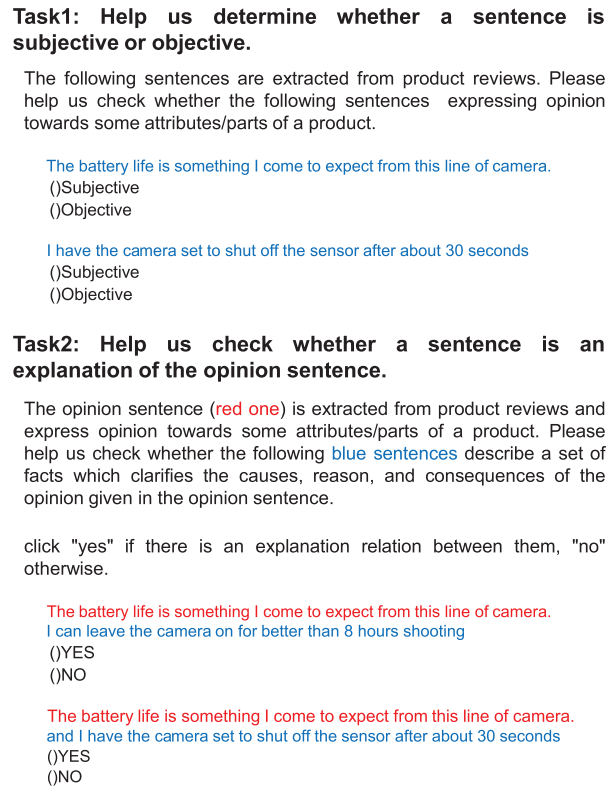

Figure 2: Screenshots of the two tasks on Amazon Mechanical Turk.

4.2 Experiments Configurations

Stanford parser (Klein and Manning, 2003) is used for extracting features from dependency parse trees. For resolving Markov logic network, we use the toolkit *thebeast* [7]. The detailed setting of thebeast engine is as follows: The inference algorithm is the MAP inference with a cutting plane approach. For parameter learning, the weights for formulas are updated by an online learning algorithm with MIRA update rule. All the initial weights are set to zeros. The number of iterations is set to 10 epochs.

Evaluation metrics used for subjectivity classification and relation extraction throughout the experiments include: Precision, Recall, and F1-score. We randomly select 80% reviews as training set and the others as testing set.

Since the dataset is newly created for this task, to compare the performance of the proposed method to other models, we also reimplemented several state-of-the-art methods for comparison.

- **CRF-Subj**: We follow the method proposed by Zhao et al. (2008), which regard the subjectivity of all clauses throughout a paragraph as a sequential flow of sentiments and use CRFs to model it. The feature sets are similar as the local formulas for MLN including words, POS tags, dependency relations, and opinion lexicon.

- **RAE-Subj**: Socher et al. (2011) proposed to use recursive autoencoders for sentence-level predication of sentiment label distributions. To compare with it, we also reimplement their method without any hand designed lexicon.

- **PDTB-Rel**: For discourse relation extraction, we use "PDTB-Styled End-to-End Discourse Parser" (Lin et al., 2010) to extract discourse level relations as baseline. Since it is a general discourse relations identification algorithms, "Cause", "Pragmatic Cause", "Instantiation", and "Restatement" relation types are treated as explanatory relation in this work.

- **SVM-Rel**: We also use LibSVM (Chang and Lin, 2011) to classify the relations between clauses. Following the configurations reported by Feng and Hirst (2012), we use linear kernel and probability estimation to model it.

4.3 Results

Table 3 shows the comparisons of the proposed method with the state-of-the-art systems on subjectivity classification and explanatory relation extraction. From the results, we can observe that recursive autoencoders based subjectivity classification method achieves slightly better performance than our method and conditional random fields based method. The performances of the proposed method are similar as CRFs'. We think that the main reason is that only lexical features are used in MLN models for subjective classification. However, conditional random fields consider not only lexical information but also inference of the contexts of sentences. RAE method learns vector space representations for multi-word phrases and uses compositional semantics to understand sentiment.

[7] http://code.google.com/p/thebeast

Methods	Subjective Classification		
	P	**R**	**F_1**
CRF-Subj	83.5%	76.9%	80.1%
RAE-Subj	**85.3**%	79.1%	**82.1**%
MLN	79.2%	**80.6**%	79.9%
Methods	Relation Extraction		
	P	**R**	**F_1**
RAE-Subj + PDTB-Rel	28.5%	38.6%	32.8%
RAE-Subj + SVM-Rel	32.4%	**89.7**%	47.6%
MLN	**56.2**%	72.9%	**63.5**%

Table 3: Performance comparisons between the proposed method and state-of-the-art methods. "MLN" represents the method proposed in this work.

For evaluating the performance of relation extraction, we combine the results of RAE with PDTB-Rel and SVM-Rel. For all the subjective clauses identified by RAE, PDTB-Rel and SVM-Rel are used to extract corresponding explanatory clauses. The results are shown in the last three rows in the Table 3. From the results, we can observe that the proposed joint model achieves best F1 score and precision among all methods. Although the proposed method achieve slightly worse result in processing subjectivity classification. We think that the error propagation is the main reason for worse results of cascaded methods. The relative improvement of MLN over SVM-Rel is more than 33.4%.

To show the effectiveness of different observed predicates, we evaluate the performances of the proposed method with different predicate sets. We subtract one observed predicate and its corresponding local formulas from the original sets at a time. The results of both subjectivity classification and relation extraction are shown in Table 4. The first row shows the result of the MLN based method with all observed predicates and local formulas. From the results we can observe that the observed predicates which are not used in the local formulas for subjectivity classification also impact the performance of subjectivity classification. We think that the performance is effected by the global formulas, which combine the procedure of subjectivity classification and relation extraction. Among all predicates, we observe that words and dependency relations play the most important roles. Without word predicate, the F1 score of subjectivity classification and relation extraction significantly drop to 51.2% and 42.9% respectively. For subjectivity classification, subjective lexicon contributes a lot for recall. For relation extraction, the impacts of clause distance and sentence distance are not as significant as the other features.

5 Related Work

Our work relates to three research areas: sentiment analysis/opinion mining, discourse-level relation extraction, and Markov logic networks. Along with the increasing requirement, subjectivity classification has recently received considerable attention from both the industry and researchers. A variety of approaches and methods have been proposed for this task from different aspects. Among them, a number of approaches focus on classifying sentiments of text in different levels (e.g. words (Kim and Hovy, 2004), phrases (Wilson et al., 2005), sentences (Zhao et al., 2008), documents (Pang et al., 2002) and so on.), and detecting the overall polarity of them.

Another research direction tries to convert the sentiment analysis task into entity identification and relation extraction. Hu and Liu (2004) proposed to use a set of methods to produce feature-based summary of a large number of customer reviews. Kobayashi et al. (2007) assumed that evaluative opinions could be structured as a frame which is composed by opinion holder, subject, aspect, and evaluation. They converted the task to two kinds of relation extraction tasks and proposed a machine learning-based method which used both contextual and statistical clues.

Analysis of some special types of sentences were also introduced in recent years. Jindal and Liu (2006) studied the problem of identifying comparative sentences. They analyzed different types of comparative sentences and proposed learning approaches to identify them. Conditional sentences were studied by Narayanan et al (2009). They analyzed the conditional sentences in both linguistic and computitional perspectives and used learning

	Subjective Classification			Relation Extraction

Table 4: Performance comparisons of different observed predicates

method to do it. They followed the *feature-based sentiment analysis* model (Hu and Liu, 2004), which also use flat frames to represent evaluations.

Since the cross sentences relations are considered in this work, the discourse-level relation extraction methods are also related to ours. Marcu and Echihabi (2002) proposed to use an unsupervised approach to recognizing discourse relations. Lin et al.(2009) analyzed the impacts of features extracted from contextual information, constituent parse trees, dependency parse trees, and word pairs. Asher et al.(2009) studied discourse segments containing opinion expressions from the perspective of linguistics. Chen et al. (2010) introduced a multi-label model to detect emotion causes. They developed two sets of linguistic features for this task base on linguistic cues. Zirn et al. (2011) proposed to use MLN framework to capture the context information in analysing (sub-)sentences.

The most similar work to ours was proposed by Somasundaran et al.(2009). They proposed to use iterative classification algorithm to capture discourse-level associations. However different to us, they focused on pairwise relationships between opinion expressions. In this paper, we used MLN framework to capture another different discourse-level relation, which exists between subject clauses or subject clause and objective clause.

Richardson and Domingos (2006) proposed Markov Logic Networks, which combines first-order logic and probabilistic graphical models. In recent years, MLN has been adopted for several natural language processing tasks and achieved a certain level of success (Singla and Domingos, 2006; Riedel and Meza-Ruiz, 2008; Yoshikawa et al., 2009; Andrzejewski et al., 2011; Jiang et al., 2012; Huang et al., 2012). Singla and Domingos (2006) modeled the entity resolution problem with MLN. They demonstrated the capability of MLN to seamlessly combine a number of previous approaches. Poon and Domingos (2008) proposed to use MLN for joint unsupervised coreference resolution. Yoshikawa et al. (2009) proposed to use Markov logic to incorporate both local features and global constraints that hold between temporal relations. Andrzejewski et al. (2011) introduced a framework for incorporating general domain knowledge, which is represented by First-Order Logic (FOL) rules, into LDA inference to produce topics shaped by both the data and the rules.

6 Conclusions

In this paper, we propose to use Markov logic networks to identify subjective text segments and extract their corresponding explanations in discourse level. We use MLN to jointly model subjectivity classification and explanatory relation extraction. Rich linguistic features and global constraints are incorporated by various logic formulas and global formulas. To evaluate the proposed method, we collected a large number of product reviews and

constructed a labeled corpus through Amazon's Mechanical Turk. Experimental results demonstrate that the proposed approach achieve better performance than state-of-the-art methods.

Abstract

We present an approach for building multi-document event threads from a large corpus of newswire articles. An event thread is basically a succession of events belonging to the same story. It helps the reader to contextualize the information contained in a single article, by navigating backward or forward in the thread from this article. A specific effort is also made on the detection of reactions to a particular event.

In order to build these event threads, we use a cascade of classifiers and other modules, taking advantage of the redundancy of information in the newswire corpus.

We also share interesting comments concerning our manual annotation procedure for building a training and testing set[1].

1 Introduction

In this paper, we explore a new way of dealing with temporal relations between events. Our task is somewhat between multidocument summarization and classification of temporal relations between events. We work with a large collection of English newswire articles, where each article relates an event: the main topic of the article is a specific event, and other older events are mentioned in order to put it into perspective. Thus, we consider that an event is associated with an article and that defining temporal relations between articles is a way to define temporal relations between events.

[1]This work has been partially funded by French National Research Agency (ANR) under project Chronolines (ANR-10-CORD-010). We would like to thank the French News Agency (AFP) for providing us with the corpus.

The task is to build a temporal graph of articles, linked between each other by the following relations:

- *Same event*, when two documents relate the same event, or when a document is an update of another one.
- *Continuation*, when an event is the continuation or the consequence of a previous one.

We also define a subset of *continuation*, called *reaction*, concerning a document relating the reaction of someone to another event.

Some examples of these three classes will be given in Section 3.

These relations can be represented by a directed graph where documents are vertices and relations are edges (as illustrated in all figures of this article). Figure 1 shows an example of such a graph.

Press articles, and especially newswire articles, are characterized by an important redundancy of related events. An important event[2] is likely to be treated by several successive articles, which will give more and more details and update some numbers (mainly, tragedy casualty updates, as shown in Figure 2). On the one hand, this redundancy is an issue since a system must not show duplicate information to the user; on the other hand, we show in this article that it can also be of great help in the process of extracting temporal graphs.

In what follows, we first review some of the related work in Section 2. Section 3 presents the annotation procedure and the resulting annotated corpus

[2]Note that we do not focus intentionally on "important" events. However, the fact is that minor events do hardly lead to dense temporal graphs.

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 958–967,
Seattle, Washington, USA, 18-21 October 2013.

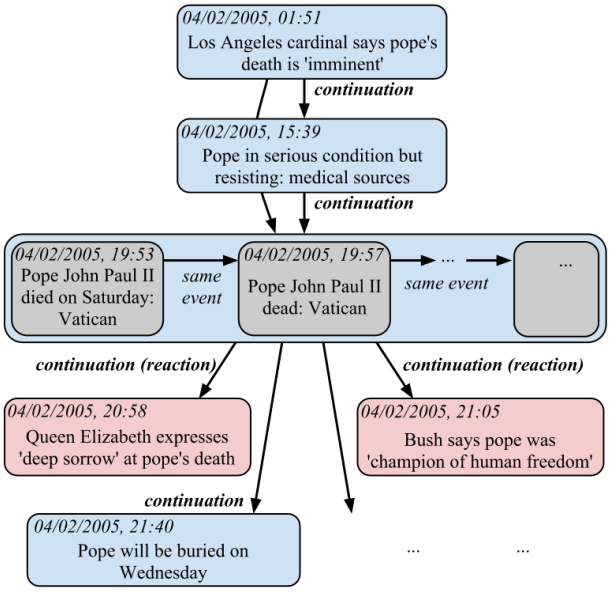

Figure 1: Example of "temporal graph": around the Pope's death. The associated text is the title of each article. Relations that can be obtained by transitivity have been hidden for clarity's sake.

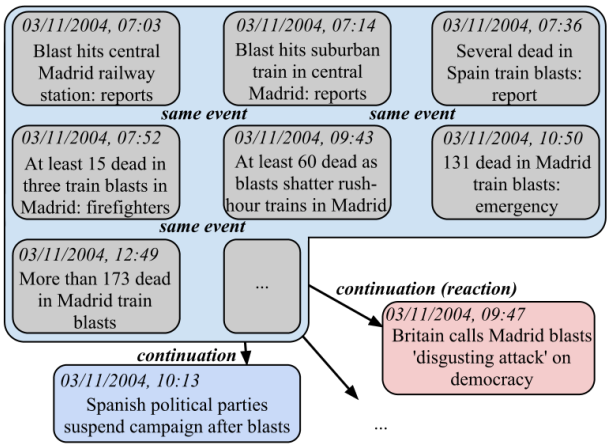

Figure 2: Example of "temporal graph": Madrid attacks, with many updates of the initial information. Note that articles gathered in this main pool of articles can be posterior to the continuations and reactions to the described event.

used for developing, learning and evaluating the system. The simple modules used to predict the *same event*, *continuation* and, possibly, *reaction* relations are described in Section 4, and results are given in Section 5.

We also propose an end-user application to this work. When a user reads an article, the system will then be able to provide her with a thread of events having occurred before or after, helping her to contextualize the information she is reading. This application is described in Section 6.

2 Related work

The identification of temporal relations between events in texts has been the focus of increasing attention because of its importance in NLP applications such as information extraction, question-answering or summarization. The evaluation campaigns TempEval 2007 (Verhagen et al., 2007) and TempEval 2010 (Verhagen et al., 2010) focused on temporal relation identification, mainly on temporal relations between events and times in the same sentence or in consecutive sentences and between events and the creation time of documents. In this context, the goal is to identify the type of a temporal relation which is known to be present. Systems having the best results (accuracy about 0.6) use statistical learning based on temporal features (modality, tense, aspect, etc.) (Mani et al., 2006; Chambers et al., 2007). More recently, Mirroshandel and Ghassem-Sani (2012) proposed a new method for temporal relation extraction by using a bootstrapping method on annotated data and have a better accuracy than state-of-the-art systems. Their method is based on the assumption that similar event pairs in topically related documents are likely to have the same temporal relations. For this work, the authors had already some collections of topically related documents and did not need to identify them.

In the 2012 i2b2 challenge (i2b, 2012), the problem was not only to identify the type of temporal relations, but also to decide whether a temporal relation existed or not between two elements, either clinical concepts or temporal expressions. But, as in TempEval, the temporal analysis were only to be performed within a single document.

Other works focus on event ordering. For example, Fujiki et al. (2003) and Talukdar et al. (2012) proposed methods for automatic acquisition of event sequences from texts. They did not use temporal information present in texts and extracted sequences of events (*e.g.* *arrest/escape*) from sentences which were already arranged in chronologi-

cal order. Chambers and Jurafsky (2008) proposed a method to learn narrative chains of events related to a protagonist in a single document. The first step consists in detecting narrative relations between events sharing coreferring arguments. Then, a temporal classifier orders partially the connected events with the *before* relation.

Concerning the identification of the *reaction* relation, to our knowledge, there is no work on the detection of reaction between several documents. Pouliquen et al. (2007), Krestel et al. (2008) and Balahur et al. (2009) focused on the identification of reported speech or opinions in quotations in a document, but not on the identification of an event which is the source of a reaction and which can possibly be in another document.

As we can see, all these approaches, as well as traditional information extraction approaches, lean on information contained by a single document, and consider an event as a word or a phrase. However, Ahmed et al. (2011) proposed a framework to group temporally and tocipally related news articles into *same story* clusters in order to reveal the temporal evolution of stories. But in these topically related clusters of documents, no temporal relation is detected between articles or events except chronological order. On this point of view, our task is closer to what is done in multidocument summarization, where a system has to detect redundant excerpts from various texts on the same topic and present results in a relevant chronological order. For example, Barzilay et al. (2002) propose a system for multidocument summarization from newswire articles describing the same event. First, similar text units from different documents are identified using statistical techniques and shallow text analysis and grouped into thematic clusters. Then, in each theme, sentences which are selected as part of the summary are ordered using the publication date of the first occurrence of events to order sentences.

3 Resources

We built an annotated collection of English articles, taken from newswire texts provided by the French news agency (AFP), spreading over the period 2004-2012. The entire collection contains about 1.5 million articles. Each document is an XML file containing a title, a creation time (DCT), a set of keywords and textual content split into paragraphs.

3.1 Selection of Article Pairs

Pairs of documents were automatically selected according to the following constraints:

- The article describes an event. Articles such as timelines, fact files, agendas or summaries were discarded (all these kinds of articles were tagged by specific keywords, making the filtering easy).
- The distance between the two DCTs does not exceed 7 days.
- There are at least 2 words in common in the set of keywords and/or 2 proper nouns in common in the first paragraph of each article.

These last two restrictions are important, but necessary, in order to give annotators a chance to find some related articles. Pure random selection of pairs over a collection of 1.5 million articles would be impractical.

We assume that the title and the first paragraph describe the event associated with the document. This is a realistic hypothesis, since the basic rules of journalism impose that the first sentence should summarize the event by informing on the "5 Ws" (*What*, *Who*, *When*, *Where*, *Why*). However, reading more than the first paragraph is sometimes necessary to determine whether a relation exists between two events.

3.2 Relation Annotation

Two annotators were asked to attribute the following relations between each pair of articles presented by the annotation interface system.

In a first annotation round, 7 types of relations were annotated:

- Three relations concerning cases where the two articles relate the same event or an update:
  - *number update*, when a document is an update of numerical data (see top of Figure 5),
  - *form update*, when the second document brings only minor corrections,

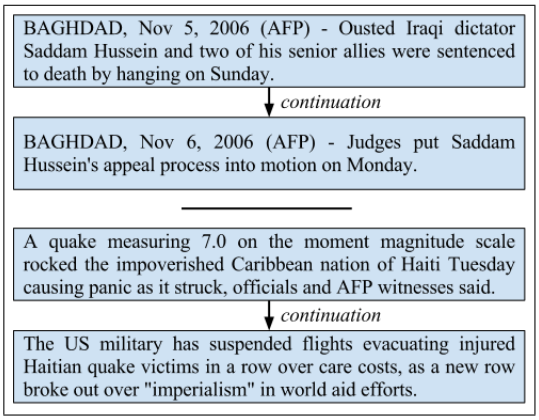

Figure 3: Examples of relation *continuation* between two documents.

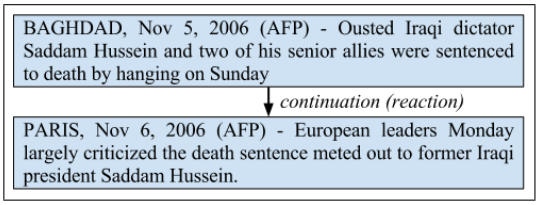

Figure 4: Examples of relation *continuation-reaction* between two documents.

  - *details*, when the second document gives more details about the events (see bottom of Figure 5).

- *development of same story*, when the two documents relate two events which are included into a third one;

- *continuation*, when an event is the continuation or the consequence of a previous one. Figure 3 shows two examples of such a relation. It is important to make clear that a *continuation* relation is more than a simple thematic relation, it implies a natural prolongation between two events. For example, two sport events of the same Olympic Games, or two different attacks in Iraq, shall not be linked together unless a direct link between both is specified in the articles.

- *reaction*, a subset of *continuation*, when a document relates the reaction of someone to another event, as illustrated by the example in Figure 4.

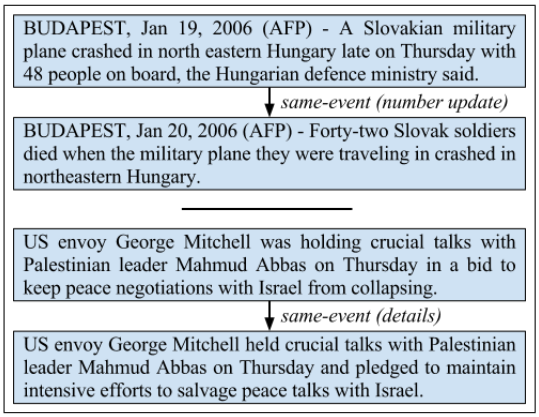

Figure 5: Example of relations *same-event* between two documents: update on casualties (top) or details (bottom).

- *nil*, when no relation can be identified between the two documents.

The inter-annotator agreement was calculated with Cohen's Kappa measure (Cohen, 1960) across 150 pairs: $\kappa = 0.68$. The agreement was low for the first 4 types of relations mostly because the difference between relations was not clear enough. We therefore aggregated the *number update*, *form update* and *details* relations into a more generic and consensual *same-event* relation (see Figure 5). We also discarded the *development of same story* relation, leaving only *same-event*, *continuation* and *reaction*.

Annotation guidelines were modified and a second annotation round was carried out: only the *same-event*, *continuation*, *reaction* and *nil* relations were annotated. Inter-annotator agreement across 150 pairs was then $\kappa = 0.83$, which is a good agreement.

3.3 Relation Set Extension

This manual annotation would have led to very sparse temporal graphs without the two following additional processes:

- When the annotator attributed a "non-nil" relation to a pair of documents, the annotation system suggested other pairs to annotate around the concerned articles.

- *Same-event* and *continuation* relations are transitive: if A *same-event* B and B *same-event* C, then A *same-event* C (and respectively for

	Pair number	Learning	Evaluation
Same event	762	458	304
Continuation	1134	748	386
Reaction	182	123	59
Nil	918	614	304
TOTAL	**2996**	1943	1053

Table 1: Characteristics of the corpus.

continuation). Then, when the annotation was done, a transitive closure was performed on the entire graph, in order to get more relations with low effort (and to detect and correct some inconsistencies in the annotations).

Finally, almost 3,000 relations were annotated. $^2/_3$ of the annotated pairs were used for development and learning phases, while $^1/_3$ were kept for evaluation purpose (cf. Table 1).

4 Building Temporal Graphs

As we explained in the introduction, the main purpose of this paper is to show that it is possible to extract temporal graphs of events from multiple documents in a news corpus. This is achieved with the help of redundancy of information in this corpus. Therefore, we will use a cascade of classifiers and other modules, each of them using the relations deduced by the previous one. All modules predict a relation between two documents (*i.e.*, two events).

We did not focus on complex algorithms or classifiers for tuning our results, and most of our features are very simple. The idea here is to show that good results can be obtained in this original and useful task. The process can be separated into 3 main stages, illustrated in Figure 6:

A. Filtering out pairs that have no relation at all, *i.e.* classifying between *nil* and *non-nil* relations;

B. Classifying between *same-event* and *continuation* relations;

C. Extracting *reactions* from the set of *continuation* relations.

All described classifiers use SMO (Platt, 1998), the SVM optimization implemented into Weka (Hall et al., 2009), with logistic models fitting (option "-M"). With this option, the confidence score of each prediction can be used, while SMO alone provides a constant probability for all instances.

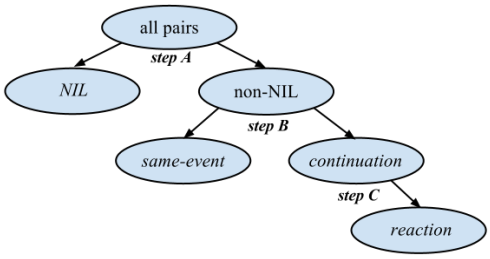

Figure 6: A 3-step classification.

From now on, when considering a pair of documents, we will refer to the older document as document 1, and to the more recent one as document 2. The relations found between documents will be represented by a directed graph where documents are vertices and relations are edges.

4.1 A. Nils *versus* non-nils

We first aim at separating *nil* relations (no relation between two events) from other relations. This step is achieved by two successive classifiers: the first one (A.1) uses mainly similarity measures between documents, while the second one (A.2) uses the relations obtained by the first one.

4.1.1 Step A.1: Nil classifier, level 1

Features provided to the SMO classifier at this first step are based on 3 different similarity measures applied to pairs of titles, pairs of first sentences, and pairs of entire documents: cosine similarity (as implemented by Lucene search engine[3]), inclusion similarity (rate of words from element 1 present in element 2) and overlap similarity (number of words present in both elements). This classifier is therefore based on only 9 features.

4.1.2 Step A.2: Nil classifier, level 2

Finding relations on a document implies that the described event is important enough to be addressed by several articles (*same-event*) or to have consequences (*continuation*). Consequently, if we find such relations concerning a document, we are more likely to find more of them, because this means that

[3] `http://lucene.apache.org`

the document has some importance. A typical example is shown in Figure 7, where an event described by several documents (on the left) has many continuations. For this reason, we build a second classifier A.2 using additional features related to the relations found at step A.1:

- Number of non-nil edges, incoming to or outgoing from document 1 (2 features); the sum of both numbers (1 extra feature);
- Number of non-nil edges, incoming to or outgoing from document 2 (2 features); the sum of both numbers (1 extra feature);
- Number of non-nil edges found involving one of the two documents (*i.e.*, the sum of all edges described above – 1 feature).

These figures have been computed on training set for training, and on result of step A.1 classifier for testing. This new information will basically help the classifier to be more optimistic toward non-nil relations for documents having already non-nil relations.

4.2 B. Same-event *versus* Continuation

We are now working only with *non-nil* relations (even if some relations may switch between *nil* and *non-nil* during the transitive closure).

4.2.1 Step B.1: Relation classifier, level 1

Distinction between *same-event* and *continuation* is made by the following sets of features:

- Date features:
  - Difference between the two document creation times (DCTs): difference in days, in hours, in minutes (3 features);
  - Whether the creation time of doc. 1 is mentioned in doc. 2. For this purpose, we use the date normalization system described in Kessler et al. (2012).
  - Cosine similarity between the first sentence of doc. 1 and sentences of doc. 2 containing the DCT of doc. 1.
  - Cosine similarity between the first sentence of doc. 1 and the most similar sentence of doc. 2.

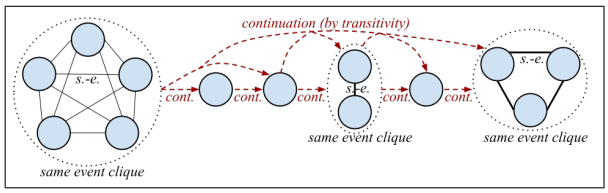

Figure 7: An example of highly-connected subgraph, corresponding to the development of an important story. Same events are grouped by cliques (see Section 4.2.3) and some redundant relations are not shown for clarity's sake.

These last three features come from the idea that a *continuation* relation can be made explicit in text by mentioning the first event in the second document.

- Temporal features: whether words introducing temporal relations occur in document 1 or document 2. These manually-collected words can be prepositions (*after, before*, etc.) or verbs (*follow, confirm, prove*, etc.).
- Reaction features: whether verbs introducing reactions occur in document 1 or document 2 (25 manually-collected verbs as *approve, accept, welcome, vow*, etc.).
- Opinion features: whether opinion words occur in document 1 or document 2. The list of opinion words comes from the MPQA subjectivity lexicon (Wilson et al., 2005).

Only *same-event* relations classified with more than 90% confidence by the classifier are kept, in order to ensure a high precision (recall will be improved at next step). This threshold has been set up on development set.

4.2.2 Step B.2: Relation classifier, level 2

As for step A.2, a second classifier is implemented, using the results of step B.1 with the same manner as A.2 uses A.1 (collecting numbers of *same-event* and *continuation* relations that have been found by the previous classifier).

4.2.3 Steps B.3 and B.4: Transitive closure by vote

As already stated, *same-event* and *continuation* relations are transitive. *Same-event* is also symmetric (A *same-event* B $\Rightarrow$ B *same-event* A). In the

graph formed by documents (vertices) and relations (edges), it is then possible to find all cliques, *i.e.* subsets of vertices such that every two vertices in the subset are connected by a *same-event* relation, as illustrated by Figure 7.

This step does not involve any learning phase. Starting from the result of last step, we find all *same-event* cliques in the graph by using the Bron and Kerbosch (1973) algorithm. The transitive closure process is then illustrated by Figure 8. If the classifier proposed a relation between some documents of a clique and some other documents (as D1, D2 and D3), then a vote is necessary:

- If the document is linked to half or more of the clique, then all missing links are created (Figure 8.a);
- Otherwise, the document is entirely disconnected from the clique (Figure 8.b).

This vote is done for *same-event* and *continuation* relations (resp. steps B.3 and B.4). Only cliques containing at least 3 nodes are used. A drawback of this voting procedure is that the final result may not be independent of the voting order, in some cases. However, it is assured that the result is consistent, *i.e.* that no document will sit in two different cliques, or that two documents from the same clique will not have two different relations toward a third document.

Note that this vote leads to improvements only if the precision of the initial classifier is sufficiently good. As we will see in Section 5.2, this is the case in our situation, but one must keep in mind that a vote leaning on too imprecise material would lead to even worse results. Some experiments on the development set show us that at least 70% precision was necessary. Another way to ensure robustness of the vote would be to apply the transitive closure only on bigger cliques (*e.g.*, containing more than 3 or 4 nodes).

4.3 C. Continuation *versus* Reaction

The approach for reaction extraction is different. We first try to determine which documents describe reactions, regardless of which event it is a reaction to. In the training set, all documents having at least one incoming *reaction* edge are considered as reaction

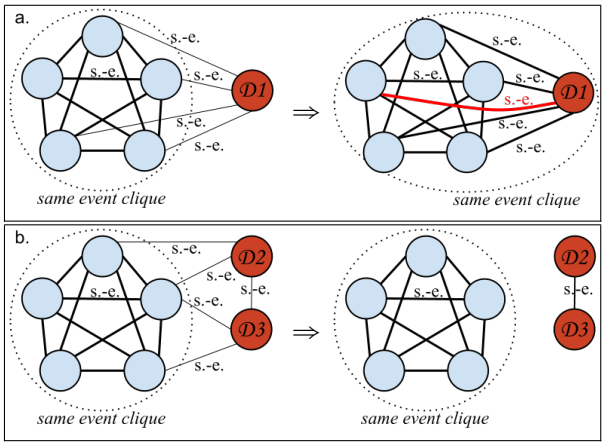

Figure 8: Vote for *same-event* transitive closure. At the top (a.), four nodes from the 5-node clique are linked to document D_1, which is enough to add D_1 to the clique. At the bottom (b.), only two nodes from the clique are linked to documents D_2 and D_3, which is not enough to add them into the clique. All edges from the clique to D_2 and D_3 are then deleted.

documents, all others are not. This distinction is then learned with the same model and features as for step B.1 (Section 4.2.1).

Once reaction documents have been selected, the question is how to decide to which other document(s) it must be linked. For example, in Figure 1, *"Queen Elizabeth expresses deep sorrow"* is a reaction to pope's death, not to other documents in the temporal thread (for example, not to other reactions or to *"Pope in serious condition"*). We did not manage to build any classifier leading to satisfying results at this point. We then proposed the two following basic heuristics, applied on all *continuation* relations found after step B:

- A reaction reacts to only one event.
- A reaction reacts to an important event. Then, among all *continuation* edges incoming to the reaction document, we choose the biggest *same-event* clique and create *reaction* edges instead of *continuations*. If there is no clique (only single nodes) or several same-size cliques, all of them are tagged as *reactions*.

This module is called step C.1. Finally, a transitive closure is performed for reactions (C.2).

Relation	Precision	Recall	F1
NIL	0.754	0.821	0.786
same-event	0.832	0.812	0.822
continuation	0.736	0.696	0.715
↳ *reaction*	0.273	0.077	0.120

Table 2: Results obtained by the baseline system. *Continuation* scores do not consider reactions, only the last row makes the distinction.

5 Results

5.1 Baseline

As a baseline, we propose a single classifier determining all classes at once, based on the same SMO classifier with the exact same parameters and all similarity-based features (on titles, first sentences and entire documents) described in Section 4.1.1.

Table 2 shows results for this baseline. Unsurprisingly, *same-event* relations are quite well classified by this baseline, since similarity is the major clue for this class. *Continuation* is much lower and only 3 reactions are well detected.

5.2 System Evaluation

Results for all successive steps described in previous section are shown in Figure 3. The final result of the entire system is the last one. The first observation is that redundancy-based steps improve performance in a significant manner:

- Classifiers A.2 and B.2, using the number of incoming or outgoing edges found at previous steps, lead to very significant improvement.
- Among transitivity closure algorithms (B.3, B.4, C.2), only *same-event* transitivity B.3 leads to significant improvement. Furthermore, as we already noticed, these algorithms must be used only when a good precision is guaranteed at previous step. Otherwise, there is a risk of inferring mostly bad relations. This is why we biased classifier at step B.1 towards precision. Finally, if this condition on precision is true, transitivity closure is a robust way to get new relations for free.

Results also tell that classification of relations *same-event* and *continuation* is encouraging. *Reaction* level gets a fair precision but a bad recall. This is not catastrophic since most of the missed reactions are tagged as *continuation*, which is still true (only 10% of the *reaction* relations are mistagged as *same-event*). However, there is big room for improvement on this point.

Step	**Relation**	**Precision**	**Recall**	**F1**
A. *NIL* vs *non-NIL classifier*				
A.1	NIL	0.764	0.815	0.788
	non-NIL	0.921	0.896	0.910
A.2 ***	NIL	0.907	0.811	0.857
	non-NIL	0.925	0.966	0.945
B. *Same-event* vs *continuation classifier*				
B.1	NIL	0.907	0.811	0.857
	same-event	0.870	0.553	0.676
	continuation	0.664	0.867	0.752
B.2 ***	NIL	0.947	0.831	0.885
	same-event	0.894	0.724	0.800
	continuation	0.744	0.911	0.819
B.3 **	NIL	0.884	0.831	0.857
	same-event	0.943	0.819	0.877
	continuation	0.797	0.906	0.848
B.4 *	NIL	0.890	0.831	0.860
	same-event	0.943	0.819	0.877
	continuation	0.798	0.911	0.851
C. *Reaction* vs *continuation*				
C.1	NIL	**0.890**	**0.831**	**0.860**
C.2	same-event	**0.943**	**0.819**	**0.877**
	continuation	**0.798**	**0.911**	**0.851**
	↳ reaction	**0.778**	**0.359**	**0.491**

Table 3: Results obtained at each step of the classification process. The significance of the improvement wrt previous step (when relevant) is indicated by the Student t-test (*: non significant; **: $p < 0.05$ (significant); ***: $p < 0.01$ (highly significant)). Steps C.1 and C.2 are aggregated, since their results are exactly the same.

6 Application

As we showed in previous section, results for classification of *same-event* and *continuation* relations between documents are good enough to use this system in an application that builds "event threads" around an input document. The use case is the following:

- The reader reads an article (let's say, about the death of John Paul II, article published on Feb. 4th, 2005 (UT) – see Figure 1).
- A link in the page suggests the user to visualize the event thread around this article.

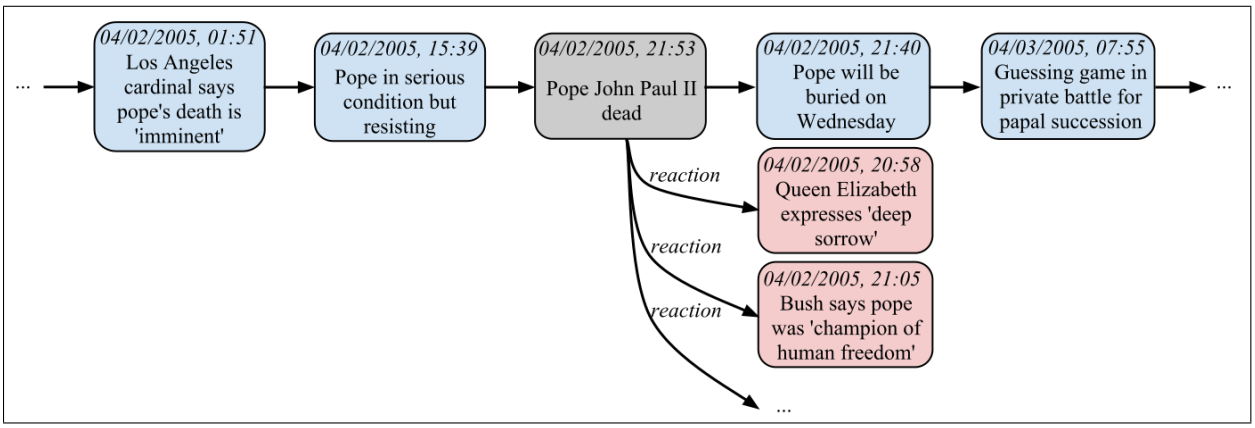

Figure 9: An example of temporal thread obtained on the death of John Paul II for user visualization (see corresponding relation graph in Figure 1).

- All articles within a period of 7 days around the event, sharing at least two keywords with the current document, are collected. All pairs are given to the system[4].
- When *same-event* cliques are found, only the longest article (often, the most recent one) of each clique is presented to the user. However, the date and time presented to the user are those of the first article relating the event.
- This leads to a graph with only *continuation* and *reaction* relations. Edges are "cleaned" so that a unique thread is visible: relations that can be obtained by transitivity are removed, edges between two documents are kept only if no document can be inserted in-between.
- Nodes are presented in chronological order. The user can visualize and navigate through this graph (the event thread shows only titles but full articles can be accessed by clicking on the node).
- When found, reactions are isolated from the main thread.
- Such a temporal thread is potentially infinite. If the user navigates through the end of the 7-day window, the system must be run again on the next time span.

[4]In case of very important events where "all pairs" would be too much, the temporal window is restrained. However, there is no real time performance issue in this system.

Figure 9 presents the result of this process on the partial temporal graph shown in Figure 1.

7 Conclusion

This article presents a task of multidocument temporal graph building. We make the assumption that each news article (after filtering) relates an event, and we present a system extracting relations between articles. This system uses simple features and algorithms but takes advantage of the important redundancy of information in a news corpus, by incorporating redundancy information in a cascade of classifiers, and by using transitivity of relations to infer new links.

Finally, we present an application presenting "event threads" to the user, in order to contextualize the information and recomposing the story of an event.

Now that the task is well defined and that encouraging results have been obtained, we envisage to enrich classifiers by more fine-grained temporal and lexical information, such as narrative chains (Chambers and Jurafsky, 2008) for *continuation* relation or event clustering (Barzilay et al., 2002) for *same-event* relation. There is no doubt that *reaction* detection can be improved a lot, by going beyond simple lexical features and discovering specific patterns. We also intend to adapt the described system to other languages than English.

Abstract

Scope detection is a key task in information extraction. This paper proposes a new approach for tree kernel-based scope detection by using the structured syntactic parse information. In addition, we have explored the way of selecting compatible features for different part-of-speech cues. Experiments on the BioScope corpus show that both constituent and dependency structured syntactic parse features have the advantage in capturing the potential relationships between cues and their scopes. Compared with the state of the art scope detection systems, our system achieves substantial improvement.

1 Introduction

The task of scope detection is to detect the linguistic scope dominated by a specific cue. Current researches in this field focus on two semantic aspects: negation and speculation. The negative scope detection is to detect the linguistic scope which is repudiated by a negative word (viz., negative cue, e.g., "*not*"). In other side, the speculative scope detection is to detect the uncertain part in a sentence corresponding to the speculative word (viz., speculative cue, e.g., "*seems*"). See the sentence 1) below, the negative cue "*not*" dominates the scope of "*not expensive*". Similarly, the speculative cue "*possible*" in sentence 2) dominates the uncertain scope "*the possible future scenarios*".

1) *The chair is* [***not*** *expensive*] *but comfortable*.
2) *Considering all that we have seen, what are now* [*the* ***possible*** *future scenarios*]*?*

The negative and speculative scope detection task consists of two basic stages. The first one is to identify the sentences involving negative or speculative meaning. The second stage is to detect the linguistic scope of the cue in sentences (Velldal et al, 2012). In this paper, we focus on the second stage. That is, by given golden cues, we detect their linguistic scopes.

We propose a tree kernel-based negation and speculation scope detection with structured syntactic parse features. In detail, we regard the scope detection task as a binary classification issue, which is to classify the tokens in a sentence as being inside or outside the scope. In the basic framework, we focus on the analysis and application of structured syntactic parse features as follows:

Both constituent and dependency syntactic features have been proved to be effective in scope detection (Özgür et al, 2009; Øvrelid et al, 2010). However, these flat features are hardly to reflect the information implicit in syntactic parse tree structures. Our intuition is that the segments of the syntactic parse tree around a negative or speculative cue is effective for scope detection. The related structures normally underlay the indirect clues to identify the relations between cues and their scopes, e.g., in sentence 1), "***but*** *something*", as a frequently co-occurred syntactic structure with "***not*** *something*", is an effective clue to determine the linguistic scope of "***not***".

The tree kernel classifier (Moschitti, 2006) based on support vector machines uses a kernel function between two trees, affording a comparison between their substructures. Therefore, a tree kernel-based scope detection approach with structured syntactic parse tree is employed. The tree

kernel has been already proved to be effective in semantic role labeling (Che et al, 2006) and relation extraction (Zhou et al, 2007).

In addition, the empirical observation shows that features have imbalanced efficiency for scope classification, which is normally affected by the part-of-speech (abbr., POS) of cues. Hence, we build the discriminative classifiers for each kind of POS of cues, then explore and select the most compatible features for them.

We construct a scope detection system by using the structured syntactic parse features based tree kernel classification. Compared with the state of the art scope detection systems, our system achieves the performance of accuracy 76.90% on negation and 84.21% on speculation (on Abstracts sub-corpus). Additionally, we test our system on different sub-corpus (Clinical Reports and Full Papers). The results show that our approach has better cross-domain performance.

The rest of this paper is organized as follows: Section 2 reviews related work. Section 3 introduces the corpus and corresponding usage in our experiments. Section 4 describes our approach and the experiments are presented in Section 5. Finally, there is a conclusion in Section 6.

2 Related Work

Most of the previous studies on negation and speculation scope detection task can be divided into two main aspects: the heuristic rule based methods and the machine learning based methods. We respectively introduce the aspects in below.

2.1 Heuristic Rule based Methods

The initial studies for scope detection are to compile effective heuristic rules (Chapman et al, 2001; Goldin et al, 2003). Recently, the heuristic rule based methods have further involved the syntactic features.

Huang et al (2007) implemented a hybrid approach to automated negation scope detection. They combined the regular expression matching with grammatical parsing: negations are classified on the basis of syntactic categories and located in parse trees. Their hybrid approach is able to identify negated concepts in radiology reports even when they are located at some distance from the negative term.

Özgür et al (2009) hypothesized that the scope of a speculation cue can be characterized by its part-of-speech and the syntactic structure of the sentence and developed rules to map the scope of a cue to the nodes in the syntactic parse tree. By given golden speculation cues, their rule-based method achieves the accuracies of 79.89% and 61.13% on the Abstracts and the Full-Papers sub-corpus, respectively.

Øvrelid et al (2010) constructed a small set of heuristic rules which define the scope for each cue. In developing these rules, they made use of the information provided by the guidelines for scope annotation in the BioScope corpus, combined with manual inspection of the training data in order to further generalize over the phenomena discussed by Vincze et al (2008) and work out interactions of constructions for various types of cues.

Apostolova et al (2011) presented a linguistically motivated rule-based system for the detection of negation and speculation scopes that performs on par with state-of-the-art machine learning systems. The rules are automatically extracted from the BioScope corpus and encode lexico-syntactic patterns in a user-friendly format. While their system was developed and tested using a biomedical corpus, the rule extraction mechanism is not domain-specific.

The heuristic rule based methods have bad robustness in detecting scopes crossing different meaning aspects (e.g., negative vs. speculative) and crossing different linguistic resources (e.g., Technical Papers vs. Clinical Reports).

2.2 Machine Learning based Methods

The machine learning based methods have been ignored until the release of the BioScope corpus (Szarvas et al, 2008), where the large-scale data of manually annotated cues and corresponding scopes can support machine learning well.

Morante et al (2008) formulated scope detection as a chunk classification problem. It is worth noting that they also proposed an effective proper post-processing approach to ensure the consecutiveness of scope. Then, for further improving the scope detection, Morante et al (2009a) applied a meta-learner that uses the predictions of the three classifiers (TiMBL/SVM/CRF) to predict the scope.

For the competitive task in CoNLL'2010 (Farkas et al, 2010), Morante et al (2010) used a

memory-based classifier based on the k-nearest neighbor rule to determine if a token is the first token in a scope sequence, the last, or neither. Therefore, in order to guarantee that all scopes are continuous sequences of tokens they apply a first post-processing step that builds the sequence of scope.

The existing machine learning based approaches substantially improve the robustness of scope detection, and have nearly 80% accuracy. However, the approaches ignore the availability of the structured syntactic parse information. This information involves more clues which can well reflect the relations between cues and scopes. Sánchez et al (2010) employed a tree kernel based classifier with CCG structures to identify speculative sentences on Wikipedia dataset. However, in Sánchez's approach, not all sentences are covered by the classifier.

3 Corpus

We have employed the BioScope corpus (Szarvas et al, 2008; Vincze et al, 2008)[1], an open resource from the biomedical domain, as the benchmark corpus. The corpus contains annotations at the token level for negative and speculative cues and at the sentence level for their linguistic scope (as shown in Figure 1).

<sentence id="S26.8"> *These findings* <xcope id="X26.8.2"> <cue type="**speculation**" ref="X26.8.2"> *indicate that* </cue> <xcope id="X26.8.1"> *corticosteroid resistance in bronchial asthma* <cue type="**negation**" ref="X26.8.1"> *can not* </cue> *be explained by abnormalities in corticosteroid receptor characteristics* </xcope></xcope> . </sentence>

(Note: <Sentence> denotes one sentence and the tag "id" denotes its serial number; <xcope> denotes the scope of a cue; <cue> denotes the cue, the tag "type" denotes the specific kind of cues and the tag "ref" is the cue's serial number.)

Figure 1. An annotated sentence in BioScope.

The BioScope corpus consists of three sub-corpora: biological Full Papers from FlyBase and BMC Bioinformatics, biological paper Abstracts from the GENIA corpus (Collier et al, 1999), and Clinical Reports. Among them, the Full Papers sub-corpus and the Abstracts sub-corpus come from the same genre. In comparison, the Clinical Reports sub-corpus consists of clinical radiology reports with short sentences.

[1] http://www.inf.u-szeged.hu/rgai/bioscope

In our experiments, if there is more than one cue in a sentence, we treat them as different cue and scope (two independent instances). The statistical data for our corpus is presented in Table 1 in below.

The average length of sentences in the negation portion is almost as long as that in speculation, while the average length of scope in negation is shorter than that in speculation. In addition, the length of sentence and scope in both Abstracts and Full Papers sub-corpora is comparative. But in Clinical Reports sub-corpus, it is shorter than that in Abstracts and Full Papers. Thus, looking for the effective features in short sentences is especially important for improving the robustness for scope detection.

		Abstract	**Paper**	**Clinical**
Negation	Sentences	1594	336	441
	Words	46849	10246	3613
	Scopes	1667	359	442

4 Methodology

We regard the scope detection task as a binary classification problem, which is to classify each token in sentence as being the element of the scope or not. Under this framework, we describe the flat syntactic features and employ them in our benchmark system. Then, we propose a tree kernel-based scope detection approach using the structured syntactic parse features. Finally, we construct the discriminative classifier for each kind of POS of cues, and select the most compatible features for each classifier.

4.1 Flat Syntactic Features

In our benchmark classification system, the features relevant to the cues or tokens are selected. Then, we have explored the constituent and dependency syntactic features for scope detection. These features are all flat ones which reflect the characteristic of tokens, cues, scopes, and the relation between them.

Basic Features: Table 2 shows the basic features which directly relate to the characteristic of cues or tokens in our basic classification.

Feature	Remark
B1	Cue.
B2	Candidate token.
B3	Part-of-speech of candidate token.
B4	Left token of candidate token.
B5	Right token of candidate token.
B6	Positional relation between cue and token.

Table 2. Basic features.

Constituent Syntactic Features: For improving the basic classification, we employ 10 constituent features belonging to two aspects. On the one hand, we regard the linguistic information of the neighbor locating around the candidate tokens as the coherent features (CS1~CS6 in Table 3). These features are used for detecting the close cooperation of a candidate token co-occurring with its neighbors in a scope. On the other hand, we regard the linguistic characteristics of the candidate tokens themselves in a syntactic tree as the inherent features (CS7~CS10 in Table 3). These features are used for determining whether the token has the direct relationship with the cue or not.

Features	Remarks
CS1	POS of left token.
CS2	POS of right token.
CS3	Syntactic category of left token.
CS4	Syntactic category of right token.
CS5	Syntactic path from left token to the cue.
CS6	Syntactic path from right token to the cue.
CS7	Syntactic category of the token.
CS8	Syntactic path from the token to the cue.
CS9	Whether the syntactic category of the token is the ancestor of the cue.
CS10	Whether the syntactic category of the cue is the ancestor of the token.

Table 3. Constituent syntactic features.

Features	Remarks
DS1	Dependency direction (*"head"or "dependent"*).
DS2	Dependency syntactic path from the token to cue.
DS3	The kind of dependency relation between the token and cue.
DS4	Whether the token is the ancestor of the cue.
DS5	Whether the cue is the ancestor of the token.

Table 4. Dependency syntactic features.

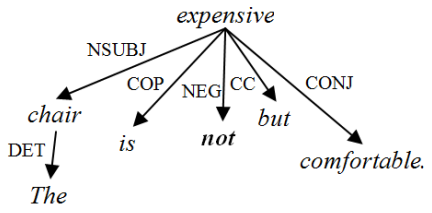
Dependency Syntactic Features: For the effectiveness to obtain the syntactic information far apart from cues, we use 5 dependency syntactic features which emphasize the dominant relationship between cues and tokens by dependency arcs as shown in Table 4.

The features in Table 2, 3, and 4 have imbalanced classification for the scope classification. Therefore, we adopt the greedy feature selection algorithm as described in Jiang et al (2006) to pick up positive features incrementally according to their contributions. The algorithm repeatedly selects one feature each time, which contributes most, and stops when adding any of the remaining features fails to improve the performance.

4.2 Structured Syntactic Features

Syntactic trees involve not only the direct bridge (e.g., syntactic path) between cue and its scope but also the related structures to support the bridge (e.g., sub-tree). The related structures normally involve implicit clues which underlay the relation between cue and its scope. Therefore, we use the constituent and dependency syntactic structures as the supplementary features to further improve the benchmark system.

Furthermore, we employ the tree kernel-based classifier to capture the structured information both in constituent and dependency parsing trees. The results of the constituent syntactic parser are typical trees which always consist of the syntactic category nodes and the terminal nodes. Thus, the constituent syntactic tree structures could be used in tree kernel-based classifier directly, but not for the dependency syntactic tree structures. As Figure 2 shows, in sentence "*The chair is not expensive but comfortable.*" the tree kernels cannot represent the relations on the arcs (e.g., "*CONJ*" between "*expensive*" and "*comfortable*"). It is hard to use the relations between tokens and cues in tree kernels.



Structure of Dependency Tree

Cue: ***not***

Scope: *not expensive*

Figure 2: The dependency tree of sentence "*The chair is not expensive but comfortable*."

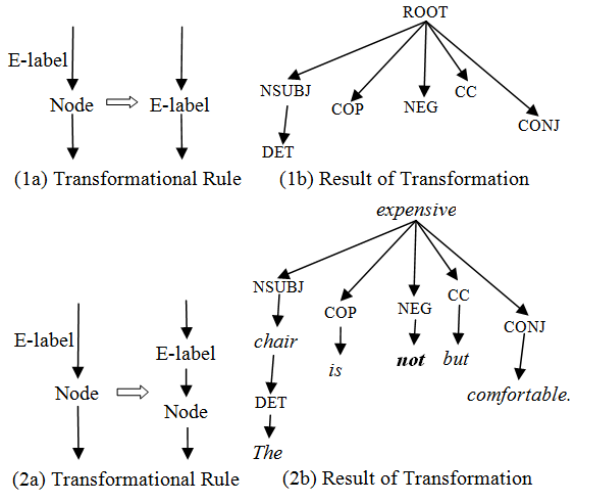


Figure 3. Two transformational rules.

To solve the problem, we transform the dependency tree into other two forms capable of being used directly as the compatible features in tree-kernel based classification. The transformational rules are described as below:

(1) Extracting the dependency relations to generate a tree of pure relations (named dependency relational frame), where the tokens on the nodes of original dependency tree are ignored and only the relation labels are used. E.g., the tokens "*chair*", "*is*", etc in Figure 2 are all deleted and replaced by the corresponding relation labels. E.g., "NSUBJ", "COP", etc are used as nodes in the dependency relational frame, see (1a) & (1b) in Figure 3.

(2) Inserting the tokens which have been deleted in step (1) into the dependency relational frame and making them follow and link with their original dependency relations. E.g., the tokens "*chair*", "*is*", etc are added below the nodes "NSUBJ", "COP", etc, see (2a) & (2b) in Figure 3.

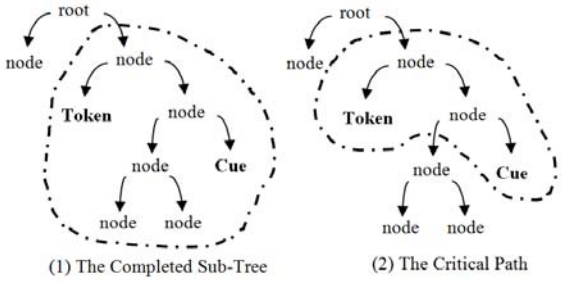

Figure 4. Two transformations for tree-kernel.

Within the constituent and dependency syntactic trees, we have employed both the Completed Sub-Tree and the Critical Path as the syntactic structure features for our classification. The former is a minimum sub-tree that involves the cues and the tokens, while the latter is the path from the cues to the tokens in the completed tree containing the primary structural information. Figure 4 shows them.

4.3 Part-of-Speech Based Classification Optimization

Motivating in part by the rule-based approach of Özgür et al (2009), we infer that features have imbalanced efficiency for scope classification, normally affected by the part-of-speech (POS) of cues.

POS of Cues	Number	POS of Cues	Number
CC	157	VB	31
IN	115	VBD	131
JJ	238	VBG	225
MD	733	VBN	112
NN	43	VBP	561
RB	137	VBZ	207

Table 5. Distribution of different POSs of speculative cues in Abstracts sub-corpus.

Table 5 shows the distribution for different POSs of cues in the Abstracts sub-corpus of BioScope for speculation detection task. The cues of different POS usually undertake different syntactic roles. Thus, there are different characteristics in triggering linguistic scopes. See the two examples below:

3) *TCF-1 contained a single DNA box in the* [***putative*** *mammalian sex-determining gene SRY*].
4) *The circadian rhythm of plasma cortisol* [***either*** *disappeared* ***or*** *was inverted*].

The speculative cue "*putative*" in sentence 3) is an adjective. The corresponding scope is its modificatory structure ("*putative mammalian sex-determining gene SRY*"). In sentence 4), "*either…or…*" is a conjunction speculation cue. Its scope is the two connected components ("*either disappeared or was inverted*"). Thus, the effective features for the adjectival cue are normally the dependency features, e.g., the features of DS1 and DS5 in Table 4, while the features for the conjunction cue are normally the constituent information, e.g., the features of CS9 in Table 3.

In Table 5, considering the different function of verb voice, we cannot combine the "VB(*)" POS. For instance, the POS of "*suggest*" in sentence 5) is "VBP" (the verb present tense). The corresponding scope does not involve the sentence subject.

The POS of "*suggested*" in sentence 6) is "VBN" (the past participle). The scope involves the subject "*An age-related decrease*".

5) *These results* [***suggest*** *that the genes might be involved in terminal granulocyte differentiation*].
6) [*An age-related decrease was* ***suggested*** *between subjects younger than 20 years*].

As a result, we have built a discriminative classifier for each kind of POS of cues, and then explored and selected the most compatible features for each classifier.

5 Experiments and Results

5.1 Experimental Setting

Considering the effectiveness of different features, we have split the Abstracts sub-corpus into 5 equal parts, within which 2 parts are used for feature selection (Feature Selection Data) and the rest for the scope detection experiments (Scope Detection Data). The Feature Selection Data are divided into 5 equal parts, within which 4 parts for training and the rest for developing. In our scope detection experiments, we divide the Scope Detection Data into 10 folds randomly, so as to perform 10-fold cross validation. As the experiment data is easily confusable, Figure 5 illustrates the allocation.

Checking the validity of our method, we use the Abstracts sub-corpus in Section 5.2, 5.3 and 5.4, while in Section 5.5 we use all of the three sub-corpora (Abstracts, Full Papers, and Clinical Reports) to test the robustness of our system when applied to different text types within the same domain.

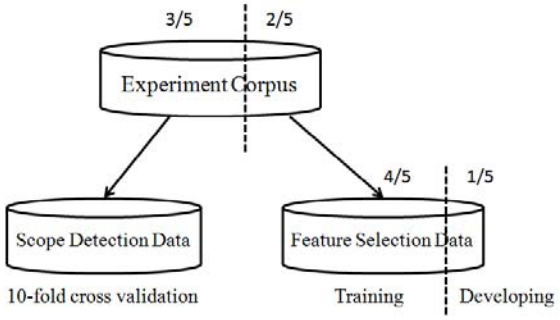

Figure 5. The allocation for experiment data.

The evaluation is made using the precision, recall and their harmonic mean, F1-score. Additionally, we report the accuracy in PCS (Percentage of Correct Scopes) applied in CoNLL'2010, within which a scope is fully correct if all tokens in a sentence have been assigned to the correct scope class for a given cue. The evaluation in terms of precision and recall measures takes a token as a unit, whereas the evaluation in terms of PCS takes a scope as a unit. The key toolkits for scope classification include:

Constituent and Dependency Parser: All the sentences in BioScope corpus are tokenized and parsed using the Berkeley Parser (Petrov et al, 2007) [2] which have been trained on the GENIA TreeBank 1.0 (Tateisi et al, 2005)[3], a bracketed corpus in PTB style. 10-fold cross-validation on GTB1.0 shows that the parser achieves 87.12% in F1-score. On the other hand, we obtain the dependency relations by the Stanford Dependencies Parser[4].

Support Vector Machine Classifier: SVM^{Light}[5] is selected as our classifier, which provides a way to combine the tree kernels with the default and custom SVM^{Light} kernels. We use the default parameter computed by SVM^{Light}.

Besides, according to the guideline of the BioScope corpus, scope must be a continuous chunk. The scope classifier may result in discontinuous blocks, as each token may be classified inside or outside the scope. Therefore, we perform the rule based post-processing algorithm proposed by Morante et al (2008) to obtain continuous scopes.

5.2 Results on Flat Syntactic Features

Relying on the results of the greedy feature selection algorithm (described in Section 4.1), we obtain 9 effective features {B1, B3, B6, CS3, CS4, CS9, DS1, DS3, DS5} (see Table 2, 3 and 4) for negation scope detection and 13 effective features {B3, B4, B5, B6, CS1, CS5, CS6, CS8, CS9, CS10, DS1, DS4, DS5} for speculation. Table 6 lists the performances on the Scope Detection Data by performing 10-fold cross validation. It shows that flat constituent and dependency syntactic features significantly improve the basic scope detection by 13.48% PCS for negation and 30.46% for speculation (χ^2; $p < 0.01$). It demonstrates that the selected syntactic features are effective for scope detection.

	Features	P	R	F	PCS
Negation	Basic	89.89	68.72	77.86	39.50
	Con.	85.72	67.80	75.66	41.81
	Dep.	90.31	69.01	78.19	40.08
	Bas.&Con.	88.86	79.07	83.61	51.64
	Bas.&Dep.	90.44	73.62	81.17	49.36
	All	91.21	76.57	83.25	52.98
	Features	**P**	**R**	**F**	**PCS**
Speculation	Basic	89.67	86.86	88.24	40.09
	Con.	96.43	87.46	91.72	66.57
	Dep.	90.84	87.04	88.89	44.45
	Bas.&Con.	95.66	92.08	93.83	69.59
	Bas.&Dep.	92.39	88.27	90.28	67.49
	All	95.71	92.09	93.86	70.55

(Note: "Bas." denotes basic features; "Con." denotes Constituent features; "Dep." denotes Dependency features; "All" contains Basic, Constituent, and Dependency features being selected.)

Table 6. Performance of flat syntactic features.

The results also show that the speculative scope detection achieves higher performance (16.98% higher in PCS) (χ^2; $p < 0.01$) than the negation scope detection. The main reason is that although the average sentence length of negation and speculation are comparable (29.97 vs. 29.39 words, in Table 1), the average length of speculation scopes is much longer than the negation (17.24 vs. 9.62 words, in Table 1) in Abstracts sub-corpus. With the shorter scopes in training data, the classifier inevitably have more negative samples. Thus, by using a token as the basic unit in our classification, the imbalanced samples will seriously mislead the classifier and result in bias on the negative samples.

In addition, both constituent and dependency flat features can improve the scope classification, for the reason that the constituent features usually provide the nearer syntactic information of the cues, and that the further syntactic information between cues and scopes have been obtained by the dependency features.

5.3 Results on Structured Syntactic Parse Features

Table 7 and Table 8 give the scope detection performance using the different structured syntactic parse features on negation and speculation respectively. Compared to the optimal system (using all of the selected flat features in Table 6) in Section 5.2, the structured syntactic parse features at best improve the scope classification nearly 17.29% on negation (PCS=70.27%) and 12.32% on speculation (PCS=82.87%) (χ^2; $p < 0.01$). It indicates that the structured syntactic parse features can provide more implicit linguistic information, as supplementary clues, to support scope classification.

The improvements also show that both the completed syntactic sub-trees and critical paths in constituent and dependency parsing trees are effective. The reason is that the completed syntactic sub-trees contain the surrounding information related to cues and tokens, while there are more direct syntactic information in the critical paths between cue and its scope.

5.4 Results on Part-of-Speech Based Classification

To confirm the assumption in Section 4.3, we have built a discriminative classifier for each kind of POS of cues. Considering that the features involving the global structured syntactic parse information in Section 4.2 are almost effective to all instances, we only use the flat syntactic features in Section 4.1.

	System	P	R	F	PCS
Negation	All Features	91.21	76.57	83.25	52.98
	POS Classifier	91.79	78.29	84.50	56.77
Speculation	**System**	**P**	**R**	**F**	**PCS**
	All Features	95.71	92.09	93.86	70.55
	POS Classifier	95.79	93.13	94.44	71.68

(Note: "All Features" System is the optimal system in Section 5.2)

Table 9. Performances of POS based classification.

Table 9 shows the performance of POS based classification. Compared with the system which only uses one classifier for all cues in Section 5.2,

the POS based classification improves 1.13% on PCS (χ^2; $p < 0.01$), as different POS kinds of cues involve respectively effective features with more related clues between cue and its scope.

Table 10 lists the performance of each POS kind of cues in speculation scope classification. There are still some low performances in some kinds of POS of cues. We consider it caused by two reasons. Firstly, some kinds of POS of cues (e.g. NN etc.) have fewer samples (just 43 samples shown in Table 5). For this reason, the training for classifier is limited. Then, for these low performance kinds of POS of cues, we may have not found the effective features for them. Although there are some kinds of cues with low performance, the whole performance of part-of-speech based classification is improved.

Cue's POS	B1~B6						CS1~CS10										DS1~DS5					PCS
	1	2	3	4	5	6	1	2	3	4	5	6	7	8	9	10	1	2	3	4	5	
CC	√				√	√				√			√			√	√	√	√		√	38.45

VBG				√	√				√	√			√		√	√	√	√		√	√	82.89
VBN				√	√				√				√		√	√	√	√		√		66.38
VBP				√	√	√	√			√	√			√	√	√	√	√		√		81.91
VBZ				√	√	√	√			√	√			√	√	√	√	√		√		77.16

Table 10. Performance of each POS kind of cues in speculation scope classification.

5.5 Results of Comparison Experiments

To get the final performance of our approach, we train the classifiers respectively by different effective features in Section 4.1 for POS kinds of cues, and use the structured syntactic parse features in Section 4.2 on Abstracts sub-corpus by performing 10-fold cross validation.

	System	Abstract	Paper	Clinical
Negation	Morante (2008)	57.33	N/A	N/A
	Morante (2009a)	73.36	50.26	87.27
	Ours	76.90	61.19	85.31
	System	**Abstract**	**Paper**	**Clinical**
Speculation	Morante (2009b)	77.13	47.94	60.59
	Özgür (2009)	79.89	61.13	N/A
	Ours	84.21	67.24	72.92

Table 11. Performance comparison of our system with the state-of-the-art ones in PCS.

The results in Table 11 show that our system outperforms the state of the art ones both on negation and speculation scope detection. Results also show that the system is portable to different types of documents, although performance varies depending on the characteristics of the corpus.

In addition, on both negation and speculation, the results on Clinical Reports sub-corpus are better than those on Full Papers sub-corpus. It is mainly due to that the clinical reports are easier to process than full papers and abstracts. The average length of sentence for negative clinical reports is 8.19 tokens, whereas for abstracts it is 29.39 and for full papers 30.49. Shorter sentences imply shorter scopes. The more unambiguous sentence structure of short sentence can make the structured constituent and dependency syntactic features easier to be processed.

6 Conclusion

This paper proposes a new approach for tree kernel-based scope detection by using the structured syntactic parse information. In particular, we have explored the way of selecting compatible features for different part-of-speech cues. Experiments show substantial improvements of our scope classification and better robustness.

However, the results on the Full Papers and the Clinical Reports sub-corpora are lower than those on the Abstracts sub-corpus for both negation and speculation. That is because the structured syntactic parse features contain some complicated and lengthy components, and the flat features cross corpus are sparse. Our future work will focus on the pruning algorithm for the syntactic structures and analyzing errors in depth in order to get more effective features for the scope detection on different corpora.

A temporal model of text periodicities using Gaussian Processes

Daniel Preoţiuc-Pietro, Trevor Cohn

Sheffield, S1 4DP, United Kingdom
{daniel,t.cohn}@dcs.shef.ac.uk

Abstract

Temporal variations of text are usually ignored in NLP applications. However, text use changes with time, which can affect many applications. In this paper we model periodic distributions of words over time. Focusing on hashtag frequency in Twitter, we first automatically identify the periodic patterns. We use this for regression in order to forecast the volume of a hashtag based on past data. We use Gaussian Processes, a state-of-the-art bayesian non-parametric model, with a novel periodic kernel. We demonstrate this in a text classification setting, assigning the tweet hashtag based on the rest of its text. This method shows significant improvements over competitive baselines.

1 Introduction

Temporal changes in text corpora are central to our understanding of many linguistic and social phenomena. Social Media platforms and the digitalization of libraries provides a vast body of timestamped data. This allows studying of the complex temporal patterns exhibited by text usage including highly non-stationary distributions and periodicities. However, temporal effects have been mostly ignored by previous work on text analysis or at best dealt with by making strong assumptions such as smoothly varying parameters with time (Yogatama et al., 2011) or modelled using a simple uni-modal distri bution (Wang and McCallum, 2006). This paper develops a temporal model for classifying microblog posts which explicitly incorporates multimodal periodic behaviours using Gaussian Processes (GPs).

We expect text usage to follow multiple periodicities at different scales. For example, people on Social Media might talk about different topics during and after work on weekdays, talk every Friday about the weekend ahead, or comment about their favorite weekly TV show during its air time. Given this, text frequencies will display periodic patterns. This applies to other text related quantities like co-occurrence values or topic distributions over time, as well as applications outside NLP like user behaviour (Preoţiuc-Pietro and Cohn, 2013).

Modelling temporal patterns and periodicities can be useful to tasks like text classification. For example a tweet containing 'music' is normally attributed to a general hashtag about music like #np (now playing). However, knowing time, if it occurs during the (weekly periodic) air time of 'American Idol' it is more likely for it to belong to #americanidol or if its mentioned in the days building up to the Video Music Awards to be assigned to #VMA.

In NLP, temporal models have treated time in overly simplistic ways and without regard to periodicities. We propose a model that first broadly identifies several types of temporal patterns: a) periodic, b) constant in time, c) falling out of use after enjoying a brief spell of popularity (e.g. internet memes, news). This is performed automatically only using training data and makes no assumptions on the existence or the length of the periods we aim to model. We demonstrate the approach by modelling frequencies of hashtag occurrences in Twitter. Hashtags are user-generated labels included in tweets by their authors in order to assign them to a conversation and can be considered as a proxy for topics.

To this end, we make use of Gaussian Processes (GP) (Rasmussen and Williams, 2005), a

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 977–988,
Seattle, Washington, USA, 18-21 October 2013.

Bayesian non-parametric model for regression. Using the *Bayesian evidence* we automatically perform model selection to classify temporal patterns. We aim to use the most suitable model for extrapolation, i.e. predicting future values from past observations. The GP is fully defined by the covariance structure assumed between the observed points, and its hyperparameters, which can be automatically learned from data. We also introduce a new kernel suitable to model the periodic behaviour we observe in text: periods of low frequency followed by bursts at regular time intervals. We demonstrate that the GP approach is more general and gives better results than frequentist models (e.g. autoregressive models) because it incorporates uncertainty explicitly and elegantly, in addition to automatic model selection and parameter fitting.

To demonstrate the practical importance of our approach, we use our GP prediction as a prior in a Naïve Bayes model for text classification showing improvements over baselines which do not account for temporal periodicities. Our approach extends to more general uses, e.g. to discriminative text regression and classification. More broadly, we aim to establish GPs as a state-of-the-art model for regression and classification in NLP. To our knowledge, this is the first paper to use GP regression for forecasting and model selection within a NLP task.

All the hashtag time series data and the implementation of the PS kernel in the popular open-source Gaussian Processes packages GPML[1] and GPy[2] are available on the author's website[3].

2 Related Work

Time varying text patterns have been of particular interest in topic modelling. Griffiths and Steyvers (2004) analyse evolution of topics over time, but without modelling time explicitly. Extensions that model time make different assumptions, usually regarding smoothing proprieties in (Wang and McCallum, 2006; Blei and Lafferty, 2006; Wang et al., 2008; Hennig et al., 2012). Yogatama et al. (2011) proposed a regulariser for generalised linear models that encourages local temporal smoothness.

Modelling periodicities is one of the standard applications of Gaussian Processes (Rasmussen and Williams, 2005). Recent work by Wilson and Adams (2013) and Durrande et al. (2013) show how different periods can be identified from data. In general, methods that assume certain periodicities at daily or weekly levels were proposed e.g. in (McInerney et al., 2013). GPs were used with text by Polajnar et al. (2011) and for Quality Estimation regression in (Cohn and Specia, 2013; Shah et al., 2013).

Temporal patterns for short, distinctive lexical items such as hashtags and memes were quantitatively studied (Leskovec et al., 2009) and clustered (Yang and Leskovec, 2011) in Social Media. (Yang et al., 2012) studies the dual role of hashtags, of bookmarks of content and symbols of community membership, in the context of hashtag adoption. (Romero et al., 2011) analyses the patterns of temporal diffusion in Social Media finding that hashtags have also a persistence factor.

For predicting future popularity of hashtags, Tsur and Rappoport (2012) use linear regression with a wide range of features. (Ma et al., 2012; Ma et al., 2013) frame the problem as classification into a number of fixed intervals and applies all the standard classifiers. None of these studies model periodicities, although the former stresses their importance for accurate predictions. For predicting the hashtag given the tweet text, Mazzia and Juett (2011) uses the Naïve Bayes classifier with the uniform and empirical prior or TF-IDF weighting.

3 Gaussian Processes

In this paper we consider Gaussian Process (GP) models of regression (Rasmussen and Williams, 2005). GP is a probabilistic machine learning framework incorporating kernels and Bayesian non-parametrics which is widely considered as state-of-the-art for regression. The GP defines a prior over functions which applied at each input point gives a response value. Given data, we can analytically infer the posterior distribution of these functions assuming Gaussian noise. The kernel of the GP defines the covariance in response values as a function of its inputs.

We can identify two different set-ups for a regression problem. If the range of values to be predicted

[1] http://www.gaussianprocess.org/gpml/code

[2] https://github.com/SheffieldML/GPy

[3] http://www.preotiuc.ro

lies *within* the bounds of the training set we call the prediction task as interpolation. If the range of the prediction is *outside* the bounds, then our problem that of extrapolation. In this respect, extrapolation is considered a more difficult task and the covariance kernel which incorporates our prior knowledge plays a major role in the prediction.

There is the case when multiple covariance kernels can describe our data. For choosing the right kernel and its hyperparameters only using the training data we employ Bayesian model selection which makes a trade-off between the fit of the training data and model complexity. We now briefly give an overview of GP regression, kernel choice and model selection. We refer the interested reader to (Rasmussen and Williams, 2005) for a detailed introduction to GPs.

3.1 Gaussian Process Regression

Consider a time series regression task where we only have one feature, the value x_t at time t. Our training data consists of n pairs $\mathcal{D} = \{(t, x_t)\}$. The model will need to predict values x_t for values of t greater than those in the dataset.

GP regression assumes a latent function f that is drawn from a GP prior $f(t) \sim \mathcal{GP}(m, k(t, t'))$ where m is the mean and k a kernel. The prediction value is obtained by the function evaluated at the corresponding data point, $x_t = f(t) + \epsilon$, where $\epsilon \sim \mathcal{N}(0, \sigma^2)$ is white-noise. The GP is defined by the mean m, here 0, and the covariance kernel function, $k(t, t')$.

The posterior at a test point t_* is given by:

$$p(x_*|t_*, \mathcal{D}) = \int_f p(x_*|t_*, f) \cdot p(f|\mathcal{D}) \qquad (1)$$

where x_* and t_* are the test value and time. The posterior $p(f|\mathcal{D})$ shows our belief over possible functions after observing the training set $\mathcal{D}$. The predictive posterior can be solved analytically with solution:

$$\begin{aligned} x_* \sim \mathcal{N}(&k_*^T (K + \sigma_n^2 I)^{-1} \mathbf{t}, \\ &k(t_*, t_*) - k_*^T (K + \sigma_n^2 I)^{-1} k_*) \end{aligned} \qquad (2)$$

where $k_* = [k(t_*, t_1) ... k(t_*, t_n)]^T$ are the kernel evaluations between the test point and all the training points, $K = \{k(t_i, t_j)\}_{j=1..n}^{i=1..n}$ is the Gram matrix over the training points and $\mathbf{t}$ is the vector of training points. The posterior of x_* includes the mean response as well as its variance, thus expressing the uncertainty of the prediction. In this paper, we will consider the forecast as the expected value. Due to the matrix inversion in 2, inference takes $O(n^3)$ time where n is the number of training points.

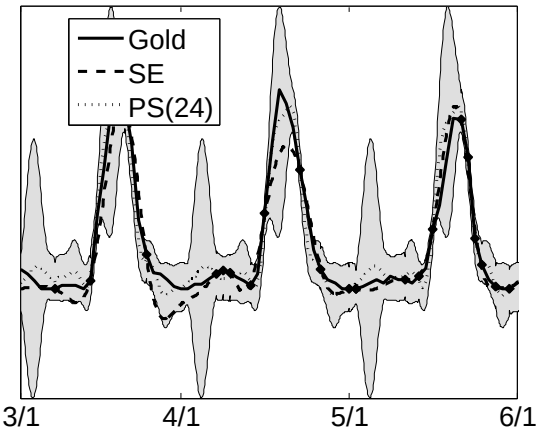

Figure 1: Interpolation for #goodmorning over 3 days with SE and PS(p=24,s=3) kernels. Prediction variance shown in grey for PS(24). Crosses represent training points.

3.2 Kernels

The covariance kernel together with its parameters fully define the GP (we assume 0 mean). The kernel induces similarities in the response between pairs of data points. Intuitively, if we want a smooth function, closer points should have high covariance compared to points that are further apart. If we want a periodic behaviour points at period length intervals should have the highest covariance. Usually, this is defined by an isotropic kernel, which means its invariant to all rigid motions.

For interpolation, a standard kernel (e.g. squared exponential) that encourages smooth functions is normally used. Figure 1 shows regression over 3 days for #goodmorning when only a random third of the values of the function are observed. We see that both the SE kernel and a periodic kernel (PS, see below) give good results.

However, for extrapolation, the choice of the kernel is paramount. The kernel encodes our prior belief about the type of function wish to learn. To illustrate this, in Figure 3, we show the time series for #goodmorning over 2 weeks and plot the regression for the

future week learned by using different kernels.

In this study we will use multiple kernels, each most suitable for a specific category of temporal patterns in our data. This includes a new kernel inspired by observed word occurrence patterns. The kernels we use are:

Constant (C): The constant kernel is $k_C(t,t') = c$. Its mean prediction will always be the value c and its assumption is that the signal is modeled only by Gaussian noise centred around this value. This describes the data best when we have a noisy signal around a stationary mean value.

Squared exponential (SE): The SE kernel or the Radial Basis Function (RBF) is the standard kernel used in most interpolation settings.

$$k_{SE}(t,t') = s^2 \cdot \exp -\frac{(t-t')^2}{2l^2} \tag{3}$$

This gives a smooth transition between neighbouring points and best describes time series with a smooth shape e.g. a uni-modal burst with a steady decrease. However, its uncertainty grows with for predictions well into the future. Its two parameters s and l are the characteristic lengthscales along the two axes. Intuitively, they control the distance of inputs on a particular axis from which the function values become uncorrelated. Using the SE kernel corresponds to Bayesian linear regression with an infinite number of basis functions (Rasmussen and Williams, 2005).

Linear (Lin): The linear kernel describes a linear relationship between outputs.

$$k_{Lin}(t,t') = s^2 + \|t \cdot t'\| \tag{4}$$

This can be obtained from linear regression by having $\mathcal{N}(0,1)$ priors on the corresponding regression weights and a prior of $\mathcal{N}(0,s^2)$ on the bias.

Periodic (PER): The periodic kernel represents a SE kernel in polar coordinates.

$$k_{PER}(t,t') = s^2 \cdot \exp -2 \cdot \left(\frac{\sin^2(2\pi(t-t')^2/p)}{l^2} \right) \tag{5}$$

It has a sinusoidal shape and is good at modelling periodically patterns that oscillate between low and high frequency. s and l are characteristic lengthscales as in the SE kernel and p is the period.

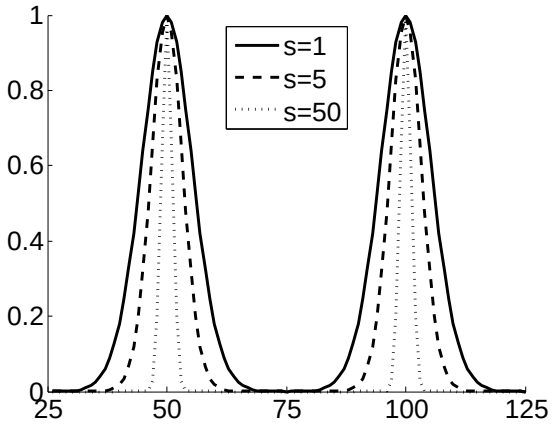

Figure 2: Behaviour of the PS kernel (p=50) with varying s. Values normalized in [0,1] interval.

Periodic spikes (PS): For textual time series, like word frequencies, we identify the following periodic behaviour: abrupt rise in usage, usually with a peak, followed by periods of low occurrence, which can be short (e.g. during the night) or long lived (e.g. the entire week except for a few hours). For modelling we introduce the following kernel:

$$k_{PS}(t,t') = \cos\left(\sin\left(\frac{2\pi \cdot (t-t')^2}{p}\right)\right) \cdot \exp\left(\frac{s\cos(2\pi \cdot (t-t')^2)}{p} - s\right) \tag{6}$$

The kernel is parameterised by its period p and a shape parameter s. The period indicates the time interval between the peaks of the function, while the shape parameter controls the *width* of the spike. The behaviour of the kernel is illustrated in Figure 2. We constrain $s \geq 1$.

In Figure 3 we see that the forecast is highly dependent on the kernel choice. We expect that for periodic data the PER and PS kernels will forecast best, maybe with the PS kernel doing a better job because it captures multiple modes of the daily increase in volume. We use for both kernels a period of 168 hours. This is because although a daily pattern exists, the weekly is stronger, with the day of the week influencing the volume of the hashtag. The NRMSE (Normalized Root Mean Square Error) in Table 1 on the held out data confirms this finding, with PS showing the lowest error.

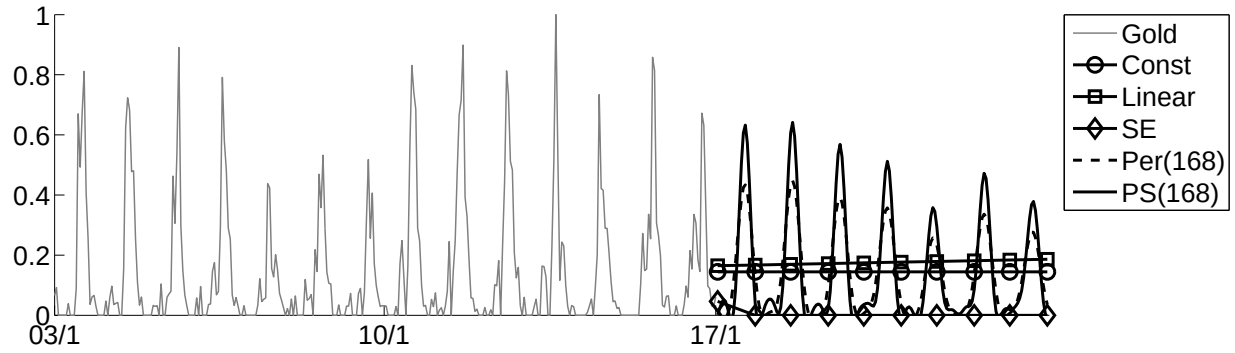

Figure 3: Extrapolation for #goodmorning over 3 weeks with GPs using different kernels.

	Const	Lin	SE	PER	PS
NLML	-41	-34	-176	-180	-192
NRMSE	0.213	0.214	0.262	0.119	0.107

Table 1: Negative Log Marginal Likelihood (NLML) shows the best fitted model for the time series in Figure 3. NRMSE computed on the third unobserved week. Lower values are better in both cases.

3.3 Model selection and optimisation

We now briefly discuss the concepts of model selection in the GP framework, by which we refer to choosing the model (kernel) from a set $\mathcal{H}_i$ and optimising the model hyperparameters θ. In our GP Bayesian inference scheme, we can compute the probability of the data given the model which involves the integral over the parameter space. This is called the *marginal likelihood* or *evidence* and is useful for model selection using only the training set:

$$p(x|\mathcal{D}, \theta, \mathcal{H}_i) = \int_f p(x|\mathcal{D}, f, \mathcal{H}_i) p(f|\theta, \mathcal{H}_i) \quad (7)$$

Our first goal is to fit the kernel by minimizing the negative log marginal likelihood (NLML) with respect to the kernel parameters θ. This approximation is also known as type II maximum likelihood (ML-II). Conditioned on kernel parameters, the evidence of a GP can be computed analytically.

Our second goal is to use the evidence for model selection because it balances the data fit and the model complexity by automatically incorporating Occam's Razor (Rasmussen and Ghahramani, 2000). Because the evidence must normalise, complex models which can account for many datasets achieve low evidence. One can think of the evidence as the probability that a random draw of the parameter values from the model class would generate the dataset $\mathcal{D}$. This way, complex models are penalised because they can describe many datasets, while the simple models can describe only a few datasets, thus the chance of a good data fit being very low. This is for example the case of the periodic bursts in Figure 3. Although the periodic kernel can fit the data, it will incur a high model complexity penalty. The PS kernel in this respect is a simpler model and can fit the data and is thus chosen as the right model.

When the dataset is observed, the evidence can select between the models. More generally, the model choice actually gives us an *implicit classification* of the temporal patterns into classes: a steady signal with noise (C kernel), a signal with local temporal patterns (SE kernel), an oscilating periodic pattern (PER kernel) or a pattern with abrupt periodic peaks (PS kernel).

We use the NLML for optimising the hyperparameters only using training data. For optimising the hyperparameters of the kernel defined in Equation 6, it is important to first identify the right period. We consider as possible periods all integer values less than half the size of the training set, and then tune the shape parameter using gradient descent to minimise NLML. We then take the $argmin$ value of those considered. We show the NLML for a sample regression in Figure 4.

The likelihood shows that there are multiple canyons in the likelihood, which can lead a convex optimisation method to local optima. These appear when p is equal or an integer multiple of the main period of the data, in this case 24. The lowest values are obtained when $p = 168$, allowing the model to accommodate the day of week effect. Our procedure is not guaranteed to reach a global optima, but

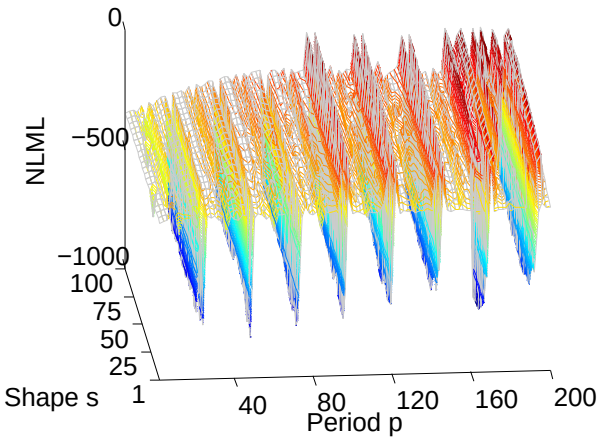

Figure 4: NLML for #goodmorning on the training set as a function of the 2 kernel parameters.

is a relatively standard technique for fitting periodic kernels (Duvenaud et al., 2013).

The flexibility of the GP framework allows us to combine kernels (e.g. $SE \cdot PS$ or $PS + Lin$) in order to identify a combination of trends (Duvenaud et al., 2013; Gönen and Alpaydin, 2011). Experiments on a subset of data showed no major benefits of combining kernels, but the computational time and model complexity increased drastically due to the extra hyperparameters. Because we will model a proportion of words within a limited time frame, there are few linear trends in the data. It might seem limiting that we only learn a single period, although we could combine periodic kernels with different periods together. But, as we have seen in the #goodmorning example (with overlapping weekly and daily patterns), if there is a combination of periods the model will select a single period which is the least common multiple.

4 Data

For our experiments we used data collected from Twitter using the public Gardenhose stream (10% representative sample of the entire Twitter stream). The data collection interval was 1 January – 28 February 2011. For simplicity in the classification task, we filtered the stream to include only tweets that have exactly one hashtag. These represent approximately 7.8% of our stream.

As text processing steps, we have tokenised all the tweets and filtered them to be written in English using the Trendminer pipeline (Preoţiuc-Pietro et al., 2012). We also remove duplicate tweets (retweets and tweets that had the same first 6 content tokens) because they likely represent duplicate content, automated messages or spam which would bias the dataset, as also stated by Tsur and Rappoport (2012). In our experiments we use the first month of data as training and the second month as testing. Note the challenging nature of this testing configuration where predictions must be made for up to 28 days into the future. We keep a total 1176 of hashtags which appear at least 500 times in both splits of the data. The vocabulary consists of all the tokens that occur more than 100 times in the dataset and start with an alphabetic letter. After processing, our dataset consists of 6,416,591 tweets with each having on average 9.55 tokens.

5 Forecasting hashtag frequency

We treat our task of forecasting the volume of a Twitter hashtag as a regression problem. Because the total number of tweets varies depending on the day and hour of day, we chose to model the proportion of tweets with the given tag in that hour. Given a time series of these values as the training set for a hashtag, we aim to predict the values in the testing set, extrapolating to the subsequent month.

Hashtags represent free-form text labels that authors add to a tweet in order to enable other users to search them to participate in a conversation. Some users use hashtags as regular words that are integral to the tweet text, some hashtags are general and refer to the same thing or emotion (#news, #usa, #fail), others are Twitter games or memes (#2010dissapointments, #musicmonday). Other hashtags refer to events which might be short lived (#worldcup2022), long lived (#25jan) or periodic (#raw, #americanidol). We chose to model hashtags because they group similar tweets (like topics), reflect real world events (some of which are periodic) and present direct means of evaluation. Note that this approach could be applied to many other temporal problems in NLP or other domains. We treat each regression problem independently, learning for each hashtag its specific model and set of parameters.

5.1 Methods

We choose multiple baselines for our prediction task in order to compare the effectiveness of our ap-

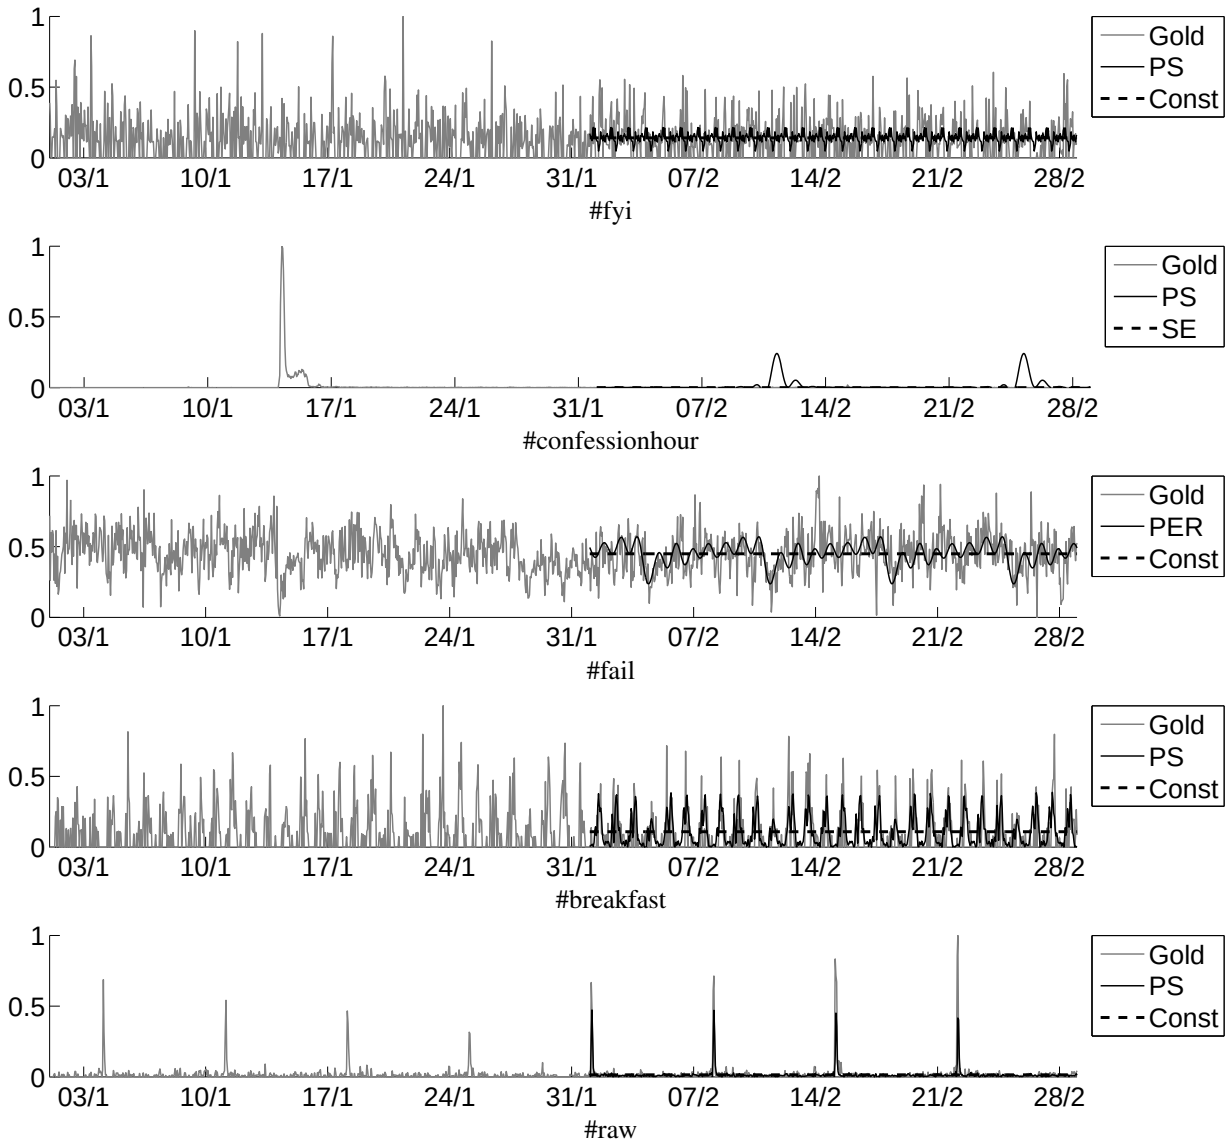

Figure 5: Sample regressions and their fit using different methods.

proach. These are:

Mean value (M): We use as prediction the mean of the values in the training set. Note that this is the same as using a GP model with a constant kernel (+ noise) with a mean equal to the training set mean.

Lag model with GP determined period (Lag+): The prediction is the mean value in the training set of the values at lag Δ where Δ is the period rounded to the closest integer as determined by our GP model. This is somewhat similar to an autoregressive (AR) model with all the coefficients except Δ set to 0. We highlight that given the period Δ this is a very strong model as it gives a mean estimate at each point. Comparing to this model we can see if the GP model can recover the underlying function that described the periodic variation and filter out the noise in the observations. Correctly identifying the period is very challenging as we discuss below.

GP regression: Gaussian Process regression using only the SE kernel (**GP-SE**), the periodic kernel (**GP-PER**), the PS kernel (**GP-PS**). The method that chooses between kernels using model selection as described in Section 3.3 is denoted as **GP+**. We will also compare to GP regression the linear kernel **(GP-Lin)**, but we will not use this as a candidate for model selection due the poor results shown below.

Hashtag	Lag(p)	Const		SE		PER		PS	
	NRMSE	NLML	NRMSE	NLML	NRMSE	NLML	NRMSE	NLML	NRMSE
#fyi	0.1578	**-322**	**0.1404**	-320	0.1898	-321	0.1405	-293	0.1456
#confessionhour	0.0404	-85	0.0107	**-186**	**0.0012**	-90	0.0327	-88	0.0440
#fail	0.1431	-376	0.1473	-395	0.4695	**-444**	**0.1387**	-424	0.1390
#breakfast	0.1363	-293	0.1508	-333	0.1773	-293	0.1514	**-367**	**0.1276**
#raw	0.0464	-1208	0.0863	-1208	0.0863	-1323	0.0668	**-1412**	**0.0454**

Table 2: NRMSE shows the best performance for forecasting and NLML shows the best model for all the regressions in Figure 5. Lower is better.

5.2 Results

We start by qualitatively analysing a few sample regressions that are representative of each category of time series under study. These are shown in Figure 5. For clarity, we only plotted a few kernels on each figure. The full evaluation statistics in NRMSE and the Bayesian evidence are show in Table 2.

For the hashtag #fyi there is no clear pattern. For this reason the model that uses the constant kernel performs best, being the simplest one that can describe the data, although the others give similar results in terms of NRMSE on the held-out testing set. While functions learned using this kernel never clearly outperform others on NRMSE on held-out data, this is very useful for interpretation of the time series, separating noisy time series from those that have an underlying periodic behaviour.

The #confessionhour example illustrates a behaviour best suited for modelling using the SE kernel. We notice a sudden burst in volume which decays over the next 2 days. This is actually the behaviour typical of 'internet memes' (this hashtag tags tweets of people posting things they would never tell anyone) as presented in Yang and Leskovec (2011). These cannot be modelled with a constant kernel or a periodic one as shown by the results on held-out data and the time series plot. The periodic kernels will fail in trying to match the large burst with others in the training data and will attribute to noise the lack of a similar peak, thus discovering wrong periods and making bad predictions. In this example, forecasts will be very close to 0 under the SE kernel, which is what we would desire from the model.

The periodic kernel best models hashtags that exhibit an oscillating pattern. For example, this best fits words that are used frequently during the day and less so during the night, like #fail. Here, the period is chosen to be one week (168) rather than one day (24) because of the weekly effect superimposed on the daily one. Our model recovers that there is a daily pattern with people tweeting about their or others' failures during the day. On weekends however, and especially on Friday evenings, people have better things to do.

The PS kernel introduced in this paper models best hashtags that have a large and short lived burst in usage. We show this by two examples. First, we choose #breakfast which has a daily and weekly pattern. As we would expect, a big rise in usage occurs during the early hours of the day, with very few occurrences at other times. Our model discovers a weekly pattern as well. This is used mainly for modelling the difference between weekends and weekdays. On weekends, the breakfast tag is more evenly spread during the hours of the morning, because people do not have to wake up for work and can have breakfast at a more flexible time than during the week. In the second example, we present a hashtag that is associated to a weekly event: #raw is used to discuss a wrestling show that airs every week for 2 hours on Monday evenings in the U.S.. With the exception of these 2 hours and the hour building up to it, the hashtag is rarely used. This behaviour is modelled very well using our kernel, with a very high value for the shape parameter ($s = 200$) compared to the previous example ($s = 11$) which captures the abrupt trend in usage. In all cases, our GP model chosen by the evidence performs better than the Lag+ model, which is a very strong method if presented with the correct period. This further demonstrates the power of the Gaussian Process framework to deal with noise in the training data and to find the underlying function of the time variation of words.

In Table 3 we present sample tags identified as

Const	SE	PER	PS
#funny	#2011	#brb	#ff
#lego	#backintheday	#coffee	#followfriday
#likeaboss	#confessionhour	#facebook	#goodnight
#money	#februarywish	#facepalm	#jobs
#nbd	#haiti	#funny	#news
#nf	#makeachange	#love	#nowplaying
#notetoself	#questionsidontlike	#rock	#tgif
#priorities	#savelibraries	#running	#twitterafterdark
#social	#snow	#xbox	#twitteroff
#true	#snowday	#youtube	#ww
49	**268**	**493**	**366**

Table 3: Sample hashtags for each category. The last line shows the total number of hashtags of each type.

Lag+	GP-Lin	GP-SE	GP-PER	GP-PS	GP+
7.29%	-3.99%	-34.5%	0.22%	7.37%	**9.22%**

Table 4: Average relative gain over mean (M) prediction for forecasting on the entire month using the different models

being part of the 4 hashtag categories, and the total number of hashtags in each.

As a means of quantitative evaluation we compute the relative NRMSE compared to the Mean (M) method for forecasting. We choose this, because we consider that NRMSE is not comparable between regression tasks due to the presence of large peaks in many time series, which distort the NRMSE values. The results are presented in Table 4 and show that our Gaussian Process model using model selection is best. Remarkably, it consistently outperforms the Lag+ model, which shows the effectiveness of the GP models to incorporate uncertainty. The GP-PS model does very well on its own. Although chosen in the model selection phase in only a third of the tasks, it performs consistently well across tasks because of its ability to model well all the periodic hashtags, be they smooth or abrupt. The GP-Lin model does worse than the average, mostly due to uni-modal time series which don't have high occurrences in the testing part of the data.

5.3 Discussion

Let us now turn to why the GP model is better for discovering periodicities than classic time series modelling methods. Measuring autocorrelation between points in the time series is used to discover the hidden periodicities in the data and in building AR models. However, the downsides of this method are: a) the incapacity of accurately finding the correct periods, because all integer multiples of the correct period will be feasible candidates and b) it leads to incorrect conclusions when there is autocorrelated noise. The second case is illustrated in Figure 6 where #confessionhour shows autocorrelation but, as seen in Figure 5, lacks a periodic component.

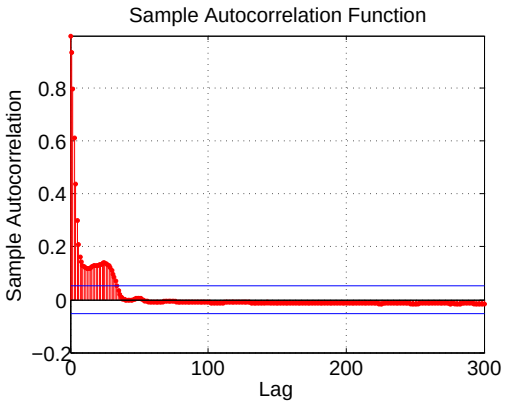

Figure 6: Sample autocorrelation for #confessionhour

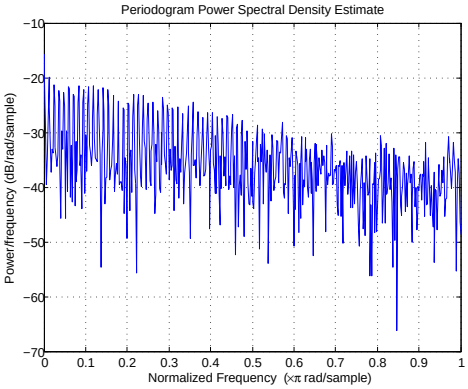

Figure 7: Power spectral density for #raw

Another approach to discovering periods in data is by computing the power spectral density. This has been used in the GP framework by Wilson and Adams (2013). For some time series, this gives a good indication of the period, as represented by a peak in the periodogram at that value. This fails to discover the correct period when dealing with large bursts like those exhibited by the #raw time series as shown in Figure 7. The lowest frequency spike corresponds to the correct period of 168, but also other candidate periods are shown as possible. The reason for this is its reliance on the Fourier Transform which decomposes the time series into a sum of oscillating patterns. These cannot model step-functions and other non-smoothly varying signals. A further discussion falls out of the scope and space constraints of this paper.

Tweet	Time	Prior	Rank	Prediction
Bruins Goal!!! Patrice Bergeron makes it 3-1 Boston	2-3am, 2 Feb 2011	E: 0.00017 P: 0.00086	7 1	#fb #bruins
i need some of Malik people	3-4am, 2 Feb 2011	E: 0.00021 P: 0.00420	7 1	#ff #thegame
Alfie u doughnut! U didn't confront Kay? SMH	7-8pm, 3 Feb 2011	E: 0.00027 P: 0.00360	8 1	#nowplaying #eastenders

Table 5: Example of tweet classification using the Naïve Bayes model with the two different priors (E - empirical, P - GP forecast). Rank shows the rank in probability of the correct class (hashtag) under the model. Time is G.M.T.

6 Text based prediction

In this section we demonstrate the usefulness of our method of modelling in an NLP task: predicting the hashtag of a tweet based on its text. In contrast to this classification approach for suggesting a tweet's hashtag, information retrieval methods based on computing similarities between tweets are very hard to scale to large data (Zangerle et al., 2011).

We choose a simple model for prediction, the Naïve Bayes Classifier. This method provides us with a straightforward way to incorporate our prior knowledge of how frequent a hashtag is in a certain time frame. This Naïve Bayes model (**NB-P**) uses the forecasted values for the respective hour as the prior on the hashtags.

For comparison we use the Most Frequent (**MF**) baseline and the Naïve Bayes with empirical prior (**NB-E**) which doesn't use any temporal forecasting information. Because there are more than 1000 possible classes we show the accuracy of the correct hashtag being amongst the top 1,5 or 50 hashtags as well as the Mean Reciprocal Rank (MRR). The results are shown in Table 6.

The results show that incorporating the forecasted values as a more informative prior for classification we obtain better predictions. The improvements are consistent in all the Match values. Also, we highlight that a 9% improvement in the forecasting task carries over to about a 2% improvement in classification. We show a few examples in which the GP learned prior makes a difference in classification in Table 5 together with the values for both priors.

With these experiments, we highlighted that there are performance gains even with only adding a more informative prior that uses periodicity information. This motivates future work to add this information to discriminative classifiers thus avoiding the need for the Naïve Bayes decomposition. The modelling framework offered by the GPs can accommodate classification, although scaling issues arise when using a large number of features or output classes. Efforts to scale GPs to a large number of variables are well understood (Candela and Rasmussen, 2005) and we will try to incorporate this in future work.

	MF	NB-E	NB-P
Match@1	7.28%	16.04%	**17.39%**
Match@5	19.90%	29.51%	**31.91%**
Match@50	44.92%	59.17%	**60.85%**
MRR	0.144	0.237	**0.252**

Table 6: Results for hashtag classification.

7 Conclusion

Periodicities play an important role when analysing the temporal dimension of text. We have presented a framework based on Gaussian Process regression for identifying periodic patterns and their parameters using only training data. We divided the periodic patterns into 2 categories: oscillating and periodic bursts by performing model selection using bayesian evidence. The periodicities we have discovered have proven useful in an NLP classification task.

In future work, we aim to model time continuously and to perform discriminative clustering in order to make better use of the learned periodicites. We will consider incorporating periodicities in other applications, such as topic models.

Abstract

Direct quotations are used for opinion mining and information extraction as they have an easy to extract span and they can be attributed to a speaker with high accuracy. However, simply focusing on direct quotations ignores around half of all reported speech, which is in the form of indirect or mixed speech. This work presents the first large-scale experiments in indirect and mixed quotation extraction and attribution. We propose two methods of extracting all quote types from news articles and evaluate them on two large annotated corpora, one of which is a contribution of this work. We further show that direct quotation attribution methods can be successfully applied to indirect and mixed quotation attribution.

1 Introduction

Quotations are crucial carriers of information, particularly in news texts, with up to 90% of sentences in some articles being reported speech (Bergler et al., 2004). Reported speech is a carrier of evidence and factuality (Bergler, 1992; Saurí and Pustejovsky, 2009), and as such, text mining applications use quotations to summarise, organise and validate information. Extraction of quotations is also relevant to researchers interested in media monitoring.

Most quotation attribution studies (Pouliquen et al., 2007; Glass and Bangay, 2007; Elson and McKeown, 2010) thus far have limited their scope to direct quotations (Ex.1a), as they are delimited by quotation marks, which makes them easy to extract. However, annotated resources suggest that direct quotations represent only a limited portion of all quotations, i.e., around 30% in the Penn Attribution Relation Corpus (PARC), which covers Wall Street Journal articles, and 52% in the Sydney Morning Herald Corpus (SMHC), with the remainder being indirect (Ex.1c) or mixed (Ex.1b) quotations. Retrieving only direct quotations can miss key content that can change the interpretation of the quotation (Ex. 1b) and will entirely miss indirect quotations.

(1) a. *"For 10 million, you can move $100 million of stocks,"* a specialist on the Big Board gripes. *"That gives futures traders a lot more power."*
b. *Police would only apply for the restrictions when "we have a lot of evidence that late-night noise... is disturbing the residents of that neighbourhood"*, Superintendent Tony Cooke said.
c. Mr Walsh said *Rio was continuing to hold discussions with its customers to arrive at a mutually agreed price*.

Previous work on extracting indirect and mixed quotations has suffered from a lack of large-scale data, and has instead used hand-crafted lexica of reporting verbs with rule-based approaches. The lack of data has also made comparing the relative merit of these approaches difficult, as existing evaluations are small-scale and do not compare multiple methods on the same data.

In this work we address this lack of clear, comparable results by evaluating two baseline meth-

	Method	Language	Test Size (quotations)	Results P	R
Krestel et al. (2008)	hand-built grammar	English	133	74%	99%
Sarmento and Nunes (2009)	patterns over text	Portuguese	570	88%	5%[1]
Fernandes et al. (2011)	ML and regex	Portuguese	205	64%[2]	67%[2]
de La Clergerie et al. (2011)	patterns over parse	French	40	87%	70%
Schneider et al. (2010)	hand-built grammar	English	N/D	56%[2]	52%[2]

Table 1: Related work on direct, indirect and mixed quotation extraction. Note that they are not directly comparable as they apply to different languages and greatly differ in evaluation style and size of test set. [1] Figure estimated by the authors for extracting 570 quotations from 26k articles. [2] Results are for quotation extraction and attribution jointly.

ods against both a token-based approach that uses a Conditional Random Field (CRF) to predict IOB labels, and a maximum entropy classifier that predicts whether parse nodes are quotations or not. We evaluate these approaches on two large-scale corpora from the news domain that together include over 18,000 quotations. One of these corpora (SMHC) is a a contribution of this work, while our results are the first presented on the other corpus (PARC). Instead of relying on a lexicon of reporting verbs, we develop a classifier to detect verbs introducing a quotation. To inform future research we present results for direct, indirect, and mixed quotations, as well as overall results.

Finally, we use the direct quotation attribution methods described in O'Keefe et al. (2012) and show that they can be successfully applied to indirect and mixed quotations, albeit with lower accuracy. This leads us to conclude that attributing indirect and mixed quotations to speakers is harder than attributing direct quotations.

With this work, we set a new state of the art in quotation extraction. We expect that the main contribution of this work will be that future methods can be evaluated in a comparable way, so that the relative merit of various approaches can be determined.

2 Background

Pareti (2012) defines an attribution as having a *source* span, a *cue* span, and a *content* span:

Source is the span of text that indicates who the content is attributed to, e.g. 'president Obama', 'analysts', 'China', 'she'.

Cue is the lexical anchor of the attribution relation, usually a verb, e.g. 'say', 'add', 'quip'.

Content is the span of text that is attributed.

Based on the type of attitude the source expresses towards a proposition or eventuality, attributions are subcategorised (Prasad et al., 2006) into *assertions* (Ex.2a) and *beliefs* (Ex.2b), which imply different degrees of commitment, *facts* (Ex.2c), expressing evaluation or knowledge, and *eventualities* (Ex.2d), expressing intention or attitude.

(2) a. Mr Abbott said *that he will win the election.*
b. Mr Abbott thinks *he will win the election.*
c. Mr Abbott knew *that Gillard was in Sydney.*
d. Mr Abbott agreed *to the public sector cuts.*

Only assertion attributions necessarily imply a speech act. Their *content* corresponds to a quotation span and their *source* is generally referred to in the literature as the *speaker*. Direct, indirect and mixed quotations differ in the degree of factuality they entail, since the former are by convention interpreted as a verbatim transcription of an utterance whereas indirect and the non-quoted portion of mixed quotations can be paraphrased forms of the original wording, and are thus filtered by the writer's perspective.

The first speaker attribution systems (Zhang et al., 2003; Mamede and Chaleira, 2004; Glass and Bangay, 2007) originate from the narrative domain and were concerned with the identification of different characters for speech synthesis applications. Direct quotation attribution, with direct quotations being given or extracted heuristically, has been the focus of further studies in both the narrative (Elson and McKeown, 2010) and news (Pouliquen et al., 2007; Liang et al., 2010) domains. The few studies that

have addressed the extraction and attribution of indirect and mixed quotations are discussed below.

Krestel et al. (2008) developed a quotation extraction and attribution system that combines a lexicon of 53 common reporting verbs and a hand-built grammar to detect constructions that match 6 general lexical patterns. They evaluate their work on 7 articles from the Wall Street Journal, which contain 133 quotations, achieving macro-averaged Precision (P) of 99% and Recall (R) of 74% for quotation span detection. PICTOR (Schneider et al., 2010) relies instead on a context-free grammar for the extraction and attribution of quotations. PICTOR yielded 75% P and 86% R in terms of words correctly ascribed to a quotation or speaker, while it achieved 56% P and 52% R when measured in terms of completely correct quotation-speaker pairs.

SAPIENS (de La Clergerie et al., 2011) extracts quotations from French news, by using a lexicon of reporting verbs and syntactic patterns to extract the complement of a reporting verb as the quotation span and its subject as the source. They evaluated 40 randomly sampled quotations and found that their system made 32 predictions and correctly identified the span in 28 of the 40 cases. Verbatim (Sarmento and Nunes, 2009) extracts quotations from Portuguese news feeds by first finding one of 35 speech verbs and then matching the sentence to one of 19 patterns. Their manual evaluation shows that 11.9% of the quotations Verbatim finds are errors and that the system identifies approximately one distinct quotation for every 46 news articles.

The system presented by Fernandes et al. (2011) also works over Portuguese news. Their work is the closest to ours as they partially apply supervised machine learning to quotation extraction. Their work introduces GloboQuotes, a corpus of 685 news items containing 1,007 quotations of which 802 were used to train an Entropy Guided Transformation Learning (ETL) algorithm (dos Santos and Milidiú, 2009). They treat quotation extraction as an IOB labelling task, where they use ETL with POS and NE features to identify the beginning of a quotation, while the inside and outside labels are found using regular expressions. Finally they use ETL to attribute quotations to their source. The overall system achieves 64% P and 67% R.

We have summarised these approaches in Table 1, which shows that the majority of evaluations thus far have been small-scale. Furthermore, the published results do not include any comparisons with previous work, which prevents a quantitative comparison of the approaches, and they do not include results broken down by whether the quotation is direct, indirect, or mixed. It is these issues that motivate our work.

	SMHC		PARC	
	Corpus	Doc	Corpus	Doc
Docs	965	-	2,280	-
Tokens	601k	623.3	1,139k	499.9
Quotations	7,991	8.3	10,526	4.6
Direct	4,204	4.4	3,262	1.4
Indirect	2,930	3.0	5,715	2.5
Mixed	857	0.9	1,549	0.6

Table 2: Comparison of the SMHC and PARC corpora, reporting their document and token size and per-type occurrence of quotations overall and per document (average).

3 Corpora

We perform our experiments over two large corpora from the news domain.

3.1 Penn Attribution Relations Corpus (PARC)

Our first corpus (Pareti, 2012), which we will refer to as PARC, is a semi-automatically built extension to the attribution annotations included in the PDTB (Prasad et al., 2008). The corpus covers 2,280 Wall Street Journal articles and contains annotations of assertions, beliefs, facts, and eventualities, which are altogether referred to as attribution relations (ARs). For this work we use only the assertions, as they correspond to quotations (direct, indirect and mixed). The drawback of this corpus is that it is not yet fully annotated, i.e., it comprises positive and unlabelled data.

The corpus includes a test set of 14 articles that are fully annotated, which enables us to properly evaluate our work and estimate that a proportion of 30-50% of ARs are unlabelled in the rest of the corpus. The test set was manually annotated by two expert annotators. The annotators identified 491 ARs, of which 22% were nested within another AR, with

an agreement score of 87%[1]. The agreement for the selection of the content and source spans of commonly annotated ARs was 95% and 94% respectively. In this work we address only non-embedded assertions, so the final test-set includes 267 quotes, totalling 321 non-discontinuous gold spans.

3.2 Sydney Morning Herald Corpus (SMHC)

We based our second corpus on the existing annotations of direct quotations within Sydney Morning Herald articles presented in O'Keefe et al. (2012). In that work we defined direct quotations as any text between quotation marks, which included the directly-quoted portion of mixed quotations, as well as scare quotes. Under that definition direct quotations could be automatically extracted with very high accuracy, so annotations in that work were over the automatically extracted direct quotations. As part of this work one annotator removed scare quotes, updated mixed quotations to include both the directly and indirectly quoted portions, and added whole new indirect quotations. The annotation scheme was developed to be comparable to the scheme used in the PARC corpus (Pareti, 2012), although the SMHC corpus only includes assertions and does not annotate the lexical *cue*.

The resulting corpus contains 7,991 quotations taken from 965 articles from the 2009 Sydney Morning Herald (we refer to this corpus as SMHC). The annotations in this corpus also include the speakers of the quotations, as well as gold standard Named Entities (NEs). We use 60% of this corpus as training data (4,872 quotations), 10% as development data (759 quotations), and 30% as test data (2,360 quotations). Early experiments were conducted over the development data, while the final results were trained on both the training and development sets and were tested on the unseen test data.

3.3 Comparison

Table 2 shows a comparison of the two corpora and the quotations annotated within them. SMHC has a higher density of quotations per document, 8.3 vs. 4.6 in PARC, since articles are fully annotated and were selected to contain at least one quotation. PARC is instead only partially annotated and comprises articles with no quotations. Excluding null-quotation articles from PARC, the average incidence of annotated quotations per article raises to 7.1. The corpora also differ in quotation type distribution, with direct quotations being largely predominant in SMHC while indirect are more common in PARC.

[1]The agreement was calculated using the *agr* metric described in Wiebe and Riloff (2005) as the proportion of commonly annotated ARs with respect to the ARs identified overall by Annotator A and Annotator B respectively

	P	R	F
B_{say}	94.4	43.5	59.5
B_{list}	75.4	71.1	73.2
k-NN	88.9	72.6	79.9

Table 3: Results for the k-NN verb-cue classifier. B_{say} classifies as verb-cue all instances of say while B_{list} marks as verb-cues all verbs from a pre-compiled list in Krestel et al. (2008).

4 Experimental Setup

4.1 Quotation Extraction

Quotation extraction is the task of extracting the *content span* of all of the direct, indirect, and mixed quotations within a given document. More precisely, we consider quotations to be acts of communication, which correspond to *assertions* in Pareti (2012). Some quotations have content spans that are split into separate, non-adjacent spans, as in example (1a). Ideally the latter span should be marked as a continuation of a quotation, however we consider this to be out of scope for this work, so we treat each span as a separate quotation.

4.2 Preprocessing

As a pre-processing step, both corpora were tokenised and POS tagged, and the potential speakers anonymised to prevent over-fitting. We used the Stanford factored parser (Klein and Manning, 2002) to retrieve both the Stanford dependencies and the phrase structure parse. Quotation marks were normalised to a single character, as the quotation direction is often incorrect for multi-paragraph quotations.

4.3 Verb-cue Classifier

Verbs are by far the most common introducer of a quotation. In PARC verbs account for 96% of all

cues, the prepositional phrase *according to* for 3%, with the remaining 1% being nouns, adverbials and prepositional groups. Attributional verbs are not a closed set, they can vary across styles and genres, and their attributional use is highly dependent on the context in which they occur. It is therefore not possible to simply rely on a pre-compiled list of common speech verbs. Quotations in PARC are introduced by 232 verb types, 87 of which are unique occurrences. Not all of the verbs are speech verbs, for example *add*, which is the second most frequent after *say*, or the manner verb *gripe* (Ex.1a).

We used the attributional cues in the PARC corpus to develop a separate component of our system to identify attribution verb-cues. The classifier predicts whether the head of each verb group is a verb-cue using the k-nearest neighbour (k-NN) algorithm, with k equal to 3. The classifier uses 20 feature types, including:

- Lexical (e.g. token, lemma, adjacent tokens)
- VerbNet classes membership
- Syntactic (e.g. node-depth in the sentence, parent and sibling nodes)
- Sentence features (e.g. distance from sentence start/end, within quotation markers).

We compared the system to one baseline, B_{say}, that marks every instance of *say* as a verb-cue, and another, B_{list}, that marks every instance of a verb that is on the list of 53 verbs presented in Krestel et al. (2008). We tested the system on the test set for PARC, which contains 1809 potential verb-cues, of which 354 are positive and 1455 are negative.

The results in Table 3 show that the verb-cue classifier can outperform expert-derived knowledge. The classifier was able to identify verb-cues with P of 88.9% and R of 72.6%. While frequently occurring verbs are highly predictive, the inclusion of VerbNet classes (Schuler, 2005) and contextual features allows for a more accurate classification of polysemous and unseen verbs.

Since PARC contains labelled and unlabelled attributions, which is detrimental for training, we used the verb-cue classifier to identify in the corpus sentences that we suspected contained an unlabelled attribution. Sentences containing a verb classified as a cue that do not contain a quotation were removed from the training set for the quotation extraction model.

4.4 Evaluation

We use two metrics, listed below, for evaluating the quotation spans predicted by our model against the gold spans from the annotation.

Strict The first is a strict metric where a predicted span is only considered to be correct if it exactly matches a span from the gold standard. The standard precision, recall, and F-score can be calculated using this definition of correctness. The drawback of this strict score is that if a prediction is incorrect by as little as one token it will be considered completely incorrect.

Partial We also consider an overlap metric (Hollingsworth and Teufel, 2005), which allows partially correct predictions to be proportionally counted. Precision (P), recall (R), and F-score for this method are:

$$P = \frac{\sum_{g \in gold} \sum_{p \in pred} overlap(g, p)}{|pred|} \quad (1)$$

$$R = \frac{\sum_{g \in gold} \sum_{p \in pred} overlap(p, g)}{|gold|} \quad (2)$$

$$F = \frac{2PR}{(P + R)} \quad (3)$$

Where $overlap(x, y)$ returns the proportion of tokens of y that are overlapped by x. For each of these metrics we report the micro-average, as the number of quotations in each document varies significantly. When reporting P for the typewise results we restrict the set of predicted quotations to only those with the requisite type, while still considering the full set of gold quotations. Similarly, when calculating R we restrict the set of gold quotations to only those with the required type.

4.5 Baselines
