Preface

Welcome to the 2013 Conference on Empirical Methods in Natural Language Processing.

EMNLP has grown to be one of the largest and most competitive conferences in computational linguistics. Organized by ACL SIGDAT (the Association for Computational Linguistics special interest group for linguistic data and corpus-based approaches to natural language processing), it features papers on all areas of interest to the SIGDAT community and aligned fields. It is being held this year as a standalone conference at the Grand Hyatt Seattle, in the heart of downtown Seattle, USA over the period October 18–21, 2013.

This year we introduced short papers to EMNLP for the first time, in an attempt to encourage submission of papers reporting smaller, more focused contributions and work in progress. We also put a lot of time and energy into "closing the loop" in the author response phase, in getting reviewers to explicitly acknowledge author responses and update their reviews where appropriate. We sincerely hope that this contributed towards further improvement in the quality of reviews and the decision-making process.

We received a record number of 772 valid submissions (not including co-submitted papers that were withdrawn from the conference), made up of 539 long papers and 233 short papers. These papers were reviewed across a total of 15 areas, of which Machine Translation (98 submissions), Semantics (87 submissions) and NLP-related Machine Learning (76) were the largest. The submissions were managed by 30 area chairs (two per area) and evaluated by a combined programme committee of 505 reviewers.

28% of the long paper submissions and 24% of the short paper submissions were accepted for publication at the conference. Five long papers were shortlisted for the best paper award, based on input from the reviewers and area chairs, and have been scheduled for presentation in a plenary session at the end of the conference, culminating in the presentation of the best paper award.

We would like to acknowledge all the hard work of the submitting authors, without whom there would, of course, be no conference. To the authors of accepted papers, we offer congratulations; to the authors of rejected papers, we offer our sincere commiserations, and dearly hope that the hard work of the programme committee provided you with valuable feedback on your research. We are eternally indebted to our dedicated and hard-working area chairs, and to the reviewers for their attention to detail and engagement with the author response/discussion phase, which was tremendously helpful in gauging the relative merits of each paper and being able to send out the notifications on time.

We are very grateful to our two invited speakers: Fernando Pereira (Research Director at Google) who will draw on his considerable experience and wisdom in presenting "Meaning in the Wild", focusing on machine understanding; and Andrew Ng (Co-CEO and Co-founder of Coursera) who will discuss the challenges and opportunities associated with the delivery of Massively Open Online Courses (MOOCs) in a talk titled "The Online Revolution: Education for Everyone", from the perspective of a true world leader in MOOC provision and Machine Learning/NLP research.

We would also like to thank the inimitable Priscilla Rasmussen who single-handedly looked after the local organisation of EMNLP 2013. We also wish to acknowledge the considerable efforts of Steven Berthard who put this volume together with peerless efficiency, Francesco Figari who took excellent

care of the conference website, and Rich Gerber from Softconf.com, who responded to any questions regarding START — the submission management system used for EMNLP 2013 — instantaneously and uncomplainingly, and helped us manage the large number of submissions smoothly. Additionally, we would like to thank Eugene Charniak, Mark Johnson and Noah Smith for serving on the best paper award committee, and providing characteristically probing and insightful critiques of the best paper award nominees.

Special thanks go to David Yarowsky, the general chair for the conference, who has provided us with much valuable advice, encouragement and assistance over the past six months. We would also like to thank the members of the SIGDAT board who advised us on various matters, and our predecessors James Henderson and Marius Pasca for nudging us in the right direction on a number of occasions.

On behalf of all attendees at the conference, we would also like to acknowledge the generosity of our sponsors/supports: Amazon, Google, the Allen Institute for Artificial Intelligence, Inome, IBM Research, Microsoft Research, Nuance and John Hopkins University.

It has been an honour to serve as Programme Chairs of EMNLP 2013. We sincerely hope that you — in equal measure — enjoy and are intellectually-stimulated by the conference, and have a pleasant stay in beautiful Seattle.

Timothy Baldwin and Anna Korhonen
EMNLP 2013 Programme Chairs

Organizers

General Chair:

David Yarowsky (John Hopkins University, USA)

Programme Chairs:

Timothy Baldwin (University of Melbourne, Australia)
Anna Korhonen (University of Cambridge, UK)

Workshops Chair:

Karen Livescu (Toyota Technological Institute at Chicago, USA)

Publication Chair:

Steven Bethard (University of Alabama at Birmingham, USA)

Area Chairs:

Phonology, Morphology, Tagging, Chunking and Segmentation:

Kemal Oflazer (Carnegie Mellon University Qatar)
Anna Feldman (Montclair State University, USA)

Syntax and Parsing:

Jennifer Foster (Dublin City University, Ireland)
Yoav Goldberg (Bar Ilan University, Israel)

Semantics:

Mark Stevenson (University of Sheffield, UK)
Luke Zettlemoyer (University of Washington, USA)

Discourse, Dialogue, and Pragmatics:

Carolyn Rose (Carnegie Mellon University, USA)
Matt Purver (Queen Mary, University of London, UK)

Language resources:

Emily M. Bender (University of Washington, USA)
Aline Villavicencio (Federal University of Rio Grande do Sul, Brazil)

Summarization and Generation:

Dragomir Radev (University of Michigan, USA)
Yang Liu (University of Texas at Dallas, USA)

NLP-related Machine Learning: theory, methods and algorithms:

Amir Globerson (The Hebrew University of Jerusalem, Israel)
Antal van den Bosch (Radboud University Nijmegen, Netherlands)

Machine Translation:

Taro Watanabe (NICT, Japan)
Kevin Knight (Information Sciences Institute, USA)

Information Retrieval and Question Answering:

Bernardo Magnini (Fondazione Bruno Kessler, Italy)
Soumen Chakrabarti (Indian Institute of Technology, India)

Information Extraction:

Mausam (Indian Institute of Technology, India)
Heng Ji (City University of New York, USA)

Spoken Language Processing:

Haizhou Li (Institute for Infocomm Research, Singapore)
Amanda Stent (AT&T Labs, USA)

Text Mining and Natural Language Processing Applications:

Hang Li (Huawei Noah's Ark Lab, Hong Kong)
Kevin Cohen (University of Colorado School of Medicine, USA)

Sentiment Analysis and Opinion Mining:

Janyce Weibe (University of Pittsburgh, USA)
Bing Liu (University of Illinois at Chicago, USA)

NLP for the Web and Social Media:

Miles Osborne (University of Edinburgh, UK)
Chin-Yew Lin (Microsoft Research Asia, China)

Computational Models of Human Language Acquisition and Processing:

Alessandro Lenci (University of Pisa, Italy)
Afra Alishahi (Tilburg University, Netherlands)

Table of Contents

Event-Based Time Label Propagation for Automatic Dating of News Articles
Tao Ge, Baobao Chang, Sujian Li and Zhifang Sui 1

Exploiting Discourse Analysis for Article-Wide Temporal Classification
Jun-Ping Ng, Min-Yen Kan, Ziheng Lin, Wei Feng, Bin Chen, Jian Su and Chew Lim Tan 12

Combining Generative and Discriminative Model Scores for Distant Supervision
Benjamin Roth and Dietrich Klakow 24

Exploring the Utility of Joint Morphological and Syntactic Learning from Child-directed Speech
Stella Frank, Frank Keller and Sharon Goldwater 30

A Joint Learning Model of Word Segmentation, Lexical Acquisition, and Phonetic Variability
Micha Elsner, Sharon Goldwater, Naomi Feldman and Frank Wood 42

Animacy Detection with Voting Models
Joshua Moore, Christopher J.C. Burges, Erin Renshaw and Wen-tau Yih 55

A Log-Linear Model for Unsupervised Text Normalization
Yi Yang and Jacob Eisenstein 61

Paraphrasing 4 Microblog Normalization
Wang Ling, Chris Dyer, Alan W Black and Isabel Trancoso 73

Question Difficulty Estimation in Community Question Answering Services
Jing Liu, Quan Wang, Chin-Yew Lin and Hsiao-Wuen Hon 85

Measuring Ideological Proportions in Political Speeches
Yanchuan Sim, Brice D. L. Acree, Justin H. Gross and Noah A. Smith 91

Learning to Freestyle: Hip Hop Challenge-Response Induction via Transduction Rule Segmentation
Dekai Wu, Karteek Addanki, Markus Saers and Meriem Beloucif 102

Modeling Scientific Impact with Topical Influence Regression
James Foulds and Padhraic Smyth 113

Joint Parsing and Disfluency Detection in Linear Time
Mohammad Sadegh Rasooli and Joel Tetreault 124

Modeling and Learning Semantic Co-Compositionality through Prototype Projections and Neural Networks
Masashi Tsubaki, Kevin Duh, Masashi Shimbo and Yuji Matsumoto 130

Studying the Recursive Behaviour of Adjectival Modification with Compositional Distributional Semantics
Eva Maria Vecchi, Roberto Zamparelli and Marco Baroni 141

Learning Latent Word Representations for Domain Adaptation using Supervised Word Clustering
Min Xiao, Feipeng Zhao and Yuhong Guo 152

Appropriately Incorporating Statistical Significance in PMI
Om P. Damani and Shweta Ghonge 163

Growing Multi-Domain Glossaries from a Few Seeds using Probabilistic Topic Models
Stefano Faralli and Roberto Navigli 170

Joint Learning of Phonetic Units and Word Pronunciations for ASR
Chia-ying Lee, Yu Zhang and James Glass 182

MCTest: A Challenge Dataset for the Open-Domain Machine Comprehension of Text
Matthew Richardson, Christopher J.C. Burges and Erin Renshaw 193

Noise-Aware Character Alignment for Bootstrapping Statistical Machine Transliteration from Bilingual Corpora
Katsuhito Sudoh, Shinsuke Mori and Masaaki Nagata 204

Optimal Beam Search for Machine Translation
Alexander Rush, Yin-Wen Chang and Michael Collins 210

An Efficient Language Model Using Double-Array Structures
Makoto Yasuhara, Toru Tanaka, Jun-ya Norimatsu and Mikio Yamamoto 222

Structured Penalties for Log-Linear Language Models
Anil Kumar Nelakanti, Cedric Archambeau, Julien Mairal, Francis Bach and Guillaume Bouchard 233

Interactive Machine Translation using Hierarchical Translation Models
Jesús González-Rubio, Daniel Ortíz-Martinez, José-Miguel Benedí and Francisco Casacuberta 244

Max-Margin Synchronous Grammar Induction for Machine Translation
Xinyan Xiao and Deyi Xiong 255

Error-Driven Analysis of Challenges in Coreference Resolution
Jonathan K. Kummerfeld and Dan Klein 265

Exploiting Zero Pronouns to Improve Chinese Coreference Resolution
Fang Kong and Hwee Tou Ng 278

Joint Coreference Resolution and Named-Entity Linking with Multi-Pass Sieves
Hannaneh Hajishirzi, Leila Zilles, Daniel S. Weld and Luke Zettlemoyer 289

Interpreting Anaphoric Shell Nouns using Antecedents of Cataphoric Shell Nouns as Training Data
Varada Kolhatkar, Heike Zinsmeister and Graeme Hirst 300

Exploring Representations from Unlabeled Data with Co-training for Chinese Word Segmentation
Longkai Zhang, Houfeng Wang, Xu Sun and Mairgup Mansur 311

Efficient Higher-Order CRFs for Morphological Tagging
Thomas Mueller, Helmut Schmid and Hinrich Schütze 322

The Effects of Syntactic Features in Automatic Prediction of Morphology
Wolfgang Seeker and Jonas Kuhn 333

Adaptor Grammars for Learning Non-Concatenative Morphology
Jan A. Botha and Phil Blunsom 345

Grounding Strategic Conversation: Using Negotiation Dialogues to Predict Trades in a Win-Lose Game
Anais Cadilhac, Nicholas Asher, Farah Benamara and Alex Lascarides 357

Unsupervised Induction of Contingent Event Pairs from Film Scenes
Zhichao Hu, Elahe Rahimtoroghi, Larissa Munishkina, Reid Swanson and Marilyn A. Walker369

Latent Anaphora Resolution for Cross-Lingual Pronoun Prediction
Christian Hardmeier, Jörg Tiedemann and Joakim Nivre 380

Towards Situated Dialogue: Revisiting Referring Expression Generation
Rui Fang, Changsong Liu, Lanbo She and Joyce Y. Chai 392

Open-Domain Fine-Grained Class Extraction from Web Search Queries
Marius Pasca 403

Unsupervised Relation Extraction with General Domain Knowledge
Oier Lopez de Lacalle and Mirella Lapata 415

Efficient Collective Entity Linking with Stacking
Zhengyan He, Shujie Liu, Yang Song, Mu Li, Ming Zhou and Houfeng Wang 426

Joint Bootstrapping of Corpus Annotations and Entity Types
Hrushikesh Mohapatra, Siddhanth Jain and Soumen Chakrabarti 436

Effectiveness and Efficiency of Open Relation Extraction
Filipe Mesquita, Jordan Schmidek and Denilson Barbosa 447

Automatic Feature Engineering for Answer Selection and Extraction
Aliaksei Severyn and Alessandro Moschitti 458

Improving Web Search Ranking by Incorporating Structured Annotation of Queries
Xiao Ding, Zhicheng Dou, Bing Qin, Ting Liu and Ji-rong Wen 468

Building Specialized Bilingual Lexicons Using Large Scale Background Knowledge
Dhouha Bouamor, Adrian Popescu, Nasredine Semmar and Pierre Zweigenbaum 479

Document Summarization via Guided Sentence Compression
Chen Li, Fei Liu, Fuliang Weng and Yang Liu 490

Anchor Graph: Global Reordering Contexts for Statistical Machine Translation
Hendra Setiawan, Bowen Zhou and Bing Xiang 501

Source-Side Classifier Preordering for Machine Translation
Uri Lerner and Slav Petrov 513

Improving Pivot-Based Statistical Machine Translation Using Random Walk
Xiaoning Zhu, Zhongjun He, Hua Wu, Haifeng Wang, Conghui Zhu and Tiejun Zhao 524

Improving Alignment of System Combination by Using Multi-objective Optimization
Tian Xia, Zongcheng Ji, Shaodan Zhai, Yidong Chen, Qun Liu and Shaojun Wang 535

Flexible and Efficient Hypergraph Interactions for Joint Hierarchical and Forest-to-String Decoding
Martin Cmejrek, Haitao Mi and Bowen Zhou 545

Factored Soft Source Syntactic Constraints for Hierarchical Machine Translation
Zhongqiang Huang, Jacob Devlin and Rabih Zbib 556

Recursive Autoencoders for ITG-Based Translation
Peng Li, Yang Liu and Maosong Sun 567

Automatically Classifying Edit Categories in Wikipedia Revisions
Johannes Daxenberger and Iryna Gurevych 578

Semi-Markov Phrase-Based Monolingual Alignment
Xuchen Yao, Benjamin Van Durme, Chris Callison-Burch and Peter Clark 590

A Constrained Latent Variable Model for Coreference Resolution
Kai-Wei Chang, Rajhans Samdani and Dan Roth 601

Centering Similarity Measures to Reduce Hubs
Ikumi Suzuki, Kazuo Hara, Masashi Shimbo, Marco Saerens and Kenji Fukumizu 613

Unsupervised Spectral Learning of WCFG as Low-rank Matrix Completion
Raphaël Bailly, Xavier Carreras, Franco M. Luque and Ariadna Quattoni 624

Identifying Phrasal Verbs Using Many Bilingual Corpora
Karl Pichotta and John DeNero 636

Deep Learning for Chinese Word Segmentation and POS Tagging
Xiaoqing Zheng, Hanyang Chen and Tianyu Xu 647

Joint Chinese Word Segmentation and POS Tagging on Heterogeneous Annotated Corpora with Multiple Task Learning
Xipeng Qiu, Jiayi Zhao and Xuanjing Huang 658

The Topology of Semantic Knowledge
Jimmy Dubuisson, Jean-Pierre Eckmann, Christian Scheible and Hinrich Schütze 669

Unsupervised Induction of Cross-Lingual Semantic Relations
Mike Lewis and Mark Steedman 681

Two-Stage Method for Large-Scale Acquisition of Contradiction Pattern Pairs using Entailment
Julien Kloetzer, Stijn De Saeger, Kentaro Torisawa, Chikara Hashimoto, Jong-Hoon Oh, Motoki Sano and Kiyonori Ohtake 693

Sarcasm as Contrast between a Positive Sentiment and Negative Situation
Ellen Riloff, Ashequl Qadir, Prafulla Surve, Lalindra De Silva, Nathan Gilbert and Ruihong Huang 704

Collective Personal Profile Summarization with Social Networks
Zhongqing Wang, Shoushan LI, Fang Kong and Guodong Zhou 715

Optimized Event Storyline Generation based on Mixture-Event-Aspect Model
Lifu Huang and Lian'en Huang 726

Automatically Determining a Proper Length for Multi-Document Summarization: A Bayesian Non-parametric Approach
Tengfei Ma and Hiroshi Nakagawa 736

A Discourse-Driven Content Model for Summarising Scientific Articles Evaluated in a Complex Question Answering Task
Maria Liakata, Simon Dobnik, Shyamasree Saha, Colin Batchelor and Dietrich Rebholz-Schuhmann 747

Optimal Incremental Parsing via Best-First Dynamic Programming
Kai Zhao, James Cross and Liang Huang 758

Exploiting Language Models for Visual Recognition
Dieu-Thu Le, Jasper Uijlings and Raffaella Bernardi 769

Mining Scientific Terms and their Definitions: A Study of the ACL Anthology
Yiping Jin, Min-Yen Kan, Jun-Ping Ng and Xiangnan He 780

Joint Learning and Inference for Grammatical Error Correction
Alla Rozovskaya and Dan Roth 791

With Blinkers on: Robust Prediction of Eye Movements across Readers
Franz Matthies and Anders Søgaard 803

Using Paraphrases and Lexical Semantics to Improve the Accuracy and the Robustness of Supervised Models in Situated Dialogue Systems
Claire Gardent and Lina M. Rojas Barahona 808

Cascading Collective Classification for Bridging Anaphora Recognition using a Rich Linguistic Feature Set
Yufang Hou, Katja Markert and Michael Strube 814

A Synchronous Context Free Grammar for Time Normalization
Steven Bethard 821

Rule-Based Information Extraction is Dead! Long Live Rule-Based Information Extraction Systems!
Laura Chiticariu, Yunyao Li and Frederick R. Reiss 827

Improving Learning and Inference in a Large Knowledge-Base using Latent Syntactic Cues
Matt Gardner, Partha Pratim Talukdar, Bryan Kisiel and Tom Mitchell 833

What is Hidden among Translation Rules
Libin Shen and Bowen Zhou 839

Converting Continuous-Space Language Models into N-Gram Language Models for Statistical Machine Translation
Rui Wang, Masao Utiyama, Isao Goto, Eiichro Sumita, Hai Zhao and Bao-Liang Lu 845

A Corpus Level MIRA Tuning Strategy for Machine Translation
Ming Tan, Tian Xia, Shaojun Wang and Bowen Zhou 851

Word Level Language Identification in Online Multilingual Communication
Dong Nguyen and A. Seza Dogruoz 857

Microblog Entity Linking by Leveraging Extra Posts

A Unified Model for Topics, Events and Users on Twitter
Qiming Diao and Jing Jiang 1869

Authorship Attribution of Micro-Messages
Roy Schwartz, Oren Tsur, Ari Rappoport and Moshe Koppel 1880

Detection of Product Comparisons - How Far Does an Out-of-the-Box Semantic Role Labeling System Take You?
Wiltrud Kessler and Jonas Kuhn 1892

A Multi-Teraflop Constituency Parser using GPUs
John Canny, David Hall and Dan Klein 1898

Fish Transporters and Miracle Homes: How Compositional Distributional Semantics can Help NP Parsing
Angeliki Lazaridou, Eva Maria Vecchi and Marco Baroni 1908

Learning Distributions over Logical Forms for Referring Expression Generation
Nicholas FitzGerald, Yoav Artzi and Luke Zettlemoyer 1914

Learning to Rank Lexical Substitutions
György Szarvas, Róbert Busa-Fekete and Eyke Hüllermeier 1926

Identifying Manipulated Offerings on Review Portals
Jiwei Li, Myle Ott and Claire Cardie 1933

Well-Argued Recommendation: Adaptive Models Based on Words in Recommender Systems
Julien Gaillard, Marc El-Beze, Eitan Altman and Emmanuel Ethis 1943

Regularized Minimum Error Rate Training
Michel Galley, Chris Quirk, Colin Cherry and Kristina Toutanova 1948

Of Words, Eyes and Brains: Correlating Image-Based Distributional Semantic Models with Neural Representations of Concepts
Andrew J. Anderson, Elia Bruni, Ulisse Bordignon, Massimo Poesio and Marco Baroni 1960

Easy Victories and Uphill Battles in Coreference Resolution
Greg Durrett and Dan Klein 1971

Breaking Out of Local Optima with Count Transforms and Model Recombination: A Study in Grammar Induction
Valentin I. Spitkovsky, Hiyan Alshawi and Daniel Jurafsky 1983

Cross-Lingual Discriminative Learning of Sequence Models with Posterior Regularization
Kuzman Ganchev and Dipanjan Das 1996

Conference Program

Saturday, October 19, 2013

(7:30-9:00) Breakfast

(9:00-9:15) Opening Remarks

(9:20-10:30) Information Extraction I

9:20–9:45 *Event-Based Time Label Propagation for Automatic Dating of News Articles*
Tao Ge, Baobao Chang, Sujian Li and Zhifang Sui

9:45–10:10 *Exploiting Discourse Analysis for Article-Wide Temporal Classification*
Jun-Ping Ng, Min-Yen Kan, Ziheng Lin, Wei Feng, Bin Chen, Jian Su and Chew Lim Tan

10:10–10:30 *Combining Generative and Discriminative Model Scores for Distant Supervision*
Benjamin Roth and Dietrich Klakow

(9:20-10:30) Language Acquisition and Processing

9:20–9:45 *Exploring the Utility of Joint Morphological and Syntactic Learning from Child-directed Speech*
Stella Frank, Frank Keller and Sharon Goldwater

9:45–10:10 *A Joint Learning Model of Word Segmentation, Lexical Acquisition, and Phonetic Variability*
Micha Elsner, Sharon Goldwater, Naomi Feldman and Frank Wood

10:10–10:30 *Animacy Detection with Voting Models*
Joshua Moore, Christopher J.C. Burges, Erin Renshaw and Wen-tau Yih

Saturday, October 19, 2013 (continued)

(9:20-10:30) NLP for Social Media I

9:20–9:45 *A Log-Linear Model for Unsupervised Text Normalization*
Yi Yang and Jacob Eisenstein

9:45–10:10 *Paraphrasing 4 Microblog Normalization*
Wang Ling, Chris Dyer, Alan W Black and Isabel Trancoso

10:10–10:30 *Question Difficulty Estimation in Community Question Answering Services*
Jing Liu, Quan Wang, Chin-Yew Lin and Hsiao-Wuen Hon

(10:30-11:00) Break

(11:00-12:35) NLP Applications I

11:00–11:25 *Measuring Ideological Proportions in Political Speeches*
Yanchuan Sim, Brice D. L. Acree, Justin H. Gross and Noah A. Smith

11:25–11:50 *Learning to Freestyle: Hip Hop Challenge-Response Induction via Transduction Rule Segmentation*
Dekai Wu, Karteek Addanki, Markus Saers and Meriem Beloucif

11:50–12:15 *Modeling Scientific Impact with Topical Influence Regression*
James Foulds and Padhraic Smyth

12:15–12:35 *Joint Parsing and Disfluency Detection in Linear Time*
Mohammad Sadegh Rasooli and Joel Tetreault

Saturday, October 19, 2013 (continued)

(11:00-12:35) Semantics I

11:00–11:25 *Modeling and Learning Semantic Co-Compositionality through Prototype Projections and Neural Networks*
Masashi Tsubaki, Kevin Duh, Masashi Shimbo and Yuji Matsumoto

11:25–11:50 *Studying the Recursive Behaviour of Adjectival Modification with Compositional Distributional Semantics*
Eva Maria Vecchi, Roberto Zamparelli and Marco Baroni

11:50–12:15 *Learning Latent Word Representations for Domain Adaptation using Supervised Word Clustering*
Min Xiao, Feipeng Zhao and Yuhong Guo

12:15–12:35 *Appropriately Incorporating Statistical Significance in PMI*
Om P. Damani and Shweta Ghonge

(11:00-12:35) Language Resources

11:00–11:25 *Growing Multi-Domain Glossaries from a Few Seeds using Probabilistic Topic Models*
Stefano Faralli and Roberto Navigli

11:25–11:50 *Joint Learning of Phonetic Units and Word Pronunciations for ASR*
Chia-ying Lee, Yu Zhang and James Glass

11:50–12:15 *MCTest: A Challenge Dataset for the Open-Domain Machine Comprehension of Text*
Matthew Richardson, Christopher J.C. Burges and Erin Renshaw

12:15–12:35 *Noise-Aware Character Alignment for Bootstrapping Statistical Machine Transliteration from Bilingual Corpora*
Katsuhito Sudoh, Shinsuke Mori and Masaaki Nagata

(12:35–2:00) Lunch

(2:00–3:15) First invited talk: Andrew Ng

(3:15–3:45) Break

Saturday, October 19, 2013 (continued)

(3:45-5:50) Machine Translation I

3:45–4:10 *Optimal Beam Search for Machine Translation*
Alexander Rush, Yin-Wen Chang and Michael Collins

4:10–4:35 *An Efficient Language Model Using Double-Array Structures*
Makoto Yasuhara, Toru Tanaka, Jun-ya Norimatsu and Mikio Yamamoto

4:35–5:00 *Structured Penalties for Log-Linear Language Models*
Anil Kumar Nelakanti, Cedric Archambeau, Julien Mairal, Francis Bach and Guillaume Bouchard

5:00–5:25 *Interactive Machine Translation using Hierarchical Translation Models*
Jesús González-Rubio, Daniel Ortíz-Martinez, José-Miguel Benedí and Francisco Casacuberta

5:25–5:50 *Max-Margin Synchronous Grammar Induction for Machine Translation*
Xinyan Xiao and Deyi Xiong

(3:45-5:50) Dialogue and Discourse

3:45–4:10 *Error-Driven Analysis of Challenges in Coreference Resolution*
Jonathan K. Kummerfeld and Dan Klein

4:10–4:35 *Exploiting Zero Pronouns to Improve Chinese Coreference Resolution*
Fang Kong and Hwee Tou Ng

4:35–5:00 *Joint Coreference Resolution and Named-Entity Linking with Multi-Pass Sieves*
Hannaneh Hajishirzi, Leila Zilles, Daniel S. Weld and Luke Zettlemoyer

5:00–5:25 *Interpreting Anaphoric Shell Nouns using Antecedents of Cataphoric Shell Nouns as Training Data*
Varada Kolhatkar, Heike Zinsmeister and Graeme Hirst

Saturday, October 19, 2013 (continued)

(3:45-5:50) Morphology and Phonology

3:45–4:10 *Exploring Representations from Unlabeled Data with Co-training for Chinese Word Segmentation*
Longkai Zhang, Houfeng Wang, Xu Sun and Mairgup Mansur

4:10–4:35 *Efficient Higher-Order CRFs for Morphological Tagging*
Thomas Mueller, Helmut Schmid and Hinrich Schütze

4:35–5:00 *The Effects of Syntactic Features in Automatic Prediction of Morphology*
Wolfgang Seeker and Jonas Kuhn

5:00–5:25 *Adaptor Grammars for Learning Non-Concatenative Morphology*
Jan A. Botha and Phil Blunsom

(6:00-7:30) Poster Session A

Grounding Strategic Conversation: Using Negotiation Dialogues to Predict Trades in a Win-Lose Game
Anais Cadilhac, Nicholas Asher, Farah Benamara and Alex Lascarides

Unsupervised Induction of Contingent Event Pairs from Film Scenes
Zhichao Hu, Elahe Rahimtoroghi, Larissa Munishkina, Reid Swanson and Marilyn A. Walker

Latent Anaphora Resolution for Cross-Lingual Pronoun Prediction
Christian Hardmeier, Jörg Tiedemann and Joakim Nivre

Towards Situated Dialogue: Revisiting Referring Expression Generation
Rui Fang, Changsong Liu, Lanbo She and Joyce Y. Chai

Open-Domain Fine-Grained Class Extraction from Web Search Queries
Marius Pasca

Unsupervised Relation Extraction with General Domain Knowledge
Oier Lopez de Lacalle and Mirella Lapata

Efficient Collective Entity Linking with Stacking
Zhengyan He, Shujie Liu, Yang Song, Mu Li, Ming Zhou and Houfeng Wang

Saturday, October 19, 2013 (continued)

Joint Bootstrapping of Corpus Annotations and Entity Types
Hrushikesh Mohapatra, Siddhanth Jain and Soumen Chakrabarti

Effectiveness and Efficiency of Open Relation Extraction
Filipe Mesquita, Jordan Schmidek and Denilson Barbosa

Automatic Feature Engineering for Answer Selection and Extraction
Aliaksei Severyn and Alessandro Moschitti

Improving Web Search Ranking by Incorporating Structured Annotation of Queries
Xiao Ding, Zhicheng Dou, Bing Qin, Ting Liu and Ji-rong Wen

Building Specialized Bilingual Lexicons Using Large Scale Background Knowledge
Dhouha Bouamor, Adrian Popescu, Nasredine Semmar and Pierre Zweigenbaum

Document Summarization via Guided Sentence Compression
Chen Li, Fei Liu, Fuliang Weng and Yang Liu

Anchor Graph: Global Reordering Contexts for Statistical Machine Translation
Hendra Setiawan, Bowen Zhou and Bing Xiang

Source-Side Classifier Preordering for Machine Translation
Uri Lerner and Slav Petrov

Improving Pivot-Based Statistical Machine Translation Using Random Walk
Xiaoning Zhu, Zhongjun He, Hua Wu, Haifeng Wang, Conghui Zhu and Tiejun Zhao

Improving Alignment of System Combination by Using Multi-objective Optimization
Tian Xia, Zongcheng Ji, Shaodan Zhai, Yidong Chen, Qun Liu and Shaojun Wang

Flexible and Efficient Hypergraph Interactions for Joint Hierarchical and Forest-to-String Decoding
Martin Cmejrek, Haitao Mi and Bowen Zhou

Factored Soft Source Syntactic Constraints for Hierarchical Machine Translation
Zhongqiang Huang, Jacob Devlin and Rabih Zbib

Recursive Autoencoders for ITG-Based Translation
Peng Li, Yang Liu and Maosong Sun

Automatically Classifying Edit Categories in Wikipedia Revisions
Johannes Daxenberger and Iryna Gurevych

Semi-Markov Phrase-Based Monolingual Alignment
Xuchen Yao, Benjamin Van Durme, Chris Callison-Burch and Peter Clark

A Constrained Latent Variable Model for Coreference Resolution
Kai-Wei Chang, Rajhans Samdani and Dan Roth

Centering Similarity Measures to Reduce Hubs
Ikumi Suzuki, Kazuo Hara, Masashi Shimbo, Marco Saerens and Kenji Fukumizu

Unsupervised Spectral Learning of WCFG as Low-rank Matrix Completion
Raphaël Bailly, Xavier Carreras, Franco M. Luque and Ariadna Quattoni

Identifying Phrasal Verbs Using Many Bilingual Corpora
Karl Pichotta and John DeNero

Deep Learning for Chinese Word Segmentation and POS Tagging
Xiaoqing Zheng, Hanyang Chen and Tianyu Xu

Joint Chinese Word Segmentation and POS Tagging on Heterogeneous Annotated Corpora with Multiple Task Learning
Xipeng Qiu, Jiayi Zhao and Xuanjing Huang

The Topology of Semantic Knowledge
Jimmy Dubuisson, Jean-Pierre Eckmann, Christian Scheible and Hinrich Schütze

Unsupervised Induction of Cross-Lingual Semantic Relations
Mike Lewis and Mark Steedman

Two-Stage Method for Large-Scale Acquisition of Contradiction Pattern Pairs using Entailment
Julien Kloetzer, Stijn De Saeger, Kentaro Torisawa, Chikara Hashimoto, Jong-Hoon Oh, Motoki Sano and Kiyonori Ohtake

Saturday, October 19, 2013 (continued)

Sarcasm as Contrast between a Positive Sentiment and Negative Situation
Ellen Riloff, Ashequl Qadir, Prafulla Surve, Lalindra De Silva, Nathan Gilbert and Ruihong Huang

Collective Personal Profile Summarization with Social Networks
Zhongqing Wang, Shoushan LI, Fang Kong and Guodong Zhou

Optimized Event Storyline Generation based on Mixture-Event-Aspect Model
Lifu Huang and Lian'en Huang

Automatically Determining a Proper Length for Multi-Document Summarization: A Bayesian Nonparametric Approach
Tengfei Ma and Hiroshi Nakagawa

A Discourse-Driven Content Model for Summarising Scientific Articles Evaluated in a Complex Question Answering Task
Maria Liakata, Simon Dobnik, Shyamasree Saha, Colin Batchelor and Dietrich Rebholz-Schuhmann

Optimal Incremental Parsing via Best-First Dynamic Programming
Kai Zhao, James Cross and Liang Huang

Exploiting Language Models for Visual Recognition
Dieu-Thu Le, Jasper Uijlings and Raffaella Bernardi

Mining Scientific Terms and their Definitions: A Study of the ACL Anthology
Yiping Jin, Min-Yen Kan, Jun-Ping Ng and Xiangnan He

Joint Learning and Inference for Grammatical Error Correction
Alla Rozovskaya and Dan Roth

With Blinkers on: Robust Prediction of Eye Movements across Readers
Franz Matthies and Anders Søgaard

Using Paraphrases and Lexical Semantics to Improve the Accuracy and the Robustness of Supervised Models in Situated Dialogue Systems
Claire Gardent and Lina M. Rojas Barahona

Cascading Collective Classification for Bridging Anaphora Recognition using a Rich Linguistic Feature Set
Yufang Hou, Katja Markert and Michael Strube

A Synchronous Context Free Grammar for Time Normalization
Steven Bethard

Rule-Based Information Extraction is Dead! Long Live Rule-Based Information Extraction Systems!
Laura Chiticariu, Yunyao Li and Frederick R. Reiss

Improving Learning and Inference in a Large Knowledge-Base using Latent Syntactic Cues
Matt Gardner, Partha Pratim Talukdar, Bryan Kisiel and Tom Mitchell

What is Hidden among Translation Rules
Libin Shen and Bowen Zhou

Converting Continuous-Space Language Models into N-Gram Language Models for Statistical Machine Translation
Rui Wang, Masao Utiyama, Isao Goto, Eiichro Sumita, Hai Zhao and Bao-Liang Lu

A Corpus Level MIRA Tuning Strategy for Machine Translation
Ming Tan, Tian Xia, Shaojun Wang and Bowen Zhou

Word Level Language Identification in Online Multilingual Communication
Dong Nguyen and A. Seza Dogruoz

Microblog Entity Linking by Leveraging Extra Posts
Yuhang Guo, Bing Qin, Ting Liu and Sheng Li

Automatic Domain Partitioning for Multi-Domain Learning
Di Wang, Chenyan Xiong and William Yang Wang

Decipherment with a Million Random Restarts
Taylor Berg-Kirkpatrick and Dan Klein

Russian Stress Prediction using Maximum Entropy Ranking
Keith Hall and Richard Sproat

Scaling to Large^3 Data: An Efficient and Effective Method to Compute Distributional Thesauri
Martin Riedl and Chris Biemann

Discriminative Improvements to Distributional Sentence Similarity
Yangfeng Ji and Jacob Eisenstein

Is Twitter A Better Corpus for Measuring Sentiment Similarity?
Shi Feng, Le Zhang, Binyang Li, Daling Wang, Ge Yu and Kam-Fai Wong

Implicit Feature Detection via a Constrained Topic Model and SVM
Wei Wang, Hua Xu and Xiaoqiu Huang

Online Learning for Inexact Hypergraph Search
Hao Zhang, Liang Huang, Kai Zhao and Ryan McDonald

(7:30-9:00) Poster Session B

Predicting the Presence of Discourse Connectives
Gary Patterson and Andrew Kehler

Japanese Zero Reference Resolution Considering Exophora and Author/Reader Mentions
Masatsugu Hangyo, Daisuke Kawahara and Sadao Kurohashi

A Dataset for Research on Short-Text Conversations
Hao Wang, Zhengdong Lu, Hang Li and Enhong Chen

Discourse Level Explanatory Relation Extraction from Product Reviews Using First-Order Logic
Qi Zhang, Jin Qian, Huan Chen, Jihua Kang and Xuanjing Huang

Building Event Threads out of Multiple News Articles
Xavier Tannier and Véronique Moriceau

Tree Kernel-based Negation and Speculation Scope Detection with Structured Syntactic Parse Features
Bowei Zou, Guodong Zhou and Qiaoming Zhu

A temporal model of text periodicities using Gaussian Processes
Daniel Preoţiuc-Pietro and Trevor Cohn

Automatically Detecting and Attributing Indirect Quotations
Silvia Pareti, Tim O'Keefe, Ioannis Konstas, James R. Curran and Irena Koprinska

Saturday, October 19, 2013 (continued)

Identifying Web Search Query Reformulation using Concept based Matching
Ahmed Hassan

The Answer is at your Fingertips: Improving Passage Retrieval for Web Question Answering with Search Behavior Data
Mikhail Ageev, Dmitry Lagun and Eugene Agichtein

Assembling the Kazakh Language Corpus
Olzhas Makhambetov, Aibek Makazhanov, Zhandos Yessenbayev, Bakhyt Matkarimov, Islam Sabyrgaliyev and Anuar Sharafudinov

Automatic Extraction of Morphological Lexicons from Morphologically Annotated Corpora
Ramy Eskander, Nizar Habash and Owen Rambow

Joint Language and Translation Modeling with Recurrent Neural Networks
Michael Auli, Michel Galley, Chris Quirk and Geoffrey Zweig

Multi-Domain Adaptation for SMT Using Multi-Task Learning
Lei Cui, Xilun Chen, Dongdong Zhang, Shujie Liu, Mu Li and Ming Zhou

Translation with Source Constituency and Dependency Trees
Fandong Meng, Jun Xie, Linfeng Song, Yajuan Lü and Qun Liu

Monolingual Marginal Matching for Translation Model Adaptation
Ann Irvine, Chris Quirk and Hal Daumé III

Efficient Left-to-Right Hierarchical Phrase-Based Translation with Improved Reordering
Maryam Siahbani, Baskaran Sankaran and Anoop Sarkar

A Systematic Exploration of Diversity in Machine Translation
Kevin Gimpel, Dhruv Batra, Chris Dyer and Gregory Shakhnarovich

Max-Violation Perceptron and Forced Decoding for Scalable MT Training
Heng Yu, Liang Huang, Haitao Mi and Kai Zhao

Identifying Multiple Userids of the Same Author
Tieyun Qian and Bing Liu

Saturday, October 19, 2013 (continued)

Gender Inference of Twitter Users in Non-English Contexts
Morgane Ciot, Morgan Sonderegger and Derek Ruths

A Multimodal LDA Model integrating Textual, Cognitive and Visual Modalities
Stephen Roller and Sabine Schulte im Walde

Combining PCFG-LA Models with Dual Decomposition: A Case Study with Function Labels and Binarization
Joseph Le Roux, Antoine Rozenknop and Jennifer Foster

Feature Noising for Log-Linear Structured Prediction
Sida Wang, Mengqiu Wang, Stefan Wager, Percy Liang and Christopher D. Manning

Improvements to the Bayesian Topic N-Gram Models
Hiroshi Noji, Daichi Mochihashi and Yusuke Miyao

An Empirical Study Of Semi-Supervised Chinese Word Segmentation Using Co-Training
Fan Yang and Paul Vozila

Ubertagging: Joint Segmentation and Supertagging for English
Rebecca Dridan

Automatic Knowledge Acquisition for Case Alternation between the Passive and Active Voices in Japanese
Ryohei Sasano, Daisuke Kawahara, Sadao Kurohashi and Manabu Okumura

Exploiting Multiple Sources for Open-Domain Hypernym Discovery
Ruiji Fu, Bing Qin and Ting Liu

A Semantically Enhanced Approach to Determine Textual Similarity
Eduardo Blanco and Dan Moldovan

Understanding and Quantifying Creativity in Lexical Composition
Polina Kuznetsova, Jianfu Chen and Yejin Choi

Sentiment Analysis: How to Derive Prior Polarities from SentiWordNet
Marco Guerini, Lorenzo Gatti and Marco Turchi

Simulating Early-Termination Search for Verbose Spoken Queries
Jerome White, Douglas W. Oard, Nitendra Rajput and Marion Zalk

Summarizing Complex Events: a Cross-Modal Solution of Storylines Extraction and Reconstruction
Shize Xu, Shanshan Wang and Yan Zhang

Image Description using Visual Dependency Representations
Desmond Elliott and Frank Keller

Semi-Supervised Feature Transformation for Dependency Parsing
Wenliang Chen, Min Zhang and Yue Zhang

Leveraging Lexical Cohesion and Disruption for Topic Segmentation
Anca-Roxana Simon, Guillaume Gravier and Pascale Sébillot

This Text Has the Scent of Starbucks: A Laplacian Structured Sparsity Model for Computational Branding Analytics
William Yang Wang, Edward Lin and John Kominek

Mining New Business Opportunities: Identifying Trend related Products by Leveraging Commercial Intents from Microblogs
Jinpeng Wang, Wayne Xin Zhao, Haitian Wei, Hongfei Yan and Xiaoming Li

Using Topic Modeling to Improve Prediction of Neuroticism and Depression in College Students
Philip Resnik, Anderson Garron and Rebecca Resnik

Predicting the Resolution of Referring Expressions from User Behavior
Nikos Engonopoulos, Martin Villalba, Ivan Titov and Alexander Koller

Chinese Zero Pronoun Resolution: Some Recent Advances
Chen Chen and Vincent Ng

Connecting Language and Knowledge Bases with Embedding Models for Relation Extraction
Jason Weston, Antoine Bordes, Oksana Yakhnenko and Nicolas Usunier

Simple Customization of Recursive Neural Networks for Semantic Relation Classification
Kazuma Hashimoto, Makoto Miwa, Yoshimasa Tsuruoka and Takashi Chikayama

Saturday, October 19, 2013 (continued)

Improving Statistical Machine Translation with Word Class Models
Joern Wuebker, Stephan Peitz, Felix Rietig and Hermann Ney

Shift-Reduce Word Reordering for Machine Translation
Katsuhiko Hayashi, Katsuhito Sudoh, Hajime Tsukada, Jun Suzuki and Masaaki Nagata

Decoding with Large-Scale Neural Language Models Improves Translation
Ashish Vaswani, Yinggong Zhao, Victoria Fossum and David Chiang

Bilingual Word Embeddings for Phrase-Based Machine Translation
Will Y. Zou, Richard Socher, Daniel Cer and Christopher D. Manning

Application of Localized Similarity for Web Documents
Peter Reberšek and Mateja Verlic

Dependency Language Models for Sentence Completion
Joseph Gubbins and Andreas Vlachos

A Walk-Based Semantically Enriched Tree Kernel Over Distributed Word Representations
Shashank Srivastava, Dirk Hovy and Eduard Hovy

Automatic Idiom Identification in Wiktionary
Grace Muzny and Luke Zettlemoyer

Elephant: Sequence Labeling for Word and Sentence Segmentation
Kilian Evang, Valerio Basile, Grzegorz Chrupała and Johan Bos

Detecting Compositionality of Multi-Word Expressions using Nearest Neighbours in Vector Space Models
Douwe Kiela and Stephen Clark

Naive Bayes Word Sense Induction
Do Kook Choe and Eugene Charniak

The VerbCorner Project: Toward an Empirically-Based Semantic Decomposition of Verbs
Joshua K. Hartshorne, Claire Bonial and Martha Palmer

Saturday, October 19, 2013 (continued)

Where Not to Eat? Improving Public Policy by Predicting Hygiene Inspections Using Online Reviews
Jun Seok Kang, Polina Kuznetsova, Michael Luca and Yejin Choi

Automatically Identifying Pseudepigraphic Texts
Moshe Koppel and Shachar Seidman

Sunday, October 20, 2013

(8:00-9:00) Breakfast

(9:15-10:30) Second invited talk: Fernando Pereira

(10:30-11:00) Break

(11:00-12:35) Machine Learning for NLP

11:25–11:50 *Dynamic Feature Selection for Dependency Parsing*
He He, Hal Daumé III and Jason Eisner

11:50–12:15 *Semi-Supervised Representation Learning for Cross-Lingual Text Classification*
Min Xiao and Yuhong Guo

12:15–12:35 *Using Crowdsourcing to get Representations based on Regular Expressions*
Anders Søgaard, Hector Martinez, Jakob Elming and Anders Johannsen

(11:00-12:35) Summarization and Generation

11:00–11:25 *Overcoming the Lack of Parallel Data in Sentence Compression*
Katja Filippova and Yasemin Altun

11:25–11:50 *Fast Joint Compression and Summarization via Graph Cuts*
Xian Qian and Yang Liu

11:50–12:15 *Inducing Document Plans for Concept-to-Text Generation*
Ioannis Konstas and Mirella Lapata

Sunday, October 20, 2013 (continued)

12:15–12:35 *Single-Document Summarization as a Tree Knapsack Problem*
Tsutomu Hirao, Yasuhisa Yoshida, Masaaki Nishino, Norihito Yasuda and Masaaki Nagata

(11:00-12:35) Information Extraction and Social Media Analysis

11:00–11:25 *A Hierarchical Entity-Based Approach to Structuralize User Generated Content in Social Media: A Case of Yahoo! Answers*
Baichuan Li, Jing Liu, Chin-Yew Lin, Irwin King and Michael R. Lyu

11:25–11:50 *Semantic Parsing on Freebase from Question-Answer Pairs*
Jonathan Berant, Andrew Chou, Roy Frostig and Percy Liang

11:50–12:15 *Scaling Semantic Parsers with On-the-Fly Ontology Matching*
Tom Kwiatkowski, Eunsol Choi, Yoav Artzi and Luke Zettlemoyer

12:15–12:35 *Classifying Message Board Posts with an Extracted Lexicon of Patient Attributes*
Ruihong Huang and Ellen Riloff

(12:35-2:00) Lunch

(2:00-3:35) Machine Translation II

2:00–2:25 *Lexical Chain Based Cohesion Models for Document-Level Statistical Machine Translation*
Deyi Xiong, Yang Ding, Min Zhang and Chew Lim Tan

2:50–3:15 *A Convex Alternative to IBM Model 2*
Andrei Simion, Michael Collins and Cliff Stein

3:15–3:35 *Pair Language Models for Deriving Alternative Pronunciations and Spellings from Pronunciation Dictionaries*
Russell Beckley and Brian Roark

Sunday, October 20, 2013 (continued)

(2:00-3:35) Semantics II

2:00–2:25 *Prior Disambiguation of Word Tensors for Constructing Sentence Vectors*
Dimitri Kartsaklis and Mehrnoosh Sadrzadeh

2:25–2:50 *Multi-Relational Latent Semantic Analysis*
Kai-Wei Chang, Wen-tau Yih and Christopher Meek

2:50–3:15 *A Study on Bootstrapping Bilingual Vector Spaces from Non-Parallel Data (and Nothing Else)*
Ivan Vulić and Marie-Francine Moens

3:15–3:35 *Deriving Adjectival Scales from Continuous Space Word Representations*
Joo-Kyung Kim and Marie-Catherine de Marneffe

(2:00-3:35) Opinion Mining and Sentiment Analysis I

2:00–2:25 *Recursive Deep Models for Semantic Compositionality Over a Sentiment Treebank*
Richard Socher, Alex Perelygin, Jean Wu, Jason Chuang, Christopher D. Manning, Andrew Ng and Christopher Potts

2:25–2:50 *Open Domain Targeted Sentiment*
Margaret Mitchell, Jacqui Aguilar, Theresa Wilson and Benjamin Van Durme

2:50–3:15 *Exploiting Domain Knowledge in Aspect Extraction*
Zhiyuan Chen, Arjun Mukherjee, Bing Liu, Meichun Hsu, Malu Castellanos and Riddhiman Ghosh

(3:35-4:05) Break

Sunday, October 20, 2013 (continued)

(4:05-5:55) Machine Translation III

4:05–4:30 *Dependency-Based Decipherment for Resource-Limited Machine Translation*
Qing Dou and Kevin Knight

4:30–4:55 *Translating into Morphologically Rich Languages with Synthetic Phrases*
Victor Chahuneau, Eva Schlinger, Noah A. Smith and Chris Dyer

4:55–5:20 *Boosting Cross-Language Retrieval by Learning Bilingual Phrase Associations from Relevance Rankings*
Artem Sokokov, Laura Jehl, Felix Hieber and Stefan Riezler

5:20–5:55 *Recurrent Continuous Translation Models*
Nal Kalchbrenner and Phil Blunsom

(4:05-5:55) Information Extraction II

4:05–4:30 *Learning Biological Processes with Global Constraints*
Aju Thalappillil Scaria, Jonathan Berant, Mengqiu Wang, Peter Clark, Justin Lewis, Brittany Harding and Christopher D. Manning

4:30–4:55 *Generating Coherent Event Schemas at Scale*
Niranjan Balasubramanian, Stephen Soderland, Mausam and Oren Etzioni

5:20–5:55 *Orthonormal Explicit Topic Analysis for Cross-Lingual Document Matching*
John Philip McCrae, Philipp Cimiano and Roman Klinger

(4:05-5:55) NLP Applications II

4:05–4:30 *Automated Essay Scoring by Maximizing Human-Machine Agreement*
Hongbo Chen and Ben He

4:55–5:20 *Success with Style: Using Writing Style to Predict the Success of Novels*
Vikas Ganjigunte Ashok, Song Feng and Yejin Choi

5:20–5:55 *A Generative Joint, Additive, Sequential Model of Topics and Speech Acts in Patient-Doctor Communication*
Byron C. Wallace, Thomas A Trikalinos, M. Barton Laws, Ira B. Wilson and Eugene Charniak

Monday, October 21, 2013

(8:00-9:00) Breakfast

(9:00-10:35) Information Extraction III

9:00–9:25 *Harvesting Parallel News Streams to Generate Paraphrases of Event Relations*
Congle Zhang and Daniel S. Weld

9:25–9:50 *Relational Inference for Wikification*
Xiao Cheng and Dan Roth

9:50–10:15 *Event Schema Induction with a Probabilistic Entity-Driven Model*
Nathanael Chambers

10:15–10:35 *Using Soft Constraints in Joint Inference for Clinical Concept Recognition*
Prateek Jindal and Dan Roth

(9:00-10:35) Opinion Mining and Sentiment Analysis II

9:00–9:25 *Exploring Demographic Language Variations to Improve Multilingual Sentiment Analysis in Social Media*
Svitlana Volkova, Theresa Wilson and David Yarowsky

9:25–9:50 *Opinion Mining in Newspaper Articles by Entropy-Based Word Connections*
Thomas Scholz and Stefan Conrad

9:50–10:15 *Collective Opinion Target Extraction in Chinese Microblogs*
Xinjie Zhou, Xiaojun Wan and Jianguo Xiao

10:15–10:35 *Detecting Promotional Content in Wikipedia*
Shruti Bhosale, Heath Vinicombe and Raymond Mooney

Monday, October 21, 2013 (continued)

(9:00-10:35) NLP for Social Media II

9:00–9:25 *Learning Topics and Positions from Debatepedia*
Swapna Gottipati, Minghui Qiu, Yanchuan Sim, Jing Jiang and Noah A. Smith

9:25–9:50 *A Unified Model for Topics, Events and Users on Twitter*
Qiming Diao and Jing Jiang

9:50–10:15 *Authorship Attribution of Micro-Messages*
Roy Schwartz, Oren Tsur, Ari Rappoport and Moshe Koppel

10:15–10:35 *Detection of Product Comparisons - How Far Does an Out-of-the-Box Semantic Role Labeling System Take You?*
Wiltrud Kessler and Jonas Kuhn

(10:35–11:00) Break

(11:00-11:45) Parsing

11:00–11:25 *A Multi-Teraflop Constituency Parser using GPUs*
John Canny, David Hall and Dan Klein

11:25–11:45 *Fish Transporters and Miracle Homes: How Compositional Distributional Semantics can Help NP Parsing*
Angeliki Lazaridou, Eva Maria Vecchi and Marco Baroni

(11:00-11:45) Semantics III

11:00–11:25 *Learning Distributions over Logical Forms for Referring Expression Generation*
Nicholas FitzGerald, Yoav Artzi and Luke Zettlemoyer

11:25–11:45 *Learning to Rank Lexical Substitutions*
György Szarvas, Róbert Busa-Fekete and Eyke Hüllermeier

Monday, October 21, 2013 (continued)

(11:00-11:45) NLP Applications III

11:00–11:25 *Identifying Manipulated Offerings on Review Portals*
Jiwei Li, Myle Ott and Claire Cardie

Abstract

Since many applications such as timeline summaries and temporal IR involving temporal analysis rely on document timestamps, the task of automatic dating of documents has been increasingly important. Instead of using feature-based methods as conventional models, our method attempts to date documents in a year level by exploiting relative temporal relations between documents and events, which are very effective for dating documents. Based on this intuition, we proposed an event-based time label propagation model called confidence boosting in which time label information can be propagated between documents and events on a bipartite graph. The experiments show that our event-based propagation model can predict document timestamps in high accuracy and the model combined with a MaxEnt classifier outperforms the state-of-the-art method for this task especially when the size of the training set is small.

1 Introduction

Time is an important dimension of any information space and can be useful in information retrieval, question-answering systems and timeline summaries. In the applications involving temporal analysis, document timestamps are very useful. For instance, temporal information retrieval models take into consideration the document's creation time for document retrieval and ranking (Kalczynski and Chou, 2005; Berberich et al., 2007) for better dealing with time-sensitive queries; some information retrieval applications such as Google Scholar can list articles published during the time a user specifies for better satisfying users' needs. In addition, timeline summarization techniques (Hu et al., 2011; Binh Tran et al., 2013) and some event-event ordering models (Chambers and Jurafsky, 2008; Yoshikawa et al., 2009) also rely on the timestamps. Unfortunately, many documents on the web do not have a credible timestamp, as Chambers (2012) reported. Therefore, it is significant to date documents, that is to predict document creation time.

One typical method for dating document is based on temporal language models, which were first used for dating by de Jong et al. (2005). They learned language models (unigram) for specific time periods and scored articles with normalized log-likelihood ratio scores. The other typical approach for the task was proposed by Nathanael Chambers (2012). In Chambers's work, discriminative classifiers – maximum entropy (MaxEnt) classifiers were used by incorporating linguistic features and temporal constraints for training, which outperforms the previous temporal language models on a subset of Gigaword Corpus (Graff et al., 2003).

However, the conventional methods have some limitations because they predict creation time of documents mainly based on feature-based models without understanding content of documents, which may lead to wrong predictions in some cases. For instance, assume that $D1$ and $D2$ are documents whose content is given as follows:

> ($D1$) Sudan *last year* accused Eritrea of backing an offensive by rebels in the eastern border region.

*Corresponding author

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1–11,
Seattle, Washington, USA, 18-21 October 2013.

($D2$) *Two years ago*, Sudan accused Eritrea of backing an offensive by rebels in the eastern border region.

Since $D1$ and $D2$ share many important features, the previous dating methods are very likely to predict the same timestamp for the two documents. However, it will be easy to infer that the creation time of $D1$ should be one year earlier than that of $D2$ if we analyze the content of the two documents.

Unlike the previous methods, this paper exploits relative temporal relations between events and documents for dating documents on the basis of an understanding of document content.

It is known that each event in a news article has a relative temporal relation with the document. By analyzing the relative temporal relation, time of the event can be known if we know the document timestamp; on the other hand, if the time of an event is known, it can also be used to predict the creation time of documents mentioning the event, which can be best demonstrated with the above-mentioned example of $D1$ and $D2$. In the example, "*last year*" is an important cue to infer that the event mentioned by the documents occurred in 2002 if we know the timestamp of $D1$ is 2003. With the information that the event occurred in 2002, it can also be inferred from the temporal expression "*Two years ago*" that $D2$ was written in 2004. In this way, the timestamp of the labeled document ($D1$) is propagated to the unlabeled document ($D2$) through the event both of them mention, which is the main intuition of this paper.

In fact, this intuition seems practical to date documents on the web because web data is very redundant. Many documents on the web can be connected via events because an event is usually mentioned by different documents. According to our analysis of a collection of news articles spanning 5 years, it is found that an event is mentioned by 3.44 news articles on average; on the other hand, a document usually refers to multiple events. Therefore, if one knows a document timestamp, time of events the document mentions can be obtained by analyzing the relative temporal relations between the document and the events. Likewise, if the time of an event is known, then it can be used to predict creation time of the documents which mention it.

Based on the intuition, we proposed an event-based time label propagation model called confidence boosting in which timestamps are propagated according to relative temporal relations between documents and events. In this way, documents can be dated with an understanding of content so that this model can date document more credibly. To our knowledge, it is the first time that the relative temporal relations between documents and events are exploited for dating documents, which is proved to be effective by the experimental results.

2 Event-based Time Label Propogation

As mentioned above, the relative temporal relations between documents and events are useful for dating documents. By analyzing the temporal relations, even if there are only a small number of documents labeled with timestamps, this information can be propagated to documents connected with them on a bipartite graph using breadth first traversal (BFS).

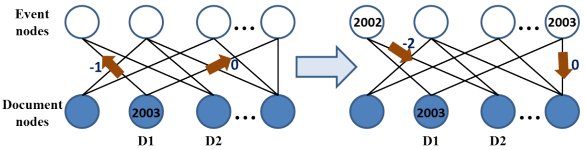

Figure 1: An example of BFS-based propagation

As shown in figure 1, there are two kinds of nodes in the bipartite graph. A document node is a single document while an event node represents an event. The edge between a document node and an event node means that the document mentions the event. Also, the edge carries the information of the relative temporal relation between the document and the event. The label propagation from node i to node j will occur if BFS condition which is defined as follows is satisfied:

$$\begin{cases} e_{ij} \in E \\ i \in L \text{ and } j \notin L \end{cases} \quad \text{(BFS condition)}$$

When the timestamp of i is propagated to j:

$$Y(j) = Y(i) + \delta(i,j)$$
$$L = L \cup \{j\}$$

where E is the set of edges of the bipartite graph, e_{ij} denotes the edge between node i and j, L is the set of nodes which have been already labeled with timestamps, $Y(i)$ is the year of node i and $\delta(i,j)$ is the relative temporal relation between node i and j.

In figure 1, the timestamp of document $D1$ is 2003, which is known. This information can be propagated to its adjacent nodes i.e. the event nodes it mentions according to the relative temporal relations. Then, these event nodes propagate their timestamps to other documents which mention them. By repeating this process, the timestamp of the document can be propagated to documents which are reachable from the initially labeled document on the bipartite graph.

Although the BFS-based propagation process can propagate timestamps from few labeled documents to a large number of unlabeled ones, it has two shortcomings for this task. First, once one timestamp is propagated incorrectly, this error will lead to more mistakes in the following propagations. If such an error occurred at the beginning of the propagation process, it would lead to propagation of errors. Second, BFS-based method cannot address conflict of predictions during propagation, which is shown in figure 2.

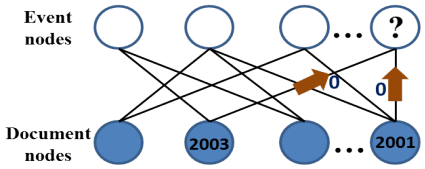

Figure 2: Conflict of predictions during propagation

To address the problems of the BFS-based method, we proposed a novel propagation model called confidence boosting model which improves the BFS-based model by optimizing the global confidence of the bipartite graph. In the confidence boosting model, every node in the bipartite graph has a confidence which measures the credibility of the predicted timestamp of the node. When the timestamp of a node is propagated to other nodes, its confidence will be also propagated to the target nodes with some loss. The loss of confidence is called confidence decay. Formally, the confidence decay process is described as follows:

$$c(j) = c(i) \times \sigma(i, j)$$

where $c(i)$ denotes confidence of node i and $\sigma(i, j)$ is the decay factor from node i to node j. For guaranteeing that timestamps can be propagated on the bipartite graph credibly, we define the following condition which is called CB (Confidence Boosting) condition:

$$\begin{cases} e_{ij} \in E \\ c(i) \times \sigma(i, j) > c(j) \end{cases} \quad \text{(CB condition)}$$

In the confidence boosting model, propagation from node i to node j will occur only if CB condition is satisfied. When timestamps are propagated on the bipartite graph, timestamps and confidence of nodes will be updated dynamically. A node with high confidence is more active than nodes with low confidence to propagate its timestamp because a node with high confidence is more likely to satisfy the CB condition for propagating its timestamp. Moreover, a prediction with low confidence can be corrected by the prediction with high confidence. Therefore, the confidence boosting model can address both propagation of errors and conflict of predictions which cannot be tackled by the BFS-based model.

However, there are challenges for running such propagation models in practice. First, the relative temporal relations between documents and events are usually unavailable. Second, events extracted from different documents do not have any connection even if they refer to the same event. Therefore, each event is connected with only one document in the bipartite graph and thus cannot propagate its timestamp to other documents unless we perform event coreference resolution. Third, propagations from generic events are very likely to lead to propagation errors because generic events can happen in any year. Also, how to set the confidence and decay factors reasonably in practice for a confidence boosting model is worthy of investigation. All these challenges for the propagation models and their corresponding solutions will be discussed in Section 3.

3 Details of Event-based Propagation Models

In this section, details of the event-based time label propagation models including challenges and their corresponding solutions are presented. We first discuss the event extraction and processing involving relative temporal relation mining, event coreference resolution and distinguishing specific extractions from generic ones in Section 3.1. Then, we show the confidence boosting algorithm in detail in Section 3.2.

3.1 Event extraction and processing

As mentioned in previous sections, events play a key role in the propagation models. We define an event as a Subject-Predicate-Object (SPO) triple. To extract events from raw text, an open information extraction software - ReVerb (Fader et al., 2011) is used. ReVerb is a program that automatically identifies and extracts relationships from English sentences. It takes raw text as input and outputs SPO triples which are called extractions.

However, extractions extracted by ReVerb cannot be used directly for our propagation models for three main reasons. First, the relative temporal relations between documents and the extractions are unavailable. Second, the extractions extracted from different documents do not have any connection even if they refer to the same event. Third, propagations from generic events are very likely to lead to propagation errors.

For addressing the three challenges for the propagation models, we first presented a rule-based method for mining the relative temporal relations between extractions and documents in Section 3.1.1. Then, an efficient event coreference resolution method is introduced in Section 3.1.2. Finally, the method for distinguishing specific extractions from generic ones is shown in Section 3.1.3.

3.1.1 Relative temporal relation mining

We used a rule-based method to extract temporal expressions and used Stanford parser (De Marneffe et al., 2006) to analyze association between the temporal expressions and the extractions. Specifically, we define that an extraction is associated with a temporal expression if there is an arc from the predicate of the extraction to the temporal expression in the dependency tree. For a certain extraction, there are the following four cases whose instances are shown in table 1 for handling.

Case 1: The extraction is associated with an absolute temporal expressions with year mentions in the sentence.

In this case, the time of the extraction is equal to the year mention:

$$Y(ex) = YearMention$$

For the example in table 1, $Y(ex) = 1999$.

Case 2: The extraction is associated with a relative temporal expression (not involving year) in the sentence.

Case	Instance
1	*In 1999*, South Korea exported 89,000 tons of pork to Japan.
2	*In April*, however, the BOI investments showed marked improvement.
	Last month, Kazini vowed to resign his top army job.
3	Julius Erving moved with his family to Florida *three years ago*.
4	The meeting focused on ways to revive the stalled Mideast peace process.

Table 1: Instances of various temporal expressions

In this case, the time of the extraction is equal to the creation time of the document:

$$Y(ex) = Y(d)$$

Case 3: The extraction is associated with a relative temporal expression (involving specific year gap) in the sentence.

In this case, the time of the extraction is computed as follows:

$$Y(ex) = Y(d) \pm YearGap$$

For the example in table 1, $Y(ex) = Y(d) - 3$.

Case 4: The extraction is not associated with any temporal expression in the sentence or the other cases.

In this case, it is difficult to recognize the relative temporal relations. However, timeliness can be leveraged to determine the relations as a heuristic method. It is known that timeliness is an important feature of news so that events reported by a news article usually took place a couple of days or weeks before the article was written. Therefore, we heuristically consider the year of the extraction is the same with that of its source document in this case:

$$Y(ex) = Y(d)$$

In the cases except case 1, the relative temporal relation between an extraction and the document it comes from can be determined. To evaluate the performance of the rule-based method, we sampled 3,000 extractions from documents written in the year of 1995-1999 of Gigaword corpus and manually labeled these extractions with a timestamp based on their context and their corresponding document timestamps as golden standard. Table 2 shows

the accuracy of each case which will be used as a part of the decay factor in the confidence boosting model.

Case	Accuracy
1	0.774(168/217)
2	0.994(844/849)
3	0.836(281/336)
4	0.861(1376/1598)
Total	0.890(2669/3000)

Table 2: Accuracy of the four cases

We define the set of these determined relative temporal relations R as follows:

$$R = \{r_{d,ex} | d = doc(ex), ex \in C_2 \cup C_3 \cup C_4\}$$
$$r_{d,ex} =< d, ex, \delta(d, ex) >$$
$$\delta(d, ex) = -\delta(ex, d) = \{0, \pm 1, \pm 2, \pm 3, ...\}$$

where C_k is the set of extractions in case k and $doc(ex)$ is the document which extraction ex comes from. $r_{d,ex}$ is a triple describing the relative temporal relation between d and ex. For example, triple $r_{d,ex} =< d, ex, -1 >$ means that the time of extraction ex is one year before the time of document d.

3.1.2 Event coreference resolution

Extractions from different documents have no connections. However, there are a great number of extractions referring to the same event. For finding such coreferential event extractions efficiently, hierarchical agglomerative clustering (HAC) is used to cluster highly similar extractions into one cluster. We use cosine to measure the similarity between extractions and select bag of words as features. Note that it is less meaningful to cluster the extractions from the same document because coreferential extractions from the same document are not helpful for timestamp propagations. For this reason, similarity between extractions from the same documents is set to 0.

For HAC, selection of threshold is important. If the threshold is set too high, only a few extractions can be clustered despite high purity; on the contrary, if the threshold is set too low, purity of clusters will descend. In fact, selection of threshold is a trade-off between the precision and recall of event coreference resolution. For selecting a suitable threshold, extractions from documents written in 1995-1999 are used as a development set.

In practice, it is difficult for us to directly evaluate the performance of the coreference resolution of event extractions without golden standard which requires much labors for manual annotations. Alternatively, entropy which measures the purity of clusters is used for evaluation because it can indirectly reflect the precision of coreference resolution to some extent:

$$\text{Entropy} = -\sum_j \frac{n_j}{n} \sum_i P(i, j) \times \log_2 P(i, j)$$

where $P(i, j)$ is the probability of finding an extraction whose timestamp is i in the cluster j, n_j is the number of items in cluster j and n is the total number of extractions. Note that timestamp of an extraction is assigned based on its document timestamp using the method proposed in Section 3.1.1.

Figure 3 shows the effect of selection of the threshold on cluster performance. It can be found that when the threshold reaches 0.8, the entropy starts descending gently and is low enough. Since we want to find as many coreferential extractions as possible on the premise that the precision is good, the threshold is set to 0.8. Note that extractions which are single in one cluster will be filtered out because they do not have any connections with any other documents.

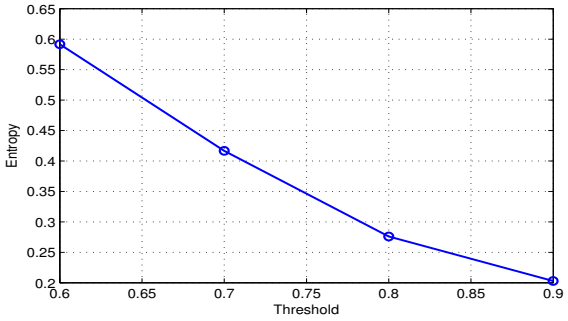

Figure 3: Entropy of clusters under different thresholds

3.1.3 Distinguishing specific events from generic ones

Not all extractions extracted by ReVerb refer to a specific event. For instance, the extraction "Germany's DAX index was down 0.2 percent" is undesirable for our task because it refers to a generic

event and this event may occur in any year. In other words, it is not able to indicate a certain timestamp and thus propagations from a generic event node are very likely to result in propagation errors. In contrast, the extraction "some of the provinces in China were hit by SARS" refers to a specific event which took place in 2003. For our task, such specific event extractions which are associated with one certain timestamp are desirable. For the sake of distinguishing such extractions from the generic ones, a MaxEnt classifier is used to classify extractions as either specific ones or generic ones.

Training Set Generation A training set is indispensable for training a MaxEnt classifier. In order to generate training examples, we performed HAC discussed in Section 3.1.2 for event coreference resolution on extractions from all documents written in May and June of 1995-1999 and then analyzed each cluster. If extractions in a cluster have different timestamps, then the extractions in this cluster will be labeled as generic extractions (negative); otherwise, extractions in the cluster are labeled as specific ones (positive). In this way, the training set can be generated without manually labeling. To avoid bias of positive and negative examples, we sampled 3,500 positive examples and 3,500 negative examples to train the model.

Feature Selection The following features were selected for training:

Named Entities: People and places are often discussed during specific time periods, particularly in news genre. Intuitively, if an extraction contains specific named entities then this extraction is less likely to be a generic event. If an extraction contains named entities, types and uninterrupted tokens of the named entities will be included as features.

Numeral: According to our analysis of the training set generated by the above-mentioned method, generic extractions usually contain numerals. For example, the extraction "15 people died in this accident" and the extraction "225 people died in this accident" have the same tokens except numerals and they are labeled as a generic event because they are clustered into one group due to high similarity but they in fact refer to different events happening in different years. Therefore, if an extraction contains numerals, the feature "NUM" will be included.

Bag of words: Bag of words can also be an indicator of specific extractions and generic ones. For example, an extraction containing 'stock', 'index', 'fell' and 'exchange' is probably a generic one.

The model obtained after training can be used to predict whether an extraction is a specific one. We define $P(S = 1|ex)$ as the probability that an extraction is a specific one, which can be provided by the classifier. Extractions whose probability to be a specific one is less than 0.05 are filtered out. For the other extractions, this probability is used as a part of the decay factor in the confidence boosting model, which will be discussed in detail in Section 3.2.

3.2 Confidence boosting

After extracting and processing the event extractions, relative temporal relations between documents and events can be constructed. This can be formally represented by a bipartite graph G=$\langle V, E\rangle$. There are two kinds of nodes on the bipartite graph: document nodes and event nodes. Slightly different with the event node mentioned in Section 2, an event node in practice is a cluster of coreferential extractions and it can be connected with multiple document nodes. Note that the bipartite graph does not contain any isolate node. For briefness, we define $DNode$ as the set of document nodes and $ENode$ as the set of event nodes. The set of edges E is formally defined as follows:
$E = \{e_{ij}, e_{ji}|i \in DNode, j \in ENode, r_{i,j} \in R\}$
where R is the set of relative temporal relations defined as Section 3.1.1.

3.2.1 Confidence and decay factor

As mentioned in Section 2, the confidence of a node measures the credibility of the predicted timestamp. According to the definition, we set the confidence of initially labeled nodes to 1 and set confidence of nodes without any timestamp to 0 in practice. When the timestamp of a node is propagated to another node, its confidence will be propagated to the target node with some loss, as discussed in Section 2. The confidence loss is caused by two factors in practice. The first one is the credibility of the relative temporal relation between two nodes and the other one depends on whether an extraction refers to a specific event.

Relative temporal relations between documents

and extractions we mined using the rule-based method in Section 3.1.1 are not absolutely correct. The credibility of the relations has an effect on the confidence decay. Formally, we used $\pi(i, j)$ to denote the credibility of the relative temporal relation between node i and node j. The credibility of a relative temporal relation in each case can be estimated through table 2. If the credibility of the relative temporal relation between i and j is low, propagation from node i to j probably leads to error. Therefore, the confidence loss should be much in this case. On contrary, if the relation is highly credible, it will be less likely that propagation errors occur. Therefore, the confidence loss should be little.

In addition, whether an extraction refers to a generic event or a specific one exerts an impact on the confidence loss. If an extraction refers to a generic event, then the extractions in the same cluster with it probably have different timestamps. Since our propagation model assumes that extractions in a cluster are coreferent and thus they should have the same timestamp, propagations from a generic event node are very likely to result in propagation errors. Therefore, the timestamp of a generic event node in fact is less credible for propagations and confidence of such event nodes should be low for limiting propagations from the nodes. For this reason, propagation from a document node to a generic event node leads to much loss of confidence. We define the probability that an event node refers to a specific event as follows:

$$P(S = 1|enode) = \frac{1}{|\mathbb{C}|} \sum_{ex \in \mathbb{C}} P(S = 1|ex)$$

where $\mathbb{C}$ is the set of extractions in the event node and $P(S = 1|ex)$ is the probability that an extraction refers to a specific event, which can be provided by the MaxEnt classifier discussed in Section 3.1.3.

Considering the two factors for confidence loss, we formally define the decay factor by (1).

$$\sigma(s, t) = \begin{cases} \pi(s, t) & \textbf{if } t \in DNode \\ \pi(s, t) \times P(S = 1|t) & \textbf{otherwise} \end{cases} \quad (1)$$

3.2.2 Confidence boosting algorithm

In confidence boosting model, the propagation from i to j will occur only if the CB condition is satisfied. The confidence boosting propagation process can be described as figure 4.

Algorithm: Confidence Boosting
Input: Array Y, Array c, Array δ, Array σ
Output: Array Y
Initialize Array c and Array Y
while $\exists i, j$ s.t. CB condition
  $Y(j) = Y(i) + \delta(i, j)$
  $c(j) = c(i) \times \sigma(i, j)$
end **while**

Figure 4: Algorithm of confidence boosting

Whenever timestamps are propagated to other nodes, the global confidence of the bipartite graph will increase. For this reason, this propagation process is called confidence boosting. In this model, a node with high confidence is more active than nodes with low confidence to propagate its timestamp. Moreover, a prediction with low confidence can be corrected by the prediction with high confidence. Therefore, the confidence boosting model can alleviate the problem of propagation of errors to some extent and handle conflict of predictions. Thus, it can propagate timestamps more credibly than the BFS-based model. It can also be proved that each node on the bipartite graph must reach the highest confidence it can reach so that the global confidence of the bipartite graph must be optimal when the confidence boosting propagation process ends regardless of propagation orders, which will be discussed in Section 3.2.3.

3.2.3 Proof of the optimality of confidence boosting

Proof by contradiction can be used to prove that propagation orders do not affect the optimality of the confidence boosting model.

Proof Assume by contradiction that there is some node that does not reach its highest confidence it can reach when a confidence boosting process in propagation order A ends:

$$\exists v_t \text{ s.t. } c_A(v_t) < c^*(v_t)$$

where $c_A(v_t)$ is the confidence of v_t when the propagation process in order A ends and $c^*(v_t)$ is the highest confidence that v_t can reach. Assume that $(v_1, v_2, \cdots, v_{t-1}, v_t)$ is the optimal propagation

path from the propagation source node v_1 to the node v_t that leads to the highest confidence of v_t, which means that $c^*(v_t) = c^*(v_{t-1}) \times \sigma(v_{t-1}, v_t)$, $c^*(v_{t-1}) = c^*(v_{t-2}) \times \sigma(v_{t-2}, v_{t-1})$, ..., $c^*(v_2) = c^*(v_1) \times \sigma(v_1, v_2)$. Then according to CB condition, since $c_A(v_{t-1}) \times \sigma(v_{t-1}, v_t) \leq c_A(v_t) < c^*(v_t) = c^*(v_{t-1}) \times \sigma(v_{t-1}, v_t)$, the inequality $c_A(v_{t-1}) < c^*(v_{t-1})$ must hold. Similarly, it can be easily inferred that $c_A(v_{t-2}) < c^*(v_{t-2})$ and finally $c_A(v_1) < c^*(v_1)$. Since v_1 is the source node whose timestamp is initially labeled and its confidence is 1, the inequality $c_A(v_1) < c^*(v_1)$ cannot hold. Thus, the assumption that $c_A(v_t) < c^*(v_t)$ cannot be satisfied. Therefore, it can be proved that each node on the bipartite graph must reach the highest confidence it can reach so that the global confidence of the bipartite graph must be optimal when confidence boosting propagation process ends no matter what order time labels are propagated in.

4 Experiments

In this section, we evaluate the performance of our time label propagation models and different automatic document dating models on the Gigaword dataset. We first present the experimental setting. Then we show experimental results and perform an analysis.

4.1 Experimental Setting

Dataset To simulate the environment of the web where data is very redundant, we use all documents written in April, June, July and September of 2000-2004 of Gigaword Corpus as dataset instead of sampling a subset of documents from each period. The dataset contains 900,199 news articles.

Pre-processing Many extractions extracted by ReVerb are short and uninformative and do not carry any valuable information for propagating temporal information. Also, some extractions do not refer to events which already happened. These extractions may affect the performance of event coreference resolution and the rule-based method proposed in Section 3.1.1 for mining relative temporal relations. Therefore, we filter out these undesirable extractions in advance with a rule-based method. The rules are shown in table 3. This preprocessing removes large numbers of "bad" extractions which are undesirable for our task. As a result, not only computation efficiency but also precision of event coreference resolution will be improved.

Rule1	If the number of tokens of the extraction is less than 5 then this extraction will be filtered out.
Rule2	If the maximum idf of terms of the extraction is less than 3.0 then this extraction will be filtered out.
Rule3	If the tense of the extraction is not past tense then this extraction will be filtered out.
Rule4	If the extraction is the content of direct quotation then this extraction will be filtered out.

Table 3: Pre-processing Rules

$\|DNode\|$	550,124
$\|ENode\|$	968,064
$\|E\|$	3,104,666

Table 4: Basic information of the bi-partite graph

Basic information of the document-event bipartite graph constructed is shown in table 4.

Evaluation To evaluate the performance of the propagation models for the task of dating on different sizes of the training set, we used different sizes of the labeled documents for training and considered the remaining documents as the test set. Note that the training set is randomly sampled from the dataset. To be more persuasive, we repeated above experiments for five times.

However, in the time label propagation process, not all documents can be labeled. For those documents which cannot be labeled in the process of propagation, a MaxEnt classifier serves as a complementary approach to predict their timestamps. For the MaxEnt classifier, unigrams and named entities are simply selected as features and the initially labeled documents as well as documents labeled during propagation process are used for training.

Baseline methods are temporal language models proposed by de Jong et al. (2005) and the state-of-the-art discriminative classifier with linguistic features and temporal constraints which was proposed

Initially Labeled	1k	5k	10k	50k	100k	200k	500k
Reached Min	443980	448653	453022	484562	518603	599724	732701

Table 6: Overall accuracy of dating models

by Nathanael Chambers (2012). In Chambers's joint model, the interpolation parameter λ is set to 0.35 which is considered optimal in his work.

4.2 Experimental Results

Table 5 shows the performance of propagation models where *Reached* denotes the number of documents labeled when the propagation process ends, *prop ratio* and *prop accuracy* are defined as follows:

$$\text{Prop Ratio} = \frac{\#ReachedDocNodes}{\#LabeledDocNodes}$$

$$\text{Prop Accuracy} = \frac{\#CorrectDocNodes - \#LabeledDocNodes}{\#ReachedDocNodes - \#LabeledDocNodes}$$

where $\#LabeledDocNodes$ is the number of initially labeled document nodes which are documents in the training set and $\#ReachedDocNodes$ is the number of document nodes labeled when the propagation process ends.

Note that prop ratio and accuracy in table 5 are the mean of the prop ratio and accuracy of the five groups of experiments. It is clear that confidence boosting model improves the prop accuracy over BFS-based model. When only 1,000 documents are initially labeled with timestamps, the confidence boosting model can propagate their timestamps to more than 400,000 documents with an accuracy of 0.494, approximately 12.8% relative improvement over the BFS counterpart, which proves effectiveness of the confidence boosting model.

However, as shown in table 5, hardly can the propagation process propagate timestamps to all documents. One reason is that the number of document nodes on the bipartite graph is only 550,124, approximately 61.1% of all documents. The other documents may not mention events which are also mentioned by other documents, which means they are isolate and thus are excluded from the bipartite graph. Also, the event coreference resolution phase does not guarantee finding all coreferential extractions; in other words, recall of event coreference resolution is not 100%. The other reason is that some documents are unreachable from the initially labeled nodes even if they are in the bipartite graph.

The overall accuracy of different dating models is shown in table 6. As with table 5, overall accuracy in table 6 is the average performance of models in the five groups of experiments. As reported by Nathanael Chambers (2012), the discriminative classifier performs much better than the temporal language models on the Gigaword dataset. In the case of 500,000 training examples, the Maxent classifier using unigram features outperforms the temporal language models by 40.5% relative accuracy. If the size of the training set is large enough, named

entities and linguistic features as well as temporal constraints will improve the overall accuracy significantly. However, if the size of the training set is small, these features will not result in much improvement.

Compared with the previous models, the propagation models predict the document timestamps much more accurately especially in the case where the size of the training set is small. When the size of the training set is 1,000, our BFS-based model and confidence boosting model combined with the MaxEnt classifier outperform Chambers's joint model which is considered the state-of-the-art model for the task of automatic dating of documents by 38.7% and 46.8% relative accuracy respectively. This is because the feature-based methods are not very reliable especially when the size of the training set is small. In contrast, our propagation models can predict timestamps of documents with an understanding of document content, which allows our method to date documents more credibly than the baseline methods. Also, by comparing table 5 with table 6, it can be found that prop accuracy is almost always higher than overall accuracy, which also verifies that the propagation models are more credible for dating document than the feature-based models. Moreover, data is so redundant that a great number of documents can be connected with events they share. Therefore, even if a small number of documents are labeled, the labeled information can be propagated to large numbers of articles through the connections between documents and events according to relative time relations. Even if the size of the training set is large, e.g. 500,000, our propagation models still outperform the state-of-the-art dating method. Additionally, some event nodes on the bipartite graph may be labeled with a timestamp during the process of propagation as a byproduct. The temporal information of the events would be useful for other temporal analysis tasks.

5 Related Work

In addition to work of de Jong et al. (2005) and Chambers (2012) introduced in previous sections, there is also other research focusing on the task of document dating. Kanhabua and Norvag (2009) improved temporal language models by incorporating temporal entropy and search statistics and applying two filtering techniques to the unigrams in the model. Kumar et al. (2011) is also based on the temporal language models, but more historically-oriented, which models the timeline from the present day back to the 18th century. In addition, they used KL-divergence instead of normalized log likelihood ratio to measure differences between a document and a time period's language model.

However, these methods are based on temporal language models so they also suffer from the problem of the method of de Jong et al. (2005). Therefore, they inevitably make wrong predictions in some cases, just as mentioned in Section 1. Compared with these methods, our event-based propagation models exploit relative temporal relations between documents and events for dating document on a basis of an understanding of document content, which is more reasonable and also proved to be more effective by the experimental results.

6 Conclusion

The main contribution of this paper is exploiting relative temporal relations between events and documents for the document dating task. Different with the conventional work which dates documents with feature-based methods, we proposed an event-based time label propagation model called confidence boosting in which timestamps are propagated on a document-event bipartite graph according to relative temporal relations between documents and events for dating documents on a basis of an understanding of document content. We discussed challenges for the propagation models and gave the corresponding solutions in detail. The experimental results show that our event-based propagation model can predict document timestamps in high accuracy and the model combined with a MaxEnt classifier outperforms the state-of-the-art method on a data-redundant dataset.

Abstract

In this paper we classify the temporal relations between pairs of events on an article-wide basis. This is in contrast to much of the existing literature which focuses on just event pairs which are found within the same or adjacent sentences. To achieve this, we leverage on discourse analysis as we believe that it provides more useful semantic information than typical lexico-syntactic features. We propose the use of several discourse analysis frameworks, including 1) Rhetorical Structure Theory (RST), 2) PDTB-styled discourse relations, and 3) topical text segmentation. We explain how features derived from these frameworks can be effectively used with support vector machines (SVM) paired with convolution kernels. Experiments show that our proposal is effective in improving on the state-of-the-art significantly by as much as 16% in terms of F_1, even if we only adopt less-than-perfect automatic discourse analyzers and parsers. Making use of more accurate discourse analysis can further boost gains to 35%.

1 Introduction

A good amount of research had been invested in understanding temporal relationships within text. Particular areas of interest include determining the relationship between an event mention and a time expression (timex), as well as determining the relationship between two event mentions. The latter, which we refer to as event-event (*E-E*) temporal classification is the focus of this work.

For a given event pair which consists of two events $e1$ and $e2$ found *anywhere* within an article, we want to be able to determine if $e1$ happens before $e2$ (BEFORE), after $e2$ (AFTER), or within the same time span as $e2$ (OVERLAP).

Consider this sentence[1]:

> At least 19 people were **killed** and 114 people were **wounded** in Tuesday's southern Philippines airport blast, officials **said**, but reports said the death toll could climb to 30. (1)

Three event mentions found within the sentence are bolded. We say that there is an OVERLAP relationship between the "**killed** – **wounded**" event pair as these two events happened together after the airport blast. Similarly there is a BEFORE relationship between both the "**killed** – **said**", and "**wounded** – **said**" event pairs, as the death and injuries happened before reports from the officials.

Being able to infer these temporal relationships allows us to build up a better understanding of the text in question, and can aid several natural language understanding tasks such as information extraction and text summarization. For example, we can build up a temporal characterization of an article by constructing a temporal graph denoting the relationships between all events within an article (Verhagen et al., 2009). This can then be used to help construct an event timeline which layouts sequentially event mentions in the order they take place (Do et al., 2012). The temporal graph can also be used in text summarization, where temporal order can be used to improve sentence ordering and thereby the eventual generated summary (Barzilay et al., 2002).

Given the importance and value of temporal relations, the community has organized shared tasks

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 12–23,
Seattle, Washington, USA, 18-21 October 2013.

to spur research efforts in this area, including the TempEval-1, -2 and -3 evaluation workshops (Verhagen et al., 2009; Verhagen et al., 2010; Uzzaman et al., 2012). Most related work in this area have focused primarily on the task defintitions of these evaluation workshops. In the task definitions, *E-E* temporal classification involves determining the relationship between events found within the same sentence, or in adjacent sentences. For brevity we will refer to this loosely as intra-sentence *E-E* temporal classification in the rest of this paper.

This definition however is limiting and insufficient. It was adopted as a trade-off between completeness, and the need to simplify the evaluation process (Verhagen et al., 2009). In particular, one deficiency is that it does not allow us to construct the complete temporal graph we seek. As illustrated in Figure 1, being able to perform only intra-sentence *E-E* temporal classification may result in a forest of disconnected temporal graphs. A sentence $s3$ separates events C and D, as such an intra-sentence *E-E* classification system will not be able to determine the temporal relationship between them. While we can determine the relationship between A and C in the figure with the use of temporal transitivity rules (Setzer et al., 2003; Verhagen, 2005), we cannot reliably determine the relationship between say A and D.

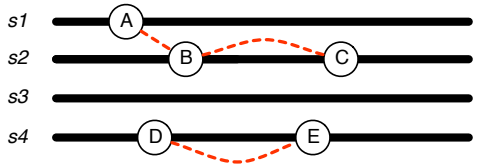

Figure 1: A disconnected temporal graph of events within an article. Horizontal lines depict sentences $s1$ to $s4$, and the circles identify events of interest.

In this work, we seek to overcome this limitation, and study what can enable effective article-wide *E-E* temporal classification. That is, we want to be able to determine the temporal relationship between two events located anywhere within an article.

The main contribution of our work is going beyond the surface lexical and syntactic features commonly adopted by existing state-of-the-art approaches. We suggest making use of semantically motivated features derived from discourse analysis instead, and show that these discourse features are superior.

While we are just focusing on *E-E* temporal classification, our work can complement other approaches such as the joint inference approach proposed by Do et al. (2012) and Yoshikawa et al. (2009) which builds on top of event-timex (*E-T*) and *E-E* temporal classification systems. We believe that improvements to the underlying *E-T* and *E-E* classification systems will help with global inference.

2 Related Work

Many researchers have worked on the *E-E* temporal classification problem, especially as part of the TempEval series of evaluation workshops. Bethard and Martin (2007) presented one of the earliest supervised machine learning systems, making use of support vector machines (SVM) with a variety of lexical and syntactic features. Kolya et al. (2010) described a conditional random field (CRF) based learner making use of similar features. Other researchers including Uzzaman and Allen (2010) and Ha et al. (2010) made use of Markov Logic Networks (MLN). By leveraging on the transitivity properties of temporal relationships (Setzer et al., 2003), they found that MLNs are useful in inferring new temporal relationships from known ones.

Recognizing that the temporal relationships between event pairs and time expressions are related, Yoshikawa et al. (2009) proposed the use of a joint inference model and showed that improvements in performance are obtained. However this gain is attributed to the joint inference model they had developed, making use of similar surface features.

To the best of our knowledge, the only piece of work to have gone beyond sentence boundaries and tackle the problem of article-wide *E-E* temporal classification is by Do et al. (2012). Making use of integer linear programming (ILP), they built a joint inference model which is capable of classifying temporal relationships between any event pair within a given document. They also showed that event co-reference information can be useful in determining these temporal relationships. However they did not make use of features directed specifically at determining the temporal relationships of event pairs

across different sentences. Other than event coreference information, they adopted the same mix of lexico-syntactic features.

Underlying these disparate data-driven methods for similar temporal processing tasks, the reviewed works all adopted a similar set of surface features including vocabulary features, part-of-speech tags, constituent grammar parses, governing grammar nodes and verb tenses, among others. We argue that these features are not sufficiently discriminative of temporal relationships because they do not explain how sentences are combined together, and thus are unable to properly differentiate between the different temporal classifications. Supporting our argument is the work of Smith (2010), where she argued that syntax cannot fully account for the underlying semantics beneath surface text. D'Souza and Ng (2013) found out as much, and showed that adopting richer linguistic features such as lexical relations from curated dictionaries (*e.g.* Webster and WordNet) as well as discourse relations help temporal classification. They had shown that the Penn Discourse TreeBank (PDTB) style (Prasad et al., 2008) discourse relations are useful. We expand on their study to assess the utility of adopting additional discourse frameworks as alternative and complementary views.

3 Making Use of Discourse

To highlight the deficiencies of surface features, we quote here an example from Lascarides and Asher (1993):

> [A] Max opened the door. The room was pitch dark.
> [B] Max switched off the light. The room was pitch dark. (2)

The two lines of text A and B in Example 2 have similar syntactic structure. Given only syntactic features, we may be drawn to conclude that they share similar temporal relationships. However in the first line of text, the events temporally OVERLAP, while in the second line they do not. Clearly, syntax alone is not going to be useful to help us arrive at the correct temporal relations.

If existing surface features are insufficient, what is sufficient? Given a *E-E* pair which crosses sentence boundaries, how can we determine the temporal relationship between them? We take our cue from the work of Lascarides and Asher (1993). They suggested instead that discourse relations hold the key to interpreting such temporal relationships.

Building on their observations, we believe that discourse analysis is integral to any solution for the problem of article-wide *E-E* temporal classification. We thus seek to exploit a series of different discourse analysis studies, including 1) the Rhetorical Structure Theory (RST) discourse framework, 2) Penn Discourse Treebank (PDTB)-styled discourse relations based on the lexicalized Tree Adjoining Grammar for Discourse (D-LTAG), and 3) topical text segmentation, and validate their effectiveness for temporal classification.

RST Discourse Framework. RST (Mann and Thompson, 1988) is a well-studied discourse analysis framework. In RST, a piece of text is split into a sequence of non-overlapping text fragments known as elementary discourse units (EDUs). Neighboring EDUs are related to each other by a typed relation. Most RST relations are *hypotactic*, where one of the two EDUs participating in the relationship is demarcated as a *nucleus*, and the other a *satellite*. The nucleus holds more importance, from the point of view of the writer, while the satellite's purpose is to provide more information to help with the understanding of the nucleus. Some RST relations are however *paratactic*, where the two participating EDUs are both marked as nuclei. A discourse tree can be composed by viewing each EDU as a leaf node. Nodes in the discourse tree are linked to one another via the discourse relations that hold between the EDUs.

RST discourse relations capture the semantic relation between two EDUs, and these often offer a clue to the temporal relationship between events in the two EDUs too. As an example, let us refer once again to Example 2. Recall that in the second line of text "**switched off**" happens BEFORE "**dark**". The RST discourse structure for the second line of text is shown on the left of Figure 2. We see that the two sentences are related via a "*Result*" discourse relation. This fits our intuition that when there is causation, there should be a BEFORE/AFTER relationship. The RST discourse relation in this case is very useful in helping us determine the relationship between the two events.

PDTB-styled Discourse Relations. Another widely adopted discourse relation annotation is the PDTB framework (Prasad et al., 2008). Unlike the RST

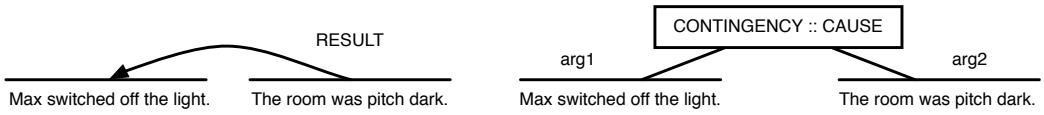

Figure 2: RST and PDTB discourse structures for the second line of text in Example 2. The structure on the left is the RST discourse structure, while the structure on the right is for PDTB.

framework, the discourse relations in PDTB build on the work on D-LTAG by Webber (2004), a lexicon-grounded approach to discourse analysis. Practically, this means that instead of starting from a pre-identified set of discourse relations, PDTB-styled annotations are more focused on detecting possible connectives (can be either explicit or implicit) within the text, before identifying the text fragments which they connect and how they are related to one another.

Applied again to the second line of text we have in Example 2, we get a structure as shown on the right side of Figure 2. From the figure we can see that the two sentences are related via a "*Cause*" relationship. Similar to what we have explained earlier for the case of RST, the presence of a causal effect here strongly hints to us that events in the two sentences share a BEFORE/AFTER relationship.

At this point we want to note the differences between the use of the RST framework and PDTB-styled discourse relations in the context of our work. The theoretical underpinnings behind these two discourse analysis are very different, and we believe that they can be complementary to each other. First, the RST framework breaks up text within an article linearly into non-overlapping EDUs. Relations can only be defined between neighboring EDUs. However this constraint is not found in PDTB-styled relations, where a text fragment can participate in one discourse relation, and a subsequence of it participate in another. PDTB relations are also not restricted only to adjacent text fragments. In this aspect, the flexibility of the PDTB relations can complement the seemingly more rigid RST framework.

Second, with PDTB-styled relations not every sentence needs to be in a relation with another as the PDTB framework does not aim to build a global discourse tree that covers all sentence pairs. This is a problem when we need to do an article-wide analysis. The RST framework does not suffer from this limitation however as we can build up a discourse tree connecting all the text within a given article.

Topical Text Segmentation. A third complementary type of inter-sentential analysis is topical text segmentation. This form of segmentation separates a piece of text into non-overlapping segments, each of which can span several sentences. Each segment represents passages or topics, and provides a coarse-grained study of the linear structure of the text (Skorochod'Ko, 1972; Hearst, 1994). The transition between segments can represent possible topic shifts which can provide useful information about temporal relationships.

Referring to Example 3[2], we have delimited the different lines of text into segments with parentheses along with a subscript. Segment (1) talks about the casualty numbers seen at a medical centre, while Segment (2) provides background information that informs us a bomb explosion had taken place. The segment boundary signals to us a possible temporal shift and can help us to infer that the bombing event took place BEFORE the deaths and injuries had occurred.

(The Davao Medical Center, a regional government hospital, recorded 19 deaths with 50 wounded. Medical evacuation workers however said the injured list was around 114, spread out at various hospitals.)$_1$
(A powerful bomb tore through a waiting shed at the Davao City international airport at about 5.15 pm (0915 GMT) while another explosion hit a bus terminal at the city.)$_2$ (3)

4 Methodology

Having motivated the use of discourse analysis for our problem, we now proceed to explain how we can make use of them for temporal classification. The different facets of discourse analysis that we are exploring in this work are structural in nature. RST

[2]From article AFP_ENG_20030304.0250 of the ACE 2005 corpus.

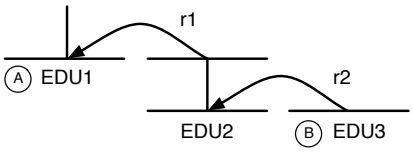

Figure 3: A possible RST discourse tree. The two circles denote two events A and B which we are interested in.

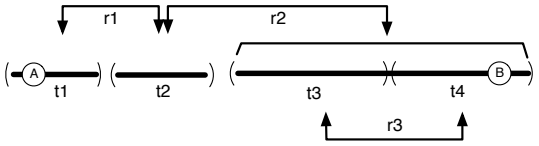

Figure 4: A possible PDTB-styled discourse annotation where the circles represent events we are interested in.

and PDTB discourse relations are commonly represented as graphs, and we can also view the output of text segmentation as a graph with individual text segments forming vertices, and the transitions between them forming edges.

Considering this, we propose the use of support vector machines (SVM), adopting a convolution kernel (Collins and Duffy, 2001) for its kernel function (Vapnik, 1999; Moschitti, 2006). The use of convolution kernels allows us to do away with the extensive feature engineering typically required to generate flat vectorized representations of features. This process is time consuming and demands specialized knowledge to achieve representations that are discriminative, yet are sufficiently generalized. Convolution kernels had also previously been shown to work well for the related problem of *E-T* temporal classification (Ng and Kan, 2012), where the features adopted are similarly structural in nature.

We now describe our use of the discourse analysis frameworks to generate appropriate representations for input to the convolution kernel.

RST Discourse Framework. Recall that the RST framework provides us with a discourse tree for an entire input article. In recent years several automatic RST discourse parsers have been made available. In our work, we first make use of the parser by Feng and Hirst (2012) to obtain a discourse tree representation of our input. To represent the meaningful portion of the resultant tree, we encode path information between the two sentences of interest.

We illustrate this procedure using the example discourse tree illustrated in Figure 3. EDUs including $EDU1$ to $EDU3$ form the vertices while discourse relations $r1$ and $r2$ between the EDUs form the edges. For a *E-E* pair, $\{A, B\}$, we can obtain a feature structure by first locating the EDUs within which A and B are found. A is found inside $EDU1$ and B is found within $EDU3$. We trace the shortest path between $EDU1$ and $EDU3$, and use this path as the feature structure for the *E-E* pair, *i.e.* $\{r1 \rightarrow r2\}$.

PDTB-styled Discourse Relations. We make use of the automatic PDTB discourse parser from Lin et al. (2013) to obtain the discourse relations over an input article. Similar to how we work with the RST discourse framework, for a given *E-E* pair, we retrieve the relevant text fragments and use the shortest path linking the two events as a feature structure for our convolution kernel classifier.

An example of a possible PDTB-styled discourse annotation is shown in Figure 4. The horizontal lines represent different sentences in an article. The parentheses delimit text fragments, $t1$ to $t4$, which have been identified as arguments participating in discourse relations, $r1$ to $r3$. For a given *E-E* pair $\{A, B\}$, we use the trace of the shortest path between them *i.e.* $\{r1 \rightarrow r2\}$ as a feature structure.

We take special care to regularize the input (as, unlike EDUs in RST, arguments to different PDTB relations may overlap, as in $r2$ and $r3$). We model each PDTB discourse annotation as a graph and employ Dijkstra's shortest path algorithm. The graph resulting from the annotation in Figure 4 is given in Figure 5. Each text fragment t_i maps to a vertex n_i in the graph. PDTB relations between text fragments form edges between corresponding vertices. As $r2$ relates $t2$ to both $t3$ and $t4$, two edges link up $n2$ to the corresponding vertices $n3$ and $n4$ respectively. By doing this, Dijkstra's algorithm will always allow us to find the desired shortest path.

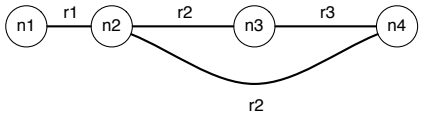

Figure 5: Graph derived from discourse annotation in Figure 4.

Topical Text Segmentation. Taking as input a complete text article, we make use of the state-of-the-art text segmentation system from Kazantseva and Szpakowicz (2011). The output of the system is a series of non-overlapping, linear text segments, which we can number sequentially.

In Figure 6 the horizontal lines represent sentences. Parentheses with subscripts mark out the segment boundaries. We can see two segments $s1$ and $s2$ here. Given a target *E-E* pair $\{A, B\}$ (represented as circles inside the figure), we identify the segment number of the corresponding segment in which each of A and B is found. We build a feature structure with the identified segment numbers, *i.e.* $\{s1 \rightarrow s2\}$ to capture the segmentation.

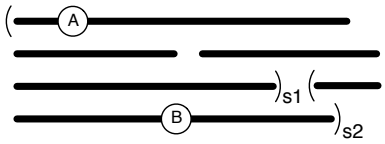

Figure 6: A possible segmentation of three sentences into two segments.

5 Results

We conduct a series of experiments to validate the utility of our proposed features.

Data Set. We make use of the same data set built by Do et al. (2012). The data set consists of 20 newswire articles which originate from the ACE 2005 corpus (ACE, 2005). Initially, the data set consist of 324 event mentions, and a total of 375 annotated *E-E* pairs. We perform the same temporal saturation step as described in Do et al. (2012), and obtained a total of 7,994 *E-E* pairs[3].

A breakdown of the number of instances by each temporal classes is shown in Table 1. Unlike earlier data sets such as that for TempEval-2 where more than half (about 55%) of test instances belong to the OVERLAP class, OVERLAP instances make up just 10% of the data set.

This difference is due mainly to the fact that our data set consists not only of intra-sentence *E-E* pairs, but also of article-wide *E-E* pairs. Figure 7 shows the number of instances for each temporal class broken down by the number of sentences (*i.e.* sentence gap) that separate the events within each *E-E* pair. We see that as the sentence gap increases, the proportion of OVERLAP instances decreases. The intuitive explanation for this is that when event mentions are very far apart in an article, it becomes more unlikely that they happen within the same time span.

Class	AFTER	BEFORE	OVERLAP
# *E-E* pairs	3,588 (45%)	3,589 (45%)	815 (10%)

Table 1: Number of *E-E* pairs in data set attributable to each temporal class. Percentages shown in parentheses.

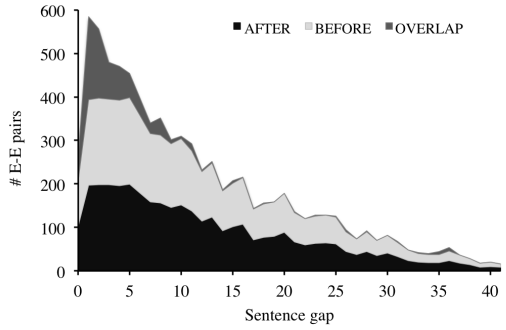

Figure 7: Breakdown of number of *E-E* pairs for each temporal class based on sentence gap.

Experiments. The work done in Do et al. (2012) is highly related to our experiments, and so we have reported the relevant results for local *E-E* classification in Row 1 of Table 2 as a reference. While largely comparable, note that a direct comparison is not possible because 1) the number of *E-E* instances we have is slightly different from what was reported, and 2) we do not have access to the exact partitions they have created for 5-fold cross-validation.

As such, we have implemented a baseline adopting similar surface lexico-syntactic features used in previous work (Mani et al., 2006; Bethard and Martin, 2007; Ng and Kan, 2012; Do et al., 2012), including 1) part-of-speech tags, 2) tenses, 3) dependency parses, 4) relative position of events in article,

[3]Though we have obtained the data set from the original authors, there was a discrepancy in the number of *E-E* pairs. The original paper reported a total of 376 annotated *E-E* pairs. Besides this, we also repeated the saturation steps iteratively until no new relationship pairs are generated. We believe this to be an enhancement as it ensures that all inferred temporal relationships are generated.

	System	Precision	Recall	F_1
(1)	DO2012	43.86	52.65	47.46
(2)	BASE	59.55	38.14	46.50
(3)	BASE + RST + PDTB + TOPICSEG	71.89	41.99	53.01
(4)	BASE + RST + PDTB + TOPICSEG + COREF	75.23	43.58	55.19
(5)	BASE + O-RST + PDTB + O-TOPICSEG + O-COREF	78.35	54.24	64.10

Table 2: Macro-averaged results obtained from our experiments. The difference in F_1 scores between each successive row is statistically significant, but a comparison is not possible between rows (1) and (2).

5) the number of sentences between the target events and 6) VerbOcean (Chklovski and Pantel, 2004) relations between events. This baseline system, and the subsequent systems we will describe, comprises of three separate one-vs-all classifiers for each of the temporal classes. The result obtained by our baseline is shown in Row 2 (*i.e.* BASE) in Table 2. We note that our baseline is competitive and performs similarly to the results obtained by Do et al. (2012). However as we do not have the raw judgements from Do's system, we cannot test for statistical significance.

We also implemented our proposed features and show the results obtained in the remaining rows of Table 2. In Row 3, RST denotes the RST discourse feature, PDTB denotes the PDTB-styled discourse features, and TOPICSEG denotes the text segmentation feature. Compared to our own baseline, there is a relative increase of 14% in F_1, which is statistically significant when verified with the one-tailed Student's paired *t*-test ($p < 0.01$).

In addition, Do et al. (2012) have shown the value of event co-reference. Therefore we have also included this feature by making use of an automatic event co-reference system by Chen et al. (2011). The result obtained after adding this feature (denoted by COREF) is shown in Row 4. The relative increase in F_1 of about 4% from Row 3 is statistically significant ($p < 0.01$) and affirms that event co-reference is a useful feature to have, together with our proposed features. We note that our complete system in Row 4 gives a 16% improvement in F_1, relative to the reference system DO2012 in Row 1.

To get a better idea of the performance we can obtain if oracular versions of our features are available, we also show the results obtained if hand-annotated RST discourse structures, text segments, as well as event co-reference information were used. Annotations for the RST discourse structures and text segments were performed by the first author (RST annotations were made following the annotation guidelines given by Carlson and Marcu (2001)). Oracular event co-reference information was included in the dataset that we have used.

In Row 5 the prefix O denotes oracular versions of the features we had proposed. From the results we see that there is a marked increase of over 15% in F_1 relative to Row 4. Compared to Do's state-of-the-art system, there is also a relative gain of at least 35%. These oracular results further confirm the importance of non-local discourse analysis for temporal processing.

6 Discussion

Ablation tests. We performed ablation tests to assess the efficacy of the discourse features used in our earlier experiments. Starting from the full system, we dropped each discourse feature in turn to see the effect this has on overall system performance. Our test is performed over the same data set, again with 5-fold cross-validation. The results in Table 3 show a statistically significant (based on the one-tailed Student's paired *t*-test) drop in F_1 in each case, which proves that each of our proposed features is useful and required.

From the ablation tests, we also observe that the RST discourse feature contributes the most to overall system performance while the PDTB discourse feature contributes the least. However we should not conclude prematurely that the former is more useful than the latter; as the results are obtained using parses from automatic systems, and are not reflective of the full utility of ground truth discourse annotations.

Useful Relations. The ablation test results showed us that discourse relations (in particular RST dis-

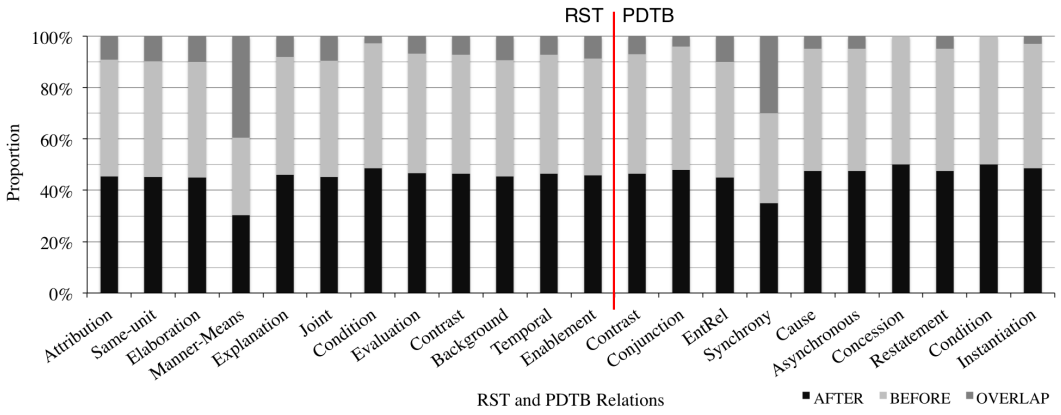

Figure 8: Proportion of occurence in temporal classes for every RST and PDTB relation.

Ablated Feature	Change in F_1	Sig
−RST	-9.03	**
−TOPICSEG	-2.98	**
−COREF	-2.18	**
−PDTB	-1.42	*

Table 3: Ablation test results. '**' and '*' denote statistically significance against the full system with $p < 0.01$ and $p < 0.05$, respectively.

course relations) are the most important in our system. We have also motivated our work earlier with the intuition that certain relations such as the RST "*Result*" and the PDTB "*Cause*" relations provide very useful temporal cues. We now offer an introspection into the use of these discourse relations.

Figure 8 illustrates the relative proportion of temporal classes in which each RST and PDTB relation appear. If the relations are randomly distributed, we should expect their distribution to follow that of the temporal classes as shown in Table 1. However we see that many of the relations do not follow this distribution. For example, we observe that several relations such as the RST "*Condition*" and PDTB "*Cause*" relations are almost exclusively found within AFTER and BEFORE event pairs only, while the RST "*Manner-means*" and PDTB "*Synchrony*" relations occur in a disproportionately large number of OVERLAP event pairs. These relations are likely useful in disambiguating between the different temporal classes.

To verify this, we examine the convolution tree fragments that lie on the support vector of our SVM classifier. The work of Pighin and Moschitti (2010) in linearizing kernel functions allows us to take a look at these tree fragments. Applying the linearization process leads to a different classifier from the one we have used. The identified tree fragments are therefore just an approximation to those actually employed by our classifier. However, this analysis still offers an introspection as to what relations are most influential for classification.

BEFORE		OVERLAP	
B1	(Temporal ...	O1	(Manner-means ...
B2	(Temporal (Elaboration ...		
B3	(Condition (Explanation ...		
B4	(Condition (Attribution ...		
B5	(Elaboration (Bckgrnd ...		

Table 4: Subset of top RST discourse fragments on support vectors identified by linearizing kernel function.

Table 4 shows a subset of the top RST discourse fragments identified for the BEFORE and OVERLAP one-vs-all classifiers. The list is in line with what we expect from Figure 8. The former consists of fragments containing relations such as "*Temporal*" and "*Condition*", while the latter has a sole fragment containing "*Manner-Means*".

To illustrate what these fragments may mean, we show several example sentences from our data set in Example 4. Sentence A consists of the tree fragment B1, *i.e.* "*(Temporal...*". Its corresponding discourse structure is illustrated in the top half of Figure 9. This fragment indicates to us (correctly) that the event "**wielded**" happened BEFORE Milosevic was "**swept out**" of power. Sentence B is made up of tree fragment O1, *i.e.* "*(Manner-means...*",

and its discourse structure is shown in the bottom half of Figure 9. As with the previous example, the fragment suggests (correctly) that there should be a OVERLAP relationship for the "**requested** – **said**" event pair.

> [A] Milosevic and his wife **wielded** enormous power in Yugoslavia for more than a decade before he was **swept out** of power after a popular revolt in October 2000.
>
> [B] The court order was **requested** by Jack Welch's attorney, Daniel K. Webb, who **said** Welch would likely be asked about his business dealings, his health and entries in his personal diary. (4)

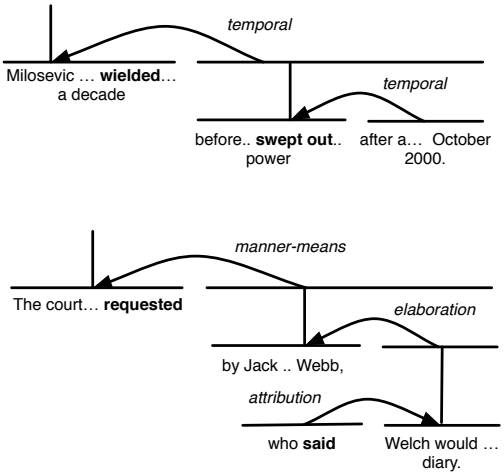

Figure 9: RST discourse structures for sentences A (top half) and B (bottom half) in Example 4.

Segment Numbers. From the ablation test results, text segmentation is the next most important feature after the RST discourse feature. This is interesting given that the defined feature structure for topical text segmentation is not the most intuitive. By using actual segment numbers, the structure may not generalize well for articles of different lengths for example, as each article may have vastly different number of segments. The transition across segments may also not carry the same semantic significance for different articles.

Our experiments have however shown that this feature design is useful in improving performance. This is likely because:

1. The default settings of the text segmentation system we had used are such that precision is favoured over recall (Kazantseva and Szpakowicz, 2011, p. 292). As such there is just an average of between two to three identified segments per article. This makes the feature more generalizable despite making use of actual segment numbers.

2. The style of writing in newswire articles which we are experimenting on generally follows common journalistic guidelines. The semantics behind the transitions across the coarse-grained segments that were identified are thus likely to be of a similar nature across many different articles.

We leave for future work an investigation into whether more fine-grained topic segments can lead to further performance gains. In particular, it will be interesting to study if work on argumentative zoning (Teufel and Kan, 2011) can be applied to newswire articles, and whether the subsequent learnt document structures can be used to delineate topic segments more accurately.

Error Analysis. Besides examining the features we had used, we also want to get a better idea of the errors made by our classifier. Recall that we are using separate one-vs-all classifiers for each of the temporal classes, so each of the three classifiers generates a column in the aggregate confusion matrix shown in Table 5. In cases where none of the SVM classifiers return a positive confidence value, we do not assign a temporal class (captured as column **N**). The high number of event pairs which are not assigned to any temporal class explains the lower recall scores obtained by our system, as observed in Table 2.

	Predicted			
	O	**B**	**A**	**N**
O	119 (14.7%)	114 (14.1%)	104 (12.8%)	474 (58.5%)
B	19 (0.5%)	2067 (57.9%)	554 (15.5%)	928 (26.0%)
A	16 (0.5%)	559 (15.7%)	2046 (57.3%)	947 (26.5%)

Table 5: Confusion matrix obtained for the full system, classifying into (**O**)VERLAP, (**B**)EFORE, (**A**)FTER, and (**N**)o result.

Additionally, an interesting observation is the low percentage of OVERLAP instances that our classifier managed to predict correctly. About 57% of BEFORE and AFTER instances are classified cor-

rectly, however only about 15% of OVERLAP instances are correct.

Figure 10 offers more evidence to suggest that our classifier works better for the BEFORE and AFTER classes than the OVERLAP class. We see that as sentence gap increases, we achieve a fairly consistent performance for both BEFORE and AFTER instances. OVERLAP instances are concentrated where the sentence gap is less than 7, with the best accuracy figure coming in below 30%.

Although not definitive, this may be because our data set consists of much fewer OVERLAP instances than the other two classes. This bias may have led to insufficient training data for accurate OVERLAP classification. It will be useful to investigate if using a more balanced data set for training can help overcome this problem.

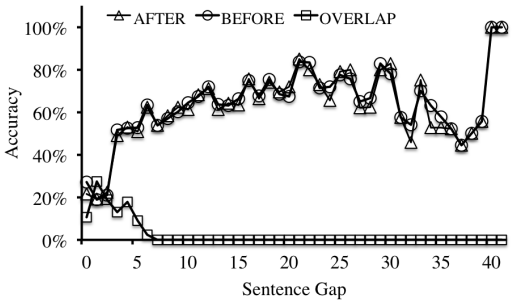

Figure 10: Accuracy of the classifer for each temporal class, plotted against the sentence gap of each *E-E* pair.

7 Conclusion

We believe that discourse features play an important role in the temporal ordering of events in text. We have proposed the use of different discourse analysis frameworks and shown that they are effective for classifying the temporal relationships of article-wide *E-E* pairs. Our proposed discourse-based features are robust and work well even though automatic discourse analysis is noisy. Experiments further show that improvements to these underlying discourse analysis systems will benefit system performance.

In future work, we will like to explore how to better exploit the various discourse analysis frameworks for temporal classification. For instance, RST relations are either *hypotactic* or *paratactic*. Marcu (1997) made use of this to generate automatic summaries by considering EDUs which are nuclei to be more salient. We believe it is interesting to examine how such information can help. We are also interested to apply discourse features in the context of a global inferencing system (Yoshikawa et al., 2009; Do et al., 2012), as we think such analyses will also benefit these systems as well.

Acknowledgments

We like to express our gratitude to Quang Xuan Do, Wei Lu, and Dan Roth for generously making available the data set they have used for their work in EMNLP 2012. We would also like to thank the anonymous reviewers who reviewed this paper for their valuable feedback.

Combining Generative and Discriminative Model Scores for Distant Supervision

Benjamin Roth, Dietrich Klakow

Abstract

Distant supervision is a scheme to generate noisy training data for relation extraction by aligning entities of a knowledge base with text. In this work we combine the output of a discriminative at-least-one learner with that of a generative hierarchical topic model to reduce the noise in distant supervision data. The combination significantly increases the ranking quality of extracted facts and achieves state-of-the-art extraction performance in an end-to-end setting. A simple linear interpolation of the model scores performs better than a parameter-free scheme based on non-dominated sorting.

1 Introduction

Relation extraction is the task of finding relational facts in unstructured text and putting them into a structured (tabularized) knowledge base. Training machine learning algorithms for relation extraction requires training data. If the set of relations is pre-specified, the training data needs to be labeled with those relations.

Manual annotation of training data is laborious and costly, however, the knowledge base may already partially be filled with instances from the relations. This is utilized by a scheme known as distant supervision (DS) (Mintz et al., 2009): text is automatically labeled by aligning (matching) pairs of entities that are contained in a knowledge base with their textual occurrences. Whenever such a match is encountered, the surrounding context (sentence) is assumed to express the relation.

This assumption, however, can fail. Consider the example given in (Takamatsu et al., 2012): If the tuple `place_of_birth(Michael Jackson, Gary)` is contained in the knowledge base, one matching context could be:

Michael Jackson *was born in* ***Gary*** *...*

And another possible context:

Michael Jackson *moved from* ***Gary*** *...*

Clearly, only the first context indeed expresses the relation and should be labeled accordingly.

Three basic approaches have been proposed to deal with noisy distant supervision instances: The *discriminative at-least-one* approach (Riedel et al., 2010), that requires that at least one of the matches for a relation-entity tuple indeed expresses the relation; The *generative* approach (Alfonseca et al., 2012) that separates relation-specific distributions from noise distributions by using hierarchical topic models; And the *pattern correlation* approach (Takamatsu et al., 2012) that assumes that contexts which match argument pairs have a high overlap in argument pairs with other patterns expressing the relation.

In this work we combine 1) a *discriminative at-least-one* learner, that requires high scores for both a dedicated noise label and the matched relation, and 2) a *generative topic model* that uses a feature-based representation to separate relation-specific patterns from background or pair-specific noise. We score surface patterns and show that combining the two approaches results in a better ranking quality of relational facts. In an end-to-end evaluation we set a threshold on the pattern scores and apply the pat-

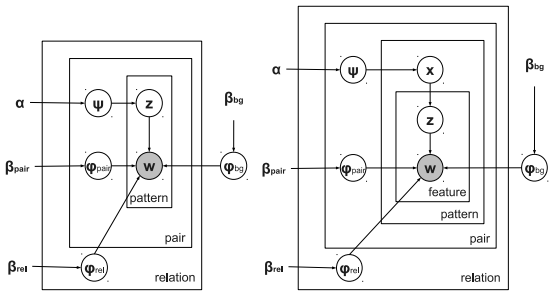

Figure 1: Hierarchical topic models. Intertext model (left) and feature model (right).

terns in a TAC KBP-style evaluation. Although the surface patterns are very simple (only strings of tokens), they achieve state-of-the-art extraction results.

2 Related Work

2.1 At-Least-One Models

The original form of distant supervision (Mintz et al., 2009) assumes all sentences containing an entity pair to be potential patterns for the relation holding between the entities. A variety of models relax this assumption and only presume that *at least one* of the entity pair occurrences is a textual manifestation of the relation. The first proposed model with an at-least-one learner is that of Riedel et al. (2010) and Yao et al. (2010). It consists of a factor graph that includes binary variables for contexts, and groups contexts together for each entity pair. MultiR (Hoffmann et al., 2011) can be viewed as a multi-label extension of (Riedel et al., 2010). A further extension is MIMLRE (Surdeanu et al., 2012), a jointly trained two-stage classification model.

2.2 Hierarchical Topic Model

The hierarchical topic model (*HierTopics*) by Alfonseca et al. (2012) models the distant supervision data by a generative model. For each corpus match of an entity pair in the knowledge base, the corresponding surface pattern is assumed to be typical for either the entity pair, the relation, or neither. This principle is then used to infer distributions over patterns of one of the following types:

1. For every entity pair, a pair-specific distribution.
2. For every relation, a relation-specific distribution.
3. A general background distribution.

The generative process assumes that for each argument pair in the knowledge base, all patterns are generated by first choosing a hidden variable z which can take on three values, B for background, R for relation and P for pair. Corresponding vocabulary distributions ($\phi_{bg}, \phi_{rel}, \phi_{pair}$) for generating the context patterns are chosen according to the value of z. The Dirichlet-smoothed vocabulary distributions are shared on the respective levels. Figure 1 shows the plate diagram of the HierTopics model.

3 Model Extensions and Combination

3.1 Generative Model

We use a feature-based extension (Roth and Klakow, 2013) of Alfonseca et al. (2012) to include bigrams for a more fine-grained representation of the patterns. For including features in the model, the model is extended with a second layer of hidden variables. A variable x represents a choice of B, R or P for every pattern, i.e. there is one variable x for every pattern. Each feature is generated conditioned on a second variable $z \in \{B, R, P\}$, i.e. there are as many variables z for a pattern as there are features for it. First, the hidden variable x is generated, then all z variables are generated for the corresponding features (see Figure 1). The values B, R or P of z depend on the corresponding x by a transition distribution:

$$P(Z_i = z | X_{j(i)} = x) = \begin{cases} p_{same}, & \text{if } z = x \\ \frac{1-p_{same}}{2}, & \text{otherwise} \end{cases}$$

where features at indices i are mapped to the corresponding pattern indices by a function $j(i)$; p_{same} is set to .99 to enforce the correspondence between pattern and feature topics. [1]

3.2 Discriminative Model

As a second feature-based model, we employ a perceptron model that enforces constraints on the labels for patterns (Roth and Klakow, 2013). The model consists of log-linear factors for the set of relations

[1] The hyper-parameters used for the feature-based topic model are $\alpha = (1, 1, 1)$ and $\beta = (.1, .001, .001)$.

Algorithm 1 At-Least-One Perceptron Training

$\theta \leftarrow 0$
for $r \in \mathcal{R}$ **do**
  for $pair \in$ kb_pairs(r) **do**
    for $s \in$ sentences$(pair)$ **do**
      for $r' \in \mathcal{R} \setminus r$ **do**
        if $P(r|s,\theta) \leq P(r'|s,\theta)$ **then**
          $\theta \leftarrow \theta + \phi(s,r) - \phi(s,r')$
        if $P(NIL|s,\theta) \leq P(r'|s,\theta)$ **then**
          $\theta \leftarrow \theta + \phi(s,NIL) - \phi(s,r')$
    if $\forall_{s \in sentences(pair)} : P(r|s,\theta) \leq P(NIL|s,\theta)$ **then**
      $s^* = \arg\max_s \frac{P(r|s,\theta)}{P(NIL|s,\theta)}$
      $\theta \leftarrow \theta + \phi(s^*,r) - \phi(s^*,NIL)$

$\mathcal{R}$ as well as a factor for the *NIL* label (no relation). Probabilities for a relation r given a sentence pattern s are calculated by normalizing over log-linear factors defined as $f_r(s) = exp\left(\sum_i \phi_i(s,r)\theta_i\right)$, with $\phi(s,r)$ the feature vector for sentence s and label assignment r, and θ_r the feature weight vector.

The learner is directed by the following semantics: First, for a sentence s that has a distant supervision match for relation r, relation r should have a higher probability than any other relation $r' \in \mathcal{R} \setminus r$. As extractions are expected to be noisy, high probabilities for NIL are enforced by a second constraint: NIL must have a higher probability than any relation $r' \in \mathcal{R} \setminus r$. Third, at least one DS sentence for an argument pair is expected to express the corresponding relation r. For sentences s for an entity pair belonging to relation r, this can be written as the following constraints:

$$\forall_{s,r'} : P(r|s) > P(r'|s) \wedge P(NIL|s) > P(r'|s)$$
$$\exists_s : P(r|s) > P(NIL|s)$$

The violation of any of the above constraints triggers a perceptron update. The basic algorithm is sketched in Algorithm 1.[2]

3.3 Model Combination

The per-pattern probabilities $P(r|pat)$ are calculated as in Alfonseca et al. (2012) and aggregated over all pattern occurrences: For the topic model, the number of times the relation-specific topic has been sampled for a pattern is divided by $n(pat)$, the number of times the same pattern has been observed. Analogously for the perceptron, the number of times a pattern co-occurs with entity pairs for r is multiplied by the perceptron score and divided by $n(pat)$.

[2]The weight vectors are averaged over 20 iterations.

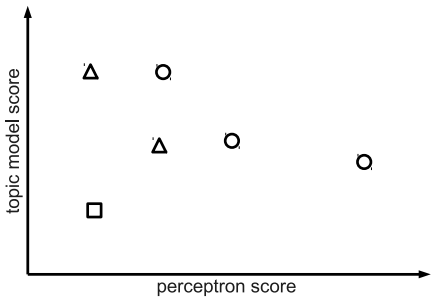

Figure 2: Score combination by non-dominated sorting: Circles indicate patterns on the Pareto-frontier, which are ranked highest. They are followed by the triangles, the square indicates the lowest ranked pattern in this example.

For the patterns of the form ***[ARG1]*** *context* ***[ARG2]***, we compute the following scores:

- **Maximum Likelihood (MLE)**: $\frac{n(pat,r)}{n(pat)}$
- **Topic Model**: $\frac{n(pat,topic(r))}{n(pat)}$
- **Perceptron**: $\frac{n(pat,r)}{n(pat)} \cdot \frac{P(r|s,\theta)}{P(r|s,\theta)+P(NIL|s,\theta)}$
- **Interpolation**: $\frac{0.5 \cdot n(pat,topic(r))}{n(pat)} + \frac{0.5 \cdot n(pat,r) \cdot P(r|s,\theta)}{n(pat) \cdot (P(r|s,\theta)+P(NIL|s,\theta))}$

The topic model and perceptron approaches are based on plausible yet fundamentally different principles of modeling noise without direct supervision. It is therefore an interesting question how complementary the models are and how much can be gained from a combination. As the two models do not use direct supervision, we also avoid tuning parameters for their combination.

We use two schemes to obtain a combined ranking from the two model scores: The first is a ranking based on non-dominated sorting by successively computing the Pareto-frontier of the 2-dimensional score vectors (Borzsony et al., 2001; Godfrey et al., 2007). The underlying principle is that all data points (patterns in our case) that are not dominated by another point[3] build the frontier and are ranked highest (see Figure 2), with ties broken by linear

[3]A data point h_1 dominates a data point h_2 if $h_1 \geq h_2$ in all metrics and $h_1 > h_2$ in at least one metric.

combination. Sorting by computing the Pareto-frontier has been applied to training machine translation systems (Duh et al., 2012) to combine the translation quality metrics BLEU, RIBES and NTER, each of which is based on different principles. In the context of machine translation it has been found to outperform a linear interpolation of the metrics and to be more stable to non-smooth metrics and non-comparable scalings. We compare non-dominated sorting with a simple linear interpolation with uniform weights.

4 Evaluation

4.1 Ranking-Based Evaluation

Evaluation is done on the ranking quality according to TAC KBP gold annotations (Ji et al., 2010) of extracted facts from all TAC KBP queries from 2009-2011 and the TAC KBP 2009-2011 corpora. First, candidate sentences are retrieved in which the query entity and a second entity with the appropriate type are contained. Candidate sentences are then used to provide answer candidates if one of the extracted patterns matches. The answer candidates are ranked according to the score of the matching pattern.

The basis for pattern extraction is the noisy DS training data of a top-3 ranked system in TAC KBP 2012 (Roth et al., 2012). The retrieval component of this system is used to obtain sentence and answer candidates (ranked according to their respective pattern scores). Evaluation results are reported as averages over per-relation results of the standard ranking metrics mean average precision (*map*), geometric map (*gmap*), precision at 5 and at 10 (*p@5*, *p@10*).

The maximum-likelihood estimator (*MLE*) baseline scores patterns by the relative frequency they occur with a certain relation. The hierarchical topic (*hier orig*) as described in Alfonseca et al. (2012) increases the scores under most metrics, however the increase is only significant for p@5 and p@10. The feature-based extension of the topic model (*hier feat*) has significantly better ranking quality. Slightly better scores are obtained by the at-least-one perceptron learner. It is interesting to see that the model combinations both by non-dominated sorting *perc+hier (pareto)* as well as uniform interpolation *perc+hier (itpl)* give a further increase in ranking quality. The simpler interpolation scheme generally works best. Figure 3 shows the Precision/Recall curves of the basic models and the linear interpolation. On the P/R curve, the linear interpolation is equal or better than the single methods on all recall levels.

method	map	gmap	p@5	p@10

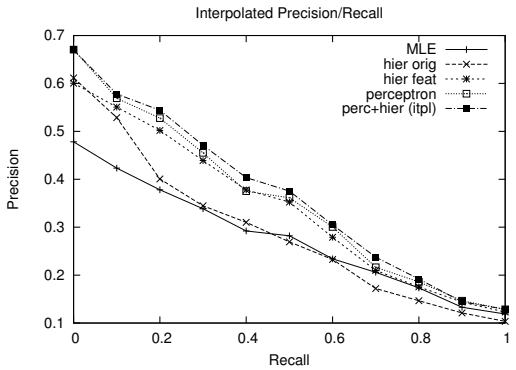

Figure 3: Precision at recall levels.

4.2 End-To-End Evaluation

We evaluate the extraction quality of the induced *perc+hier (itpl)* patterns in an end-to-end setting. We use the evaluation setting of (Surdeanu et al., 2012) and the results obtained with their pipeline for MIMLRE and their re-implementation of MultiR as a point of reference.

In Surdeanu et al. (2012) evaluation is done using a subset of queries from the TAC KBP 2010 and 2011 evaluation. The source corpus is the TAC KBP source corpus and a 2010 Wikipedia dump. Only those answers are considered in scoring that are contained in a list of possible answers from their candidates (reducing the number of gold answers from 1601 to 576 and thereby considerably increasing the value of reported recall).

For evaluating our patterns, we take the same

queries for testing as Surdeanu et al. (2012). As the document collection, we use the TAC KBP source collection and a Wikipedia dump from 07/2009 that was available to us. From this document collection, we use our retrieval pipeline of Roth et al. (2012) and take those sentences that contain query entities and slot filler candidates according to NE-tags. We filter out all candidates that are not contained in the list of candidates considered in (Surdeanu et al., 2012), and use the same reduced set of 576 gold answers as the key. We tune a single threshold parameter $t = .3$ on held-out development data and take all patterns with higher scores. Table 2 shows that results obtained with the induced patterns compare well with state-of-the-art relation extraction systems.

method	Recall	Precision	F1
MultiR	.200	.306	.242
MIMLRE	.314	.247	.277
perc+hier (itpl)	.248	.401	.307

Table 2: TAC Scores on (Surdeanu et al., 2012) queries.

4.3 Illustration: Top-Ranked Patterns

Figure 4 shows top-ranked patterns for **per:title** and **org:top_members_employees**, the two relations with most answers in the gold annotations. For maximum likelihood estimation the score is 1.0 if the patterns occurs only with the relation in question – this includes all cases where the pattern is only found once in the corpus. While this could be circumvented by frequency thresholding, we leave the long tail of the data as it is and let the algorithm deal with both frequent and infrequent patterns.

One can see that while the maximum likelihood patterns contain some reasonable relational contexts, they are less prototypical and more prone to distant supervision errors. The patterns scored high by the proposed combination generalize better, variation at the top is achieved by re-combining elements that carry relational meaning (*"is an"*, *"vice president"*, *"president director"*) or are closely correlated to the particular relation.

5 Conclusion

We have combined two models based on distinct principles for noise reduction in distant supervision: a feature-based extension of a hierarchical topic model, and an at-least-one perceptron. Interpolation increases the quality of extractions and achieves state-of-the-art extraction performance. A combination scheme based on non-dominated sorting, that was inspired by work on combining machine translation metrics, was not as good as a simple linear combination of scores. We think that the good results motivate research into more integrated combinations of noise reduction approaches.

Abstract

Children learn various levels of linguistic structure concurrently, yet most existing models of language acquisition deal with only a single level of structure, implicitly assuming a sequential learning process. Developing models that learn multiple levels simultaneously can provide important insights into how these levels might interact synergistically during learning. Here, we present a model that jointly induces syntactic categories and morphological segmentations by combining two well-known models for the individual tasks. We test on child-directed utterances in English and Spanish and compare to single-task baselines. In the morphologically poorer language (English), the model improves morphological segmentation, while in the morphologically richer language (Spanish), it leads to better syntactic categorization. These results provide further evidence that joint learning is useful, but also suggest that the benefits may be different for typologically different languages.

1 Introduction

Models of language acquisition seek to infer linguistic structure from data with minimal amounts of prior knowledge, in order to discover which characteristics of the input data are useful for learning, and thus potentially utilised by human learners. Most previous work has focused on learning individual aspects of linguistic structure. However, children clearly learn multiple aspects in parallel, rather than sequentially, implying that models of language acquisition should also incorporate joint learning. Joint models investigate the interaction between different levels of linguistic structure during learning. These interactions are often (but not necessarily) synergistic, enabling better, more robust, learning by making use of cues from multiple sources. Recent models using joint learning to model language acquisition have spanned various domains including phonology, word segmentation, syntax and semantics (Feldman et al., 2009; Elsner et al., 2012; Doyle and Levy, 2013; Johnson, 2008; Kwiatkowski et al., 2012).

In this paper we examine the joint learning of syntactic categories and morphology, which are acquired by children at roughly the same age (Clark, 2003b), implying possible interactions in the learning process. Both morphology and word order depend on categorising words based on their morpho-syntactic function. However, previous models of syntactic category learning have relied principally on surrounding context, i.e., word order constraints, whereas models of morphology use word-internal cues. Our joint model integrates both sources of information, allowing the model to flexibly weigh them according to their utility.

Languages differ in the richness of their morphology and strictness of word order. These characteristics appear to be (anti)correlated, with rich morphology co-occurring with free word order and vice versa (Blake, 2001; McFadden, 2003). The timecourse of acquisition is also influenced by language typology: learners of morphologically rich languages become productive in morphology earlier (Xanthos et al., 2011), suggesting that richer morphology may be more salient for learners than impoverished morphology. Sentence comprehension in children also shows cross-linguistic differences in the cues used to make sense of non-canonical sentence structure: learners of a morphologically rich language (Turkish) disregard word order in

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 30–41,
Seattle, Washington, USA, 18-21 October 2013.

favour of morphology, whereas learners of English favour word order (Slobin, 1982; MacWhinney et al., 1984). These interactions between morphology and word order suggest that a joint model will be better able to support the differences in cue strength (rich morphology versus strict word order), and thus be more language-general, than single-task models.

Both syntactic category and morphology induction have been the focus of much recent work. (See Hammarström and Borin (2011) for an overview of unsupervised morphology learning, likewise Christodoulopoulos et al. (2010) for a comparison of part of speech/syntactic category induction systems.) However, given the tightly coupled nature of these two tasks, there has been surprisingly little work in *joint* learning of morphology and syntactic categories. Systems for inducing syntactic categories often make use of morpheme-like features, such as word-final characters (Smith and Eisner, 2005; Haghighi and Klein, 2006; Berg-Kirkpatrick et al., 2010; Lee et al., 2010), or model words at the character-level (Clark, 2003a; Blunsom and Cohn, 2011), but do not include morphemes explicitly. Other systems (Dasgupta and Ng, 2007; Christodoulopoulos et al., 2011) use morphological segmentations learned by a separate morphology model as features in a pipeline approach.

Models of morphology induction generally operate over a lexicon, i.e. a list of word types, rather than token corpora (Goldsmith, 2006; Creutz and Lagus, 2007; Kurimo et al., 2010). These models find morphological categories on the basis of word-internal features, without taking syntactic context into account (which is of course not available in a lexicon).

Lee et al. (2011) and Sirts and Alumäe (2012) present models that infer morphological segmentations and syntactic categories jointly, although Lee et al. (2011) do not evaluate the inferred syntactic categories. Both make use of a word-type constraint which limits each word form to a single analysis (i.e., all instances of *ducks* are assigned to a single category and will have the same morpheme analysis, ignoring the gold standard distinction between a plural noun and third person singular verb). This can make inference more tractable, and often increases performance, but does not respect the ambiguity inherent in natural language, both over syntactic categories and morphological analyses. The degree of ambiguity is language dependent, so that even if a type-constraint is perhaps relatively unproblematic in English, it will pose problems in morphologically richer languages. Furthermore, these two models make use of an array of heuristics that may not allow them to be easily generalisable across languages and datasets (e.g., likelihood scaling (Sirts and Alumäe, 2012), sequential suffix matching (Lee et al., 2011)).

In this paper, we present a joint model composed of two well-known individual models. This allows us to cleanly investigate the effects of joint learning and its potential benefits over the single task models. The simplicity of our models also allows us to avoid modelling and inference heuristics.

Previous models have used adult-directed written texts, which differs significantly from the type of language available to child learners. We test our joint model on child-directed utterances in English (a morphologically poor language) and Spanish (with richer morphology)[1]. Our results indicate that our joint model is able to flexibly accommodate languages with differing levels of morphological richness. The joint model matches the performance of single task models on both tasks, demonstrating that the additional complexity is not a problem (i.e., it does not add noise). Moreover, the joint model improves performance significantly on the task corresponding to the language's weaker cue, indicating a transfer of information from the stronger cue. The fact that the nature of this improvement varies by language provides evidence that joint learning can effectively accommodate typological diversity.

2 Model

The task is to assign word tokens to part of speech categories and simultaneously segment the tokens into morphemes. We assume a relatively simple yet commonly used concatenative morphology which models a word as a stem plus (possibly null) suffix[2].

[1]There are languages with much richer morphology than Spanish, but none with a child-directed corpus suitably annotated for evaluation.

[2]Fullwood and O'Donnell (2013) recently presented a model of non-concatenative morphology that could be integrated into this model; however, it does not perform well on English (and presumably other mostly concatenative languages).

Since this is an unsupervised model, the inferred categories and morphemes lack meaningful labels, but ideally will correspond to gold standard categories and morphemes.

2.1 Word Order

We model a sequence of words as a Hidden Markov Model (HMM) with a non-parametric emission distribution. As usual, the latent states of the HMM represent syntactic categories. The tag sequence is generated by a trigram Dirichlet-multinomial distribution, where transition parameters τ are drawn from a symmetric Dirichlet distribution with the hyperparameter α_t. Each tag t_i in the sequence is then drawn from the transition distribution conditioned on the previous two tags:

$$\begin{aligned} \tau_{(t,t')} &\sim \text{Dir}(\alpha_t) \\ t_i = t | t_{i-1} = t', t_{i-2} = t'', \tau &\sim \text{Mult}(\tau_{(t',t'')}) \end{aligned}$$

This model is token-based, permitting different tokens of the same word type to have different syntactic categories. Most recent models have included a constraint forcing all tokens of a given type into the same category, which improves performance but often complicates inference. The Bayesian HMM's performance is therefore not state-of-the-art, but is comparable to other token-based models (Christodoulopoulos et al., 2010) and the model is easy to extend within the Bayesian framework, allowing us to compare multiple versions.

This part of the model is parametric, operating over a fixed number of tags T, and is identical to the formulation of tag transitions in the Bayesian HMM (Goldwater and Griffiths, 2007). However, we replace the BHMM's emission distribution with the morphologically-informed distributions described below. As in the BHMM, the emission distributions are conditioned on the tag, i.e., each tag has its own morphology.

2.2 Morphology

The morphology model introduced by Goldwater et al. (2006) generates morphological analyses for a set of tokens. These analyses consist of a tag plus a stem and suffix pair, which are concatenated to form the observed words. Both stem s and suffix f are generated from Dirichlet-multinomials conditioned on the tag t:

$$\begin{aligned} \kappa &\sim \text{Dir}(\alpha_\kappa) \\ t | \kappa &\sim \text{Mult}(\kappa) \\ \sigma &\sim \text{Dir}(\alpha_s) \\ s | t, \sigma &\sim \text{Mult}(\sigma_t) \\ \phi &\sim \text{Dir}(\alpha_f) \\ f | t, \phi &\sim \text{Mult}(\phi_t) \end{aligned}$$

The αs are hyperparameters governing the Dirichlet distributions from which the multinomials κ, σ, ϕ are drawn. In turn, t, s, and f are drawn from these multinomials.

The probability of a word under this model is the sum of the probabilities of all possible analyses $l = (t, s, f)$:

$$P_0(w) = \sum_l P_0(l) = \sum_{\substack{t,s,f \text{ s.t.} \\ s \oplus f = w}} P(s|t) P(f|t) P(t) \quad (1)$$

where $s \oplus f = w$ denotes that the concatenation of stem and suffix results in the word w.

On its own, this distribution over morphological analyses makes independence assumptions that are too strong: most word tokens of a word type have the same analysis, but P_0 will re-generate that analysis for every token. To resolve this problem, a Pitman-Yor process (PYP) is placed over the generating distribution above. The Pitman-Yor process has been found to be useful for representing the power-law distributions common in natural language (Teh, 2006; Goldwater and Griffiths, 2007; Blunsom and Cohn, 2011).

The distribution of draws from a Pitman-Yor process (which, in our case, determines the distribution of word tokens with each morphological analysis) is commonly described using the metaphor of a Chinese restaurant. A series of customers (tokens $\boldsymbol{z} = z_1 \ldots z_N$) enter a restaurant with an infinite number of initially empty tables. Upon entering, each customer is seated at a table k with probability

$$p(z_i = k | z_1 \ldots z_{i-1}, a, b) = \quad (2)$$
$$\begin{cases} \frac{n_k - a}{i - 1 + b} & \text{if } 1 \le k \le K \\ \frac{Ka + b}{i - 1 + b} & \text{if } k = K + 1 \end{cases}$$

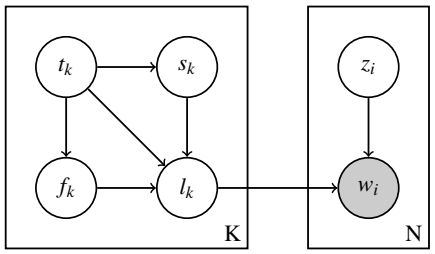

Figure 1: Plate diagram depicting the morphology model (adapted from Goldwater et al. (2006)). Hyperparameters have been omitted for clarity. The left-hand plate depicts the base distribution P_0; note that the morphological analyses l_k are generated deterministically as (t_k, s_k, f_k). The observed words w_i are also deterministic given $z_i = k$ and l_k, since $w_i = s_k \oplus f_k$.

where n_k is the number of customers already sitting at table k, K is the total number of tables occupied by the $i-1$ previous customers, and $0 \leq a < 1$ and $b \geq 0$ are hyperparameters of the process. The probability of being seated at a table increases with the number of customers already seated at that table, creating a 'rich-get-richer' power-law distribution of tokens to tables; a and b control the amount of reuse of existing tables, with smaller values leading to more reuse.

Crucially, each table serves a dish generated by the base distribution P_0—i.e., the dish is a morphological analysis $l_k = (t, s, f)$—and all the customers seated at the same table share the same dish, which is generated only once (at the point when that table is first occupied). The model can thus reuse the analysis for a particular word and avoid regenerating the same analysis multiple times. Note that multiple tables may have identical analyses, $l_k = l_{k'}$. Figure 1 illustrates how the full PYP morphology model generates the observed sequence of word tokens.

2.3 Combined Model

The full model (Figure 2) combines the latent tag sequence with the morphology model. Tag tokens are generated conditioned on local context, not the base distribution, as in the morphology model. Instead of a single PYP generating morphological analyses for all tokens, as in the Goldwater et al. (2006) model, we have a separate PYP for each tag type, i.e., each tag has its own restaurant with its own customers (the tokens labeled with that tag) and its own morphological analyses. The distribution of customers

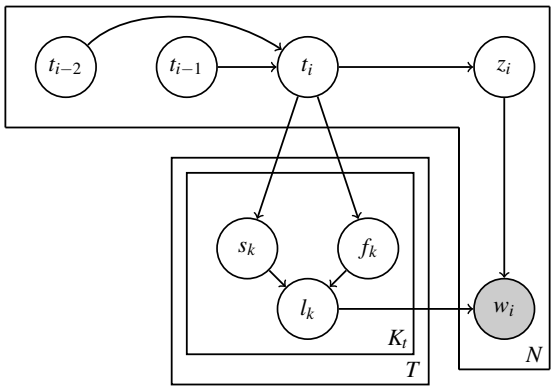

Figure 2: Plate diagram depicting the joint model. Hyperparameters have been omitted for clarity. The L-shaped plate contains the tokens, while the square plates contain the morphological analyses. The t are latent tags, z_i is an assignment to a morphological analysis $l_k = (s_k, f_k)$, and w_i is the observed word. T is the number of distinct tags, and K_t the number of tables used by tag type t.

in each of the tag-specific restaurants is still determined by Equation 2, except that all of the counts and indices are with respect to only the tokens and tables assigned to that tag.

Each tag-specific PYP (restaurant) also has a separate base distribution, $P_0^{(t)}$, resulting in distinct distributions over stems and suffixes for each tag. The analyses generated by the base distributions consist of (stem, suffix) pairs; the tag is given by the identity of the generating PYP.

$$P_0^{(t)}(w) = \sum_l P_0^{(t)}(l = (s, f)) = \sum_{\substack{s,f \text{ s.t.} \\ s \oplus f = w}} P(s|t)P(f|t) \tag{3}$$

The full joint posterior distribution of a sequence of words, tags, and morpheme analyses is shown in Figure 3. Note that all tag-specific morphology models share the same Pitman-Yor parameters a and b.

3 Inference

We use Gibbs sampling for inference over the three sets of discrete variables: tags $\boldsymbol{t}$, their assignments to morphological analyses (tables) $\boldsymbol{z}$, and the analyses themselves $\boldsymbol{l}$.

Each iteration of the sampler has two stages: First the morphological analyses $\boldsymbol{l}$ are sampled, and then each token samples a new tag and a new assignment to an analysis/table. Because the table assignments

$$P(\boldsymbol{t},\boldsymbol{l},\boldsymbol{z}|\alpha_t,a,b,\alpha_s,\alpha_f) = P(\boldsymbol{t}|\alpha_t)P(\boldsymbol{l}|\boldsymbol{t},\alpha_s,\alpha_f)P(\boldsymbol{z}|a,b) \tag{4}$$

$$P(\boldsymbol{t}|\alpha_t) = \prod_{i=2}^{N} P(t_i|t_{i-1},t_{i-2},\boldsymbol{t}_{1\ldots i-1},\alpha_t) = \prod_{t,t'=1}^{T} \frac{\Gamma(T\alpha_t)}{\Gamma(n_{tt'}+T\alpha_t)} \prod_{t''=1}^{T} \frac{\Gamma(n_{tt't''}+\alpha_t)}{\Gamma(\alpha_t)} \tag{5}$$

$$P(\boldsymbol{l}|\boldsymbol{t},\alpha_s,\alpha_f) = \prod_{t=1}^{T}\prod_{k=1}^{K_t} P_t(l_k=(s,f)|\boldsymbol{l}_{1\ldots k-1},\alpha_s,\alpha_f) \tag{6}$$

$$= \prod_{t=1}^{T} \frac{\Gamma(S\alpha_s)}{\Gamma(m_t+S\alpha_s)} \frac{\Gamma(F\alpha_f)}{\Gamma(m_t+F\alpha_f)} \prod_{s=1}^{S} \frac{\Gamma(m_{ts}+\alpha_s)}{\Gamma(\alpha_s)} \prod_{f=1}^{F} \frac{\Gamma(m_{tf}+\alpha_f)}{\Gamma(\alpha_f)} \tag{7}$$

$$P(\boldsymbol{z}|a,b) = \prod_{t=1}^{T}\prod_{i=1}^{N_t} P(z_i|t,\boldsymbol{z}_{1\ldots i-1},a,b) \tag{8}$$

$$= \prod_{t=1}^{T} \frac{\Gamma(1+b)}{\Gamma(n_t+b)} \prod_{k=1}^{K_t} (ka+b) \frac{\Gamma(n_k-a)}{\Gamma(1-a)} \tag{9}$$

Figure 3: The posterior distribution of our joint model. Because the sequence of words $\boldsymbol{w}$ is deterministic given analyses $\boldsymbol{l}$ and assignments to analyses (tables) $\boldsymbol{z}$, the joint posterior over all variables $P(\boldsymbol{w},\boldsymbol{t},\boldsymbol{l},\boldsymbol{z}|\alpha_t,a,b,\alpha_s,\alpha_f)$ is equal to $P(\boldsymbol{t},\boldsymbol{l},\boldsymbol{z}|\alpha_t,a,b,\alpha_s,\alpha_f)$ when $l_{z_i}=w_i$ for all i, and 0 otherwise. We give equations for the non-zero case. ns refer to token counts, ms to table counts. We add two dummy tokens at the start, end, and between sentences to pad the context history.

are conditioned on tags (i.e., a token must be assigned to a table in the correct PYP restaurant) resampling the tag requires immediate resampling of the table assignment as well.

3.1 Initialization

The tags are initialized uniformly at random. For each token, a segmentation point is chosen uniformly at random (we disallow segmentations with a null stem). If this segmentation is new within the PYP associated with that token's tag, a new table is created for the token in that PYP. If it matches an existing analysis, z_i is sampled from the existing tables $\boldsymbol{k}$ plus a possible new table k'.

3.2 Morphological Analyses

Each l_k represents the morphological analysis for the set of tokens assigned to table k. Resampling the segmentation point (stem and suffix identity) of the analysis changes the segmentation of all of the word tokens assigned to that analysis. Note that the tag is not included in l_k in the combined model, because the tag identity is dependent on the local contexts of all the tokens seated at the table.

Analyses are sampled from a product of Dirichlet-multinomial posteriors as follows:

$$p(l_k=(s,f)|t,\boldsymbol{l}^{\setminus k}) = \frac{m_s^{\setminus k}+\alpha_s}{m^{\setminus k}+S\alpha_s} \frac{m_f^{\setminus k}+\alpha_f}{m^{\setminus k}+F\alpha_f} \tag{10}$$

where m_s and m_f are the number of analyses for this tag that share a stem or suffix with l_k, and m is the total number of analyses for this tag. S and F are the total number of stems and suffixes in the model. $\boldsymbol{l}^{\setminus k}$ indicates that the current analysis l_k has been removed from the distribution and the appropriate counts, to create the correct conditioning distribution for the Gibbs sampler.

3.3 Tags

Tags are sampled from the product of posteriors of the transition and emission distributions. The transition distribution is a standard Dirichlet-multinomial posterior. Calculating the emission distribution probability, i.e. the marginal probability of the word given the tag, involves summing over the probability of all the existing tables in the given PYP that emit the correct word, plus the probability of a new table being created, which also includes the probability of a new analysis from $P_0^{(t)}$.

More precisely, tags are sampled from the following distribution:

$$
\begin{aligned}
& p(t_i = t | w_i = w, \boldsymbol{t}^{\setminus i}, \boldsymbol{z}^{\setminus i}, \boldsymbol{l}, \alpha_t, a, b) \qquad (11) \\
& \propto p(t_i = t | t_{i-1}, t_{i-2}, \boldsymbol{t}^{\setminus i}, \alpha_t) \times p(w | t, \boldsymbol{z}^{\setminus i}, \boldsymbol{l}) \\
& = p(t_i = t | t_{i-1}, t_{i-2}, \boldsymbol{t}^{\setminus i}, \alpha_t) \\
& \times \Big(\sum_{k \text{ s.t. } l_k = w} p(z_i = k | t, w, \boldsymbol{z}^{\setminus i}) + p(z_i = k_{\text{new}} | t, w, \boldsymbol{z}^{\setminus i}) \Big) \\
& = \frac{n_{t_{i-2} t_{i-1} t} + \alpha_t}{n_{t_{i-2} t_{i-1}} + T \alpha_t} \\
& \times \Big(\sum_{k \text{ s.t. } l_k = w} \frac{n_k - a}{n_t + b} + \frac{K_t a + b}{n_t + b} P_0^{(t)}(w) \Big)
\end{aligned}
$$

where $l_k = w$ matches tables compatible with w, i.e., the concatenation of stem and suffix form the word, $s_{l_k} \oplus f_{l_k} = w$. n_k is the number of words assigned to the table k and K_t is the total number of tables in the PYP for tag t. Note that all counts are obtained after the removal of the current t_i and z_i, i.e., from $\boldsymbol{t}^{\setminus i}$ and $\boldsymbol{z}^{\setminus i}$.

3.4 Table Assignments

Once a new tag has been sampled for a token, the table assignment must be resampled conditioned on the new tag. The assignment z_i is drawn over all compatible tables in the tag's PYP (that is, where $l_k = w$), plus a possible new table:

$$
p(z_i = k | t_i = t, \boldsymbol{w}, \boldsymbol{z}^{\setminus i}, a, b) \propto \qquad (12)
$$
$$
\begin{cases}
\frac{n_k - a}{n_t + b} & \text{if } 1 \leq k \leq K_t \\
\frac{K_t a + b}{n_t + b} \, P_0^{(t)}(w) & \text{if } k = K_t + 1
\end{cases}
$$

$P_0^{(t)}$ is calculated by summing over the probability of all possible segmentations for a new analysis for word w_i, using Equation 3. If a new table is drawn ($k > K_t$) then we also sample a new analysis for that table from $P_0^{(t)}$.

4 Preliminary Experiments

An important argument for joint learning is that it affords increased flexibility and robustness across a wider range of input data. A model that relies on word order cannot learn syntactic categories from a morphologically complex language with free word order; likewise a model attempting to categorise words using morphology alone will fail on a language without morphology. An effective joint model will be able to make use of the different cues in both language types in a flexible way.

Language A

Table 1: Example sentences in the synthetic languages. Words in Category 1 are made of characters `a-d`, Category 2 `e-h`, Category 3 `m-p`, Category 4 `r-u`. Suffixes in Language B are separated with periods (.) for illustrative purposes only.

In order to test the proposed model, we run two experiments on synthetic languages, which simulate languages in which either word order or morphology is the sole cue. Most natural languages fall between these extremes, but these experiments show that our model can capture the full spectrum.

Language A is a strict word order language lacking morphology. It has a vocabulary of 200 word types, split into four different categories. The 50 word types in each category are created by combining four letters, with replacement, into four-letter words, with a different set of letters used in each category[3]. Words within a category may thus share beginning or ending characters, which could be posited as stems or suffixes by the model, but since only 50 of 256 possible strings are used, there will be no strong evidence for consistent stem and suffixes (i.e. stems appearing with multiple suffixes and vice versa). Each sentence in Language A consists of five words in one of twenty possible category sequences. In these sequences, each category is either followed by itself or the next category (i.e. [2,2,2,3,4] is valid but [2,4,3,1,4] is not). Word order is thus strongly constrained by category membership.

Language B has free word order, with category membership signalled by suffixes. Words are cre-

[3]We achieved the same results with a language using the same four characters in all categories, but using different characters makes the categories human-readable. The model does not have a orthographic/phonological component and so will not recognise the within-category similarity, other than possibly positing spurious stems or suffixes.

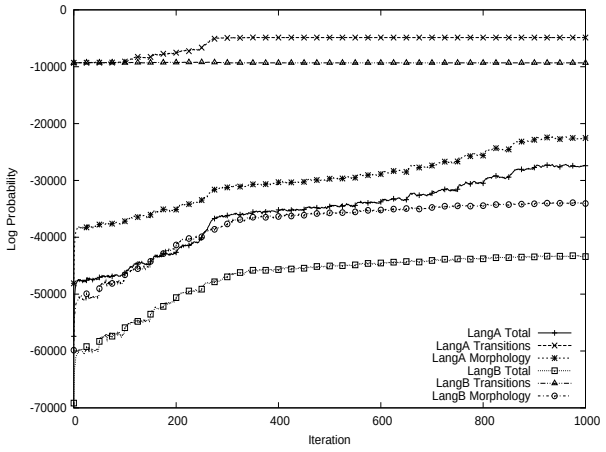

Figure 4: Log probability of the sampler state over 1000 iterations on Languages A and B.

ated by the concatenation of a stem and a suffix, where the stems are the same as the words in language A (50 stems in each of four categories). One of six category-specific suffixes is appended to each stem, resulting in 300 word types per category. Each suffix is two letters long, created by combining three possible letters (the same letters used to create the stems), thus making mis-segmentation possible (for instance, up to three of the suffixes could have the same final letter). Sentences are again five words long, but the sequence of categories is drawn at random, resulting in uniformly random word order. See Table 1 for example sentences in both languages.

We create a 5000 word corpus for each language, and run our model on these corpora. Hyperparameters are set to the same values in both languages[4].

We run the sampler on each dataset for 1000 iterations with simulated annealing. In both cases, the correct solution is found by iteration 500. Figure 4 shows that the morphology component continues to increase the log probability by increasing the number of tokens seated at a table. Note that the correct solution in Language A involves learning a very peaked transition distribution as well as an even more extreme distribution over suffixes (where only the null suffix has high probability), whereas the same distributions in Language B are much flatter. The fact that the same hyperparameter setting is able to correctly identify the two language extremes indicates that the model is robust to hyperparameter values.

These experiments demonstrate that our joint model is able to learn correctly even when only either morphology or word order is informative in a language. We now turn to acquisition data from natural languages in which both morphology and word order are useful cues but to varying degrees.

5 CDS Experiments

5.1 Data

We use two corpora, Eve (Brown, 1973) and Ornat (Ornat, 1994), from the CHILDES database (MacWhinney, 2000). These corpora consist of the child-directed utterances heard by two children, the former learning English and the latter Spanish. These have been annotated for part of speech categories and morphemes.

The CHILDES corpora are tagged with a very rich set of part of speech tags (74 tags), which we collapse to a smaller set of tags[5]. The Eve corpus has 61224 tokens and is thus larger than the Spanish corpus, which has 40497 tokens. However, the English corpus has only 17 gold suffix types, while Spanish has 83. The increased richness of Spanish morphology also has an effect on the number of word types in the corpus: the Spanish dataset has 3046 word types, whereas the larger English dataset has only 1957.

Morphology is annotated using a stem-affix encoding which does not directly correspond to our segmentation-based model. The word *running* is annotated as *run*-ING, *jumping* as *jump*-ING; the annotation is thus agnostic about ortho-morphemic segmentation (i.e., whether to segment as *run.ning* or *runn.ing*), whereas the model is forced to choose a segmentation point. Syncretic suffixes (sharing an identical surface form) are disambiguated: *sings* is annotated as *sing*-3S, *plums* as *plum*-PL. Conversely, the annotation scheme merges allomorphs into a single suffix: infinitive verbs in Spanish, for instance, are encoded as ending with -INF, corresponding to *-ar*, *-er*, and *-ir* surface forms.

[4]The PYP parameters are set to $a = 0.1, b = 1.0$ and the HMM transition parameter $\alpha_t = 1.0$; the parameters in the base distribution are $\alpha_s, \alpha_f = 0.001, \alpha_k = 0.5$.

[5]These are 13 for English (ADJ, ADV, AUX, CONJ, DET, INF, NOUN, NEG, OTH, PART, PREP, PRO, VERB) and 10 for Spanish, since the gold standard does not distinguish AUX, PART or INF.

We ignore irregular/non-affixing forms annotated with *&* (e.g. *was*, annotated as *be&PAST*) and use only hyphen-separated suffixes to evaluate. Where multiple suffixes are concatenated together (e.g., *dog*-DIM-PL) we treat this as a single suffix (-DIM-PL) for evaluation purposes.

In Spanish, many words are annotated as having a suffix of effectively zero length, e.g. the imperative *gusta* is annotated as *gusta*-2S&IMP. We replace these suffixes (where the stem is equal to the word) with a null suffix, excluding them from evaluation, as they are impossible for a segmentation-based model to find.

5.2 Evaluation

Tags are evaluated using VM (Rosenberg and Hirschberg, 2007), as has become standard for this task (Christodoulopoulos et al., 2010). VM is a measure of the normalised cross-entropy between gold and proposed clusters; it ranges between 0 and 100, with higher scores being better.

We also use VM to evaluate the morphological segmentation: all tokens with a common suffix are clustered together, and these clusters are compared against the gold suffix clusters[6]. Using a clustering metric avoids the need to evaluate against a gold segmentation point (which the annotation lacks). Tag membership is added to the non-null model suffixes, so that a final *-s* suffix found in tag 2 is distinguished from the same suffix found in tag 8 (creating suffixes -s-T8 and -s-T2), analogous to the gold annotation distinction between syncretic morphemes -PL and -3S.

Note that ceiling performance of our model on Suffix VM will be below 100, since our model cannot cluster allomorphs, which are represented by a single abstract morpheme in the gold standard.

5.3 Baselines

We test the full model, MORTAG, against a number of variations to investigate the advantages of jointly modelling the two tasks.

Two variants remove the transition distributions, and thus local syntactic context, from the model. MORTAGNOTRANS is the full model without transitions between tag tokens; morphology PYP draws remain conditioned on token tags. We add a Dirichlet prior over tags ($\alpha_t = 0.1$) to encourage tag sparsity (analogous to the transition distribution in the full model). MORCLUSTERS is the original model of Goldwater et al. (2006), in which tags (called clusters in the original) are drawn by P_0.

MORTAGNOSEG is a variant in which the only available suffix is the null suffix; thus segmentations are trivial and only tags are inferred. This model is approximately equivalent to a simple Bayesian HMM but with the addition of PYPs within the emission distribution. We also evaluate against tags found by the BHMM, with a Dirichlet-multinomial emission distribution and no morphology.

MORTAGTRUETAGS is the full model but with all tags fixed to their gold values. This model gives us oracle-type results for morphology. (Due to the annotation scheme used in CHILDES, oracle morphological segmentations are unavailable, so we were unable to test a model with gold morphology and inferred tags.)

5.4 Experimental Procedure

Hyperparameter values for the Pitman-Yor process were found using grid search on a development set (Section 10 of Eve and Section 8 of Ornat; these sections are removed from the dataset we report results on). We use the values which give the best Suffix VM performance on the development data; however we stress that the development results did not vary greatly over a wide range of hyperparameter values, and only deteriorated significantly at extreme values of a.

There are a number of other hyperparameters in the model which we set to fixed values. The transition hyperparameter α_t is set to 0.1 in all models. We set the hyperparameters for the stem and suffix distributions in the morphology base distribution P_0 to 0.001 for both α_s and α_f; α_k over tags in the MORCLUSTERS model is set to 0.5. The number of possible stems and suffixes is given by the dataset: in the Eve dataset there are 5339 candidate stems and 6617 candidate suffixes; in the Ornat dataset these numbers are 8649 and 6598, respectively. The number of tags available to the model is set to the number of gold tags in the data.

[6] We also evaluated stem morpheme clusters and found near-ceiling performance due to the high number of null-suffix words in both corpora.

	Tag VM	Suffix VM
MORTAG	59.1(1.9)	41.9(10.0)
MORCLUSTERS	22.4(1.0)*	28.0(11.9)*
MORTAGNOTRANS	19.3(1.2)*	24.4(5.2)*
MORTAGNOSEG	59.4(1.7)	–
BHMM	56.2(2.3)*	–
MORTAGTRUETAGS	–	42.5(5.2)

Table 2: English Eve corpus results. Standard deviations are in parentheses; $*$ denotes a significant difference from the MORTAG model.

	Tag VM	Suffix VM
MORTAG	43.4(2.6)	41.4(2.5)
MORCLUSTERS	20.3(2.5)*	46.5(3.2)
MORTAGNOTRANS	14.4(1.7)*	36.4(2.0)*
MORTAGNOSEG	39.6(3.7)*	–
BHMM	36.4(0.7)*	–
MORTAGTRUETAGS	–	59.8(0.4)*

Table 3: Spanish Ornat corpus results. Standard deviations are in parentheses; $*$ denotes a significant difference from the MORTAG model.

Sampling is run for 5000 iterations with annealing. Inspection of the posterior log-likelihood indicates that the models converge after about 1000 iterations. We run inference over all models ten times and report the average performance. Significance is reported using the non-parametric Wilcoxon rank-sum test with a significance level of $\rho < 0.05$.

5.5 Results: English

Results on the English Eve corpus are shown in Table 2. We use PYP parameters $a = 0.3$ and $b = 10$, though we found similar performance over a wide range of values of a and b. Our results show a clear improvement in the morphological segmentations found by the joint model and stable tagging performance across all models with context information.

The syntactic clusters found by models using only morphological patterns, MORTAGNOTRANS and MORCLUSTERS, are clearly inferior and lead to low Tag VM results. The models with local syntactic context all perform approximately equally well in terms of finding tags. We find no improvement on tagging performance in English when adding morphology, compared to the MORTAGNOSEG baseline in which words are not segmented. However, we do see a small but significant improvement over the BHMM for both of these models, due to the replacement of the multinomial emission distribution in the BHMM with the PYP.

Morphological segmentations, as measured by Suffix VM, clearly improve with the addition of local contexts (and the ensuing better tags): the full model outperforms the baselines without syntactic contexts. On this dataset, the joint MORTAG model even matches the performance of the model using oracle tags. The standard deviation over Suffix VM scores is quite large for MORTAG and MORCLUSTERS; this is due to frequent words having two high probability segmentations (most notably *is*, which in some runs was segmented as *i.s*).

5.6 Results: Spanish

For the Spanish Ornat corpus, we found slightly different optimal PYP hyperparameters and set $a = 0.1$ and $b = 0.1$. Results are shown in Table 3.

The Spanish results pattern in the opposite way as English. Here we see a statistically significant improvement in tagging performance of the full joint model over both models without morphology (MORTAGNOSEG and BHMM). Models without context information again find much worse tags, mainly because (as in English) function words are not identifiable by suffixes.

However, the full model does not find better morphological segmentations than the MORCLUSTERS model, despite better tags (the two models' Suffix VM scores are not statistically significantly different). We also see that the difference between the segmentations found by the model using gold tags and estimated tags is quite large. This is due to the oracle model finding the rarer suffixes which were not distinguished by the models with noisier tags. This demonstrates the importance of syntactic categorisation for the morpheme induction task, and suggests that a more sophisticated tagging model (with better performance) may yet improve morpheme segmentation performance in Spanish.

6 Conclusion

We have presented a model of joint syntactic category and morphology induction. Operating within a generative Bayesian framework means that combining single-task components is straightforward and well-founded. Our model is token-based, allowing for syntactic and morphemic ambiguity.

To our knowledge, this is the first joint model to be tested on child-directed speech data, which is less complex than the newswire corpora used by previous joint models. Child-directed speech may be simple enough for joint learning not to be necessary: our results indicate the contrary, namely that joint learning is indeed helpful when learning from realistic acquisition data.

We tested this model on two languages with different morphological characteristics. On English, a language with relatively little morphology, especially in child directed speech, we found that better categorisation of words yielded much better morphology in terms of suffixes learned. Conversely, in Spanish we saw less difference on the morphology task between models with categories inferred solely from morphemic patterns and models that also used local syntactic context for categorisation. However, in Spanish we saw an improvement in the tagging task when morphology information was included.

This suggests that English and Spanish make different word-order and morphology trade-offs. In English, local context provides at least as much information as morphology in terms of determining the correct syntactic category, but knowing a good estimate of the correct syntactic category is useful for determining a word's morphology. In Spanish, a word's morphology can more easily be determined simply by looking at frequent suffixes within a purely morphological system. On the other hand, word order is freer, making local syntactic context unreliable, so taking morphological information into account can improve tagging. These differences between languages demonstrate the benefits of joint learning, which enables the learner to more flexibly utilise the information available in the input data.

Abstract

We present a cognitive model of early lexical acquisition which jointly performs word segmentation and learns an explicit model of phonetic variation. We define the model as a Bayesian noisy channel; we sample segmentations and word forms simultaneously from the posterior, using beam sampling to control the size of the search space. Compared to a pipelined approach in which segmentation is performed first, our model is qualitatively more similar to human learners. On data with variable pronunciations, the pipelined approach learns to treat syllables or morphemes as words. In contrast, our joint model, like infant learners, tends to learn multiword collocations. We also conduct analyses of the phonetic variations that the model learns to accept and its patterns of word recognition errors, and relate these to developmental evidence.

1 Introduction

By the end of their first year, infants have acquired many of the basic elements of their native language. Their sensitivity to phonetic contrasts has become language-specific (Werker and Tees, 1984), and they have begun detecting words in fluent speech (Jusczyk and Aslin, 1995; Jusczyk et al., 1999) and learning word meanings (Bergelson and Swingley, 2012). These developmental cooccurrences lead some researchers to propose that phonetic and word learning occur jointly, each one informing the other (Swingley, 2009; Feldman et al., 2013). Previous computational models capture some aspects of this joint learning problem, but typically simplify the problem considerably, either by assuming an unrealistic degree of phonetic regularity for word segmentation (Goldwater et al., 2009) or assuming pre-segmented input for phonetic and lexical acquisition (Feldman et al., 2009; Feldman et al., in press; Elsner et al., 2012). This paper presents, to our knowledge, the first broad-coverage model that learns to segment phonetically variable input into words, while simultaneously learning an explicit model of phonetic variation that allows it to cluster together segmented tokens with different phonetic realizations (e.g., *[ju]* and *[jɪ]*) into lexical items (*/ju/*).

We base our model on the Bayesian word segmentation model of Goldwater et al. (2009) (henceforth GGJ), using a noisy-channel setup where phonetic variation is introduced by a finite-state transducer (Neubig et al., 2010; Elsner et al., 2012). This integrated model allows us to examine how solving the word segmentation problem should affect infants' strategies for learning about phonetic variability and how phonetic learning can allow word segmentation to proceed in ways that mimic the idealized input used in previous models.

In particular, although the GGJ model achieves high segmentation accuracy on phonemic (non-variable) input and makes errors that are qualitatively similar to human learners (tending to undersegment the input), its accuracy drops considerably on phonetically noisy data and it tends to oversegment rather than undersegment. Here, we demonstrate that when the model is augmented to account for phonetic variability, it is able to learn common phonetic changes

and by doing so, its accuracy improves and its errors return to the more human-like undersegmentation pattern. In addition, we find small improvements in lexicon accuracy over a pipeline model that segments first and then performs lexical-phonetic learning (Elsner et al., 2012). We analyze the model's phonetic and lexical representations in detail, drawing comparisons to experimental results on adult and infant speech processing. Taken together, our results support the idea that a Bayesian model that jointly performs word segmentation and phonetic learning provides a plausible explanation for many aspects of early phonetic and word learning in infants.

2 Related Work

Nearly all computational models used to explore the problems addressed here have treated the learning tasks in isolation. Examples include models of word segmentation from phonemic input (Christiansen et al., 1998; Brent, 1999; Venkataraman, 2001; Swingley, 2005) or phonetic input (Fleck, 2008; Rytting, 2007; Daland and Pierrehumbert, 2011; Boruta et al., 2011), models of phonetic clustering (Vallabha et al., 2007; Varadarajan et al., 2008; Dupoux et al., 2011) and phonological rule learning (Peperkamp et al., 2006; Martin et al., 2013).

Elsner et al. (2012) present a model that is similar to ours, using a noisy channel model implemented with a finite-state transducer to learn about phonetic variability while clustering distinct tokens into lexical items. However (like the earlier lexical-phonetic learning model of Feldman et al. (2009; in press)) their model assumes known word boundaries, so to perform both segmentation and lexical-phonetic learning, they use a pipeline that first segments using GGJ and then applies their model to the results.

Neubig et al. (2010) also present a transducer-based noisy channel model that performs joint inference on two out of the three tasks we consider here; their model assumes fixed probabilities for phonetic changes (the noise model) and jointly infers the word segmentation and lexical items, as in our 'oracle' model below (though unlike our system their model learns from phone lattices rather than a single transcription). They evaluate only on phone recognition, not scoring the inferred lexical items.

Recently, Börschinger et al. (2013) did present a joint learner for segmentation, phonetic learning, and lexical clustering, but the model and inference are tailored to investigate word-final /*t*/-deletion, rather than aiming for a broad coverage system as we do.

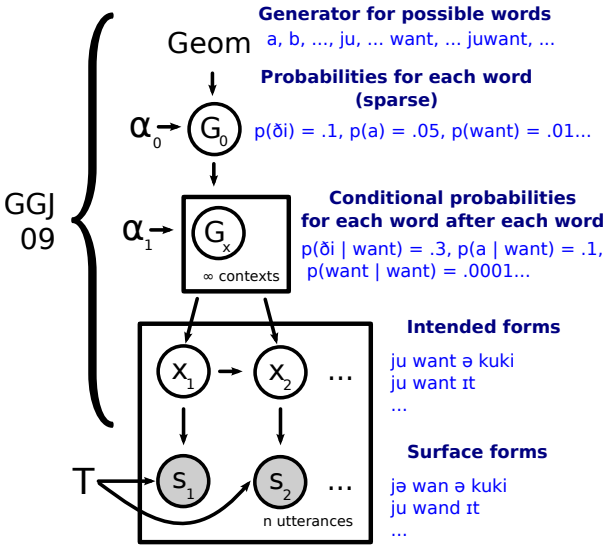

Figure 1: The graphical model for our system (Eq. 1-4). Note that the s_i are not distinct observations; they are concatenated together into a continuous sequence of characters which constitute the observations.

3 Model

We follow several previous models of lexical acquisition in adopting a Bayesian noisy channel framework (Eq. 1-4; Fig. 1). The model has two components: a *source* distribution $P(X)$ over utterances without phonetic variability X, i.e., *intended forms* (Elsner et al., 2012) and a *channel* or *noise* distribution $T(S|X)$ that translates them into the observed surface forms S. The boundaries between surface forms are then deterministically removed so that the actual observations are just the unsegmented string of characters in the surface forms.

$$G_0|\alpha_0, p_{stop} \sim DP(\alpha_0, Geom(p_{stop})) \quad (1)$$

$$G_x|G_0, \alpha_1 \sim DP(\alpha_1, G_0) \quad (2)$$

$$X_i|X_{i-1} \sim G_{X_{i-1}} \quad (3)$$

$$S|X;\theta \sim T(S|X;\theta) \quad (4)$$

The source model is an exact copy of GGJ[1]: to generate the intended-form word sequences X, we

[1]We use their best reported parameter values: $\alpha_0 = 3000, \alpha_1 = 100, p_{stop} = .2$ and for unigrams, $\alpha_0 = 20$.

sample a random language model from a hierarchical Dirichlet process (Teh et al., 2006) with character strings as atoms. To do so, we first draw a unigram distribution G_0 from a Dirichlet process prior whose base distribution generates intended form word strings by drawing each phone in turn until the stop character is drawn (with probability p_{stop}). Then, for each possible context word x, we draw a conditional distribution on words following that context $G_x = P(X_i = \bullet | X_{i-1} = x)$ using G_0 as a prior. Finally, we sample word sequences $x_1 \dots x_n$ from the bigram model.

The channel model is a finite transducer with parameters θ which independently rewrites single characters from the intended string into characters of the surface string. We use MAP point estimates of these parameters; single characters (without n-gram context) are used for computational efficiency. Also for efficiency, the transducer can insert characters into the surface string, but cannot delete characters from the intended string. As in several previous phonological models (Dreyer et al., 2008; Hayes and Wilson, 2008), the probabilities are learned using a feature-based log-linear model. For features, we use all the unigram features from Elsner et al. (2012), which check faithfulness to voicing, place and manner of articulation (for example, for $k \rightarrow g$, active features are *faith-manner*, *faith-place*, *output-g* and *voiceless-to-voiced*).

Below, we present two methods for learning the transducer parameters θ. The *oracle* transducer is estimated using the gold-standard word segmentations and intended forms for the dataset; it represents the best possible approximation under our model of the actual phonetics of the dataset. We can also estimate the transducer using the *EM* algorithm. We first initialize a simple transducer by putting small weights on the faithfulness features to encourage phonologically plausible changes. With this initial model, we begin running the sampler used to learn word segmentations. After several hundred sampler iterations, we start re-estimating the transducer by maximum likelihood after each iteration. We regularize our estimates by adding 200 pseudocounts for the rewrite $x \rightarrow x$ during training (rather than regularizing the weights for particular features). We also show *segment only* results for a model without the transducer component (i.e., $S = X$); this recovers the GGJ baseline.

4 Inference

Inference for this model is complicated for two reasons. First, the hypothesis space is extremely large. Since we allow the input string to be probabilistically lengthened, we cannot be sure how long it is, nor which characters it contains. Second, our hypotheses about nearby characters are highly correlated due to lexical effects. When deciding how to interpret *[wənt]*, if we posit that the intended vowel is */ʌ/*, the word is likely to be */wʌn/* "one" and the next word begins with */t/*; if instead we posit that the vowel is */ɔ/*, the word is probably */wɔnt/* "want". Thus, inference methods that change only one character at a time are unlikely to mix well. Since they cannot simultaneously change the vowel and resegment the */t/*, they must pass through a low-probability intermediate state to get from one state to the other, so will tend to get stuck in a bad local minimum. A Gibbs sampler which inserts or deletes a single segment boundary in each step (Goldwater et al., 2009) suffers from this problem.

Mochihashi et al. (2009) describe an inference method with higher mobility: a block sampler for the GGJ model that samples from the posterior over analyses of a whole utterance at once. This method encodes the model as a large HMM, using dynamic programming to select an analysis. We encode our own model in the same way, constructing the HMM and composing it with the transducer (Mohri, 2004) to form a larger finite-state machine which is still amenable to forward-backward sampling.

4.1 Finite-state encoding

Following Mochihashi et al. (2009) and Neubig et al. (2010), we can write the original GGJ model as a Hidden Semi-Markov model. States in the HMM, written `ST:[`w`][`C`]`, are labeled with the previous word w and the sequence of characters C which have so far been incorporated into the current word. To produce a word boundary, we transition from `ST:[`w`][`C`]` to `ST:[`C`][]` with probability $P(x_i = C | x_{i-1} = w)$. We can also add the next character s to the current word, transitioning from `ST:[`w`][`C`]` to `ST:[`w`][`$C:s$`]`, at no cost (since the full cost of the word is paid at its boundary, there

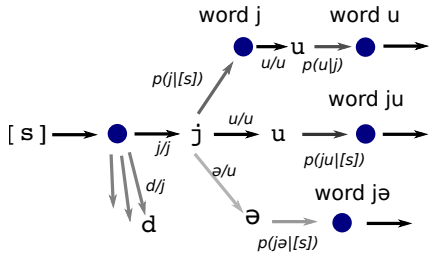

Figure 2: A fragment of the composed finite-state machine for word segmentation and character replacement for the surface string *ju*. The start state [s] is followed by a word boundary (filled circle); the next intended character is probably *j* but can be *d* or others with lower probability. After *j* can be a word boundary (forming the intended word *j*), or another character such as *u*, *ə* or other (not shown) alternatives.

is no cost for the individual characters)[2].

In addition to analyses using known words, we can also encode the uniform-geometric prior over unknown words using a finite-state machine. We can choose to select a word from the prior by transitioning to a state `ST:[`$Geom$`][]` with probability $P(\text{new word}|x_{i-1} = w)$ immediately after a word boundary. While in $Geom$, we can transition to a new $Geom$ state and produce any character with uniform probability $P(c) = (1-P_{stop})\frac{1}{|C|}$; otherwise, we can end the word, transitioning to `ST:[`$unk.word$`][]`, with probability P_{stop}.

This construction is also approximate; it ignores the possibility that the prior will generate a known word w, in which case our final transition ought to be to `ST:[`w`][]` instead of `ST:[`$unk.word$`][]`. This approximation means we do not need to add context to the $Geom$ state to remember the sequence of characters it produced, which allows us to keep only a single $Geom$ state on the chart at each timestep.

When we compose this model with the channel model, the number of states expands. Each state must now keep track of the previous word, what intended characters C have been posited and what surface characters S have been recognized, `ST:[`w`][`C`][`S`]`. To recognize the current word, we transition to `ST:[`C`][][][]` with probability $P(x_i = C|x_{i-1} = w)$. To parse a new surface character s by positing intended character x (note that x might be ϵ), we transition to `ST:[`w`][`$C:x$`][`$S:s$`]` with probability $T(s|x)$. (As above, we pay no cost for our choice of x, which is paid for when we recognize the word; however, we must pay for s.) For efficiency, we do not allow the G_0 states to hypothesize different surface and intended characters, so when we initially propose an unknown word, it must surface as itself.[3]

4.2 Beam sampler

This machine has too many states to fully fill the chart before backward sampling, so we restrict the set of trajectories under consideration using beam sampling (Van Gael et al., 2008) and simulated annealing.

The beam sampler is closely related to the standard beam search technique, which uses a probability cutoff to discard parts of the FST which are unlikely to figure in the eventual solution. Unlike conventional beam search, the sampler explores using stochastic cutoffs, so that all trajectories are explored, but most of the bad ones are explored infrequently, leading to higher efficiency.

We design our beam sampler to restrict the set of potential intended characters at each timestep. In particular, given a stream of input characters $S = s_1 \dots s_n$, we introduce a set of auxiliary cutoff variables $U = u_1 \dots u_n$. The u_i variables represent limits on the probability of the emission of surface character s_i; we exclude any hypothesized x_i whose probability of generating s_i, $T(s_i|x_i)$, is less than u_i. To create a beam sampling scheme, we must devise a distribution for U given a state sequence Q (as discussed above, the sequence of states encodes the intended character sequence and the segmentation of the surface string), $P_u(U|Q)$ and then incorporate the probability of U into the forward messages.

If q_i is the state in Q at which s_i is generated, and x_i the corresponding intended character, we require that $P_u < T(s_i|x_i)$; that is, the cutoffs must not exclude any states in the sequence Q. We define P_u

[2] Though not mentioned by Mochihashi et al. (2009) or Neubig et al. (2010), this construction is not exact, since transitions in a Bayesian HMM are exchangeable but not independent (Beal et al., 2001): if a word occurs twice in an utterance, its probability is slightly higher the second time. For single utterances, this bias is small and easy to correct for using a Metropolis-Hastings acceptance check (Börschinger and Johnson, 2012) using the path probability from the HMM as the proposal.

[3] Again, this approximation is corrected for by the Metropolis-Hastings step.

as a λ-mixture of two distributions:

$$P_u(u|s_i, x_i) = \lambda U[0, min(.05, T(s_i|x_i))] + (1-\lambda)T(s_i|x_i)Beta(5, 1e-5)$$

The former distribution is quite unrestrictive, while the latter prefers to prune away nearly all the states. Thus, for most characters in the string, we do not permit radical changes, while for a fraction, we do.

We follow Huggins and Wood (2013), who extended Van Gael et al. (2008) to the case of a non-uniform P_u, to define our forward message α as:

$$\alpha(q_i, i) \propto P(q_i, S_{0..i}, U_{0..i}) \quad (5)$$
$$= \sum_{q_{i-1}} P_u(u_i|s_i, x_i)T(s_i|x_i)\alpha(q_{i-1}, i-1)$$

This is the standard HMM forward message, augmented with the probability of u. Since $P_u(\cdot|s_i, x_i)$ is required to be less than $T(s_i|x_i)$, it will be 0 whenever $T(s_i|x_i) < u$; this is how the u variables function as cutoffs. In practice, we use the u variables to filter the lexical items that begin at each position i in advance, using a simple 0/1 edit distance Markov model which runs faster than our full model. (For example, we can quickly check if the current U allows *want* as the intended form for *wɔlk* at i; if not, we can avoid constructing the prefix `ST:[`x_{i-1}`][wa][wɔ]` since the continuation will fail.)

The algorithm's speed depends on the size and uncertainty of the inferred LM: large numbers of plausible words mean more states to explore. When inference starts, and the system is highly uncertain about word boundaries, it is therefore reasonable to limit the exploration of the character sequence. We do so by annealing in two ways: as in Goldwater et al. (2009), we raise $P(X)$ (Eq. 3) to a power t which increases linearly from .3. To sample from the posterior, we would want to end with $t = 1$, but as in previous noisy-channel models (Elsner et al., 2012; Bahl et al., 1980) we get better results when we emphasize the LM at the expense of the channel and so end at $t = 2$. Meanwhile, as t rises and we explore fewer implausible lexical sequences, we can explore the character sequence more. We begin by setting the λ interpolation parameter of P_u to 0 to minimize exploration and increase it linearly to .3 (allowing the system to change about a third of the characters on each sweep). This is similar to the scheme for altering P_u in Huggins and Wood (2013).

4.3 Dataset and metrics

We use the corpus released by Elsner et al. (2012), which contains 9790 child-directed English utterances originally from the Bernstein-Ratner corpus (Bernstein-Ratner, 1987) and later transcribed phonemically (Brent, 1999). This standard word segmentation dataset was modified by Elsner et al. (2012) to include phonetic variation by assigning each token a pronunciation independently selected from the empirical distribution of pronunciations of that word type in the closely-transcribed Buckeye Speech Corpus (Pitt et al., 2007). Following previous work, we hold out the last 1790 utterances as unseen test data during development. In the results presented here, we run the model on all 9790 utterances but score only these 1790. We average results over 5 runs of the model with different random seeds.

We use standard metrics for segmentation and lexicon recovery. For segmentation, we report precision, recall and F-score for word boundaries (*bds*), and for the positions of word tokens in the surface string (*srf*; both boundaries must be correct).

For normalization of the pronunciation variation, we follow Elsner et al. (2012) in measuring how well the system clusters together variant pronunciations of the same lexical item, without insisting that the intended form the system proposes for them match the one in our corpus. For example, if the system correctly clusters *[ju]* and *[jɪ]* together but assigns them the incorrect intended form */jɪ/*, we can still give credit to this cluster if it is the one that overlaps best with the gold-standard */ju/* cluster. To compute these scores, we find the optimal one-to-one mapping between our clusters of pronunciations and the true lexical entries, then report scores for mapped tokens (*mtk*; boundaries and mapping to gold standard cluster must be correct) and mapped types[4] (*mlx*).

[4]Elsner et al. (2012) calls the *mlx* metric *lexicon F*, which is possibly confusing. We map the clusters to a gold-standard lexicon (plus potentially some words that don't correspond to anything in the gold standard) and compute a type-level F-score on this lexicon.

	Prec	Rec	F-score
Pipeline (segment, then cluster): (Elsner et al., 2012)			
Bds	70.4	**93.5**	80.3
Srf	56.5	69.7	62.4
Mtk	44.2	**54.5**	48.8
Mlx	48.6	43.1	45.7
Bigram model, segment only			
Bds	73.9 (-0.6:0.7)	91.0 (-0.6:0.4)	**81.6** (-0.5:0.6)
Srf	60.8 (-0.7:1.1)	**70.8** (-0.8:0.9)	65.4 (-0.6:1.0)
Mtk	41.6 (-0.6:1.2)	48.4 (-0.5:1.2)	44.8 (-0.6:1.2)

Mlx	43.0 (-1.0:1.4)	49.5 (-1.5:1.1)	46.0 (-1.0:1.3)

Table 1: Mean segmentation (*bds*, *srf*) and normalization (*mtk*, *mlx*) scores on the test set over 5 runs. Parentheses show min and max scores as differences from the mean.

5 Results and discussion

In the following sections, we analyze how our model with variability compares to GGJ on noisy data. We give quantitative scores and also show that qualitative patterns of errors are often similar to those of human learners and listeners.

5.1 Clean versus variable input

We begin by evaluating our model as a word segmentation system. (Table 1 gives segmentation and normalization scores for various models and baselines on the 1790 test utterances.) We first confirm that our inference method is reasonable. The bigram model without variability ("segment only") should have the same segmentation performance as the standard `dpseg` implementation of GGJ. This is the case: `dpseg` has boundary F of 80.3 and token F of 62.4; we get 81.6 and 65.4. Thus, our sampler is finding good solutions, at least for the no-variability model.

We compare segmentation scores between the "segment only" system and the two bigram models with transducers ("oracle" and "EM"). While these systems all achieve similar segmentation scores, they do so in different ways. "Segment only" finds a solution with boundary precision 73.9% and boundary recall 91.0% for a total F of 81.6%. The low precision and high recall here indicate a tendency to oversegment; when the analysis of a given subsequence is unclear, the system prefers to chop it into small chunks. The bigram models which incorporate transducers score P: 76.1, R: 83.8 (oracle) and P: 80.1, R: 83.0 (EM), indicating that they prefer to find longer sequences (undersegment) more.

In previous experiments on datasets without variation, GGJ also has a strong tendency to undersegment the data (boundary P: 90.1, R: 80.3), which Goldwater et al. argue is rational behavior for an ideal learner seeking a parsimonious explanation for the data. Undersegmentation occurs especially when ignoring lexical context (a unigram model), but to some extent even in bigram models. Human learners also tend to learn collocations as single words (Peters, 1983; Tomasello, 2000), and the GGJ model has been shown to capture several other effects seen in laboratory segmentation tasks (Frank et al., 2010). Together, these findings support the idea that human learners may behave in important respects like the Bayesian ideal learners that Goldwater et al. presented.

However, experiments on data with variation have called these conclusions into question. In particular, GGJ has previously been shown to oversegment rather than undersegment as the input grows noisier (Fleck, 2008), and our results replicate this finding (oversegmentation for the "segment only" model). In addition, the GGJ bigram model, which achieves much higher segmentation accuracy than the unigram model on clean data, actually performs worse on very noisy data (Jansen et al., 2013). Infants are known to track statistical dependencies across words (Gómez and Maye, 2005), so it is worrisome that these dependencies hurt GGJ's segmentation accuracy when learning from noisy data.

Our results show that modeling phonetic variability reverses the problematic trends described above. Although the models with phonetic variability show similar overall segmentation accuracy on noisy data to the original GGJ model, the pattern of errors changes, with less oversegmentation and more un-

dersegmentation. Thus, their qualitative performance on variable data resembles GGJ's on clean data, and therefore the behavior of human learners.

5.2 Phonetic variability

We next analyze the model's ability to normalize variations in the pronunciation of tokens, by inspecting the *mtk* score. The "segment only" baseline is predictably poor, F: 44.8. The pipeline model scores 48.8, and our oracle transducer model matches this exactly. The EM transducer scores better, F: 49.6. Although the confidence intervals overlap slightly, the EM system also outperforms the pipeline on the other F-measures; altogether, these results suggest at least a weak learning synergy (Johnson, 2008) between segmentation and phonetic learning.

It is interesting that EM can perform better than the oracle. However, EM is more conservative about which sound changes it will allow, and thus tends to avoid mistakes caused by the simplicity of the transducer model. Since the transducer works segment-by-segment, it can apply rare contextual variations out of context. EM benefits from not learning these variations to begin with.

We can also compare the bigram and unigram versions of the model. The unigram model is a reasonable segmenter, though not quite as good as the bigram model, with boundary F of 76.4 and token F of 60.9 (compared to 79.8 and 64.4 using the bigram model). However, it is not good at normalizing variation; its *mtk* score is comparable to the baseline at 44.8%[5]. Although bigram context is only moderately effective for telling where words are, the model seems heavily reliant on lexical context to decide *what* words it is hearing.

5.3 Error analysis

To gain more insight into the differing behavior of our model versus a pipelined system, we inspect the intended word strings X proposed by each one in detail. Below, we categorize the kinds of intended word strings that the model might propose to span a given gold-standard word token:

Correct Correctly segmented, mapped to the correct lexical item (e.g., gold intended */ju/*, surface segmentation *[ju]*, intended */ju/*)

Wrong form Correctly segmented, mapped to the wrong lexical item (*/ju/*, surf. *[ju]*, int. */jɛs/*)

Colloc Missegmented as part of a sequence whose boundaries correspond to real word boundaries (*/ju•want/*, surf. *[juwant]*, int. */juwant/*)

Corr. colloc As above, but proposed lexical item maps to this word (*/ar•ju/*, surf. *[arjə]* int. */ju/*)

Split Missegmented with a word-internal boundary (*/dɔgiz/*, surf. *[dɔ•giz]*, int. */dɔ•giz/*)

Corr. split As above, but one proposed word maps correctly (*/dɔgi/*, surf. *[dɔg•i]*, int. */dɔgi•ə/*)

One boundary One boundary correct, the other wrong (*/ju•wa…/*, surf. *[juw]*, int. */juw/*)

Other Not a collocation, both boundaries are wrong (*/du•ju•wa…/*, surf. *[ujuw]*, int. */ujuw/*)

	EM-learned	Segment only
Correct	49.88	47.61
Wrong form	17.96	23.73
Collocation	14.25	7.59
Split	8.26	15.18
One bound	7.11	15.18
Corr. colloc.	1.35	< 0.01
Other	0.75	0.22
Corr. split	0.43	0.66

Table 2: Distribution (%) of error types (see text) in a single run on the full dataset.

Table 2 shows the distribution over intended word strings proposed by the "segment only" baseline and the EM-learned transducer. Both systems propose a large number of correct forms, and the most common error category is "wrong form" (lexical error without segmentation error), an error which could potentially be repaired in a pipeline system. However, the remaining errors represent segmentation mistakes which a pipeline could not repair. Here the two systems behave quite differently. The EM-learned transducer analyses 14% of real tokens as parts of multiword collocations like "doyou"; in another 1.35%, the underlying content word is even correctly detected. The non-variable system, on the other hand, analyses 15% of real tokens by splitting them into pieces. Since infant learners tend to learn collocations, this supports our analysis that the model with variation better models human behavior.

[5] Elsner et al. (2012) show a similar result for a unigram version of their pipelined system.

EM	*ju*: 805, *duju*: 239, *juwan*: 88, *jɪ*: 58, *eˑju*: 54, *judu*: 47, *jæ*: 39, *julʌk*: 39, *ʃu*: 30, *u*: 23, *ʒu*: 18, *j*: 17, *jeˑ*: 16, *tʃu*: 15, *aj*:15, *ðerjugo*: 12, *dʒu*: 12
GGJ	*ju*: 498, *jɪ*: 280, *jə*: 165, *ji*: 119, *duju*: 106, *dujɪ*: 44, *kɪnju*: 39, *i*: 32, *u*: 29, *kɪnjɪ*: 29, *julʌk*: 24, *juwan*: 23, *j*: 22, *ʃu*: 19, *jʊ*: 18, *eˑju*: 18, *ɹ*:16, *ʒu*: 15, *dʒ•u*: 13, *jɛ*: 12, *ʃɪ*: 11, *θæŋkju*: 11

Table 3: Forms proposed with frequency > 10 for gold-standard tokens of "you" in one sample from EM-transducer and segment-only (GGJ) system.

To illustrate this behavior anecdotally, we present the distribution of intended word strings spanning tokens whose gold intended form is */ju/* "you" (Table 3). The EM-learned solution proposes 805 tokens of */ju/*, which is the correct analysis[6]; the "segment only" system instead finds varying forms like */jɪ/*, */jæ/* etc. This is unsurprising and could be repaired by a suitable pipelined system. However, the EM system also proposes 239 instances of "doyou", 88 instances of "youwant", 54 instances of "areyou" and several other collocations. The "segment only" system finds some of these collocations, split into different versions: for instance 106 instances of */duju/* and 44 of */dujɪ/*. In a pipelined system, we could combine these variants to find 150 instances— but this is still 89 instances short of the 239 found when allowing for variability. The same pattern holds for "youlike" and "youwant". Because the non-variable system must learn each variant separately, it learns only the most common instances of these long collocations, and analyzes infrequent variants differently.

We also perform this analysis specifically for words beginning with vowels. Infants show a delay in their ability to segment these words from continuous speech (Mattys and Jusczyk, 2001; Nazzi et al., 2005; Seidl and Johnson, 2008), and Seidl and Johnson (2008) suggest a perceptual explanation— initial vowels can be hard to hear and often exhibit variation due to coarticulation or resyllabification. Although our dataset does not contain coarticulation as such, it should show this pattern of greater variation, which we hypothesize might lead to difficulty in segmenting and recognizing vowel-initial words.

The model's behavior is consistent with this hypothesis (Table 4). Both the "segment only" and EM transducer models find approximately the same proportion of vowel-initial tokens, and both systems do somewhat better on consonant-initial words than vowel-initial words. The advantage is stronger for the transducer model, which gets only 41.5% of vowel-initial tokens correct as opposed to 52.1% of consonant-initial words. It proposes more collocations for vowel-initial words (19.2%) than for consonants (12.5%). In cases where they do not propose a collocation, both systems are somewhat more likely to find the right boundary of a vowel-initial token than the left boundary (although again this difference is larger for the EM system); this suggests that the problem is indeed caused by the initial segment.

Segment only	Vow. init	Cons. init
Correct	47.5	51.7
Wrong form	18.6	15.7
Collocation	14.6	12.2
Split	6.2	10.8
Right bd. corr.	5.8	3.6
Left bd. corr.	4.6	3.8
EM transducer	**Vow. init**	**Cons. init**
Correct	41.5	52.1
Wrong form	20.4	17.3
Collocation	19.2	12.5
Split	5.2	9.1
Right bd. corr.	6.2	2.7
Left bd. corr.	2.7	3.1

Table 4: Most common error types (%; see text) for intended forms beginning with vowels or consonants. Rare error types are not shown. "One bound" errors are split up by which boundary is correct.

5.4 Phonetic Learning

We next compare phonetic variations learned by the model to characteristics of infant speech perception. Infants show an asymmetry between consonants and vowels, losing sensitivity to non-native vowel contrasts by eight months (Kuhl et al., 1992; Bosch and Sebastián-Gallés, 2003) but to non-native consonant contrasts only by 10-12 months (Werker and Tees, 1984). The observed ordering is somewhat puzzling when one considers the availability for distributional information (Maye et al., 2002), which is much stronger for stop consonants than for vowels (Lisker and Abramson, 1964; Peterson and Barney, 1952). Infants are also conservative in generalizing across phonetic variability, showing a delayed abil-

[6]Not all the variants are merged, however. *jɪ*, *jæ*, *ʃu* etc. are still occasionally analyzed as separate lexical items.

ity to generalize across talkers, affects, and dialects. They have difficulty recognizing word tokens that are spoken by a different talker or in a different tone of voice until 11 months (Houston and Jusczyk, 2000; Singh et al., 2004), and the ability to adapt to unfamiliar dialects appears to develop even later, between 15 and 19 months (Best et al., 2009; Heugten and Johnson, in press; White and Aslin, 2011).

Similar to infants, our model shows both a vowel-consonant asymmetry and a reluctance to accept the full range of adult phonetic variability. Table 5 shows some segment-to-segment alternations learned in various transducers. The oracle learns a large amount of variation (*u* surfaces as itself only 68% of the time) involving many different segments, whereas EM is similar to infant learners in learning a more conservative solution with fewer alternations overall. Moreover, EM appears to identify patterns of variability in vowels before consonants. It learns a similar range of alternations for *u* as in the oracle, although it treats the sound as less variable than it actually is. It learns much less variability for consonants; it picks up the alternation of *ð* with *s* and *z*, but predicts that *ð* will surface as itself 91% of the time when the true figure is only 69%. And it fails to learn any meaningful alternations involving *k*. These results suggest that patterns of variability in vowels are more evident than patterns of variability in consonants when infants are beginning to solve the word segmentation problem.

To investigate the effect of data size on this conservativism, we ran the system on 1000 utterances instead of 9790. This leads to an even more conservative solution, with variations for *u* but none of the others (although *i* and *ð* still vary more than *k*).

5.5 Segmentation and recognition errors

A particularly interesting set of errors are those that involve both a missegmentation and a simultaneous misrecognition, since the joint model is prone to such errors while the pipelined model is not. Relatively little is known about infants' misrecognitions of words in fluent speech, although it is clear that they find words in medial position harder (Plunkett, 2005; Seidl and Johnson, 2006). However, adults make missegmentation/misrecognition errors fairly often, especially when listening to noisy audio (Butterfield and Cutler, 1988). Such errors are more common when the misrecognized word belongs to a prosodically rare class and when the incorrectly hypothesized string contains frequent words (Cutler, 1990); phonetically ambiguous words are also more commonly recognized as the more frequent of two options (Connine et al., 1993). For the indefinite article "a" (often reduced to *[ə]*), lexical context is the main factor in deciding between ambiguous interpretations (Kim et al., 2012). In rapid speech, listeners have few phonetic cues to indicate whether it is present at all (Dilley and Pitt, 2010). Below, we analyze various misrecognitions made by our system (using the EM transducer), and find some similar effects.

System	x	top 4 outputs s							
Oracle	*u*	*u*	.68	*ə*	.05	*a*	.04	*ʊ*	.04
	i	*i*	.85	*ɪ*	.03	*ə*	.03	*ɛ*	.02
	ð	*ð*	.69	*s*	.07	[*ϕ*]	.07	*z*	.04
	k	*k*	.93	*d*	.02	*g*	.02		
	[*ϕ*]	*r*	.21	*h*	.11	*d*	.01	*ə*	.07
EM (full)	*u*	*u*	.75	*ə*	.08	*ɪ*	.04	*ʊ*	.03
	i	*i*	.90	*ɪ*	.04	*ɛ*	.02		
	ð	*ð*	.91	*s*	.03	*z*	0.1		
	k	*k*	.98						
	[*ϕ*]	*ə*	.32	*ɪ*	.14	*n*	.13	*t*	.13
EM (only 1000 utts)	*u*	*u*	.82	*ɪ*	.04	*ə*	.04	*a*	.02
	i	*i*	.97						
	ð	*ð*	.95						
	k	*k*	.99						
	[*ϕ*]	*ə*	.21	*ɪ*	.18	*t*	.12	*s*	.12

Table 5: Learned phonetic alternations: top 4 outputs s with $p > .001$ for inputs $x =$ uw (/u/), iy (/i/), dh (/ð/), k (/k/) and [ϕ], the null character. Outputs from [ϕ] are insertions. The oracle allows [ϕ] as an output (deletion) but for computational reasons, the model does not.

The easiest cases to analyze are those with no missegmentation: the proposed boundaries are correct, and the proposed lexical entry corresponds to a real word[7], but not the correct one. Most of them correspond to homophones (Table 6).

Common cases with a missegmentation include *it* and *is*, *a* and *is*, *it's* and *is*, *who*, *who's* and *whose*, *that's* and *what's*, and *there* and *there's*. In general, these errors involve words which sometimes appear

[7]The one-to-one mapping can be misleading, as it may map a large cluster to a real word on the basis of one or two tokens if all other tokens correspond to a different word already used for another cluster. We manually filter out a few cases like this.

Actual	proposed	count
/*tu*/ "two"	/*tə*/ "to"	95
/*kin*/ "can"	/*kænt*/ "can't"	67
/*ɛn*/ "and"	/*æn*/ "an"	61
/*hɪz*/ "his"	/*ɪz*/ "is"	57
/*ðə*/ "the"	/*ə*/ "ah"	51
/*wəts*/ "what's"	/*wants*/ "wants"	40
/*wan*/ "want"	/*won*/ "won't"	39
/*yu*/ "you"	/*yæ*/ "yeah"	39
/*fɚ*/ "for"	/*fɔr*/ "four"	30
/*hir*/ "here"	/*hil*/ "he'll"	28

Table 6: Top ten errors involving confusion between real, correctly segmented words: the most common pronunciation of the actual token and its orthographic form, the same for the proposed token, and the frequency.

with a morpheme or clitic (which can easily be missegmented as part of something else), words which differ by one segment, and frequent function words which often appear in similar contexts. These tendencies match those shown by adult human listeners.

A particularly distinctive set of joint recognition and segmentation errors are those where an entire real token is treated as phonetic "noise"— that is, it is segmented along with an adjacent word, and the system clusters the whole sequence as a token of that word. The most common examples are "that's a" identified as "that's", "have a" identified as "have", "sees a" identified as "sees" and other examples involving "a", a word which also frequently confuses humans (Kim et al., 2012; Dilley and Pitt, 2010). However, there are also instances of "who's in" as "who's", "does it" as "does", and "can you" as "can".

6 Conclusion

We have presented a model that jointly infers word segmentation, lexical items, and a model of phonetic variability; we believe this is the first model to do so on a broad-coverage naturalistic corpus[8]. Our results show a small improvement in both segmentation and normalization over a pipeline model, providing evidence for a synergistic interaction between these learning tasks and supporting claims of interactive learning from the developmental literature on infants. We also reproduced several experimental findings; our results suggest that two vowel-consonant asymmetries, one from the word segmentation literature and another from the phonetic learning literature, are linked to the large variability in vowels found in natural corpora. The model's correspondence with human behavioral results is by no means exact, but we believe these kinds of predictions might help guide future research on infant phonetic and word learning.

Abstract

Animacy detection is a problem whose solution has been shown to be beneficial for a number of syntactic and semantic tasks. We present a state-of-the-art system for this task which uses a number of simple classifiers with heterogeneous data sources in a voting scheme. We show how this framework can give us direct insight into the behavior of the system, allowing us to more easily diagnose sources of error.

1 Introduction

Animacy detection has proven useful for a variety of syntactic and semantic tasks, such as anaphora and coreference resolution (Orăsan and Evans, 2007; Lee et al., 2013), verb argument disambiguation (Dell'Orletta et al., 2005) and dependency parsing (Øvrelid and Nivre, 2007). Existing approaches for animacy detection typically rely on two types of information: linguistic databases, and syntactic cues observed from the corpus. They usually combine two types of approaches: rule based systems, and machine learning techniques. In this paper we explore a slightly different angle: we wish to design an animacy detector whose decisions are *interpretable and correctable*, so that downstream semantic modeling systems can revisit those decisions as needed. Thus here, we avoid defining a large number of features and then using a machine learning method such as boosted trees, since such methods, although powerful, result in hard-to-interpret systems. Instead, we explore combining interpretable voting models using machine learning only to reweight their votes. We show that such an approach can indeed result in a high performing system, with animacy detection accuracies in the mid 90% range, which compares well with other reported rates. Ensemble methods are well known (see for example, Dietterich (2000)) but our focus here is on using them for interpretability while still maintaining accuracy.

* Work performed while visiting Microsoft Research.

2 Previous Work

2.1 Definitions of Animacy

Previous work uses several different definitions of animacy. Orăsan and Evans (2007) define animacy in the service of anaphora resolution: an NP is considered animate "*if its referent can also be referred to using one of the pronouns he, she, him, her, his, hers, himself, herself, or a combination of such pronouns (e.g. his/her)*". Although useful for the task at hand, this has counterintuitive consequences: for example, *baby* may be considered animate or inanimate, and *ant* is considered inanimate (Ibid., Figure 1). Others have argued that animacy should be captured by a hierarchy or by categories (Aissen, 2003; Silverstein, 1986). For instance, Zaenen et al. (2004) propose three levels of animacy (*human*, *other animate* and *inanimate*), which cover ten categories of noun phrases, with categories like ORG (organization), ANIM (animal) and MAC (intelligent machines such as robots) categorised as *other animate*. Bowman and Chopra (2012) report results for animacy defined both this way and with the categories collapsed to a binary (*animate, inanimate*) definition.

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 55–60,
Seattle, Washington, USA, 18-21 October 2013.

2.2 Methods for Animacy Detection

Evans and Orăsan (2000) propose a rule-based system based on the WordNet taxonomy (Fellbaum, 1998). Each synset is ascribed a binary animacy label based on its unique beginner. A given noun is then associated with the fraction of its animate synsets (where all synsets are taken to be animate or inanimate) and one minus that fraction, similarly for a given verb. Animacy is then ascribed by applying a series of rules imposing thresholds on those fractions, together with rules (and a gazetteer) to detect names and acronyms, and a rule triggered by the occurrence of *who*, or reflexives, in the NP. In later work, Orăsan and Evans (2007) extend the algorithm by propagating animacy labels in the WordNet graph using a chi-squared test, and then apply a k-nearest neighbor classifier based on four lexical features. In their work, the only context used was the animacy of the verb in the NP, for heads of subject NPs (e.g., the subject of *eat* is typically animate). Øvrelid (2009) and Bowman and Chopra (2012) extend this idea by using dependency relations to generate features for their classifier, enabled by corpora created by Zaenen et al. (2004). In another approach, Ji and Lin (2009) apply a simple "relative-pronoun" pattern to the Google n-gram corpus (Brants and Franz, 2006) to assign animacy (see the List model in Section 5 for details). Although the animacy decision is again context-independent, such a list provides a strong baseline and thus benefit applications like anaphora resolution (Lee et al., 2013).

3 The Task

We adopt a definition of animacy closest to the binary version in Bowman and Chopra (2012): we define an entity to be animate if it is alive and has the ability to move under its own will. We adopt this simple definition because it fits well with the common meaning and is therefore less error prone, both in terms of incorporation into higher level models, and for labeling (Orăsan and Evans (2007) report that the labeling of animacy tuned for anaphora proved challenging for the judges). We also apply the label to single noun tokens where possible: the only exceptions are compound names ("*Sarah Jones*") which are treated as single units. Thus, for example, "*puppy food*" is treated as two words, with *puppy* animate and *food* inanimate. A more complete definition would extend this to all noun phrases, so that *puppy food* as a unit would be inanimate, a notion we plan to revisit in future work. Note that even this simple definition presents challenges, so that a binary label must be applied depending on the predominant meaning. In "*A plate of chicken*," *chicken* is treated as inanimate since it refers to food. In "*Caruso (1873-1921) is considered one of the world's best opera singers. He...*," although at the time of writing clearly *Caruso* was not alive, the token is still treated as animate here because the subsequent writing refers to a live person.

4 The Data

We used the MC160 dataset, which is a subset of the MCTest dataset and which is composed of 160 grade level reading comprehension stories generated using crowd sourcing (Richardson et al., 2013). Workers were asked to write a short story (typically less than 300 words) with a target audience of 5 to 7 year olds. The available vocabulary was limited to approximately 8000 words, to model the reading ability of a first or second grader. We labeled this data for animacy using the definition given above. The first 100 of the 160 stories were used as the training set, and the remaining 60 were used for the test set. These animacy labels will be made available on the web site for MCTest (Richardson et al., 2013).

5 The Models

Since one of our key goals is interpretability we chose to use an ensemble of simple voting models. Each model is able to vote for the categories *Animal*, *Person*, *Inanimate*, or to abstain. The distinction between *Animal* and *Person* is only used when we combine votes, where *Animal* and *Person* votes appear as distinct inputs for the final voting combination model. Some voters do not distinguish between *Person* and *Animal*, and vote for *Animate* or *Inanimate*. Our models are:

List: The n-gram list method from (Ji and Lin, 2009). Here, the frequencies with which the relative pronouns *who*, *where*, *when*, and *which* occur are considered. Any noun followed most frequently by *who* is classified as *Animate*, and any other noun

in the list is classified as *Inanimate*. This voter abstains when the noun is not present in the list.

Anaphora Design: The WordNet-based approach of Evans and Orăsan (2000).

WordNet: A simple approach using WordNet. This voter chooses *Animal* or *Person* if the unique beginner of the first synset of the noun is either of these, and *Inanimate* otherwise.

WordSim: This voter uses the contextual vector space model of Yih and Qazvinian (2012) computed using Wikipedia and LA Times data. It uses short lists of hand-chosen signal words for the categories *Animal*, *Person*, and *Inanimate* to produce a "response" of the word to each category. This response is equal to the maximum cosine similarity in the vector space of the query word to any signal word in the category. The final vote goes to the category with the highest response.

Name: We used an in-house named entity tagger. This voter can recognize some inanimate entities such as cities, but does not distinguish between people and animals, and so can only vote *Animate*, *Inanimate* or *Abstain*.

Dictionaries: We use three different dictionary sources (Simple English Wiktionary, Full English Wiktionary, and the definitions found in WordNet) with a recursive dictionary crawling algorithm. First, we fetch the first definition of the query and use a dependency tree and simple heuristics to find the head noun of the definition, ignoring qualification NPs like "piece" or "member." If this noun belongs to a list of per-category signal words, the voter stops and votes for that category. Otherwise, the voter recursively runs on the found head noun. To prevent cycling, if no prediction is made after 10 recursive lookups, the voter abstains.

Transfer: For each story, we first process each sentence and detect instances of the patterns *x am/is/was/are/were y* and *y named x*. In each of these cases, we use majority vote of the remaining voters to predict the animacy of *y* and transfer its vote to *x*, applying this label (as a vote) to all instances of *x* in the text.

The *WordSim* and *Dictionaries* voters share lists of signal words, which were chosen early in the experimental process using the training set. The signal words for the *Animal* category were *animal* and *mammal*[1]. *Person* contains *person* and *people*. Finally, *Inanimate* uses *thing*, *object*, *space*, *place*, *symbol*, *food*, *structure*, *sound*, *measure*, and *unit*.

We considered two methods for combining voters: majority voting (where the reliable *Name* voter overrides the others if it does not abstain) and a linear reweighting of votes. In the reweighting method, a feature vector is formed from the votes. Except for *WordSim*, this vector is an indicator vector of the vote – either *Animal*, *Person*, *Animate* (if the voter doesn't distinguish between animals and people), *Inanimate*, or *Abstain*.

For *Dictionaries*, the vector's non-zero component is multiplied by the number of remaining allowed recursive calls that can be performed, plus one (so that a success on the final lookup gives a 1). For example, if the third lookup finds a signal word and chooses *Animal*, then the component corresponding to *Animal* will have a value of 9.

For *WordSim*, instead of an indicator vector, the responses to each category are used, or an indicator for abstain if the model does not contain the word. If the word is in the model, a second vector is appended containing the ratio of the maximum response to the second-largest response in the component for the maximum response category. These per-voter feature vectors are concatenated to form a 35 dimensional vector, and a linear SVM is trained to obtain the weights for combining the votes.

6 Results

We used the POS tagger in MSR SPLAT (Quirk et al., 2012) to extract nouns from the stories in the MC160 dataset and used these as labeled examples for the SVM. This resulted in 5,120 extracted nouns in the 100 training stories and 3,009 in the 60 test stories. We use five-fold cross-validation on the training set to select the SVM parameters. 57.2% of the training examples were inanimate, as were 58.1% of the test examples.

Table 1 gives the test accuracy of each voter. *List*

[1]This was found to work well given typical dictionary definitions despite the fact that people are also mammals.

List	Anaphora	WNet	WSim	Dict	Name
84.6	77.1	78.8	57.6	74.3	16.0

Table 1: Accuracy of various individual voters on the test set. Abstentions are counted as errors. Note that *Transfer* depends on a secondary source for classification, and is therefore not listed here.

	Majority	SVM
N+WN+D+WS+AD+L	87.7	95.0
N+WN+WS	80.1	95.0
N+WN+D+WS+AD+L+T	87.4	95.0
N+WN+D+WS	86.4	94.8
N+WN+WS+AD+L	86.5	94.7
N+WN+D+WS+T	86.8	94.0
N+WN+D	86.1	93.7
N+WN	89.3	93.0
N+D	82.6	93.0
N+AD	87.6	89.4
N+L	85.4	88.9

Table 2: Accuracy of various combinations of voters among Name (N), Anaphora Design (AD), List (L), WordNet (WN), WordSim (WS), Dictionary (D), and Transfer (T) under majority voting and SVM schemes. Bold indicates a statistically significant difference over the next lower bolded entry with $p < 0.01$, for the SVM.

comes out on top when taken alone, but we see in later results that it is less critical when used with other voters. *Name* performs poorly on its own, but later we will see that it is a very accurate voter which frequently abstains.

Table 2 gives the test performance of various combinations of voters, both under majority vote and reweighting. Statistical significance was tested using a paired t-test, and bold indicates a method was significant over the next lower bold line with p value $p < 0.01$. We see a very large gain from the SVM reweighting: 14.9 points in the case of *Name+WordNet+WordSim*.

In Table 3, we show the results of ablation experiments on the voters. We see that the most valuable sources of information are *WordSim* and *Dictionaries*.

Finally, in Table 4, we show a breakdown of which voters cause the most errors, for the majority vote system. In this table, we considered only "final errors," i.e. errors that the entire system makes. Over all such errors, we counted the number of times

	Majority	SVM
WordSim	87.6	93.7
SimpleWikt (dict)	87.3	94.1
FullWikt (dict)	86.4	94.3
Dict	87.4	94.5
Name	86.6	94.7
List	86.4	94.8
WordNet (dict)	88.7	94.8
WordNet	87.5	94.9
Anaphora Design	88.6	94.9
Transfer	87.7	95.0

Table 3: Test accuracy when leaving out various voters, using both majority vote and and reweighting. Bold indicates statistical significance over the next lower bold line with $p < 0.01$.

each voter chose incorrectly, giving a count of how many times each voter contributed to a final error. We see that the *Anaphora Design* system has the largest number of errors on both train and test sets. After this, *WordNet*, *List*, and *WordNet (dict)* are also large sources of error. On the other hand, *Name* and *WordSim* have very few errors, indicating high reliability. The table also gives the number of *critical errors*, where the voter selected the wrong category *and* was a deciding vote (that is, when changing its vote would have resulted in a correct overall classification). We see a similar pattern here, with *Anaphora Design* causing the most errors and *WordSim* and *Name* among the most reliable. We included *Anaphora Design* even though it uses a different definition of animacy, to determine if its vote was nevertheless valuable.

Error tables such as these show how voting models are more interpretable *and therefore correctable* compared to more complex learned models. The tables indicate the largest sources of error and suggest changes that could be made to increase accuracy. For example, we could make significant gains by improving *WordNet*, *WordNet (dictionary)*, or *List*, whereas there is relatively little reason to adjust *WordSim* or *Name*.

7 Conclusions

We have shown that linear combinations of voting models can give animacy detection rates in the mid 90% range. This is well above the accuracy found

	Errors		Critical	
	Train	Test	Train	Test
Anaphora Design	555	266	117	76
WordNet	480	228	50	45
List	435	195	94	45
Transfer	410	237	54	58
WordNet (dict)	385	194	84	65
SimpleWikt (dict)	175	111	39	16
FullWikt (dict)	158	67	1	5
WordSim	107	89	11	19
Name	71	55	27	19

Table 4: *Errors* column: number of errors on train and test where a source voted incorrectly, and was thus at least in part responsible for an error of the overall system. *Critical* column: number of errors on train and test where a source voted incorrectly, and in addition cast a deciding vote. Results are for majority vote.

by using the n-gram method of (Ji and Lin, 2009), which is used as an animacy detection component in other systems. In this sense the work presented here improves upon the state of the art, but there are caveats, since other workers define animacy differently and so a direct comparison with their work is not possible. Our method has the added advantage of interpretability, which we believe will be useful when using it as a component in a larger system.

Acknowledgments

We wish to thank Andrzej Pastusiak for his help with the labeling tool.

Abstract

We present a unified unsupervised statistical model for text normalization. The relationship between standard and non-standard tokens is characterized by a log-linear model, permitting arbitrary features. The weights of these features are trained in a maximum-likelihood framework, employing a novel sequential Monte Carlo training algorithm to overcome the large label space, which would be impractical for traditional dynamic programming solutions. This model is implemented in a normalization system called UNLOL, which achieves the best known results on two normalization datasets, outperforming more complex systems. We use the output of UNLOL to automatically normalize a large corpus of social media text, revealing a set of coherent orthographic styles that underlie online language variation.

1 Introduction

Social media language can differ substantially from other written text. Many of the attempts to characterize and overcome this variation have focused on *normalization*: transforming social media language into text that better matches standard datasets (Sproat et al., 2001; Liu et al., 2011). Because there is little available training data, and because social media language changes rapidly (Eisenstein, 2013b), fully supervised training is generally not considered appropriate for this task. However, due to the extremely high-dimensional output space — arbitrary sequences of words across the vocabulary — it is a very challenging problem for unsupervised learning. Perhaps it is for these reasons that the most successful systems are pipeline architectures that cobble together a diverse array of techniques and resources, including statistical language models, dependency parsers, string edit distances, off-the-shelf spellcheckers, and curated slang dictionaries (Liu et al., 2011; Han and Baldwin, 2011; Han et al., 2013).

We propose a different approach, performing normalization in a maximum-likelihood framework. There are two main sources of information to be exploited: local context, and surface similarity between the observed strings and normalization candidates. We treat the local context using standard language modeling techniques; we treat string similarity with a log-linear model that includes features for both surface similarity and word-word pairs.

Because labeled examples of normalized text are not available, this model cannot be trained in the standard supervised fashion. Nor can we apply dynamic programming techniques for unsupervised training of locally-normalized conditional models (Berg-Kirkpatrick et al., 2010), as their complexity is quadratic in the size of label space; in normalization, the label space is the vocabulary itself, with at least 10^4 elements. Instead, we present a new training approach using Monte Carlo techniques to compute an approximate gradient on the feature weights. This training method may be applicable in other unsupervised learning problems with a large label space.

This model is implemented in a normalization system called UNLOL (**u**nsupervised **n**ormalization in a **LO**g-**L**inear model). It is a lightweight proba-

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 61–72,
Seattle, Washington, USA, 18-21 October 2013.

bilistic approach, relying only on a language model for the target domain; it can be adapted to new corpora text or new domains easily and quickly. Our evaluations show that UNLOL outperforms the state-of-the-art on standard normalization datasets. In addition, we demonstrate the linguistic insights that can be obtained from normalization, using UNLOL to identify classes of orthographic transformations that form coherent linguistic styles.

2 Background

The text normalization task was introduced by Sproat et al. (2001), and attained popularity in the context of SMS messages (Choudhury et al., 2007b). It has become still more salient in the era of widespread social media, particularly Twitter. Han and Baldwin (2011) formally define a normalization task for Twitter, focusing on normalizations between single tokens, and excluding multi-word tokens like `lol` (*laugh out loud*). The normalization task has been criticized by Eisenstein (2013b), who argues that it strips away important social meanings. In recent work, normalization has been shown to yield improvements for part-of-speech tagging (Han et al., 2013), parsing (Zhang et al., 2013), and machine translation (Hassan and Menezes, 2013). As we will show in Section 7, accurate automated normalization can also improve our understanding of the nature of social media language.

Supervised methods Early work on normalization focused on labeled SMS datasets, using approaches such as noisy-channel modeling (Choudhury et al., 2007a) and machine translation (Aw et al., 2006), as well as hybrid combinations of spelling correction and speech recognition (Kobus et al., 2008; Beaufort et al., 2010). This work sought to balance language models (favoring words that fit in context) with transformation models (favoring words that are similar to the observed text). Our approach can also be seen as a noisy channel model, but unlike this prior work, no labeled data is required.

Unsupervised methods Cook and Stevenson (2009) manually identify several word formation types within a noisy channel framework. They parametrize each formation type with a small number of scalar values, so that all legal transformations of a given type are equally likely. The scalar parameters are then estimated using expectation maximization. This work stands apart from most of the other unsupervised models, which are pipelines.

Contractor et al. (2010) use string edit distance to identify closely-related candidate orthographic forms and then decode the message using a language model. Gouws et al. (2011) refine this approach by mining an "exception dictionary" of strongly-associated word pairs such as *you*/`u`. Like Contractor et al. (2010), we apply string edit distance, and like Gouws et al. (2011), we capture strongly related word pairs. However, rather than applying these properties as filtering steps in a pipeline, we add them as features in a unified log-linear model.

Recent approaches have sought to improve accuracy by bringing more external resources and complex architectures to bear. Han and Baldwin (2011) begin with a set of string similarity metrics, and then apply dependency parsing to identify contextually-similar words. Liu et al. (2011) extract noisy training pairs from the search snippets that result from carefully designed queries to Google, and then train a conditional random field (Lafferty et al., 2001) to estimate a character-based translation model. They later extend this work by adding a model of visual priming, an off-the-shelf spell-checker, and local context (Liu et al., 2012a). Hassan and Menezes (2013) use a random walk framework to capture contextual similarity, which they then interpolate with an edit distance metric. Rather than seeking additional external resources or designing more complex metrics of context and similarity, we propose a unified statistical model, which learns feature weights in a maximum-likelihood framework.

3 Approach

Our approach is motivated by the following criteria:

- **Unsupervised**. We want to be able to train a model without labeled data. At present, labeled data for Twitter normalization is available only in small quantities. Moreover, as social media language is undergoing rapid change (Eisenstein, 2013b), labeled datasets may become stale and increasingly ill-suited to new spellings and words.

- **Low-resource**. Other unsupervised approaches take advantage of resources such as slang dictionaries and spell checkers (Han and Baldwin, 2011; Liu et al., 2011). Resources that characterize the current state of internet language risk becoming outdated; in this paper we investigate whether high-quality normalization is possible without any such resources.

- **Featurized**. The relationship between any pair of words can be characterized in a number of different ways, ranging from simple character-level rules (e.g., *going*/`goin`) to larger substitutions (e.g., *someone*/`sum1`), and even to patterns that are lexically restricted (e.g., *you*/`u`, *to*/`2`). For these reasons, we seek a model that permits many overlapping features to describe candidate word pairs. These features may include simple string edit distance metrics, as well as lexical features that memorize specific pairs of standard and nonstandard words.

- **Context-driven**. Learning potentially arbitrary word-to-word transformations without supervision would be impossible without the strong additional cue of local context. For example, in the phrase

  `give me suttin to believe in`,

  even a reader who has never before seen the word `suttin` may recognize it as a phonetic transcription of *something*. The relatively high string edit distance is overcome by the strong contextual preference for the word *something* over orthographically closer alternatives such as *button* or *suiting*. We can apply an arbitrary target language model, leveraging large amounts of unlabeled data and catering to the desired linguistic characteristics of the normalized content.

- **Holistic**. While several prior approaches — such as normalization dictionaries — operate at the token level, our approach reasons over the scope of the entire message. The necessity for such holistic, joint inference and learning can be seen by changing the example above to:

  `gimme suttin 2 beleive innnn`.

  None of these tokens are standard (except `2`, which appears in a nonstandard sense here), so without joint inference, it would not be possible to use context to help normalize `suttin`. Only by jointly reasoning over the entire message can we obtain the correct normalization.

These desiderata point towards a featurized sequence model, which must be trained without labeled examples. While there is prior work on training sequence models without supervision (Smith and Eisner, 2005; Berg-Kirkpatrick et al., 2010), there is an additional complication not faced by models for tasks such as part-of-speech tagging and named entity recognition: the potential label space of standard words is large, on the order of at least 10^4. Naive application of Viterbi decoding — which is a component of training for both Contrastive Estimation (Smith and Eisner, 2005) and the locally-normalized sequence labeling model of Berg-Kirkpatrick et al. (2010) — will be stymied by Viterbi's quadratic complexity in the dimension of the label space. While various pruning heuristics may be applied, we instead look to Sequential Monte Carlo (SMC), a randomized algorithm which approximates the necessary feature expectations through weighted samples.

4 Model

Given a set of source-language sentences $S = \{\mathbf{s}_1, \mathbf{s}_2, \ldots\}$ (e.g., Tweets), our goal is to transduce them into target-language sentences $T = \{\mathbf{t}_1, \mathbf{t}_2, \ldots\}$ (standard English). We are given a target language model $P(\mathbf{t})$, which can be estimated from some large set of unlabeled target-language sentences. We denote the vocabularies of source language and target language as ν_S and ν_T respectively.

We define a log-linear model that scores source and target strings, with the form

$$P(\mathbf{s}|\mathbf{t};\theta) \propto \exp\left(\theta^{\mathsf{T}}\mathbf{f}(\mathbf{s},\mathbf{t})\right). \quad (1)$$

The desired conditional probability $P(\mathbf{t}|\mathbf{s})$ can be obtained by combining this model with the target language model, $P(\mathbf{t}|\mathbf{s}) \propto P(\mathbf{s}|\mathbf{t};\theta)P(\mathbf{t})$. Since no labeled data is available, the parameters θ must be estimated by maximizing the log-likelihood of the source-language data. We define the log-likelihood

$\ell_\theta(\mathbf{s})$ for a source-language sentence $\mathbf{s}$ as follows:

$$\ell_\theta(\mathbf{s}) = \log P(\mathbf{s}) = \log \sum_{\mathbf{t}} P(\mathbf{s}|\mathbf{t};\theta)P(\mathbf{t})$$

We would like to maximize this objective by making gradient-based updates.

$$\begin{aligned}\frac{\partial \ell_\theta(\mathbf{s})}{\partial \theta} &= \frac{1}{P(\mathbf{s})}\sum_{\mathbf{t}} P(\mathbf{t})\frac{\partial}{\partial\theta}P(\mathbf{s}|\mathbf{t};\theta) \\ &= \sum_{\mathbf{t}} P(\mathbf{t}|\mathbf{s})\left(\mathbf{f}(\mathbf{s},\mathbf{t}) - \sum_{\mathbf{s}'} P(\mathbf{s}'|\mathbf{t})\mathbf{f}(\mathbf{s}',\mathbf{t})\right) \\ &= E_{\mathbf{t}|\mathbf{s}}[\mathbf{f}(\mathbf{s},\mathbf{t}) - E_{\mathbf{s}'|\mathbf{t}}[\mathbf{f}(\mathbf{s}',\mathbf{t})]]\end{aligned} \tag{2}$$

We are left with a difference in expected feature counts, as is typical in log-linear models. However, unlike the supervised case, here *both* terms are expectations: the outer expectation is over all target sequences (given the observed source sequence), and the nested expectation is over all source sequences, given the target sequence. As the space of possible target sequences $\mathbf{t}$ grows exponentially in the length of the source sequence, it will not be practical to compute this expectation directly.

Dynamic programming is the typical solution for computing feature expectations, and can be applied to sequence models when the feature function decomposes locally. There are two reasons this will not work in our case. First, while the forward-backward algorithm would enable us to compute $E_{\mathbf{t}|\mathbf{s}}$, it would not give us the nested expectation $E_{\mathbf{t}|\mathbf{s}}[E_{\mathbf{s}'|\mathbf{t}}]$; this is the classic challenge in training globally-normalized log-linear models without labeled data (Smith and Eisner, 2005). Second, both forward-backward and the Viterbi algorithm have time complexity that is quadratic in the dimension of the label space, at least 10^4 or 10^5. As we will show, Sequential Monte Carlo (SMC) algorithms have a number of advantages in this setting: they permit the efficient computation of both the outer and inner expectations, they are trivially parallelizable, and the number of samples provides an intuitive tuning tradeoff between accuracy and speed.

4.1 Sequential Monte Carlo approximation

Sequential Monte Carlo algorithms are a class of sampling-based algorithms in which latent variables are sampled sequentially (Cappe et al., 2007). They are particularly well-suited to sequence models, though they can be applied more broadly. SMC algorithms maintain a set of weighted hypotheses; the weights correspond to probabilities, and in our case, the hypotheses correspond to target language word sequences. Specifically, we approximate the conditional probability,

$$P(\mathbf{t}_{1:n}|\mathbf{s}_{1:n}) \approx \sum_{k=1}^{K} \omega_n^k \delta_{\mathbf{t}_{1:n}^k}(\mathbf{t}_{1:n}),$$

where ω_n^k is the normalized weight of sample k at word n ($\tilde{\omega}_n^k$ is the unnormalized weight), and $\delta_{\mathbf{t}_{1:n}^k}$ is a delta function centered at $\mathbf{t}_{1:n}^k$.

At each step, and for each hypothesis k, a new target word is sampled from a *proposal distribution*, and the weight of the hypothesis is then updated. We maintain feature counts for each hypothesis, and approximate the expectation by taking a weighted average using the hypothesis weights. The proposal distribution will be described in detail later.

We make a Markov assumption, so that the emission probability $P(\mathbf{s}|\mathbf{t})$ decomposes across the elements of the sentence $P(\mathbf{s}|\mathbf{t}) = \prod_n^N P(s_n|t_n)$. This means that the feature functions $\mathbf{f}(\mathbf{s},\mathbf{t})$ must decompose on each $\langle s_n, t_n\rangle$ pair. We can then rewrite (1) as

$$P(\mathbf{s}|\mathbf{t};\theta) = \prod_n^N \frac{\exp\left(\theta^\mathsf{T}\mathbf{f}(s_n,t_n)\right)}{Z(t_n)} \tag{3}$$

$$Z(t_n) = \sum_s \exp\left(\theta^\mathsf{T}\mathbf{f}(s,t_n)\right). \tag{4}$$

In addition, we assume that the target language model $P(\mathbf{t})$ can be written as an N-gram language model, $P(\mathbf{t}) = \prod_n P(t_n|t_{n-1},\ldots t_{n-k+1})$. With these assumptions, we can view normalization as a finite state-space model in which the target language model defines the prior distribution of the process and Equation 3 defines the likelihood function. We are able to compute the the posterior probability $P(\mathbf{t}|\mathbf{s})$ using *sequential importance sampling*, a member of the SMC family.

The crucial idea in sequential importance sampling is to update the hypotheses $\mathbf{t}_{1:n}^k$ and their weights ω_n^k so that they approximate the posterior distribution at the next time step, $P(\mathbf{t}_{1:n+1}|\mathbf{s}_{1:n+1})$.

Assuming the proposal distribution has the form $Q(\mathbf{t}^k_{1:n}|\mathbf{s}_{1:n})$, the importance weights are given by

$$\omega^k_n \propto \frac{P(\mathbf{t}^k_{1:n}|\mathbf{s}_{1:n})}{Q(\mathbf{t}^k_{1:n}|\mathbf{s}_{1:n})} \tag{5}$$

In order to update the hypotheses recursively, we rewrite $P(\mathbf{t}_{1:n}|\mathbf{s}_{1:n})$ as:

$$\begin{aligned}P(\mathbf{t}_{1:n}|\mathbf{s}_{1:n}) &= \frac{P(s_n|\mathbf{t}_{1:n},\mathbf{s}_{1:n-1})P(\mathbf{t}_{1:n}|\mathbf{s}_{1:n-1})}{P(s_n|\mathbf{s}_{1:n-1})}\\ &= \frac{P(s_n|t_n)P(t_n|\mathbf{t}_{1:n-1},\mathbf{s}_{1:n-1})P(\mathbf{t}_{1:n-1}|\mathbf{s}_{1:n-1})}{P(s_n|\mathbf{s}_{1:n-1})}\\ &\propto P(s_n|t_n)P(t_n|t_{n-1})P(\mathbf{t}_{1:n-1}|\mathbf{s}_{1:n-1}),\end{aligned}$$

assuming a bigram language model. We further assume the proposal distribution Q can be factored as:

$$\begin{aligned}Q(\mathbf{t}_{1:n}|\mathbf{s}_{1:n}) &= Q(t_n|\mathbf{t}_{1:n-1},\mathbf{s}_{1:n})Q(\mathbf{t}_{1:n-1}|\mathbf{s}_{1:n-1})\\ &= Q(t_n|t_{n-1},s_n)Q(\mathbf{t}_{1:n-1}|\mathbf{s}_{1:n-1}).\end{aligned} \tag{6}$$

Then the unnormalized importance weights simplify to a recurrence:

$$\tilde{\omega}^k_n = \frac{P(s_n|t^k_n)P(t^k_n|t^k_{n-1})P(\mathbf{t}^k_{1:n-1}|\mathbf{s}_{1:n-1})}{Q(t_n|t_{n-1},s_n)Q(\mathbf{t}^k_{1:n-1}|\mathbf{s}_{1:n-1})} \tag{7}$$

$$= \omega^k_{n-1}\frac{P(s_n|t^k_n)P(t^k_n|t^k_{n-1})}{Q(t_n|t_{n-1},s_n)} \tag{8}$$

Therefore, we can approximate the posterior distribution $P(t_n|\mathbf{s}_{1:n}) \approx \sum_{k=1}^K \omega^k_n \delta_{t^k_n}(t_n)$, and compute the outer expectation as follows:

$$E_{\mathbf{t}|\mathbf{s}}[\mathbf{f}(\mathbf{s},\mathbf{t})] = \sum_{k=1}^K \omega^k_N \sum_{n=1}^N \mathbf{f}(s_n, t^k_n) \tag{9}$$

We compute the nested expectation using a non-sequential Monte Carlo approximation, assuming we can draw $s^{\ell,k} \sim P(s|t^k_n)$.

$$E_{\mathbf{s}|\mathbf{t}^k}[\mathbf{f}(\mathbf{s},\mathbf{t}^k)] = \frac{1}{L}\sum_{n=1}^N \sum_{\ell=1}^L \mathbf{f}(s^{\ell,k}_n, t^k_n)$$

This gives the overall gradient computation:

$$\begin{aligned}E_{\mathbf{t}|\mathbf{s}}[\mathbf{f}(\mathbf{s},\mathbf{t}) - E_{\mathbf{s}'|\mathbf{t}}[\mathbf{f}(\mathbf{s}',\mathbf{t})]] &= \frac{1}{\sum_{k=1}^K \tilde{\omega}^k_N}\sum_{k=1}^K \tilde{\omega}^k_N\\ &\times \sum_{n=1}^N \left(\mathbf{f}(s_n,t^k_n) - \frac{1}{L}\sum_{\ell=1}^L \mathbf{f}(s^{\ell,k}_n, t^k_n)\right)\end{aligned} \tag{10}$$

where we sample t^k_n and update ω^k_n while moving from left-to-right, and sample $s^{\ell,k}_n$ at each n. Note that although the sequential importance sampler moves left-to-right like a filter, we use only the final weights ω_N to compute the expectation. Thus, the resulting expectation is based on the distribution $P(\mathbf{s}_{1:N}|\mathbf{t}_{1:N})$, so that no backwards "smoothing" pass (Godsill et al., 2004) is needed to eliminate bias. Other applications of sequential Monte Carlo make use of resampling (Cappe et al., 2007) to avoid degeneration of the hypothesis weights, but we found this to be unnecessary due to the short length of Twitter messages.

4.2 Proposal distribution

The major computational challenge for dynamic programming approaches to normalization is the large label space, equal to the size of the target vocabulary. It may appear that all we have gained by applying sequential Monte Carlo is to convert a computational problem into a statistical one: a naive sampling approach will have little hope of finding the small high-probability region of the high-dimensional label space. However, sequential importance sampling allows us to address this issue through the proposal distribution, from which we sample the candidate words t_n. Careful design of the proposal distribution can guide sampling towards the high-probability space. In the asymptotic limit of an infinite number of samples, any non-pathological proposal distribution will ultimately arrive at the desired estimate, but a good proposal distribution can greatly reduce the number of samples needed.

Doucet et al. (2001) note that the optimal proposal — which minimizes the variance of the importance weights conditional on $\mathbf{t}_{1:n-1}$ and $\mathbf{s}_{1:n}$ — has the following form:

$$Q(t^k_n|s_n,t^k_{n-1}) = \frac{P(s_n|t^k_n)P(t^k_n|t^k_{n-1})}{\sum_{t'}P(s_n|t')P(t'|t^k_{n-1})} \tag{11}$$

Sampling from this proposal requires computing the normalized distribution $P(s_n|t_n^k)$; similarly, the update of the hypothesis weights (Equation 8) requires the calculation of Q in its normalized form. In each case, the total cost is the product of the vocabulary sizes, $\mathcal{O}(\#|\nu_T|\#|\nu_S|)$, which is not tractable as the vocabularies become large.

In low-dimensional settings, a convenient solution is to set the proposal distribution equal to the transition distribution, $Q(t_n^k|s_n, t_{n-1}^k) = P(t_n^k|t_{n-1}^k, \ldots, t_{n-k+1}^k)$. This choice is called the "bootstrap filter," and it has the advantage that the weights $\omega^{(k)}$ are exactly identical to the product of emission likelihoods $\prod_n P(s_n|t_n^k)$. The complexity of computing the hypothesis weights is thus $\mathcal{O}(\#|\nu_S|)$. However, because this proposal ignores the emission likelihood, the bootstrap filter has very little hope of finding a high-probability sample in high-entropy contexts.

We strike a middle ground between efficiency and accuracy, using a proposal distribution that is closely related to the overall likelihood, yet is tractable to sample and compute:

$$\begin{aligned} Q(t_n^k|s_n, t_{n-1}^k) &\stackrel{def}{=} \\ &\frac{P(s_n|t_n^k)Z(t_n^k)P(t_n^k|t_{n-1}^k)}{\sum_{t'} P(s_n|t')Z(t')P(t'|t_{n-1}^k)} \\ =&\frac{\exp\left(\theta^\mathsf{T}\mathbf{f}(s_n, t_n)\right) P(t_n^k|t_{n-1}^k)}{\sum_{t'} \exp\left(\theta^\mathsf{T}\mathbf{f}(s_n, t')\right) P(t'|t_{n-1}^k)} \end{aligned} \quad (12)$$

Here, we simply replace the likelihood distribution in (11) by its unnormalized version.

To update the unnormalized hypothesis weights $\tilde{\omega}_n^k$, we have

$$\tilde{\omega}_n^k = \omega_{n-1}^k \frac{\sum_{t'} \exp\left(\theta^\mathsf{T}\mathbf{f}(s_n, t')\right) P(t'|t_{n-1}^k)}{Z(t_n^k)} \quad (13)$$

The numerator requires summing over all elements in ν_T and the denominator $Z(t_n^k)$ requires summing over all elements in ν_S, for a total cost of $\mathcal{O}(\#|\nu_T| + \#|\nu_S|)$.

4.3 Decoding

Given an input source sentence $\mathbf{s}$, the decoding problem is to find a target sentence $\mathbf{t}$ that maximizes $P(\mathbf{t}|\mathbf{s}) \propto P(\mathbf{s}|\mathbf{t})P(\mathbf{t}) = \prod_n^N P(s_n|t_n)P(t_n|t_{n-1})$.

Feature name	Description
word-word pair	A set of binary features for each source/target word pair $\langle s, t\rangle$
string similarity	A set of binary features indicating whether s is one of the top N string similar non-standard words of t, for $N \in \{5, 10, 25, 50, 100, 250, 500, 1000\}$

Table 1: The feature set for our log-linear model

As with learning, we cannot apply the usual dynamic programming algorithm (Viterbi), because of its quadratic cost in the size of the target language vocabulary. This must be multiplied by the cost of computing the normalized probability $P(s_n|t_n)$, resulting in a prohibitive time complexity of $\mathcal{O}(\#|\nu_S|\#|\nu_T|^2 N)$.

We consider two approximate decoding algorithms. The first is to simply apply the proposal distribution, with linear complexity in the size of the two vocabularies. However, this decoder is not identical to $P(\mathbf{t}|\mathbf{s})$, because of the extra factor of $Z(t)$ in the numerator. Alternatively, we can apply the proposal distribution for selecting target word candidates, then apply the Viterbi algorithm only within these candidates. The total cost is $\mathcal{O}(\#|\nu_S|T^2 N)$, where T is the number of target word candidates we consider; this will asymptotically approach $P(\mathbf{t}|\mathbf{s})$ as $T \to \#|\nu_T|$. Our evaluations use the more expensive proposal+Viterbi decoding, but accuracy with the more efficient proposal-based decoding is very similar.

4.4 Features

Our system uses the feature types described in Table 1. The word pair features are designed to capture lexical conventions, e.g. *you*/u. We only consider word pair features that fired during training. The string similarity features rely on the similarity function proposed by Contractor et al. (2010), which has proven effective for normalization in prior work. We bin this similarity to create binary features indicating whether a string s is in the top-N most similar strings to t; this binning yields substantial speed improvements without negatively impacting accuracy.

5 Implementation and data

The model and inference described in the previous section are implemented in a software system for normalizing text on twitter, called UNLOL: **u**nsupervised **n**ormalization in a **LO**g-**L**inear model. The final system can process roughly 10,000 Tweets per hour. We now describe some implementation details.

5.1 Normalization candidates

Most tokens in tweets do not require normalization. The question of how to identify which words are to be normalized is still an open problem. Following Han and Baldwin (2011), we build a dictionary of words which are permissible in the target domain, and make no attempt to normalize source strings that match these words. As with other comparable approaches, we are therefore unable to normalize strings like `ill` into *I'll*. Our set of "in-vocabulary" (IV) words is based on the GNU aspell dictionary (v0.60.6), containing 97,070 words. From this dictionary, we follow Liu et al. (2012a) and remove all the words with a count of less than 20 in the Edinburgh Twitter corpus (Petrović et al., 2010) — resulting in a total of 52,449 target words. All single characters except `a` and `i` are excluded, and `rt` is treated as in-vocabulary. For all in-vocabulary words, we define $P(s_n|t_n) = \delta(s_n, t_n)$, taking the value of zero when $s_n \neq t_n$. This effectively prevents our model from attempting to normalize these words.

In addition to words that are in the target vocabulary, there are many other strings that should not be normalized, such as names and multiword shortenings (e.g. *going to*/`gonna`).[1] We follow prior work and assume that the set of normalization candidates is known in advance during test set decoding (Han et al., 2013). However, the unlabeled training data has no such information. Thus, during training we attempt to normalize all tokens that (1) are not in our lexicon of IV words, and (2) are composed of letters, numbers and the apostrophe. This set includes contractions like "gonna" and "gotta", which would not appear in the test set, but are nonetheless normalized during training. For each OOV token, we conduct a pre-normalization step by reducing any repetitions of more than two letters in the nonstandard words to exactly two letters (e.g., `cooool` → `cool`).

[1] Whether multiword shortenings should be normalized is arguable, but they are outside the scope of current normalization datasets (Han and Baldwin, 2011).

5.2 Language modeling

The Kneser-Ney smoothed trigram target language model is estimated with the SRILM toolkit Stolcke (2002), using Tweets from the Edinburgh Twitter corpus that contain no OOV words besides hashtags and username mentions (following (Han et al., 2013)). We use this language model for both training and decoding. We occasionally find training contexts in which the trigram $\langle t_n, t_{n-1}, t_{n-2} \rangle$ is unobserved in the language model data; features resulting from such trigrams are not considered when computing the weight gradients.

5.3 Parameters

The Monte Carlo approximations require two parameters: the number of samples for sequential Monte Carlo (K), and the number of samples for the non-sequential sampler of the nested expectation (L, from Equation 10). The theory of Monte Carlo approximation states that the quality of the approximation should only improve as the number of samples increases; we obtained good results with $K = 10$ and $L = 1$, and found relatively little improvement by increasing these values. The number of hypotheses considered by the decoder is set to $T = 10$; again, the performance should only improve with T, as we more closely approximate full Viterbi decoding.

6 Experiments

Datasets We use two existing labeled Twitter datasets to evaluate our approach. The first dataset — which we call LWWL11, based on the names of its authors Liu et al. (2011) — contains 3,802 individual "nonstandard" words (i.e., words that are not in the target vocabulary) and their normalized forms. The rest of the message in which the words is appear is not available. As this corpus does not provide linguistic context, its decoding must use a unigram target language model. The second dataset — which is called LexNorm1.1 by its authors Han and Baldwin (2011) — contains 549 complete tweets with 1,184 nonstandard tokens (558 unique word types).

Method	Dataset	Precision	Recall	F-measure
(Liu et al. 2011)	LMML11	68.88	68.88	68.88
(Liu et al. 2012)		69.81	69.81	69.81
UNLOL		**73.04**	**73.04**	**73.04**
(Han and Baldwin, 2011)	LexNorm 1.1	75.30	75.30	75.30
(Liu et al. 2012)		84.13	78.38	81.15
(Hassan et al. 2013)		**85.37**	56.4	69.93
UNLOL		82.09	**82.09**	**82.09**
UNLOL	LexNorm 1.2	82.06	82.06	82.06

Table 2: Empirical results

In this corpus, we can decode with a trigram language model.

Close analysis of LexNorm1.1 revealed some inconsistencies in annotation (for example, `y'all` and `2` are sometimes normalized to *you* and *to*, but are left unnormalized in other cases). In addition, several annotations disagree with existing resources on internet language and dialectal English. For example, `smh` is normalized to *somehow* in LexNorm1.1, but `internetslang.com` and `urbandictionary.com` assert that it stands for *shake my head*, and this is evident from examples such as `smh at this girl`. Similarly, `finna` is normalized to *finally* in LexNorm1.1, but from the literature on African American English (Green, 2002), it corresponds to *fixing to* (e.g., `i'm finna go home`). To address these issues, we have produced a new version of this dataset, which we call LexNorm1.2 (after consulting with the creators of LexNorm1.1). LexNorm1.2 differs from version 1.1 in the annotations for 172 of the 2140 OOV words. We evaluate on LexNorm1.1 to compare with prior work, but we also present results on LexNorm1.2 in the hope that it will become standard in future work on normalization in English. The dataset is available at `http://www.cc.gatech.edu/~jeisenst/lexnorm.v1.2.tgz`.

To obtain unlabeled training data, we randomly sample 50 tweets from the Edinburgh Twitter corpus Petrović et al. (2010) for each OOV word. Some OOV words appear less than 50 times in the corpus, so we obtained more training tweets for them through the Twitter search API.

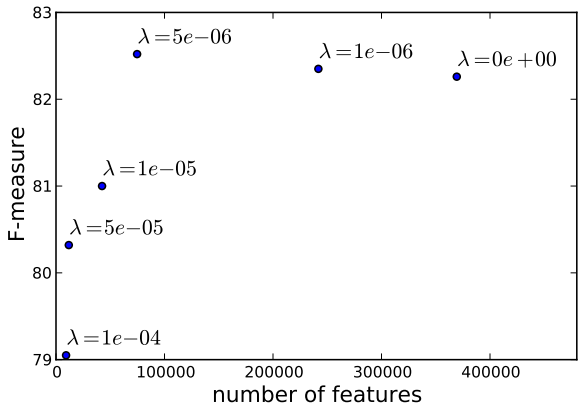
Metrics Prior work on these datasets has assumed perfect detection of words requiring normalization, and has focused on finding the correct normalization for these words (Han and Baldwin, 2011; Han et al., 2013). Recall has been defined as the proportion of words requiring normalization which are normalized correctly; precision is defined as the proportion of normalizations which are correct.

Results We run our training algorithm for two iterations (pass the training data twice). The results are presented in Table 2. Our system, UNLOL, achieves the highest published F-measure on both datasets. Performance on LexNorm1.2 is very similar to LexNorm1.1, despite the fact that roughly 8% of the examples were relabeled.

In the normalization task that we consider, the tokens to be normalized are specified in advance. This is the same task specification as in the prior work against which we compare. At test time, our system attempts normalizes all such tokens; every error is thus both a false positive and false negative, so precision equals to recall for this task; this is also true for Han and Baldwin (2011) and Liu et al. (2011).

It is possible to trade recall for precision by refusing to normalize words when the system's confidence falls below a threshold. A good setting of this threshold can improve the F-measure, but we did not report these results because we have no development set for parameter tuning.

Regularization One potential concern is that the number of non-zero feature weights will continually increase until the memory cost becomes overwhelming. Although we did not run up against mem-



λ	Dataset	F-measure	# of features
10^{-4}	LexNorm 1.1	79.05	9,281
5×10^{-5}		80.32	11,794
10^{-5}		81.00	42,466
5×10^{-6}		**82.52**	74,744
10^{-6}		82.35	241,820
0		82.26	369,366
5×10^{-6}	LexNorm 1.2	82.23	74,607

Figure 1: Effect of L1 regularization on the F-measure and the number of features with non-zero weights

ory limitations in the experiments producing the results in Table 2, this issue can be addressed through the application of L1 regularization, which produces sparse weight vectors by adding a penalty of $\lambda||\theta||_1$ to the log-likelihood. We perform online optimization of the L1-regularized log-likelihood by applying the truncated gradient method (Langford et al., 2009). We use an exponential decreasing learning rate $\eta_k = \eta_0 \alpha^{k/N}$, where k is the iteration counter and N is the size of training data. We set $\eta_0 = 1$ and $\alpha = 0.5$. Experiments were run until 300,000 training instances were observed, with a final learning rate of less than $1/32$. As shown in Figure 1, a small amount of regularization can dramatically decrease the number of active features without harming performance.

7 Analysis

We apply our normalization system to investigate the orthographic processes underlying language variation in social media. Using a dataset of 400,000 English language tweets, sampled from the month of August in each year from 2009 to 2012, we apply UNLOL to automatically normalize each token. We then treat these normalizations as labeled training data, and examine the Levenshtein alignment between the source and target tokens. This alignment gives approximate character-level transduction rules to explain each OOV token. We then examine which rules are used by each author, constructing a matrix of authors and rules.[2]

Factorization of the author-rule matrix reveals sets of rules that tend to be used together; we might call these rulesets "orthographic styles." We apply non-negative matrix factorization (Lee and Seung, 2001), which characterizes each author by a vector of k style loadings, and simultaneously constructs k style dictionaries, which each put weight on different orthographic rules. Because the loadings are constrained to be non-negative, the factorization can be seen as sparsely assigning varying amounts of each style to each author. We choose the factorization that minimizes the Frobenius norm of the reconstruction error, using the NIMFA software package (`http://nimfa.biolab.si/`).

The resulting styles are shown in Table 3, for $k = 10$; other values of k give similar overall results with more or less detail. The styles incorporate a number of linguistic phenomena, including: expressive lengthening (styles 7-9; see Brody and Diakopoulos, 2011); g- and t-dropping (style 5, see Eisenstein 2013a) ; th-stopping (style 6); and the dropping of several word-final vowels (styles 1-3). Some of these styles, such as t-dropping and th-stopping, have direct analogues in spoken language varieties (Tagliamonte and Temple, 2005; Green, 2002), while others, like expressive lengthening, seem more unique to social media. The relationships between these orthographic styles and social variables such as geography and demograph-

[2]We tried adding these rules as features and retraining the normalization system, but this hurt performance.

style	rules	examples
1. you; o-dropping	*y*/_ *ou*/_u **y*/⋆_ *o*/_	u, yu, 2day, knw, gud, yur, wud, yuh, u've, toda, everthing, everwhere, ourself
2. e-dropping, u/o	*be*/b_ *e*/_ *o*/u *e**/_⋆	b, r, luv, cum, hav, mayb, bn, remembr, btween, gunna, gud
3. a-dropping	*a*/_ **a*/⋆_ *re*/r_ *ar*/_r	r, tht, wht, yrs, bck, strt, gurantee, elementry, wr, rlly, wher, rdy, preciate, neway
4. g-dropping	*g**/_⋆ *ng*/n_ *g*/_	goin, talkin, watchin, feelin, makin

10. a-adding	_/a __/ma _/m _*/a⋆	ima, outta, needa, shoulda, woulda, mm, comming, tomm, boutt, ppreciate

Table 3: Orthographic styles induced from automatically normalized Twitter text

ics must be left to future research, but they offer a promising generalization of prior work that has focused almost exclusively on exclusively on lexical variation (Argamon et al., 2007; Eisenstein et al., 2010; Eisenstein et al., 2011), with a few exceptions for character-level features (Brody and Diakopoulos, 2011; Burger et al., 2011).

Note that style 10 is largely the result of mistaken normalizations. The tokens ima, outta, and needa all refer to multi-word expressions in standard English, and are thus outside the scope of the normalization task as defined by Han et al. (2013). UNLOL has produced incorrect single-token normalizations for these terms: *i*/ima, *out*/outta, and *need*/needa. But while these normalizations are wrong, the resulting style nonetheless captures a coherent orthographic phenomenon.

8 Conclusion

We have presented a unified, unsupervised statistical model for normalizing social media text, attaining the best reported performance on the two standard normalization datasets. The power of our approach comes from flexible modeling of word-to-word relationships through features, while exploiting contextual regularity to train the corresponding feature weights without labeled data. The primary technical challenge was overcoming the large label space of the normalization task; we accomplish this using sequential Monte Carlo. Future work may consider whether sequential Monte Carlo can offer similar advantages in other unsupervised NLP tasks. An additional benefit of our joint statistical approach is that it may be combined with other downstream language processing tasks, such as part-of-speech tagging (Gimpel et al., 2011) and named entity resolution (Liu et al., 2012b).

Acknowledgments

We thank the reviewers for thoughtful comments on our submission. This work also benefitted from discussions with Timothy Baldwin, Paul Cook, Frank Dellaert, Arnoud Doucet, Micha Elsner, and Sharon Goldwater. It was supported by NSF SOCS-1111142.

Abstract

Compared to the edited genres that have played a central role in NLP research, microblog texts use a more informal register with nonstandard lexical items, abbreviations, and free orthographic variation. When confronted with such input, conventional text analysis tools often perform poorly. Normalization — replacing orthographically or lexically idiosyncratic forms with more standard variants — can improve performance. We propose a method for learning normalization rules from machine translations of a parallel corpus of microblog messages. To validate the utility of our approach, we evaluate extrinsically, showing that normalizing English tweets and then translating improves translation quality (compared to translating unnormalized text) using three standard web translation services as well as a phrase-based translation system trained on parallel microblog data.

1 Introduction

Microblogs such as Twitter, Sina Weibo (a popular Chinese microblog service) and Facebook have received increasing attention in diverse research communities (Han and Baldwin, 2011; Hawn, 2009, *inter alia*). In contrast to traditional text domains that use carefully controlled, standardized language, microblog content is often informal, with less adherence to conventions regarding punctuation, spelling, and style, and with a higher proportion of dialect or pronouciation-derived orthography. While this diversity itself is an important resource for studying, e.g., sociolinguistic variation (Eisenstein et al., 2011; Eisenstein, 2013), it poses challenges to NLP applications developed for more formal domains. If retaining variation due to sociolinguistic or phonological factors is not crucial, **text normalization** can improve performance on downstream tasks (§2).

This paper introduces a data-driven approach to learning normalization rules by conceiving of normalization as a kind of paraphrasing and taking inspiration from the bilingual pivot approach to paraphrase detection (Bannard and Callison-Burch, 2005) and the observation that translation is an inherently "simplifying" process (Laviosa, 1998; Volansky et al., 2013). Starting from a parallel corpus of microblog messages consisting of English paired with several other languages (Ling et al., 2013), we use standard web machine translation systems to *re-translate* the non-English segment, producing $\langle$English original, English MT$\rangle$ pairs (§3). These are our normalization examples, with MT output playing the role of normalized English. Several techniques for identifying high-precision normalization rules are proposed, and we introduce a character-based normalization model to account for predictable character-level processes, like repetition and substitution (§4). We then describe our decoding procedure (§5) and show that our normalization model improve translation quality for English–Chinese microblog translation (§6).[1]

2 Why Normalize?

Consider the English tweet shown in the first row of Table 1 which contains several elements that NLP

Table 1: Translations of an English microblog message into Mandarin, using three web translation services.

orig.	*To DanielVeuleman yea iknw imma work on that*
MT[1]	啊iknw DanielVeuleman伊马工作，
MT[2]	DanielVeuleman 是iknw 凋谢关于工作，
MT[3]	到DanielVeuleman是的iknw imma这方面的工作

Table 2: Translations of Chinese original post to English using web-based service.

orig.	To DanielVeuleman yea iknw imma work on that
orig.	对DanielVeuleman说，是的，我知道，我正在向那方面努力
MT[1]	Right DanielVeuleman say, yes, I know, I'm Xiangna efforts
MT[2]	DanielVeuleman said, Yes, I know, I'm that hard
MT[3]	Said to DanielVeuleman, yes, I know, I'm to that effort

systems trained on edited domains may not handle well. First, it contains several nonstandard abbreviations, such as, *yea*, *iknw* and *imma* (abbreviations of *yes*, *I know* and *I am going to*). Second, there is no punctuation in the text although standard convention would dictate that it should be used. To illustrate the effect this can have, consider now the translations produced by Google Translate,[2] Microsoft Bing,[3] and Youdao,[4] shown in rows 2–4. Even with no knowledge of Chinese, it is not hard to see that all engines have produced poor translations: the abbreviation *iknw* is left translated by all engines, and *imma* is variously deleted, left untranslated, or transliterated into the meaningless sequence 伊马 (pronounced *yī mǎ*).

While normalization to a form like *To Daniel Veuleman: Yes, I know. I am going to work on that.* does indeed lose some information (information important for an analysis of sociolinguistic or phonological variation clearly goes missing), it expresses the propositional content of the original in a form that is more amenable to processing by traditional tools. Translating the normalized form with Google Translate produces 要丹尼尔*Veuleman*：是的，我知道。我打算在那工作。, which is a substantial improvement over all translations in Table 1.

3 Obtaining Normalization Examples

We want to treat normalization as a supervised learning problem akin to machine translation, and to do so, we need to obtain pairs of microblog posts and their normalized forms. While it would be possible to ask annotators to create such a corpus, it would be quite expensive to obtain large numbers of examples. In this section, we propose a method for creating normalization examples without any human annotation, by leveraging existing tools and data resources.

The English example sentence in Table 1 was selected from the **μtopia parallel corpus** (Ling et al., 2013), which consists of *self-translated* messages from Twitter and Sina Weibo (i.e., each message contains a translation of itself). Row 2 of Table 2 shows the Mandarin self-translation from the corpus. The key observation is what happens when we *automatically* translate the Mandarin version back into English. Rows 3–5 shows automatic translations from three standard web MT engines. While not perfect, the translations contain several correctly normalized subphrases. We will use such *re-translations* as a source of (noisy) normalization examples. Since such self-translations are relatively numerous on microblogs, this technique can provide a large amount of data.

Of course, to motivate this paper, we argued that NLP tools — like the very translation systems we propose to use — often fail on unnormalized input. Is this a problem? We argue that it is not for the following two reasons.

Normalization in translation. Work in translation studies has observed that translation tends to be a *generalizing* process that "smooths out" author- and work-specific idiosyncrasies (Laviosa, 1998; Volansky et al., 2013). Assuming this observation is robust, we expect that dialectal variant forms found in microblogs to be normalized in translation. Therefore, if the parallel segments in our microblog parallel corpus did indeed originate through a translation process (rather than, e.g., being generated as two independent utterances from a bilingual), we may then state the following assumption about the distribution of variant forms in a parallel segment

[2] http://translate.google.com/
[3] http://www.bing.com/translator
[4] http://fanyi.youdao.com/

$\langle \mathbf{e}, \mathbf{f} \rangle$: *if **e** contains nonstandard lexical variants, then **f** is likely to be a normalized translation using with fewer nonstandard lexical variants (and vice-versa).*

Uncorrelated orthographic variants. Any written language has the potential to make creative use of orthography: alphabetic scripts can render approximations of pronunciation variants; logographic scripts can use homophonic substitutions. However, the kinds of innovations used in particular languages will be language specific (depending on details of the phonology, lexicon, and orthography of the language). However, for language pairs that differ substantially in these dimensions, it may not always be possible (or at least easy) to preserve particular kinds of nonstandard orthographic forms in translation. Consider the (relatively common) pronoun-verb compounds like *iknw* and *imma* from our motivating example: since Chinese uses a logographic script without spaces, there is no obvious equivalent.

3.1 Variant–Normalized Parallel Corpus

For the two reasons outlined above, we argue that we will be able to translate back into English using MT, even when the underlying English part of the parallel corpus has a great deal of nonstandard content. We leverage this fact to build the normalization corpus, where the original English tweet is treated as the variant form, and the automatic translation obtained from another language is considered a potential normalization.[5]

Our process is as follows. The microblog corpus of Ling et al. (2013) contains sentence pairs extracted from Twitter and Sina Weibo, for multiple language pairs. We use all corpora that include English as one of the languages in the pair. The respective non-English side is translated into English using different translation engines. The different sets we used and the engines we used to translate are shown in Table 3. Thus, for each original English post **o**, we obtain n paraphrases $\{\mathbf{p}_i\}_{i=1}^{n}$, from n different translation engines.

[5]We additionally assume that the translation engines are trained to output more standardized data, so there will be additional normalizing effect from the machine translation system.

Table 3: Corpora Used for Paraphrasing.

Lang. Pair	Source	Segs.	MT Engines

ZH-EN	Twitter	113K	Google, Bing, Youdao
AR-EN	Twitter	114K	Google, Bing
RU-EN	Twitter	119K	Google, Bing
KO-EN	Twitter	78K	Google, Bing
JA-EN	Twitter	75K	Google, Bing

3.2 Alignment and Filtering

Our parallel microblog corpus was crawled automatically and contains many misaligned sentences. To improve precision, we attempt to find the similarity between the (unnormalized) original and each of the normalizations using an alignment based on the one used in METEOR (Denkowski and Lavie, 2011), which computes the best alignment between the original tweet and each of the normalizations but modified to permit domain-specific approximate matches. To address lexical variants, we allow fuzzy word matching, that is, we allow lexically similar, such as *yea* and *yes* to be aligned (similarity is determined by the Levenshtein distance). We also perform phrasal matchings, such as *ikwn* to *i know*. To do so, we extend the alignment algorithm from word to phrasal alignments. More precisely, given the original post **o** and a candidate normalization **n**, we wish to find the optimal segmentation producing a good alignment. A segmentation $\mathbf{s} = \langle s_1, \ldots, s_{|\mathbf{s}|} \rangle$ is a sequence of segments that aligns as a block to a source word. For instance, for the sentence *yea iknw imma work on that*, one possible segmentation could be s_1 =*yea ikwn*, s_2 =*imma* and s_3 =*work on that*.

Model. We define the score of an alignment **a** and segmentation **s** in using a model that makes semi-Markov independence assumptions, similar to the work in (Bansal et al., 2011), $u(\mathbf{a}, \mathbf{s} \mid \mathbf{o}, \mathbf{n}) =$

$$\prod_{i=1}^{|\mathbf{s}|} \Big[u_e(s_i, a_i \mid \mathbf{n}) \times u_t(a_i \mid a_{i-1}) \times u_\ell(|s_i|) \Big]$$

In this model, the maximal scoring segmentation and alignment can be found using a polynomial time dynamic programming algorithm. Each segment can be aligned to any word or segment in **o**. The aligned segment for s_k is defined as a_k. For the

score of a segment correspondence $u_e(s, a \mid \mathbf{n})$, we assume that this can be estimated using the lexical similarity between segments, which we define to be $1 - \frac{L(s_k,a_k)}{\max\{|s_k|,|a_k|\}}$, where $L(x, y)$ denotes the Levenshtein distance between strings x and y, normalized by the highest possible distance between those segments.

For the alignment score u_t, we assume that the relative order of the two sequences will be mostly monotonous. Thus, we approximate u_t with the following density $pos_s(a_k) - pos_e(a_{k-1}) \sim \mathcal{N}(1, 1)$, where the pos_s is the index of the first word in the segment and pos_e the one of the last word.

After finding the Viterbi alignments, we compute the similarity measure $\tau = \frac{|A|}{|A|+|U|}$, used in (Resnik and Smith, 2003), where $|A|$ and $|U|$ are the number of words that were aligned and unaligned, respectively. In this work, we extract the pair if $\tau > 0.2$.

4 Normalization Model

From the normalization corpus, we learn a normalization model that generalizes the normalization process. That is, from the data we observe that *To DanielVeuleman yea iknw imma work on that* is normalized to *To Daniel Veuleman: yes, I know. I am going to work on that.* However, this is not useful, since the chances of the exact sentence *To DanielVeuleman yea iknw imma work on that* occurring in the data is low. We wish to learn a process to convert the original tweet into the normalized form.

There are two mechanisms that we use in our model. The first (§4.1) learns word–word and phrase–phrase mappings. That is, we wish to find that *DanielVeuleman* is normalized to *Daniel Veuleman*, that *iknw* is normalized to *I know* and that *imma* is normalized to *I am going*. These mappings are more useful, since whenever *iknw* occurs in the data, we have the option to normalize it to *I know*. The second (§4.2) learns character sequence mappings. If we look at the normalization *DanielVeuleman* to *Daniel Veuleman*, we can see that it is only applicable when the exact word *DanielVeuleman* occurs. However, we wish to learn that it is uncommon for the letters *l* and *v* to occur in the same word sequentially, so that be can add missing spaces in words that contain the *lv* character sequence, such as normalizing *phenomenalvoter* to *phenomenal voter*.

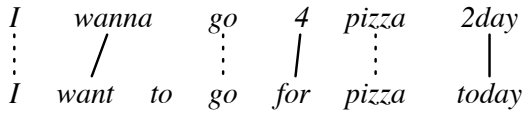

Figure 1: Variant–normalized alignment with the variant form above and the normalized form below; solid lines show potential normalizations, while dashed lines represent identical translations.

However, there are also cases where this is not true, for instance, in the word *velvet*, we do not wish to separate the letters *l* and *v*. Thus, we shall describe the process we use to decide when to apply these transformations.

4.1 From Sentences To Phrases

The process to find phrases from sentences has been throughly studied in Machine Translation. This is generally done in two steps, Word Alignments and Phrase Extraction.

Alignment. The first step is to find the word-level alignments between the original post and its normalization. This is a well studied problem in MT, referred as Word Alignment (Brown et al., 1993). Many alignment models have been proposed, such as, the HMM-based word alignment models (Vogel et al., 1996) and the IBM models (Och and Ney, 2003). Generally, a symmetrization step is performed, where the bidirectional alignments are combined heuristically. In our work, we use the fast aligner proposed in (Dyer et al., 2013) to obtain the word alignments. Figure 1 shows an example of an word aligned pair of a tweet and its normalization.

Phrase Extraction. The phrasal extraction step (Ling et al., 2010), uses the word aligned sentences and extracts phrasal mappings between the original tweet and its normalization, named phrase pairs. For instance, in Figure 1, we would like to extract the phrasal mapping from *go 4* to *go for*, so that we learn that the word *4* in the context of *go* is normalized to the proposition *for*. To do this, the most common approach is to use the template proposed in (Och and Ney, 2004), which allows phrase pairs to be extracted, if there is at least one word alignment within the pair, and there are no

Table 4: Fragment of the phrase normalization model built, for each original phrase **o**, we present the top-3 normalized forms ranked by $f(\mathbf{n} \mid \mathbf{o})$.

Original (**o**)	Normalization (**n**)	$f(\mathbf{n} \mid \mathbf{o})$
wanna	want to	0.4679
wanna	will	0.0274
wanna	going to	0.0114
4	4	0.5641
4	for	0.01795
go 4	go for	1.0000

words inside the pair that are aligned to words not in the pair. For instance, in the example above, the phrase pair that normalizes *wanna* to *want to* would be extracted, but the phrase pair normalizing *wanna* to *want to go* would not, because the word *go* in the normalization is aligned to a word not in the pair.

Phrasal Features. After extracting the phrase pairs, a model is produced with features derived from phrase pair occurrences during extraction. This model is equivalent to phrasal translation model in MT, but we shall refer to it as the normalization model. For a phrase pair $\langle \mathbf{o}, \mathbf{n} \rangle$, where **o** is the original phrase, and **n** is the normalized phrase, we compute the normalization relative frequency $f(\mathbf{n} \mid \mathbf{o}) = \frac{C(\mathbf{n},\mathbf{o})}{C(\mathbf{o})}$, where $C(\mathbf{n}, \mathbf{o})$ denotes the number of times **o** was normalized to **n** and $C(\mathbf{o})$ denotes the number of times **o** was seen in the extracted phrase pairs. Table 4 gives a fragment of the normalization model. The columns represent the original phrase, its normalization and the probability, respectively.

In Table 4, we observe that the abbreviation *wanna* is normalized to *want to* with a relatively high probability, but it can also be normalized to other equivalent expressions, such as *will* and *going to*. The word *4* by itself has a low probability to be normalized to the preposition *for*. This is expected, since this decision cannot be made without context. However, we see that the phrase *go 4* is normalized to *go for* with a high probability, which specifies that within the context of *go*, *4* is generally used as a preposition.

4.2 From Phrases to Characters

While we can learn lexical variants that are in the corpora using the phrase model, we can only address word forms that have been observed in the corpora.

Table 5: Fragment of the character normalization model where examples representative of the lexical variant generation process are encoded in the model.

Original (**o**)	Normalization (**n**)	$f(\mathbf{n} \mid \mathbf{o})$
o o o	o o	0.0223
o o o	o	0.0439
s	c	0.0331
z	s	0.0741
s h	c h	0.019
2	t o	0.014
4	f o r	0.0013
0	o	0.0657
i n g f o r	i n g <space> f o r	0.4545
g f	g <space> f	0.01028

This is quite limited, since we cannot expect all the word forms to be present, such as all the possible orthographic errors for the word *cat*, such as *catt*, *kat* and *caaaat*. Thus, we will build a character-based model that learns the process lexical variants are generated at the subword level.

Our character-based model is similar to the phrase-based model, except that, rather than learning word-based mappings from the original tweet and the normalization sentences, we learn character-based mappings from the original phrases to the normalizations of those phrases. Thus, we extract the phrase pairs in the phrasal normalization model, and use them as a training corpora. To do this, for each phrase pair, we add a start token, *<start>*, and a end token, *<end>*, at the beginning and ending of the phrase pair. Afterwards, we separate all characters by space and add a space token *<space>* where spaces were originally. For instance, the phrase pair normalizing *DanielVeuleman* to *Daniel Veuleman* would be converted to *<start> d a n i e l v e u l e m a n <end>* and *<start> d a n i e l <space> v e u l e m a n <end>*.

Character-based Normalization Model - To build the character-based model, we proceed using the same approach as in the phrasal normalization model. We first align characters using Word Alignment Models, and then we perform phrase extraction to retrieve the phrasal character segments, and build the character-based model by collecting statistics. Once again, we provide examples of entries in the model in Table 5.

We observe that many of the normalizations dealt with in the previous model by memorizing phrases are captured with string transformations. For instance, from phrase pairs such as *tooo* to *too* and *sooo* to *so*, we learn that sequences of *o*'s can be reduced to 2 or 1 *o*. Other examples include orthographic substitutions, such as *2* for *to* and *4* for *for* (as found in *2gether*, *2morrow*, *4ever* and *4get*). Moreover, orthographic errors can be generated from mistaking characters with similar phonetic properties, such as, *s* to *c*, *z* to *s* and *sh* to *ch*, generating lexical variants such as *reprecenting*. Finally, we learn that the number *0* that resembles the letter *o*, can be used as a replacement, as in *g00d*. Finally, we can see that the rule *ingfor* to *ing for* attempts to find segmentation errors, such as *goingfor*, where a space between *going* and *for* was omitted.[6]

5 Normalization Decoder

In section 4, we built two models to learn the process of normalization, the phrase-based model and the character-based model. In this section, we describe the decoder we used to normalize the sentences.

The advantage of the phrase-based model is that it can make decisions for normalization based on context. That is, it contains phrasal units, such as, *go 4*, that determine, when the word *4* should be normalized to the preposition *for* and when to leave it as a number. However, it cannot address words that are unseen in the corpora. For instance, if the word form *4ever* is not seen in the training corpora, it is not be able to normalize it, even if it has seen the word *4get* normalized to *forget*. On the other hand, the character-based model learns subword normalizations, for instance, if we see the word *nnnnno* normalized to *no*, we can learn that repetitions of the letter *n* are generally shorted to *n*, which allows it to generate new word forms. This model has strong generalization potential, but the weakness of the character-based model is that it fails to consider the context of the normalization that the phrase-based model uses to make normalization decisions. Thus, our goal in this section is describe a decoder that uses both models to improve the quality of the normalizations.

5.1 Phrasal Decoder

We use Moses, an off-the-shelf phrase-based MT system (Koehn et al., 2007), to "translate" the original tweet its normalized form using the phrasal model (§4.1). Aside form the normalization probability, we also use the common features used in MT. These are the reverse normalization probability, the lexical and reverse lexical probabilities and the phrase penalty. We also use the MSD reordering model proposed in (Koehn et al., 2005), which adds reordering features.[7] The final score of each phrase pair is given as a sum of weighted log features. The weights for these features are optimized using MERT (Och, 2003). In our work, we sampled 150 tweets randomly from Twitter and normalized them manually, and used these samples as development data for MERT. As for the character-based model features, we simply rank the training phrase pairs by their relative frequency the $f(\mathbf{n} \mid \mathbf{o})$, and use the top-1000 phrase pairs as development set. Finally, a language model is required during decoding as a prior, since it defines the type of language that is produced by the output. We wish to normalized to formal language, which is generally better processed by NLP tools. Thus, for the phrase model, we use the English NIST dataset composed of 8M sentences in English from the news domain to build a 5-gram Kneser-Ney smoothed language model.

5.2 Character and Phrasal Decoder

We now turn to how to apply the character-based (§4.2), together with the phrasal model. For this model, we again use Moses, treating each character as a "word". The simplest way to combine both methods is first to decode the input **o** sentence with the character-based decoder, normalizing each word independently and then normalizing the resulting output using the phrase-based decoder, which enables the phrase model to score the outputs of the character model in context.

[6] Note that this captures the context in which such transformations are likely to occur: there are not many words that contain the sequence *ingfor*, so the probability that these should be normalized by inserting a space is high. On the other hand, we cannot assume that if we observe the sequence *gf*, we can safely separate these with a space. This is because, there are many words that contain this sequence, such as the abbreviation of *gf*(*girlfriend*), *dogfight*, and *bigfoot*.

[7] Reordering helps find lexical variants that are generated by transposing characters, such as, *mabye* to *maybe*.

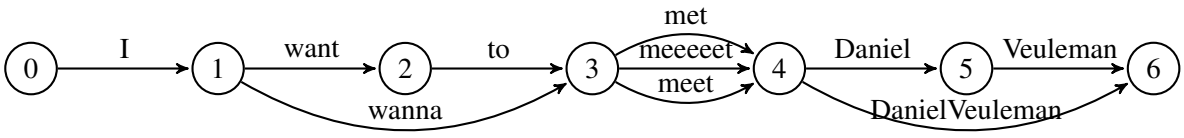

Figure 2: Example output lattice of the character-based decoder, for the sentence *I wanna meeeeet DanielVeuleman*.

Our process is as follows. Given the input sentence **o**, with the words $o_1, \ldots, o_m$, where m is the number of words in the input, we generate for each word o_i a list of n-best normalization candidates $z^1_{o_i}, \ldots, z^n_{o_i}$. We further filter the candidates using two criteria. We start by filtering each candidate $z^j_{o_i}$ that occurs less frequently than the original word o_i. This is motivated by our observation that lexical variants occur far less than the respective standard form. Second, we build a corpus of English language Twitter consisting of 70M tweets, extract the unigram counts, and perform Brown clustering (Brown et al., 1992) with $k = 3000$ clusters. Next, we calculate the cluster similarity between o_i and each surviving candidate, $z^j_{o_i}$. We filter the candidate if the similarity is less than 0.8. The similarity between two clusters represented as *bit strings*, $S[c(o_i), c(z^j_{o_i})]$, calculated as:

$$S(x, y) = \frac{2 \cdot |lpm\{x, y)\}|}{|x| + |y|},$$

where lpm computes the longest common prefix of the contexts and $|x|$ is the length of the bit string.[8] If a candidate contains more than one word (because a space was inserted), we set its count as the minimum count among its words. To find the cluster for multiple word units, we concatenate the words together, and find the cluster with the resulting word if it exists. This is motivated by the fact that it is common for missing spaces to exist in microblog corpora, generating new word forms, such as *wantto*, *goingfor*, and given a large enough corpora as the one we used, these errors occur frequently enough to be placed in the correct cluster. In fact, the variants such as *wanna* and *tmi*, occur in the same clusters as the words *wantto* and *toomuchinformation*.

Remaining candidates are combined into a word lattice, enabling us to perform lattice-based decoding with the phrasal model (Dyer et al., 2008). Figure 2, provides an example of such a lattice for the variant sentence *I wanna meeeet DanielVeuleman*.

5.3 Learning Variants from Monolingual Data

Until now, we learned normalizations from pairs of original tweets and their normalizations. We shall now describe a process to leverage monolingual documents to learn new normalizations, since the monolingual data is far easier to obtain than parallel data. This process is similar to the work in (Han et al., 2012), where confusion sets of contextually similar words are built initially as potential normalization candidates. We again use the $k = 3000$ Brown clusters,[9] and this time consider the contents of each cluster as a set of possible normalization variants. For instance, we find that the cluster that includes the word *never*, also includes the variant forms *neverrrr*, *neva* and *nevahhh*. However, the cluster also contains non-variant forms, such as *gladly* and *glady*. Thus, we want to find that *neverrrr* maps to *never*, while *glady* maps to *gladly* in the same cluster. Our work differs from previous work in that, rather than defining features manually, we use our character-based decoder to find the mappings between lexical variants and their normalizations.

For every word type w_i in cluster $c(w_i) = \{w_1, \ldots, w_n\}$, we generate a set of possible candidates for each word $w^1_i, \ldots, w^m_i$. Then, we build a directed acyclic graph (DAG), where every word. We add an edge between w_i and w_j, if w_i can be decoded into w_j using the character model from the previous section, and also if w_i occurs less than w_j; the second condition guarantees that the graph will be acyclic. Sample graphs are shown in Figure 3.

Afterwards, we find the number of paths between all nodes in the graph (this can be computed efficiently in $O(|V| + |E|)$ time). Then, for each word

[8] Brown clusters are organized such that more words with more similar distributions share common prefixes.

[9] The Brown clustering algorithm groups words together based on contextual similarity.

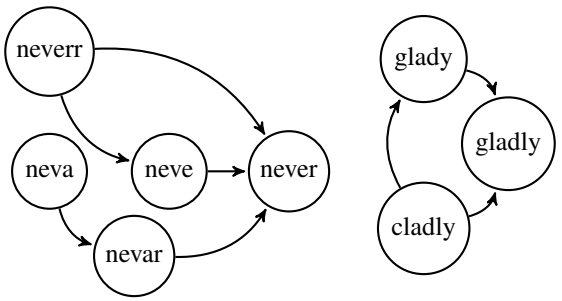

Figure 3: Example DAGs, built from the cluster containing the words *never* and *gladly*.

w_i, we find the w_j to which it has the highest number of paths to and extract the normalization of w_i to w_j. In case of a tie, we choose the word w_j that occurs more often in the monolingual corpora. This is motivated by the fact that normalizations are transitive. Thus, even if *neva* cannot be decoded directly to *never*, we can use *nevar* as an intermediate step to find the correct normalization. This is performed for all the clusters, and the resulting dictionary of lexical variants mapped to their standard forms is added to the training data of the character-based model.

6 Experiments

We evaluate our normalization model intrinsically by testing whether our normalizations more closely resemble standardized data, and then extrinsically by testing whether we can improve the translation quality of in-house as well as online Machine Translation systems by normalizing the input.

6.1 Setup

We use the gold standard by Ling et al. (2013), composed by 2581 English-Mandarin microblog sentence pairs. From this set, we randomly select 1290 pairs for development and 1291 pairs for testing.

The normalizer model is trained on the corpora extracted and filtered in section 3, in total, there were 1.3M normalization pairs used during training. The test sentences are normalized using four different setups. The first setup leaves the input sentence unchanged, which we call **No Norm**. The second uses the phrase-based model to normalize the input sentence, which we will denote **Norm+phrase**. The third uses the character-based model to output lattices, and then decodes with the phrase based model, which we will denote **Norm+phrase+char**. Finally, we test the same model after adding the training data extracted using monolingual documents, which we will refer as **Norm+phrase+char+mono**.

To test the normalizations themselves, we used Google Translate to translate the Mandarin side of the 1291 test sentence pairs back to English and use the original English tweet. While, this is by itself does not guarantee that the normalizations are correct, since the normalizations could be syntactically and semantically incorrect, it will allow us to check whether the normalizations are closer to those produced by systems trained on news data. This experiment will be called **Norm**.

As an application and extrinsic evaluation for our normalizer, we test if we can obtain gains on the MT task on microblog data by using our normalizer prior to translation. We build two MT systems using Moses. Firstly, we build a out-of-domain model using the full 2012 NIST Chinese-English dataset (approximately 8M sentence pairs), which is dataset from the news domain, and we will denote this system as **Inhouse+News**. Secondly, we build a in-domain model using the 800K sentence pairs from μtopia corpora (Ling et al., 2013). We also add the NIST dataset to improve coverage. We call this system **Inhouse+News+Weibo**. To train these systems, we use the Moses phrase-based MT system with standard features (Koehn et al., 2003). For reordering, we use the MSD reordering model (Axelrod et al., 2005). As the language model, we train a 5-gram model with Kneser-ney smoothing using a 10M tweets from twitter. Finally, the weights were tuned using MERT (Och, 2003). As for online systems, we consider the systems used to generate the paraphrase corpora in section 3, which we will denote as **Online A**, **Online B** and **Online C**[10]

The normalization and MT results are evaluated with BLEU-4 (Papineni et al., 2002) comparing the produced translations or normalizations with the appropriate reference.

6.2 Results

Results are shown in Table 6. In terms of the normalizations, we observe a much better match between

[10]The names of the systems are hidden to not violate the privacy issues in the terms and conditions of these online systems.

Table 6: Normalization and MT Results. Rows denote different normalizations, and columns different translation systems, except the first column (Norm), which denotes the normalization experiment. Cells display the BLEU score of that experiment.

Condition	Norm	Moses (News)	Moses (News+Weibo)	Online A	Online B	Online C
baseline	19.90	15.10	24.37	20.09	17.89	18.79
norm+phrase	21.96	15.69	24.29	20.50	18.13	18.93
norm+phrase+char	22.39	15.87	24.40	20.61	18.22	19.08
norm+phrase+char+mono	**22.91**	**15.94**	**24.46**	**20.78**	**18.37**	**19.21**

the normalized text with the reference, than the original tweets. In most cases, adding character-based models improves the quality of the normalizations.

We observe that better normalizations tend to lead to better translations. The relative improvements are most significant, when moving from No Norm to **norm+phrase** normalization. This is because, we are normalizing words that are not seen in general MT system's training data, but occur frequently in microblog data, such as *wanna* to *want to*, *u* to *you* and *im* to *i'm*. The only exception is in the **Inhouse+News+Weibo** system, where the normalization deteriorates the results. This is to be expected, since this system is trained on the same microblog data used to learn the normalizations. However, we can observe on **norm+phrase+char** that if we add the character-based model, we can observe improvements for this system as well as for all other ones. This is because the model is actually learning normalizations that are unseen in the data. Some examples of these normalization include, normalizing *lookin* to *looking*, *nutz* to *nuts* and *maimi* to *miami* but also separating *peaceof* to *peace of*. The fact that these improvements are obtained for all systems is strong evidence that we are actually producing good normalizations, and not overfitting to one of the systems that we used to generate our data. The gains are much smaller from **norm+phrase** to **norm+phrase+char**, since the improvements we obtain come from normalizing less frequent words. Finally, we can obtain another small improvement by adding monolingual data to the character-based model in **norm+phrase+char+mono**.

7 Related Work

Most of the work in microblog normalization is focused on finding the standard forms of lexical variants (Yang and Eisenstein, 2013; Han et al., 2013; Han et al., 2012; Kaufmann, 2010; Han and Baldwin, 2011; Gouws et al., 2011; Aw et al., 2006). A lexical variant is a variation of a standard word in a different lexical form. This ranges from minor or major spelling errors, such as *jst*, *juxt* and *jus* that are lexical variants of *just*, to abbreviations, such as *tmi* and *wanna*, which stand for *too much information* and *want to*, respectively. Jargon can also be treated as variants, for instance *cday* is a slang word for *birthday*, in some groups.

There are many rules that govern the process lexical variants are generated. Some variants are generated from orthographic errors, caused by some mistake from the user when writing. For instance, the variants *representin*, *representting*, or *reprecenting* can be generated by a spurious letter swap, insertion or substitution by the user. One way to normalize these types of errors is to attempt to insert, remove and swap words in a lexical variant until a word in a dictionary of standard words is found (Kaufmann, 2010). Contextual features are another way to find lexical variants, since variants generally occur in the same context as their standard form. This includes orthographic errors, abbreviations and slang. However, this is generally not enough to detect lexical variants, as many words share similar contexts, such as *already*, *recently* and *normally*. Consequently, contextual features are generally used to generate a confusion set of possible normalizations of a lexical variant, and then more features are used to find the correct normalization (Han et al., 2012). One simple approach is to compute the Levenshtein distance to find lexical similarities between words, which would effectively capture the mappings between *representting*, *reprecenting* and *representin* to *representing*. However, a pronunciation model (Tang et al., 2012)

would be needed to find the mapping between *g8*, *2day* and *4ever* to *great*, *today* and *forever*, respectively. Moreover, visual character similarity features would be required to find the mapping between *g00d* and ι to *good* and *i*.

Clearly, learning this process is a challenging task, and addressing each different case individually would require vast amounts of resources. Furthermore, once we change the language to normalize to another language, the types of rules that generate lexical variants would radically change and a new set of features would have to be engineered. We believe that to be successful in normalizing microblogs, the process to learn new lexical variants should be learned from data, making as few assumptions as possible. We learn our models without using any type of predefined features, such as phonetic features or lexical features. In fact, we will not assume that most words and characters map to themselves, as it is assumed in methods using the Levenshtein distance (Kaufmann, 2010; Han et al., 2012; Wang and Ng, 2013). All these mappings are learned from our data. Furthermore, in the work above, the dictionaries built using these methods assume that lexical variants are mapped to standard forms in a word-to-word mapping. Thus, variants such as *wanna*, *gonna* and *imma* are not normalizable, since they are normalized to multiple words *want to*, *going to* and *I am gonna*. Moreover, there are segmentation errors that occur from missing spaces, such as *sortof* and *goingfor*, which also map to more than one word to *sort of* and *going for*. These cases shall also be addressed in our work.

Wang and Ng (2013) argue that microblog normalization is not simply to map lexical variants into standard forms, but that other tasks, such as punctuation correction and missing word recovery should be performed. Consider the example tweet *you free?*, while there are no lexical variants in this message, the authors consider that it is the normalizer should recover the missing article *are* and normalize this tweet to *are you free?*. To do this, the authors train a series of models to detect and correct specific errors. While effective for narrow domains, training models to address each specific type of normalization is not scalable over all types of normalizations that need to be performed within the language, and the fact that a set of new models must be implemented for another language limits the applicability of this work.

Another strong point of the work above is that a decoder is presented, while the work on building dictionaries only normalize out of vocabulary (OOV) words. The work on (Han et al., 2012) trains a classifier to decide whether to normalize a word or not, but is still preconditioned on the fact that the word in question is OOV. Thus, lexical variants, such as, *4* and *u*, with the standard forms *for* and *you*, are left untreated, since they occur in other contexts, such as *u* in *u s a*. Inspired by the work above, we also propose a decoder based on the existing off-the-self decoder Moses (Koehn et al., 2007).

Finally, the work in (Xu et al., 2013) obtains paraphrases from Twitter, by finding tweets that contain common entities, such as *Obama*, that occur during the same period by matching temporal expressions. The resulting paraphrase corpora can also be used to train a normalizer.

8 Conclusion

We introduced a data-driven approach to microblog normalization based on paraphrasing. We build a corpora of tweets and their normalizations using parallel corpora from microblogs using MT techniques. Then, we build two models that learn generalizations of the normalization process, one the phrase level and on the character level. Then, we build a decoder that combines both models during decoding. Improvements on multiple MT systems support the validity of our method.

In future work, we shall attempt to build normalizations for other languages. We shall also attempt to learn an unsupervised normalization model with only monolingual data, similar to the work for MT in (Ravi and Knight, 2011).

Abstract

In this paper, we address the problem of estimating question difficulty in community question answering services. We propose a competition-based model for estimating question difficulty by leveraging pairwise comparisons between questions and users. Our experimental results show that our model significantly outperforms a PageRank-based approach. Most importantly, our analysis shows that the text of question descriptions reflects the question difficulty. This implies the possibility of predicting question difficulty from the text of question descriptions.

1 Introduction

In recent years, community question answering (CQA) services such as Stackoverflow[1] and Yahoo! Answers[2] have seen rapid growth. A great deal of research effort has been conducted on CQA, including: (1) question search (Xue et al., 2008; Duan et al., 2008; Suryanto et al., 2009; Zhou et al., 2011; Cao et al., 2010; Zhang et al., 2012; Ji et al., 2012); (2) answer quality estimation (Jeon et al., 2006; Agichtein et al., 2008; Bian et al., 2009; Liu et al., 2008); (3) user expertise estimation (Jurczyk and Agichtein, 2007; Zhang et al., 2007; Bouguessa et al., 2008; Pal and Konstan, 2010; Liu et al., 2011); and (4) question routing (Zhou et al., 2009; Li and King, 2010; Li et al., 2011).

However, less attention has been paid to ***question difficulty estimation*** in CQA. Question difficulty estimation can benefit many applications: (1) Experts are usually under time constraints. We do not want to bore experts by routing every question (including both easy and hard ones) to them. Assigning questions to experts by matching question difficulty with expertise level, not just question topic, will make better use of the experts' time and expertise (Ackerman and McDonald, 1996). (2) Nam et al. (2009) found that winning the point awards offered by the reputation system is a driving factor in user participation in CQA. Question difficulty estimation would be helpful in designing a better incentive mechanism by assigning higher point awards to more difficult questions. (3) Question difficulty estimation can help analyze user behavior in CQA, since users may make strategic choices when encountering questions of different difficulty levels.

To the best of our knowledge, not much research has been conducted on the problem of estimating question difficulty in CQA. The most relevant work is a PageRank-based approach proposed by Yang et al. (2008) to estimate task difficulty in crowdsourcing contest services. Their key idea is to construct a graph of tasks: creating an edge from a task t_1 to a task t_2 when a user u wins task t_1 but loses task t_2, implying that task t_2 is likely to be more difficult than task t_1. Then the standard PageRank algorithm is employed on the task graph to estimate PageRank score (i.e., difficulty score) of each task. This approach implicitly assumes that task difficulty is the only factor affecting the outcomes of competitions (i.e. the best answer). However, the outcomes of competitions depend on both the difficulty levels of tasks and the expertise levels of competitors (i.e.

other answerers).

Inspired by Liu et al. (2011), we propose a competition-based approach which jointly models question difficulty and user expertise level. Our approach is based on two intuitive assumptions: (1) given a question answering thread, the difficulty score of the question is higher than the expertise score of the asker, but lower than that of the best answerer; (2) the expertise score of the best answerer is higher than that of the asker as well as all other answerers. Given the two assumptions, we can determine the question difficulty score and user expertise score through pairwise comparisons between (1) a question and an asker, (2) a question and a best answerer, (3) a best answerer and an asker, and (4) a best answerer and all other non-best answerers.

The main contributions of this paper are:

• We propose a competition-based approach to estimate question difficulty (Sec. 2). Our model significantly outperforms the PageRank-based approach (Yang et al., 2008) for estimating question difficulty on the data of Stack Overflow (Sec. 3.2).

• Additionally, we calibrate question difficulty scores across two CQA services to verify the effectiveness of our model (Sec. 3.3).

• Most importantly, we demonstrate that different words or tags in the question descriptions indicate question difficulty levels. This implies the possibility of predicting question difficulty purely from the text of question descriptions (Sec. 3.4).

2 Competition based Question Difficulty Estimation

CQA is a virtual community where people can ask questions and seek opinions from others. Formally, when an asker u_a posts a question q, there will be several answerers to answer her question. One answer among the received ones will be selected as the best answer by the asker u_a or voted by the community. The user who provides the best answer is called the best answerer u_b, and we denote the set of all non-best answerers as $S = \{u_{o_1}, \cdots, u_{o_M}\}$. Assuming that question difficulty scores and user expertise scores are expressed on the same scale, we make the following two assumptions:

• The difficulty score of question q is higher than the expertise score of asker u_a, but lower than that of the best answerer u_b. This is intuitive since the best answer u_b correctly responds to question q that asker u_a does not know.

• The expertise score of the best answerer u_b is higher than that of asker u_a and all answerers in S. This is straightforward since the best answerer u_b solves question q better than asker u_a and all non-best answerers in S.

Let's view question q as a pseudo user u_q. Taking a competitive viewpoint, each pairwise comparison can be viewed as a two-player competition with one winner and one loser, including (1) one competition between pseudo user u_q and asker u_a, (2) one competition between pseudo user u_q and the best answerer u_b, (3) one competition between the best answerer u_b and asker u_a, and (4) $|S|$ competitions between the best answerer u_b and all non-best answers in S. Additionally, pseudo user u_q wins the first competition and the best answerer u_b wins all remaining $(|S| + 2)$ competitions.

Hence, the problem of estimating the question difficulty score (and the user expertise score) is cast as a problem of learning the relative skills of players from the win-loss results of the generated two-player competitions. Formally, let $\mathcal{Q}$ denote the set of all questions in one category (or topic), and $\mathcal{R}_q$ denote the set of all two-player competitions generated from question $q \in \mathcal{Q}$, i.e., $\mathcal{R}_q = \{(u_a \prec u_q), (u_q \prec u_b), (u_a \prec u_b), (u_{o_1} \prec u_b), \cdots, (u_{o_{|S|}} \prec u_b)\}$, where $j \prec i$ means that user i beats user j in the competition. Define

$$\mathcal{R} = \bigcup_{q \in \mathcal{Q}} \mathcal{R}_q \tag{1}$$

as the set of all two-player competitions. Our problem is then to learn the relative skills of players from $\mathcal{R}$. The learned skills of the pseudo question users are question difficulty scores, and the learned skills of all other users are their expertise scores.

TrueSkill In this paper, we follow (Liu et al., 2011) and apply TrueSkill to learn the relative skills of players from the set of generated competitions $\mathcal{R}$ (Equ. 1). TrueSkill (Herbrich et al., 2007) is a Bayesian skill rating model that is developed for estimating the relative skill levels of players in games. In this paper, we present a two-player version of TrueSkill with no-draw.

TrueSkill assumes that the practical performance of each player in a game follows a normal distribu-

tion $\mathcal{N}(\mu, \sigma^2)$, where μ means the skill level of the player and σ means the uncertainty of the estimated skill level. Basically, TrueSkill learns the skill levels of players by leveraging Bayes' theorem. Given the current estimated skill levels of two players (priori probability) and the outcome of a new game between them (likelihood), TrueSkill model updates its estimation of player skill levels (posterior probability). TrueSkill updates the skill level μ and the uncertainty σ intuitively: (a) if the outcome of a new competition is expected, i.e. the player with higher skill level wins the game, it will cause small updates in skill level μ and uncertainty σ; (b) if the outcome of a new competition is unexpected, i.e. the player with lower skill level wins the game, it will cause large updates in skill level μ and uncertainty σ. According to these intuitions, the equations to update the skill level μ and uncertainty σ are as follows:

$$\mu_{winner} = \mu_{winner} + \frac{\sigma^2_{winner}}{c} \cdot v\left(\frac{t}{c}, \frac{\varepsilon}{c}\right), \quad (2)$$

$$\mu_{loser} = \mu_{loser} - \frac{\sigma^2_{loser}}{c} \cdot v\left(\frac{t}{c}, \frac{\varepsilon}{c}\right), \quad (3)$$

$$\sigma^2_{winner} = \sigma^2_{winner} \cdot \left[1 - \frac{\sigma^2_{winner}}{c^2} \cdot w\left(\frac{t}{c}, \frac{\varepsilon}{c}\right)\right], \quad (4)$$

$$\sigma^2_{loser} = \sigma^2_{loser} \cdot \left[1 - \frac{\sigma^2_{loser}}{c^2} \cdot w\left(\frac{t}{c}, \frac{\varepsilon}{c}\right)\right], \quad (5)$$

where $t = \mu_{winner} - \mu_{loser}$ and $c^2 = 2\beta^2 + \sigma^2_{winner} + \sigma^2_{loser}$. Here, ε is a parameter representing the probability of a draw in one game, and $v(t, \varepsilon)$ and $w(t, \varepsilon)$ are weighting factors for skill level μ and standard deviation σ respectively. Please refer to (Herbrich et al., 2007) for more details. In this paper, we set the initial values of the skill level μ and the standard deviation σ of each player the same as the default values used in (Herbrich et al., 2007).

3 Experiments

3.1 Data Set

In this paper, we use Stack Overflow (SO) for our experiments. We obtained a publicly available data set[3] of SO between July 31, 2008 and August 1, 2012. SO contains questions with various topics, such as programming, mathematics, and English. In this paper, we use SO C++ programming (SO/CPP) and mathematics[4] (SO/Math) questions for our main experiments. Additionally, we use the data of Math Overflow[5] (MO) for calibrating question difficulty scores across communities (Sec. 3.3). The statistics of these data sets are shown in Table 1.

	SO/CPP	**SO/Math**	**MO**
# of questions	122,012	51,174	27,333
# of answers	357,632	94,488	65,966
# of users	67,819	16,961	12,064

Table 1: The statistics of the data sets.

To evaluate the effectiveness of our proposed model for estimating question difficulty scores, we randomly sampled 300 question pairs from both SO/CPP and SO/Math, and we asked experts to compare the difficulty of every pair. We had two graduate students majoring in computer science annotate the SO/CPP question pairs, and two graduate students majoring in mathematics annotate the SO/Math question pairs. When annotating each question pair, only the titles, descriptions, and tags of the questions were shown, and other information (e.g. users, answers, etc.) was excluded. Given each pair of questions (q_1 and q_2), the annotators were asked to give one of four labels: (1) $q_1 \succ q_2$, which means that the difficulty of q_1 was higher than q_2; (2) $q_1 \prec q_2$, which means that the difficulty of q_1 was lower than q_2; (3) $q_1 = q_2$, which means that the difficulty of q_1 was equal to q_2; (4) Unknown, which means that the annotator could not make a decision. The agreements between annotators on both SO/CPP (kappa value $= 0.741$) and SO/Math (kappa value $= 0.873$) were substantial. When evaluating models, we only kept the pairs that annotators had given the same labels. There were 260 SO/CPP question pairs and 280 SO/Math question pairs remaining.

3.2 Accuracy of Question Difficulty Estimation

We employ a standard evaluation metric for information retrieval: accuracy (Acc), defined as follows:

$$Acc = \frac{\text{the number of correct pairwise comparisons}}{\text{the total number of pairwise comparisons}}.$$

We use the *PageRank*-based approach proposed by Yang et al. (2008) as a baseline. As described in

[3] http://blog.stackoverflow.com/category/cc-wiki-dump/

[4] http://math.stackexchange.com

[5] http://mathoverflow.net

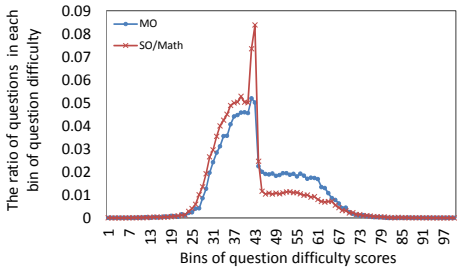

Figure 1: The distributions of calibrated question difficulty scores of MO and SO/Math.

Sec. 1, this is the most relevant method for our problem. Table 2 gives the accuracy of the baseline and our *Competition*-based approach on SO/CPP and SO/Math. From the results, we can see that (1) the proposed *Competition*-based approach significantly outperformed the *PageRank*-based approach on both data sets; (2) *PageRank*-based approach only achieved a similar performance as randomly guessing. This is because the *PageRank*-based approach only models the outcomes of competitions affected by question difficulty. However, the outcomes of competitions depend on both the question difficulty levels and the expertise levels of competitors. Our *Competition*-based approach considers both these factors for modeling the competitions. The experimental results demonstrate the advantage of our approach.

	Acc@**SO/CPP**	*Acc*@**SO/Math**
PageRank	50.38%	48.93%
Competition	66.54%	71.79%

Table 2: Accuracy on SO/CPP and SO/Math.

3.3 Calibrating Question Difficulty across CQA Services

Both MO and SO/Math are CQA services for asking mathematics questions. However, these two services are designed for different audiences, and they have different types of questions. MO's primary goal is asking and answering research level mathematics questions[6]. In contrast, SO/Math is for people studying mathematics at any level in related fields[7]. Usually, the community members in MO are not interested in basic mathematics questions. If a posted question is too elementary, someone will suggest moving it to SO/Math. Similarly, if a posted question is advanced, the community members in SO/Math will recommend moving it to MO. Hence, it is expected that the ratio of difficult questions in MO is higher than SO/Math. In this section, we examine whether our competition-based model can identify such differences.

We first calibrate the estimated question difficulty scores across these two services on a same scale. The key idea is to link the users who participate in both services. In both MO and SO/Math, users can specify their home pages. We assume that if a user u_1 on MO and a user u_2 on SO/Math have the same home page URL, they should be linked as one natural person in the real world. We successfully linked 633 users. They provided $18,196$ answers in SO/Math among which $10,993$ (60.41%) were selected as the best answers. In contrast, they provided $8,044$ answers in MO among which $3,215$ (39.97%) were selected as the best answers. This shows that these users reflect more competitive contests in MO. After the common users are linked, we have a joint data set of MO and SO/Math. Then, we can calibrate the estimated question difficulty scores across the two services by performing the competition-based model on the joint data set. Figure 1 shows the distributions of the calibrated question difficulty scores of MO and SO/Math on the same scale. As expected, we observed that the ratio of difficult questions in MO was higher than SO/Math. Additionally, these two distributions were significantly different (Kolmogorov-Smirnov Test, p-value < 0.05). This demonstrates that our competition-based model successfully identified the difference between questions on two CQA services.

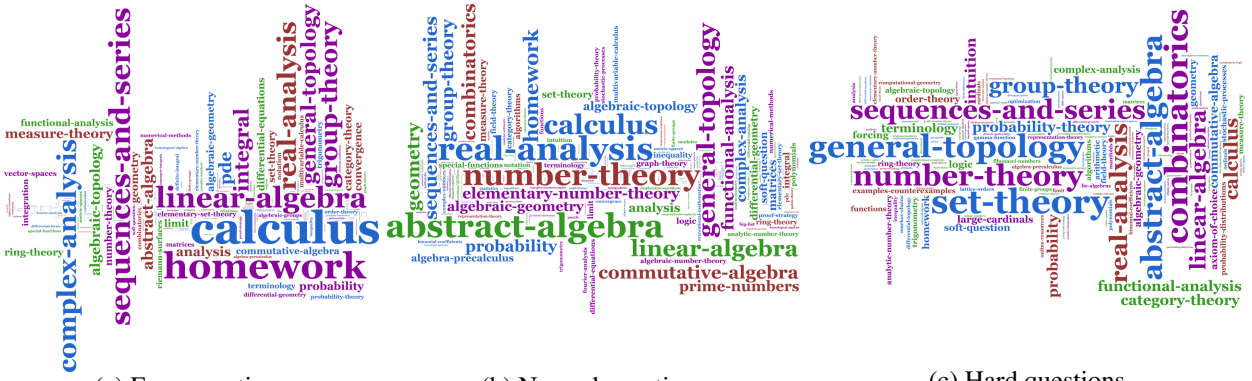
3.4 Analysis on the Question Descriptions

In this section, we analyze the text of question descriptions on the scale of question difficulty scores estimated by the competition model.

Micro Level We first examine the frequency distributions of individual words over the question difficulty scores. Figure 3 shows the examples of four words in SO/CPP. We observe that the words *'list'* and *'array'* have the lowest mean of difficulty scores, compared to the words *'virtual'* and *'gcc'*. This is reasonable, since *'list'* and *'array'* are related

[6] http://mathoverflow.net/faq

[7] http://area51.stackexchange.com/proposals/3355/mathematics



(a) Easy questions (b) Normal questions (c) Hard questions

Figure 2: Tag clouds on SO/Math questions with different difficulty levels

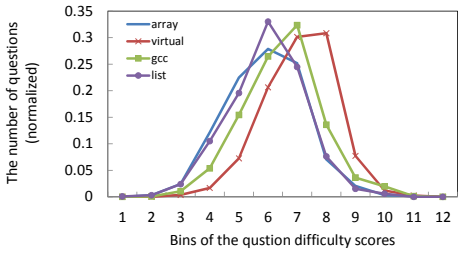


Figure 3: The frequency distributions of words on the scale of question difficulty scores (SO/CPP).

to basic concepts in programming language, while *'virtual'* and *'gcc'* are related to more advanced topics. It can be observed that the order of the means of the difficulty scores of these words are well aligned to our learning process.

Macro Level We evenly split the range of question difficulty scores into n buckets, and we grouped the questions into the n buckets according to which bucket their difficulty scores were in. Then, we had n question buckets and each bucket corresponded to a word distribution of questions. Let variable X denote the distance between the difficulty scores in two question buckets (which is the difference between the average difficulty scores of questions in the two buckets), and variable Y denote the Jensen-Shannon distance between word distributions in two question buckets. We examined the correlation between variable X and variable Y. The experimental results showed that the correlation between these two variables were strongly positive. Specifically, the correlation coefficient on SO/CPP was 0.8129 and on SO/Math was 0.7412. In other words, when the distance between the difficulty scores of two buckets become larger, the two word distributions in the two buckets become less similar, and vice versa.

We further visualized the word distribution in each question bucket. We set n as 3, and we had three question buckets: (1) easy questions; (2) normal questions; and (3) hard questions. Figure 3.4 plots the tag clouds of SO/Math questions in the three buckets. The size of tags is proportional to the frequency of tags in each bucket. We observed that (1) the tag *'homework'* and *'calculus'* become smaller from easy questions to hard questions; (2) the tag *'set-theory'* becomes larger. These observations also reflect our learning process.

The above experimental results show that different words or tags of question descriptions reflect the question difficulty levels. This implies the possibility of predicting question difficulty purely from the text of question descriptions.

4 Conclusion and Future Work

In this paper, we address the problem of estimating question difficulty in CQA services. Our proposed competition-based model for estimating question difficulty significantly outperforms the PageRank-based approach. Most importantly, our analysis shows that the text of question descriptions reflects the question difficulty. In the future, we would like to explore predicting question difficulty from the text of question descriptions. We also will investigate non-technical areas, where there might be no strongly distinct notion of experts and non-experts.

Abstract

We seek to measure political candidates' ideological positioning from their speeches. To accomplish this, we infer ideological cues from a corpus of political writings annotated with known ideologies. We then represent the speeches of U.S. Presidential candidates as sequences of cues and lags (filler distinguished only by its length in words). We apply a domain-informed Bayesian HMM to infer the proportions of ideologies each candidate uses in each campaign. The results are validated against a set of preregistered, domain expert-authored hypotheses.

1 Introduction

The artful use of language is central to politics, and the language of politicians has attracted considerable interest among scholars of political communication and rhetoric (Charteris-Black, 2005; Hart, 2009; Deirmeier et al., 2012; Hart et al., 2013) and computational linguistics (Thomas et al., 2006; Fader et al., 2007; Gerrish and Blei, 2011, *inter alia*). In American politics, candidates for office give speeches and write books and manifestos expounding their ideas. Every political season, however, there are accusations of candidates "flip-flopping" on issues, with opinion shows, late-night comedies, and talk radio hosts replaying clips of candidates contradicting earlier statements. Presidential candidate Mitt Romney's own aide infamously proclaimed in 2012: "I think you hit a reset button for the fall campaign [i.e., the general election]. Everything changes. It's almost like an Etch-a-Sketch. You can kind of shake it up and we start all over again."

A more general observation, often stated but not yet, to our knowledge, tested empirically, is that successful primary candidates "move to the center" before a general election. The expectation follows directly from long-standing and widely influential theories of political competition that are collectively referred to in their simplest form as the "median voter theorem" (Hotelling, 1929; Black, 1948; Downs, 1957). Thus it is to be expected that when a set of voters that are more ideologically concentrated are replaced by a set who are more widely dispersed across the ideological spectrum, as occurs in the transition between the United States primary and general elections, that candidates will present themselves as more moderate in an effort to capture enough votes to win.

Do political candidates in fact stray ideologically at opportune moments? More specifically, can we measure candidates' ideological positions from their prose at different times? Following much work on *classifying* the political ideology expressed by a piece of text (Laver et al., 2003; Monroe and Maeda, 2004; Hillard et al., 2008), we start from the assumption that a candidate's choice of words and phrases reflects a deliberate attempt to signal common cause with a target audience, and as a broader strategy, to respond to political competitors. Our central hypothesis is that, despite candidates' intentional vagueness, differences in position—among candidates or over time—can be automatically detected and described as *proportions* of ideologies expressed in a speech.

In this work, we operationalize ideologies in a novel empirical way, exploiting political writings published in explicitly ideological books and magazines (§2).[1] The corpus then serves as evidence for

[1] We consider general positions in terms of broad ideological groups that are widely discussed in current political discourse (e.g., "Far Right," "Religious Right," "Libertarian,"'

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 91–101,
Seattle, Washington, USA, 18-21 October 2013.

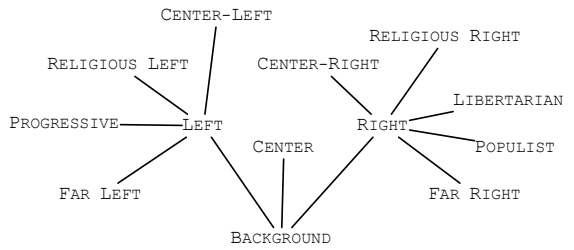

Figure 1: Ideology tree showing the labels for the ideological corpus in §2.1 (excluding BACKGROUND) and corresponding to states in the HMM (§3.3).

a probabilistic model that allows us to automatically infer compact, human-interpretable lexicons of cues strongly associated with each ideology.

These lexicons are used, in turn, to create a low-dimensional representation of political speeches: a speech is a sequence of cues interspersed with lags. Lags correspond to the lengths of sequences of non-cue words, which are treated as irrelevant to the inference problem at hand. In other words, a speech is represented as a series alternating between cues signaling ideological positions and uninteresting filler.

Our main contribution is a probabilistic technique for inferring proportions of ideologies expressed by a candidate (§3). The inputs to the model are the cue-lag representation of a speech and a domain-specific topology relating ideologies to each other. The topology tree (shown in Figure 1) encoding the closeness of different ideologies and, by extension, the odds of transitioning between them within a speech. Bayesian inference is used to manage uncertainty about the associations between cues and ideologies, probabilities of traversing each of the tree's edges, and other parameters.

We demonstrate the usefulness of the measurement model by showing that it accurately recovers pre-registered beliefs regarding narratives widely accepted—but not yet tested empirically—about the 2008 and 2012 U.S. Presidential elections (§4).

2 First Stage: Cue Extraction

We first present a data-driven technique for automatically constructing "cue lexicons" from texts labeled with ideologies by domain experts.

etc.). Analysis of positions on specific issues is left for future work.

POPULIST RIGHT	5	407,054
RELIGIOUS RIGHT	6	441,530

Table 1: Ideology corpus statistics. Note that some documents are not labeled with finer-grained ideologies.

2.1 Ideological Corpus

We start with a collection of contemporary political writings whose authors are perceived as representative of one particular ideology. Our corpus consists of two types of documents: books and magazines. Books are usually written by a single author, while each magazine consists of regularly published issues with collections of articles written by several authors. A political science domain expert who is a co-author of this work manually labeled each element in a collection of 112 books and 10 magazine titles[2] with one of three coarse ideologies: LEFT, RIGHT, or CENTER. Documents that were labeled LEFT and RIGHT were further broken down into more fine-grained ideologies, shown in Fig. 1.[3] Table 1 summarizes key details about the ideological corpus.

In addition to ideology labels, individual chapters within the books were manually tagged with topics that the chapter was about. For instance, in Barack Obama's book *The Audacity of Hope*, his chapter

[2]There are 765 magazine issues, which are published bi-weekly to quarterly, depending on the magazine. All of a magazine's issues are labeled with the same ideology.

[3]We cannot claim that these texts are "pure" examples of the ideologies they are labeled with (i.e., they may contain parts that do not match the label). By finding relatively few terms strongly associated with texts sharing a label, our model should be somewhat robust to impurities, focusing on those terms that are indicative of whatever drew the expert to identify them as (mostly) sharing an ideology.

titled "Faith" is labeled as RELIGIOUS. Not all chapters have clearly defined topics, and as such, these chapters are simply labeled MISC. Magazines are not labeled with topics because each issue of a magazine generally touches on multiple topics. There are a total of 61 topics; the full list can be found in the supplementary materials, along with a table summarizing key details about the corpus, which contains 32.8 million tokens.

2.2 Cue Discovery Model

We use the ideological corpus to infer ideological cues: terms that are strongly associated with an ideology. Because our ideologies are organized hierarchically, we required a technique that can account for multiple effects within a single text. We further require that the sets of cue terms be small, so that they can be inspected by domain experts. We therefore turn to the sparse additive generative (SAGE) models introduced by Eisenstein et al. (2011).

Like other probabilistic language models, SAGE assigns probability to a text as if it were a bag of terms. It differs from most language models in parameterizing the distribution using a generalized linear model, so that different effects on the log-odds of terms are additive. In our case, we define the probability of a term w conditioned on attributes of the text in which it occurs. These attributes include both the ideology and its coarsened version (e.g., a FAR RIGHT book also has the attribute RIGHT). For simplicity, let $\mathcal{A}(d)$ denote the set of attributes of document d and $\mathcal{A} = \bigcup_d \mathcal{A}(d)$. The parametric form of the distribution is given, for term w in document d, by:

$$p(w \mid \mathcal{A}(d); \boldsymbol{\eta}) = \frac{\exp\left(\eta^0_w + \sum_{a \in \mathcal{A}(d)} \eta^a_w\right)}{Z(\mathcal{A}(d), \boldsymbol{\eta})}$$

Each of the η weights can be a positive or negative value influencing the probability of the word, conditioned on various properties of the document. When we stack an attribute a's weights into a vector across all words, we get an $\boldsymbol{\eta}^a$ vector, understood as an effect on the term distribution. (We use $\boldsymbol{\eta}$ to refer to the collection of all of these vectors.) The effects in our model, described in terms of attributes, are:

- $\boldsymbol{\eta}^0$, the background (log) frequencies of words, fixed to the empirical frequencies in the corpus. Hence the other effects can be understood as *deviations* from this background distribution.
- $\boldsymbol{\eta}^{i_c}$, the coarse ideology effect, which takes different values for LEFT, RIGHT, and CENTER.
- $\boldsymbol{\eta}^{i_f}$, the fine ideology effect, which takes different values for the fine-grained ideologies corresponding to the leaves in Fig. 1.
- $\boldsymbol{\eta}^t$, the topic effect, taking different values for each of the 61 manually assigned topics. We further include one effect for each magazine series (of which there are 10) to account for each magazine's idiosyncrasies (topical or otherwise).
- $\boldsymbol{\eta}^d$, a document-specific effect, which captures idiosyncratic usage within a single document.

Note that the effects above are not mutually exclusive, although some effects never appear together due to constraints imposed by their semantics (e.g., no book is labeled both LEFT and RIGHT).

When estimating the parameters of the model (the $\boldsymbol{\eta}$ vectors), we impose a sparsity-inducing ℓ_1 prior that forces many weights to zero. The objective is:

$$\max_{\boldsymbol{\eta}} \sum_d \sum_{w \in d} \log p(w \mid \mathcal{A}(d); \boldsymbol{\eta}) - \sum_{a \in \mathcal{A}} \lambda_a \|\boldsymbol{\eta}^a\|_1$$

This objective function is convex but requires special treatment due to non-differentiability when any elements are zero; we use the OWL-QN algorithm to solve it (Andrew and Gao, 2007). To reduce the complexity of the hyperparameter space (the possible values of all λ_a) and to encourage similar levels of sparsity across the different effect vectors, we let, for each ideology attribute a,

$$\lambda_a = \lambda \cdot |\mathcal{V}(a)| \,/ \max_{a' \in \mathcal{A}} |\mathcal{V}(a')|$$

where $\mathcal{V}(a)$ is the set of term types appearing in the data with attribute a (i.e., its vocabulary) , and λ is a hyperparameter we can adjust to control the amount of sparsity in the SAGE vectors. For the non-ideology effects, we fix $\lambda_a = 10$ (not tuned).

2.3 Bigram and Trigram Lexicons

After estimating parameters, we are left with sparse $\boldsymbol{\eta}^a$ for each attribute. We are only interested, however, in the ideological attributes $\mathcal{I} \subset \mathcal{A}$. For an ideological attribute $i \in \mathcal{I}$, we take the terms with positive elements of this vector to be the cues for ideology i; call this set $\mathcal{L}(i)$ and let $\mathcal{L} = \bigcup_{i \in \mathcal{I}} \mathcal{L}(i)$.

Because political texts use a fair amount of multiword jargon, we initially represented each document as a bag of unigrams, bigrams, and trigrams, ignoring the fact that these "overlap" with each other.[4] While this would be inappropriate in language modeling and is inconsistent with our model's independence assumptions among words, it is sensible since our goal is to identify cues that are statistically associated with attributes like ideologies.

Preliminary trials revealed that unigrams tend to dominate in such a model, since their frequency counts are so much higher. Further, domain experts found them harder to interpret out of context compared to bigrams and trigrams. We therefore included only bigrams and trigrams as terms in our cue discovery model.

2.4 Validation

The term selection method we have described can be understood as a form of feature selection that reasons globally about the data and tries to control for some effects that are not of interest (topic or document idiosyncrasies). We compared the approach to two classic, simple methods for feature selection: ranking based on pointwise mutual information (PMI) and weighted average PMI (WAPMI) (Schneider, 2005; Cover and Thomas, 2012). Selected features were used to classify the ideologies of held-out documents from our corpus.[5] We evaluated these feature selection methods within naïve Bayes classification in a 5-fold cross-validation setup. We vary λ for the SAGE model and compare the results to equal-sized sets of terms selected by PMI and WAPMI. We consider SAGE with and without topic effects.

Figure 2 visualizes accuracy against the number of features for each method. Bigrams and trigrams consistently outperform unigrams (McNemar's, $p < 0.05$). Otherwise, there are no significant differences in performance except WAPMI

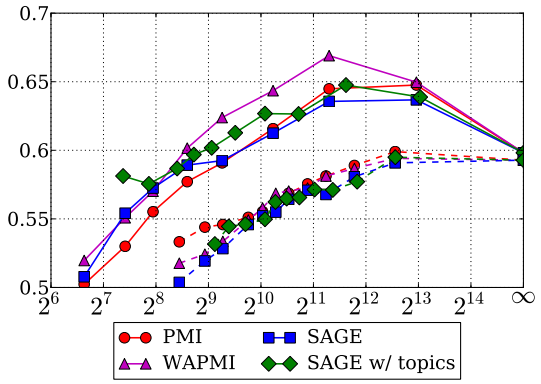

Figure 2: Plot of average classification accuracy for 5-fold cross validation against the number of features. Dashed lines refer to using only unigram features, while solid lines refer to using bigram and trigram features.

with bigrams/trigrams at its highest point. SAGE with topics is slightly (but not significantly) better than without. We conclude that SAGE is a competitive choice for cue discovery, noting that a principled way of controlling for topical and document effects—offered by SAGE but not the other methods—may be even more relevant to our task than classification accuracy.

2.5 Cue Lexicon

We ran SAGE on the the full ideological book corpus, including topic effects, and setting $\lambda = 30$, obtained a set of $|\mathcal{L}| = 8,483$ cue terms. The supplementary materials include top cue terms associated with various ideologies and a heatmap of similarities among SAGE vectors.

We conducted a small, relatively informal study in which seven subjects (including four scholars of American politics) were asked to match brief descriptions of the classes, including prominent prototypical individuals exemplifying each, to cue terms. About 70% of ideologies were correctly matched by experts, with relatively few confusions between LEFT and RIGHT. More details are given in supplementary materials.

3 Second Stage: Cue-Lag Ideological Proportions

The main contribution of this paper is a technique for measuring ideology proportions in the prose of political candidates. We adopt a Bayesian approach that manages our uncertainty about the cue lexi-

[4]Generative models that produce the same evidence more than once are sometimes called "deficient," but model deficiency does not necessarily imply that the model is ineffective. Some of the IBM models for statistical machine translation provide a classic example (Brown et al., 1993).

[5]The text was tokenized and stopwords removed. Punctuation, numbers, and web addresses were normalized. Tokens appearing less than 20 times in training data, or in fewer than 5 documents were removed.

con $\mathcal{L}$, the tendencies of political speakers to "flip-flop" among ideological types, and the relative "distances" among different ideologies. The representation of a candidate's ideology as a mixture among discrete, hierarchically related categories can be distinguished from continuous representations ("scaling" or "spatial" models) often used in political science, especially to infer positions from Congressional roll-call voting patterns (Poole and Rosenthal, 1985; Poole and Rosenthal, 2000; Clinton et al., 2004). Moreover, the ability to draw inferences about individual policy-makers' ideologies from their votes on proposed legislation is severely limited by institutional constraints on the types of legislation that is actually subject to recorded votes.

3.1 Political Speeches Corpus

We gathered transcribed speeches given by candidates of the two main parties (Democrats and Republicans) during the 2008 and 2012 Presidential election seasons. Each election season is comprised of two stages: (i) the primary elections, where candidates seek the support of their respective parties to be nominated as the party's Presidential candidate, and (ii) the general elections where the parties' chosen candidates travel across the states to garner support from all citizens. Each candidate's speeches are partitioned into *epochs* for each election; e.g., those that occur before the candidate has secured enough pledged delegates to win the party nomination are "from the primary." Table 2 presents a breakdown of the candidates and speeches in our corpus.

3.2 Cue-Lag Representation

Our measurement model only considers ideological cues; other terms are treated as filler. We therefore transform each speech into a **cue-lag** representation.

The representation is a sequence of alternating cues (elements from the ideological lexicon $\mathcal{L}$) and integer "lags" (counts of non-cue terms falling between two cues). This will allow us to capture the intuition that a candidate may use longer lags between evocations of different ideologies, while nearby cues are likely to be from similar ideologies.

To map a speech into the cue-lag representation, we simply match all elements of $\mathcal{L}$ in the speech and replace sequences of other words by their lengths. When a trigram cue strictly includes a bigram cue, we take only the trigram. When two cues partially overlap, we treat them as consecutive cue terms and set the lag to 0. Figure 3 shows an example of our cue-lag representation.

Party	Pri'08	Gen'08	Pri'12	Gen'12
Democrats*	167	-	-	-
Republicans†	50	-	49	-
Obama (D)	78	81	-	99
McCain (R)	9	159	-	-
Romney (R)	8	‡(13)	19	19

*Democrats in our corpus are: Joe Biden, Hillary Clinton, John Edwards, and Bill Richardson in 2008 and Barack Obama in both 2008 and 2012.

†Republicans in our corpus are: Rudy Giuliani, Mike Huckabee, John McCain, and Fred Thompson in 2008, Michelle Bachmann, Herman Cain, Newt Gingrich, Jon Huntsman, Rick Perry, and Rick Santorum in 2012, and Ron Paul and Mitt Romney in both 2008 and 2012.

‡For Romney, we have 13 speeches which he gave in the period 2008-2011 (between his withdrawal from the 2008 elections and before the commencement of the 2012 elections). While these speeches are not technically part of the regular Presidential election campaign, they can be seen as his preparation towards the 2012 elections, which is particularly interesting as Romney has been accused of having inconsistent viewpoints.

Table 2: Breakdown of number of speeches in our political speech corpus by epoch. On average, 2,998 tokens, and 95 cue terms are found in each speech document.

3.3 CLIP: An Ideology HMM

The model we use to infer ideologies, **cue-lag ideological proportions** (CLIP), is a hidden Markov model. Each state corresponds to an ideology (Fig. 1) or BACKGROUND. The emission from a state consists of (i) a cue from $\mathcal{L}$ and (ii) a lag value. The high-level generative story for a single speech with T cue-lag pairs is as follows:

1. Parameters are drawn from conjugate priors (details in §3.3.3).
2. Let the initial state be the BACKGROUND state.
3. For $t \in \{1, 2, \ldots, T\}$:[6]
   (a) Transition to state S_t based on the transition distribution, discussed in §3.3.1. This transition is conditioned on the previous state S_{t-1} and the lag at timestep $t-1$, denoted by L_{t-1}.

[6]The length of the sequence is assumed to be exogenous, so that no stop state needs to be defined.

Original sentence	Just compare this President's record with **Ronald Reagan's** first term. **President Reagan** also faced an **economic crisis**. In fact, in 1982, the **unemployment rate** peaked at nearly 11 percent. But in the two years that followed, he delivered a true recovery **economic growth** and **job creation** were three times higher than in the Obama Economy.
Cue-lag representation	$\ldots \xrightarrow{6}$ ronald_reagan $\xrightarrow{2}$ presid_reagan $\xrightarrow{3}$ econom_crisi $\xrightarrow{5}$ unemploy_rate $\xrightarrow{17}$ econom_growth $\xrightarrow{1}$ job_creation $\xrightarrow{9} \ldots$

Figure 3: Example of the cue-lag representation.

(b) Emit cue term W_t from the lexicon $\mathcal{L}$ and lag L_t based on the emission distribution, discussed in §3.3.2.

We turn next to the transitions and emissions.

3.3.1 Ideology Topology and Transition Parameterization

CLIP assumes that each cue term uttered by a politician is generated from a hidden state corresponding to an ideology. The ideologies are organized into a tree based on their hierarchical relationships; see Fig. 1. In this study, the tree is fixed according to our domain knowledge of current American politics; in future work it might be enriched with greater detail or its structure learned automatically.

The ideology tree is used in defining the transition distribution in the HMM, but not to directly define the topology of the HMM. Importantly, each state may transition to any other state, but the transition *distribution* is defined using the graph, so that ideologies that are closer to each other will tend to be more likely to transition to each other. To transition between two states s_i and s_j, a walk must be taken in the tree from vertex s_i to vertex s_j. We emphasize that the walk corresponds to a *single* transition—the speaker does not emit anything from the states passed through along the path.

A simplified version of our transition distribution, for exposition, is given as follows:

$$p_{tree}(s_j \mid s_i; \boldsymbol{\zeta}, \boldsymbol{\theta}) = \left(\prod_{\langle u,v\rangle \in Path(s_i,s_j)} (1-\zeta_u)\theta_{u,v}\right) \zeta_{s_j}$$

$Path(s_i, s_j)$ refers to the sequence of edges in the tree along the unique path from s_i to s_j. Each of these edges $\langle u, v\rangle$ must be traversed, and the probability of doing so, conditioned on having already reached u, is $(1-\zeta_u)$—i.e., not stopping in u—times $\theta_{u,v}$—i.e., selecting vertex v from among those that share an edge with u. Eventually, s_j is reached, and the walk ends, incurring probability ζ_{s_j}.

In order to capture the intuition that a longer lag after a cue term should increase the entropy over the next ideology state, we introduce a **restart** probability, which is conditioned on the length of the most recent lag, ℓ. The probability of restarting the walk from the BACKGROUND state is a noisy-OR model with parameter ρ. This gives the transition distribution:

$$p(s_j \mid s_i, \ell; \boldsymbol{\zeta}, \boldsymbol{\theta}, \rho) = (1-\rho)^{\ell+1} p_{tree}(s_j \mid s_i; \boldsymbol{\zeta}, \boldsymbol{\theta}) + (1-(1-\rho)^{\ell+1}) p_{tree}(s_j \mid s_{\text{BACKGROUND}}; \boldsymbol{\zeta}, \boldsymbol{\theta})$$

Note that, if $\rho = 1$, there is no Markovian dependency between states (i.e., there is always a restart), so CLIP reverts to a mixture model.

This approach allows us to parameterize the full set of $|\mathcal{I}|^2$ transitions with $O(|\mathcal{I}|)$ parameters.[7] Since the graph is a tree and the walks are not allowed to backtrack, the only ambiguity in the transition is due to the restart probability; this distinguishes CLIP from other algorithms based on random walks (Brin and Page, 1998; Mihalcea, 2005; Toutanova et al., 2004; Collins-Thompson and Callan, 2005).

3.3.2 Emission Parameterization

Recall that, at time step t, CLIP emits a cue from the lexicon $\mathcal{L}$ and an integer-valued lag. For each state s, we let the probability of emitting cue w be denoted by $\psi_{s,w}$; $\boldsymbol{\psi}_s$ is a multinomial distribution over the entire lexicon $\mathcal{L}$. This allows our approach to handle ambiguous cues that can associate with more than one ideology, and also to associate a cue with a different ideology than our cue discovery method proposed, if the signal from the data is sufficiently strong. We assume each lag to be generated by a Poisson distribution with global parameter ν.

[7] More precisely, there are $|\mathcal{I}|$ edges (since there are $|\mathcal{I}|+1$ vertices including BACKGROUND), each with a $\boldsymbol{\theta}$-parameter in each direction. For a vertex with degree d, however, there are only $d-1$ degrees of freedom, so that there are $2|\mathcal{I}|-(|\mathcal{I}|+1) = |\mathcal{I}|-1$ degrees of freedom for $\boldsymbol{\theta}$. There are $|\mathcal{I}|$ $\boldsymbol{\zeta}$-parameters and a single ρ, for a total of $2|\mathcal{I}|$ degrees of freedom.

3.3.3 Inference and Learning

Above we described CLIP's transitions and emissions. Because our interest is in measuring proportions—and, as we will see, in *comparing* those proportions across speakers and campaign periods—we require a way to allow variation in parameters across different conditions. Specifically, we seek to measure differences in time spent in each ideology state. This can be captured by allowing each speaker to have a different $\boldsymbol{\theta}$ and $\boldsymbol{\zeta}$ in each stage of the campaign. On the other hand, we expect that a speaker draws from his ideological lexicon similarly across different epochs—there is a single $\boldsymbol{\psi}$ shared between different epochs.

In order to manage uncertainty about the parameters of CLIP, to incorporate prior beliefs based on our ideology-specific cue lexicons $\{\mathcal{L}(i)\}_i$, and to allow sharing of statistical strength across conditions, we adopt a Bayesian approach to inference. This will allow principled exploration of the posterior distribution over the proportions of interest.

We place a symmetric Dirichlet prior on the tree walk probabilities $\boldsymbol{\theta}$; its parameter is α. For the cue emission distribution associated with ideology i, $\boldsymbol{\psi}_{s_i}$, we use an *informed* Dirichlet prior with two different values, β_{cue} for cues in $\mathcal{L}(i)$, and a smaller β_{def} for those in $\mathcal{L} \setminus \mathcal{L}(i)$.[8]

Learning proceeds by collapsed Gibbs sampling for the hidden states and slice sampling (with vague priors) for the hyperparameters (α, $\boldsymbol{\beta}$, ρ, and $\boldsymbol{\zeta}$). Details of the sampler are given in the supplementary materials. At each Gibbs step, we resample the ideology state and restart indicator variable for every cue term in every speech.

We ran our Gibbs sampler for 75,000 iterations, discarding the first 25,000 iterations for burn-in, and collected samples at every 10 iterations. Further, we perform the slice sampling step at every 5,000 iterations. For each candidate, we collected 5,000 posterior samples which we use to infer his/her ideological proportions.

In order to determine the amount of time a candidate spends in each ideology, we denote the unit of time in terms of half the lag before and after each cue term, i.e., when a candidate draws a cue term from ideology i during timestep t, we say that he spends $\frac{1}{2}(L_{t-1} + L_t)$ amount of time in ideology i. Averaging over all the samples returned by our sampler and normalizing it by the length of the documents in each epoch, we obtain a candidate's expected ideological proportions within the epoch.

[8] This implies that a term can, in the posterior distribution, be associated with an ideology i of whose $\mathcal{L}(i)$ it was not a member. In fact, this occurred frequently in our runs of the model.

4 Pre-registered Hypotheses

The traditional way to evaluate a text analysis model in NLP is, of course, to evaluate its output against gold-standard judgements by humans. In the case of recent political speeches, however, we are doubtful that such judgments can be made objectively at a fine-grained level. While we are confident about gross categorization of books and magazines in our ideological corpus (§2.1), many of which are *overtly* marked by their ideological assocations, we believe that human estimates of ideological proportions, or even association of particular tokens with ideologies they may evoke, may be overly clouded by the variation in annotator ideology and domain expertise.

We therefore adopt a different method for evaluation. Before running our model, we identified a set of hypotheses, which we **pre-registered** as expectations. These are categorized into groups based on their strength and relevance to judging the validity of the model. *Strong* hypotheses are those that constitute the lowest bar for face validity; if violated, they suggest a flaw in the model. *Moderate* hypotheses are those that match the intuition of domain experts conducting the research, or extant theory. Violations suggest more examination is required, and may raise the possibility that further testing might be pursued to demonstrate the hypothesis is false. Our 13 principal hypotheses are enumerated in Table 3.

5 Evaluation

We compare the posterior proportions inferred by CLIP with several baselines:

- HMM: rather than §3.3.1, a fully connected, traditional transition matrix is used.
- MIX: a mixture model; at each timestep, we *always* restart ($\rho = 1$). This eliminates Markovian dependencies between ideologies at nearby timesteps, but still uses the ideology tree in defining the probabilities of each state through $\boldsymbol{\theta}$.

Hypotheses	CLIP	HMM	MIX	NORES
Sanity checks (strong):				
S1. Republican primary candidates should tend to draw more from RIGHT than from LEFT.	*12/12	10/13	13/13	12/13
S2. Democratic primary candidates should tend to draw more from LEFT than from RIGHT.	4/5	5/5	5/5	5/5
S3. In general elections, Democrats should draw more from the LEFT than the Republicans and vice versa for the RIGHT.	4/4	4/4	3/4	0/4
S total	20/21	19/22	21/22	17/22
Primary hypotheses (strong):				
P1. Romney, McCain and other Republicans should almost never draw from FAR LEFT, and extremely rarely from PROGRESSIVE.	29/32	*21/31	27/32	29/32
P2. Romney should draw more heavily from the RIGHT than Obama in both stages of the 2012 campaign.	2/2	2/2	1/2	1/2
Primary hypotheses (moderate):				
P3. Romney should draw more heavily on words from the LIBERTARIAN, POPULIST, RELIGIOUS RIGHT, and FAR RIGHT in the primary compared to the general election. In the general election, Romney should draw more heavily on CENTER, CENTER–RIGHT and LEFT vocabularies.	2/2	2/2	0/2	2/2
P4. Obama should draw more heavily on words from the PROGRESSIVE in the 2008 primary than in the 2008 general election.	0/1	0/1	0/1	1/1
P5. In the 2008 general election, Obama should draw more heavily on the CENTER, CENTER–LEFT, and RIGHT vocabularies than in the 2008 primary.	1/1	1/1	1/1	1/1
P6. In the 2012 general election, Obama should sample more from the LEFT than from the RIGHT, and should sample more from the LEFT vocabularies than Romney.	2/2	2/2	0/2	0/2
P7. McCain should draw more heavily from the FAR RIGHT, POPULIST, and LIBERTARIAN in the 2008 primary than in the 2008 general election.	0/1	1/1	1/1	1/1
P8. In the general 2008, McCain should draw more heavily from the CENTER, CENTER–RIGHT, and LEFT vocabularies than in the 2008 primary.	1/1	1/1	1/1	1/1
P9. McCain should draw more heavily from the RIGHT than Obama in both stages of the campaign.	2/2	2/2	2/2	1/2
P10.Obama and other Democrats should very rarely draw from FAR RIGHT.	6/7	5/7	7/7	4/7
P total	45/51	37/50	40/51	41/51

Table 3: Pre-registered hypotheses used to validate the measurement model; number of statements evaluated correctly by different models. *Some differences were not significant at $p = 0.05$ and are not included in the results.

- NORES, where we *never* restart ($\rho = 0$). This strengthens the Markovian dependencies.

In MIX, there are no temporal effects between cue terms, although the structure of our ideology tree encourages the speaker to draw from coarse-grained ideologies over fine-grained ideologies. On the other hand, the strong Markovian dependency between states in NORES would encourage the model to stay local within the ideology tree. In our experiments, we will see how that the ideology tree and the random treatment of restarting both contribute to our model's inferences.

Table 3 presents a summary of which hypotheses the models' inferences are in accordance with. CLIP is not consistently outperformed by any of the competing baselines.

Sanity checks (S1–3) CLIP correctly identifies sixteen LEFT/RIGHT alignments of primary candidates (S1, S2), but is unable to determine one candidate's orientation; it finds Jon Huntsman to spend roughly equal proportions of speech-time drawing on LEFT and RIGHT cue terms. Interestingly, Huntsman, who had served as U.S. Ambassador to China under Obama, was considered the one moderate in the 2012 Republican field. MIX correctly identifies all thirteen Republicans, while NORES places McCain from the 2008 primaries as mostly LEFT-leaning and HMM misses three of thirteen, including Perry and Gingrich, who might be deeply

disturbed to find that they are misclassified as LEFT-leaning. As for the Democratic primary candidates (S2), CLIP's one questionable finding is that John Edwards spoke slightly more from the RIGHT than the LEFT. For the general elections (S3), CLIP and HMM correctly identify the relative amount of time spent in LEFT/RIGHT between Obama and his Republican competitors. NORES had the most trouble, missing all four. CLIP finds Obama spending slightly more time on the RIGHT than on the LEFT in the 2008 general elections but nevertheless, Obama is still found to spend more time engaging in LEFT-speak than McCain.

Name interference When we looked at the cue terms actually used in the speeches, we found one systematic issue: the inclusion of candidates' names as cue terms. Terms mentioning John McCain are associated with the RIGHT, so that Obama's mentions of his opponent are taken as evidence for rightward positioning; in total, mentions of McCain contributed 4% absolute to Obama's RIGHT ideological proportion. Similarly, *barack_obama* and *presid_obama* are LEFT cues (though *senat_obama* is a RIGHT cue). In future work, we believe filtering candidate names in the first stage will be beneficial.

Strong hypotheses P1 and P2 CLIP and the variants making use of the ideology tree were in agreement on most of the strong primary hypotheses. Most of these involved our expectation that the Republican candidates would rarely draw on FAR LEFT and PROGRESSIVE LEFT. Our qualitative hypotheses were not specific about how to quantify "rare" or "almost never." We chose to find a result inconsistent with a P1 hypothesis any time a Republican had proportions greater than 5% for either ideology. The notable deviations for CLIP were Fred Thompson (13% from the PROGRESSIVE LEFT during the 2008 primary) and Mitt Romney (12% from the PROGRESSIVE LEFT between the 2008 and 2012 elections, 13% from the FAR LEFT during the 2012 general election). This model did no worse than other variants here and much better than one: HMM had 10 inconsistencies out of 32 opportunities, suggesting the importance of the ideology tree.

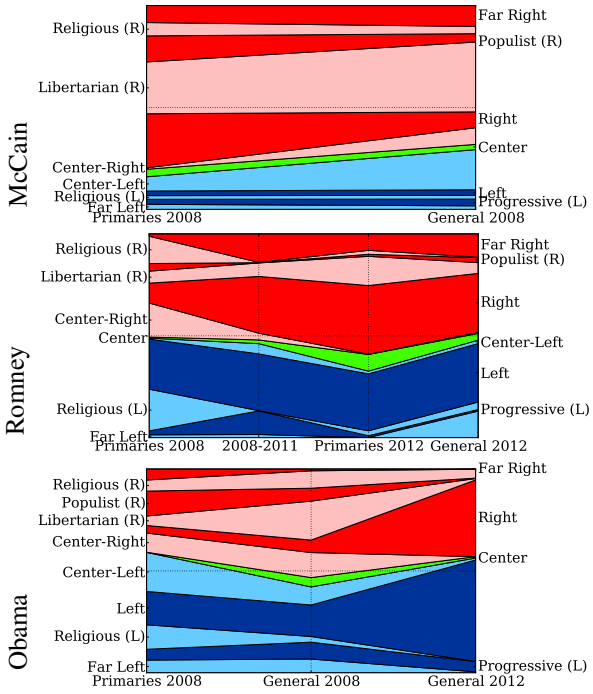

Figure 4: Proportion of time spent in each ideology by McCain, Romney, and Obama during the 2008 and 2012 Presidential election seasons.

"Etch-a-Sketch" hypotheses Hypotheses P3, P4, P5, P7, and P8 are all concerned with differences between the primary and general elections: successful primary candidates are expected to "move to the center." A visualization of CLIP's proportions for McCain, Romney, and Obama is shown in Figure 4, with their speeches grouped together by different epochs. The model is in agreement with most of these hypotheses. It did not confirm P4—Obama appears to CLIP to be more PROGRESSIVE in the 2008 general election than in the primary, though the difference is small (3%) and may be within the margin of error. Likewise, in P7, the difference between McCain drawing from FAR RIGHT, POPULIST and LIBERTARIAN between the 2008 primary and general elections is only 2% and highly uncertain, with a 95% credible interval of 44–50% during the primary (vs. 47–50% in the general election).

Fine-grained ideologies Fine-grained ideologies are expected to account for smaller proportions, so that making predictions about them is quite difficult. This is especially true for primary elections, where a broader palette of ideologies is expected to be drawn from, but we have fewer speeches from each candi-

date. CLIP's inconsistency with P10, for example, comes from assigning 5.4% of Obama's 2008 primary cues to FAR RIGHT.

CLIP's inferences on the corpus of political speeches can be browsed at http://www.ark.cs.cmu.edu/CLIP. We emphasize that CLIP and its variants are intended to quantify the ideological content candidates express in *speeches*, not necessarily their *beliefs* (which may not be perfectly reflected in their words), or even how they are described by pundits and analysts (who draw on far more information than is expressed in speeches). CLIP's deviations from the hypotheses are suggestive of potential improvements to cue extraction (§2), but also of incorrect hypotheses. We expect future research to explore a richer set of linguistic cues and attributes beyond ideology (e.g., topics and framing on various issues). We plan to use CLIP as a text analysis method to support substantive inquiry in political science, such as following trends in expressed ideology over time.

6 Related Work

As early as the 1960s, there has been research on modeling ideological beliefs using automated systems (Abelson and Carroll, 1965; Carbonell, 1978; Sack, 1994). These early works model ideology at a sophisticated level, involving the actors, actions and goals; they require manually constructed knowledge bases. Poole and Rosenthal (1985) used congressional roll call data to demonstrate the ideological divide in Congress, and provided a methodology for measuring ideological positions. Gerrish and Blei (2011; 2012) augmented the methodology with text from congressional bills using probabilistic models to uncover lawmakers' positions on specific political issues, putting them on a left-right spectrum, while Thomas et al. (2006) made use of floor debate speeches to predict votes. Likewise, taking advantage of the proliferation of text today, numerous techniques have been developed to identify topics and perspectives in the media (Gentzkow and Shapiro, 2005; Lin et al., 2008; Fortuna et al., 2009; Gentzkow and Shapiro, 2010); determine the political leanings of a document or author (Laver et al., 2003; Efron, 2004; Mullen and Malouf, 2006; Fader et al., 2007); or recognize stances in debates (Somasundaran and Wiebe, 2009; Anand et al., 2011). Going beyong lexical indicators, Greene and Resnik (2009) investigated syntactic features to identify perspectives or implicit sentiment.

7 Conclusions

We introduced CLIP, a domain-informed, Bayesian model of ideological proportions in political language. We showed how ideological cues could be discovered from a lightly labeled corpus of ideological writings, then incorporated into CLIP. The resulting inferences are largely consistent with a set of preregistered hypotheses about candidates in the 2008 and 2012 Presidential elections.

Learning to Freestyle: Hip Hop Challenge-Response Induction via Transduction Rule Segmentation

Dekai Wu Karteek Addanki Markus Saers Meriem Beloucif

Abstract

We present a novel model, Freestyle, that learns to improvise rhyming and fluent responses upon being challenged with a line of hip hop lyrics, by combining both bottom-up token based rule induction and top-down rule segmentation strategies to learn a stochastic transduction grammar that simultaneously learns both phrasing and rhyming associations. In this attack on the woefully under-explored natural language genre of music lyrics, we exploit a strictly unsupervised transduction grammar induction approach. Our task is particularly ambitious in that no use of any *a priori* linguistic or phonetic information is allowed, even though the domain of hip hop lyrics is particularly noisy and unstructured. We evaluate the performance of the learned model against a model learned only using the more conventional bottom-up token based rule induction, and demonstrate the superiority of our combined token based and rule segmentation induction method toward generating higher quality improvised responses, measured on fluency and rhyming criteria as judged by human evaluators. To highlight some of the inherent challenges in adapting other algorithms to this novel task, we also compare the quality of the responses generated by our model to those generated by an out-of-the-box phrase based SMT system. We tackle the challenge of selecting appropriate training data for our task via a dedicated rhyme scheme detection module, which is also acquired via unsupervised learning and report improved quality of the generated responses. Finally, we report results with Maghrebi French hip hop lyrics indicating that our model performs surprisingly well with no special adaptation to other languages.

1 Introduction

The genre of lyrics in music has been severely understudied from the perspective of computational linguistics despite being a form of language that has perhaps had the most impact across almost all human cultures. With the motivation of spurring further research in this genre, we apply stochastic transduction grammar induction algorithms to address some of the modeling issues in song lyrics. An ideal starting point for this investigation is hip hop, a genre that emphasizes rapping, spoken or chanted rhyming lyrics against strong beats or simple melodies. Hip hop lyrics, in contrast to poetry and other genres of music, present a significant number of challenges for learning as it lacks well-defined structure in terms of rhyme scheme, meter, or overall meaning making it an interesting genre to bring to light some of the less studied modeling issues.

The domain of hip hop lyrics is particularly unstructured when compared to classical poetry, a domain on which statistical methods have been applied in the past. Hip hop lyrics are unstructured in the sense that a very high degree of variation is permitted in the meter of the lyrics, and large amounts of colloquial vocabulary and slang from the subculture are employed. The variance in the permitted meter makes it hard to make any assumptions about the stress patterns of verses in order to identify the rhyming words used when generating output. The broad range of unorthodox vocabulary used in hip hop make it difficult to use off-the-shelf NLP tools for doing phonological and/or morphological analysis. These problems are further exacerbated by differences in intonation of the same word and lack of robust transcription (Liberman, 2010).

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 102–112,
Seattle, Washington, USA, 18-21 October 2013.

We argue that stochastic transduction grammars,[1] given their success in the area of machine translation and efficient unsupervised learning algorithms, are ideal for capturing the structural relationship between lyrics. Hence, our FREESTYLE system models the problem of improvising a rhyming response given any hip hop lyric challenge as transducing a challenge line into a rhyming response. We use a stochastic transduction grammar induced in a completely unsupervised fashion using a combination of token based rule induction and segmenting (Saers *et al.*, 2013) as the underlying model to fully-automatically learn a challenge-response system and compare its performance against a simpler token based transduction grammar model. Both our models are completely unsupervised and use no prior phonetic or linguistic knowledge whatsoever despite the highly unstructured and noisy domain.

We believe that the challenge-response system based on an interpolated combination of token based rule induction and rule segmenting transduction grammars will generate more fluent and rhyming responses compared to one based on token based transduction grammars models. This is based on the observation that token based transduction grammars suffer from a lack of fluency; a consequence of the degree of expressivity they permit. Therefore, as a principal part of our investigation we compare the quality of responses generated using a combination of token based rule induction and top-down rule segmenting transduction grammars to those generated by pure token based transduction grammars.

We also hypothesize that in order to generate fluent and rhyming responses, it is not sufficient to train the transduction grammars on all adjacent lines of a hip hop verse. Therefore, we propose a data selection scheme using a rhyme scheme detector acquired through unsupervised learning to generate the training data for the challenge-response systems. The rhyme scheme detector segments each verse of a hip hop song into stanzas and identifies the lines in each stanza that rhyme with each other which are then added as training instances. We demonstrate the superiority of our training data selection method by comparing the quality of the responses generated by the models trained on data selected with and without using the rhyme scheme detector.

Unlike conventional spoken and written language, disfluencies and backing vocals[2] occur very frequently in the domain of hip hop lyrics which affect the performance of NLP models designed for processing well-formed sentences. We propose two strategies to mitigate the effect of disfluencies on our model performance and compare their efficacy using human evaluations. Finally, in order to illustrate the challenges faced by other NLP algorithms, we contrast the performance of our model against a conventional, widely used phrase-based SMT model.

A brief terminological note: "stanza" and "verse" are frequently confused and sometimes conflated. Worse yet, their usage for song lyrics is often contradictory to that for poetry. To avoid ambiguity we consistently follow these technical definitions for segments in decreasing size of granularity:

verse a large unit of a song's lyrics. A song typically contains several verses interspersed with choruses. In the present work, we do not differentiate choruses from verses. In song lyrics, a verse is most commonly represented as a separate paragraph.

stanza a segment within a verse which has a meter and rhyme scheme. Stanzas often consist of 2, 3, or 4 lines, but stanzas of more lines are also common. Particularly in hip hop, a single verse often contains many stanzas with different rhyme schemes and meters.

line a segment within a stanza consisting of a single line. In poetry, strictly speaking this would be called a "verse", which however conflicts with the conventional use of "verse" in song lyrics.

In Section 2, we discuss some of the previous work that applies statistical NLP methods to less conventional domains and problems. We describe our experimental conditions in Section 3. We compare the performance of token and segment based transduction grammar models in Section 4. We compare our data selection schemes and disfluency handling strategies in Sections 5 and 6. Finally, in

[1] Also known in SMT as "synchronous grammars".

[2] Particularly the repetitive chants, exclamations, and interjections in hip hop "hype man" style backing vocals.

Section 7 we describe some preliminary results obtained using our approach on improvising hip hop responses in French and conclude in Section 8.

2 Related work

Although a few attempts have been made to apply statistical NLP learning methods to unconventional domains, Freestyle is among the first to tackle the genre of hip hop lyrics (Addanki and Wu, 2013; Wu *et al.*, 2013a,b). Our preliminary work suggested the need for further research to identify models that capture the correct generalizations to be able to generate fluent and rhyming responses. As a step towards this direction, we contrast the performance of interpolated bottom-up token based rule induction and top-down segmenting transduction grammar models and token based transduction grammar models. We briefly describe some of the past work in statistical NLP on unconventional domains below.

Most of the past work either uses some form of prior linguistic knowledge or enforces harsher constraints such as set number of words in a line, or a set meter which are warranted by more structured domains such as poetry. However, in hip hop lyrics it is hard to make any linguistic or structural assumptions. For example, words such as sho, flo, holla which frequently appear in the lyrics are not part of any standard lexicon and hip hop does not require a set number of syllables in a line, unlike poems. Also, surprising and unlikely rhymes in hip hop are frequently achieved via intonation and assonance, making it hard to apply prior phonological constraints.

A phrase based SMT system was trained to "translate" the first line of a Chinese couplet or *duilian* into the second by Jiang and Zhou (2008). The most suitable next line was selected by applying linguistic constraints to the n best output of the SMT system. However in contrast to Chinese couplets, which adhere to strict rules requiring, for example, an identical number of characters in each line and one-to-one correspondence in their metrical length, the domain of hip hop lyrics is far more unstructured and there exists no clear constraint that would ensure fluent and rhyming responses to hip hop challenge lyrics. Barbieri *et al.* (2012) use controlled Markov processes to semi-automatically generate lyrics that satisfy the structural constraints of rhyme and meter. Tamil lyrics were automatically generated given a melody using conditional random fields by A. *et al.* (2009). The lyrics were represented as a sequence of labels using the *KNM* system where *K*, *N* and *M* represented the long vowels, short vowels and consonants respectively.

Genzel *et al.* (2010) used SMT in conjunction with stress patterns and rhymes found in a pronunciation dictionary to produce translations of poems. Although many constraints were applied in translating full verses of poems, it was challenging to satisfy all the constraints. Stress patterns were assigned to words given the meter of a line in Shakespeare's sonnets by Greene *et al.* (2010), which were then combined with a language model to generate poems. Sonderegger (2011) attempted to infer the pronunciation of words in old English by identifying the rhyming patterns using graph theory. However, their heuristic of clustering words with similar IPA endings resulted in large clusters of false positives such as bloom and numb. A language-independent generative model for stanzas in poetry was proposed by Reddy and Knight (2011) via which they could discover rhyme schemes in French and English poetry.

3 Experimental conditions

Before introducing our Freestyle models, we first detail our experimental assumptions and the evaluation scheme under which the responses generated by different models are compared against one another. We describe our training data as well as a phrase-based SMT (PBSMT) contrastive baseline. We also define the evaluation scheme used to compare the responses of different systems on criteria of fluency and rhyming.

3.1 Training data

We used freely available user generated hip hop lyrics on the Internet to provide training data for our experiments. We collected approximately 52,000 English hip hop song lyrics amounting to approximately 800Mb of raw HTML content. The data was cleaned by stripping HTML tags, metadata and normalized for special characters and case differences. The processed corpus contained 22 million tokens with 260,000 verses and 2.7 million lines of hip hop lyrics. As human evaluation using expert hip hop

listeners is expensive, a small subset of 85 lines was chosen as the test set to provide challenges for comparing the quality of responses generated by different systems.

3.2 Evaluation scheme

The performance of various FREESTYLE versions was evaluated on the task of generating a improvised fluent and rhyming response given a single line of a hip hop verse as a challenge. The output of all the systems on the test set was given to three independent frequent hip hop listeners for manual evaluation. They were asked to evaluate the system outputs according to fluency and the degree of rhyming. They were free to choose the tune to make the lyrics rhyme as the beats of the song were not used in the training data. Each evaluator was asked to score the response of each system on the criterion of fluency and rhyming as being *good*, *acceptable* or *bad*.

3.3 Phrase-based SMT baseline

In order to evaluate the performance of an out-of-the-box phrase-based SMT (PBSMT) system toward this novel task of generating rhyming and fluent responses, a standard Moses baseline (Koehn *et al.*, 2007) was also trained in order to compare its performance with our transduction grammar induction model. A 4-gram language model which was trained on the entire training corpus using SRILM (Stolcke, 2002) was used to generate responses in conjunction with the phrase-based translation model. As no automatic quality evaluation metrics exist for hip hop responses analogous to BLEU for SMT, the model weights cannot be tuned in conventional ways such as MERT (Och, 2003). Instead, a slightly higher than typical language model weight was empirically chosen using a small development set to produce fluent outputs.

4 Interpolated segmenting model vs. token based model

We compare the performance of transduction grammars induced via interpolated token based and rule segmenting (ISTG) versus token based transduction grammars (TG) on the task of generating a rhyming and fluent response to hip hop challenges. We use the framework of stochastic transduction grammars, specifically bracketing ITGs (inversion transduction grammars) (Wu, 1997), as our translation model for "transducing" any given challenge into a rhyming and fluent response. Our choice is motivated by the significant amount of empirical evidence for the representational capacity of transduction grammars across a spectrum of natural language tasks such as textual entailment (Wu, 2006), mining parallel sentences (Wu and Fung, 2005) and machine translation (Zens and Ney, 2003). Further, existence of efficient learning algorithms (Saers *et al.*, 2012; Saers and Wu, 2011) that make no language specific assumptions, make inversion transduction grammars a suitable framework for our modeling needs. Examples of lexical transduction rules can be seen in Tables 3 and 5. In addition, the grammar also includes structural transduction rules for the straight case $A \rightarrow [A\ A]$ and also the inverted case $A \rightarrow \langle A\ A \rangle$.

4.1 Token based vs. segmental ITGs

The degenerate case of ITGs are token based ITGs wherein each translation rule contains at most one token in input and output languages. Efficient induction algorithms with polynomial run time exist for token based ITGs and the expressivity they permit has been empirically determined to capture most of the word alignments that occur across natural languages. The parameters of the token based ITGs can be estimated using expectation maximization through an efficient dynamic programming algorithm in conjunction with beam pruning (Saers and Wu, 2011).

In contrast to token based ITGs, each rule in a segmental ITG grammar can contain more than one token in both input and output languages. In machine translation applications, segmental models produce translations that are more fluent as they can capture lexical knowledge at a phrasal level. However, only a handful of purely unsupervised algorithms exist for learning segmental ITGs under matched training and testing assumptions. Most other approaches in SMT use a variety of ad hoc heuristics for extracting segments from token alignments, justified purely by short term improvements in automatic MT evaluation metrics such as BLEU (Papineni *et al.*, 2002) which cannot be transferred to our current task. Instead, we use a completely unsupervised learning algorithm for segmental ITGs that stays strictly within the transduction grammar optimization framework for both training and testing as proposed in Saers

et al. (2013).

Saers *et al.* (2013) induce a phrasal inversion transduction grammar via interpolating the bottom-up rule chunking approach proposed in Saers *et al.* (2012) with a top-down rule segmenting approach driven by a minimum description length objective function (Solomonoff, 1959; Rissanen, 1983) that trades off the maximum likelihood against model size. Saers *et al.* (2013) report improvements in BLEU score (Papineni *et al.*, 2002) on their translation task. In our current approach instead of using a bottom-up rule chunking approach we use a simpler token based grammar instead. Given two grammars (G_a and G_b) and an interpolation parameter α the probability function of the interpolated grammar is given by:

$$p_{a+b}(r) = \alpha p_a(r) + (1-\alpha) p_b(r)$$

for all rules r in the union of the two rule sets, and where p_{a+b} is the rule probability function of the combined grammar and p_a and p_b are the rule probability functions of G_a and G_b respectively. The pseudocode for the top-down rule segmenting algorithm is shown in 1. The algorithm uses the methods `collect_biaffixes`, `eval_dl`, `sort_by_delta` and `make_segmentations`. These methods collect all the biaffixes in an ITG, evaluate the difference in description length, sort candidates by these differences, and commit to a given set of candidates, respectively. The suitable interpolation parameter is chosen empirically based on the responses generated on a small development set.

We compare the performance of inducing a token based ITG versus inducing a segmental ITG using interpolated bottom-up token based rule induction and top-down rule segmentation. To highlight some of the inherent challenges in adapting other algorithms to this novel task, we also compare the quality of the responses generated by our model to those generated by an off-the-shelf phrase based SMT system.

Algorithm 1 Iterative rule segmenting learning driven by minimum description length.

until δ_sum ≥ 0
return Φ
```

4.2 Decoding heuristics

We use our in-house ITG decoder implemented according to the algorithm mentioned in Wu (1996) for the generating responses to challenges by decoding with the trained transduction grammars. The decoder uses a CKY-style parsing algorithm (Cocke, 1969) with cube pruning (Chiang, 2007). The decoder builds an efficient hypergraph structure which is then scored using the induced grammar. The trained transduction grammar model was decoded using the 4-gram language model and the model weights determined as described in 3.3.

In our decoding algorithm, we restrict the reordering to only be monotonic as we want to produce output that follows the same rhyming order of the challenge. Interleaved rhyming order is harder to evaluate without the larger context of the song and we do not address that problem in our current model. We also penalize singleton rules to produce responses of similar length as successive lines in a stanza are typically of similar length. Finally, we add a penalty to *reflexive* translation rules that map the same surface form to itself such as $A \rightarrow$ yo/yo. We obtain these rules with a high probability due to the presence of sentence pairs where both the input and output are identical strings as many stanzas in our data contain repeated chorus lines.

4.3 Results: Rule segmentation improves responses

Results in Table 1 indicate that the ISTG outperforms the TG model towards the task of generating fluent and rhyming responses. On the criterion of fluency,

Table 1: Percentage of ≥*good* and ≥*acceptable* (i.e., either good or acceptable) responses on fluency and rhyming criteria. PBSMT, TG and ISTG models trained using corpus generated from all adjacent lines in a verse. PBSMT+RS, TG+RS, ISTG+RS are models trained on rhyme scheme based corpus selection strategy. Disfluency correction strategy was used in all cases.

model	*fluency (≥good)*	*fluency (≥acceptable)*	*rhyming (≥good)*	*rhyming (≥acceptable)*
PBSMT	3.14%	4.70%	1.57%	4.31%
TG	21.18%	54.51%	23.53%	39.21%
ISTG	**26.27%**	**57.64%**	**27.45%**	**48.23%**
PBSMT+RS	30.59%	43.53%	1.96%	9.02%
TG+RS	**34.12%**	60.39%	20.00%	42.74%
ISTG+RS	30.98%	**61.18%**	**30.98%**	**53.72%**

Table 2: Transduction rules learned by ISTG model.

transduction grammar rule	*log prob.*
$A \rightarrow$ long/wrong	-11.6747
$A \rightarrow$ rhyme/time	-11.6604
$A \rightarrow$ felt bad/couldn't see what i really had	-11.3196
$A \rightarrow$ matter what you say/leaving anyway	-11.8792
$A \rightarrow$ arhythamatic/this rhythm is sick	-12.3492

the ISTG model produces a significantly higher fraction of sentences rated *good* (26.27% vs. 21.18%) and ≥*acceptable* (57.64% vs. 54.51%). Higher fraction of responses generated by the ISTG model are rated as *good* (27.45% vs. 23.53%) and ≥*acceptable* (57.64% vs. 54.51%) compared to the TG model. Both TG and ISTG model perform significantly better than the PBSMT baseline. Upon inspecting the learned rules, we noticed that the ISTG models capture rhyming correspondences both at the token and segmental levels. Table 2 shows some examples of the transduction rules learned by ISTG grammar trained using rhyme scheme detection.

5 Data selection via rhyme scheme detection vs. adjacent lines

We now compare two data selection approaches for generating the training data for transduction grammar induction via a rhyme scheme detection module and choosing all adjacent lines in a verse. We also briefly describe the training of the rhyme scheme detection module and determine the efficacy of our data selection scheme by training the ISTG model, TG model and the PBSMT baseline on training data generated with and without employing the rhyme scheme detection module. As the rule segmenting approach was intended to improve the fluency as opposed to the rhyming nature of the responses, we only train the rule segmenting model on the randomly chosen subset of all adjacent lines in the verse. Further, adding adjacent lines as the training data to the segmenting model maintains the context of the responses generated thereby producing higher quality responses. The segmental transduction grammar model was combined with the token based transduction grammar model trained on data selected with and without using rhyme scheme detection model.

5.1 Rhyme scheme detection

Although our approach adapts a transduction grammar induction model toward the problem of generating fluent and rhyming hip hop responses, it would be undesirable to train the model directly on all the successive lines of the verses—as done by Jiang and Zhou (2008)—due to variance in hip hop rhyming patterns. For example, adding successive lines of a stanza which follows **ABAB** rhyme scheme as training instances to the transduction grammar causes incorrect rhyme correspondences to be learned. The fact that a verse (which is usually represented as a separate paragraph) may contain multiple stanzas of varying length and rhyme schemes worsens this problem. Adding all possible pairs of lines in a verse as training examples not only introduces a lot of noise but also explodes the size of the training data due to the large size of the verse.

We employ a rhyme scheme detection model (Addanki and Wu, 2013) in order to select training instances that are likely to rhyme. Lines belonging to

the same stanza and marked as rhyming according to the rhyme scheme detection model are added to the training corpus. We believe that this data selection scheme will improve the rhyming associations learned during the transduction grammar induction thereby biasing the model towards producing fluent and rhyming output.

The rhyme scheme detection model proposes a HMM based generative model for a verse of hip hop lyrics similar to Reddy and Knight (2011). However, owing to the lack of well-defined verse structure in hip hop, a number of hidden states corresponding to stanzas of varying length are used to automatically obtain a *soft-segmentation* of the verse. Each state in the HMM corresponds to a stanza with a particular rhyme scheme such as **AA**, **ABAB**, **AAAA** while the emissions correspond to the final words in the stanza. We restrict the maximum length of a stanza to be four to maintain a tractable number of states and further only use states to represent stanzas whose rhyme schemes could not be partitioned into smaller schemes without losing a rhyme correspondence.

The parameters of the HMM are estimated using the EM algorithm (Devijer, 1985) using the corpus generated by taking the final word of each line in the hip hop lyrics. The lines from each stanza that rhyme with each other according to the Viterbi parse using the trained model are added as training instances for transduction grammar induction. As the source and target languages are identical, each selected pair generates two training instances: a challenge-response and a response-challenge pair.

The training data for the rhyme scheme detector was obtained by extracting the end-of-line tokens from each verse. However, upon data inspection we noticed that shorter lines in hip hop stanzas are typically joined with a comma and represented as a single line of text and hence all the tokens before the commas were also added to the training corpus. We obtained a corpus containing 4.2 million tokens corresponding to potential rhyming candidates comprising of around 153,000 unique token types.

We evaluated the performance of our rhyme scheme detector on the task of correctly labeling a given verse with rhyme schemes. As our model is completely unsupervised, we chose a random sample of 75 verses from our training data as our test set. Two native English speakers who were frequent hip hop listeners were asked to partition the verse into stanzas and assign them with a gold standard rhyme scheme. Precision and recall were aggregated for the Viterbi parse of each verse against this gold standard and f-score was calculated. The rhyme scheme detection module employed in our data selection obtained a precision of 35.81% and a recall of 57.25%, giving an f-score of 44.06%.

5.2 Training data selection via rhyme scheme detection

We obtained around 600,000 training instances upon extracting a training corpus using rhyme scheme detection module as described in Section 5.1. We added those lines that were adjacent *and* labeled as rhyming by the rhyme scheme detector as training instances resulting in a training corpus of size 200,000.

5.3 Training data selection via adjacent lines

Considering all adjacent lines in a verse resulted in a corpus with over 5 million training instances. In order to ensure fair comparison of models trained on data selected using rhyme scheme detection, we randomly chose 200,000 training instances from the generated corpus. The training corpus thus generated shared around 15% of training instances with the corpus generated through our proposed data selection scheme.

5.4 Results: Rhyme scheme detection helps

Results in Table 1 indicate that using the rhyme scheme detector for training data selection helps produce significantly more fluent responses compared to using adjacent lines. A possible explanation for this could be that adding all adjacent lines as training instances introduces a lot of noise into the model which hurts the fluency of the responses generated. Also, the cumulative fraction of sentences that were labeled *good* or ≥*acceptable* on the criterion of rhyming is larger when rhyme scheme detection was used to generate the training data (although the TG model trained on the corpus generated using adjacent lines produces a higher percentage of rhyming responses that were rated *good*). Given the significantly higher rate of response fluency when using rhyme scheme detection, we argue that using rhyme scheme detector for data selection is beneficial.

Table 3: English hip hop challenge-response examples.

challenge	man i **die** to **see** em all thun i just don't **care**
TG+RS	in the **sky** and **me** the in polla and the you **there**

TG+RS	and the you this **alone** i i gotta **on**
TG	and i you my on the a home we
PBSMT+RS	cause you and your friends aint nothing but

It is also interesting to note from Table 1 that ISTG+RS performs better than TG+RS indicating that transduction grammar induced via interpolating token based grammar and rule segmenting produces better responses than token based transduction grammar on both data selection schemes. Although the average fraction of responses rated *good* on fluency are slightly lower for ISTG+RS compared to TG+RS (34.12% vs. 30.98%), the fraction of responses rated ≥*acceptable* are higher (61.18% vs. 57.64%). It is important to note that the fraction of sentences rated *good* and ≥*acceptable* on rhyming are much larger for ISTG+RS model. Although the fluency of the responses generated by PBSMT+RS drastically improves compared to PBSMT it still lags behind the TG+RS and ISTG+RS models on both fluency and rhyming. The results in Table 1 confirm our hypothesis that off-the-shelf SMT systems are not guaranteed to be effective on our novel task.

5.5 Challenge-response examples

Table 3 shows some of the challenges and the corresponding responses of PBSMT+RS, TG+RS and TG model. While PBSMT+RS and TG+RS models generate responses reflecting a high degree of fluency, the output of the TG contains a lot of articles. It is interesting to note that TG+RS produces responses comparable to PBSMT+RS despite being a token based transduction grammar. However, PBSMT tends to produce responses that are too similar to the challenge. Moreover, TG models produce responses that indeed rhyme better (shown in boldface). In fact, TG tries to rhyme words not only at the end but also in middle of the lines, as our transduction grammar model captures structural associations more effectively than the phrase-based model.

6 Disfluency handling via disfluency correction and filtering

In this section, we compare the effect of two disfluency mitigating strategies on the quality of the responses generated by the PBSMT baseline and token based transduction grammar model with and without using rhyme scheme detection.

6.1 Correction vs. filtering

Error analysis of our initial runs showed a disturbingly high proportion of responses generated by our system that contained disfluencies with successive repetitions of words such as the and I. Upon inspection of data we noticed that the training lyrics actually did contain such disfluencies and backing vocal lines, amounting to 10% of our training data. We therefore compared two alternative strategies to tackle this problem. The first strategy involved filtering out all lines from our training corpus which contained such disfluencies. In the second strategy, we implemented a disfluency detection and correction algorithm (for example, the the the, which frequently occurred in the training corpus, was corrected to simply the). The PBSMT baseline and the TG model were trained on both the filtered and corrected versions of the training corpus and the quality of the responses were compared.

6.2 Results: Disfluency correction helps

The results in Table 4 indicate that the disfluency correction strategy outperforms the filtering strategy for both TG and TG+RS models. For the model TG+RS, disfluency correction generated 34.12% *good* responses in terms of fluency, while the filtering strategy produced only 28.63% *good* responses. Similarly for the model TG, disfluency correction produced 21.8% of responses with *good* fluency and the filtering strategy produced only 17.25%. Disfluency correction strategy produces higher fraction of responses with ≥*acceptable* fluency compared to the filtering strategy for both TG and TG+RS models. This result is not surprising, as harshly pruning

Table 4: Effect of the disfluency correction strategies on fluency of the responses generated for the TG induction models vs PBSMT baselines using both rhyme scheme detection and adjacent lines as the corpus selection method.

model+disfluency strat.	fluency (good)	fluency (≥acceptable)	rhyming (good)	rhyming (≥acceptable)
PBSMT+filtering	**4.3%**	**13.72%**	3.53%	7.06%
PBSMT+correction	3.14%	4.70%	1.57%	4.31%
PBSMT+RS+filtering	**31.76%**	**43.91%**	12.15%	21.17%
PBSMT+RS+correction	30.59%	43.53%	1.96%	9.02%
TG+filtering	17.25%	46.27%	18.04%	33.33%
TG+correction	**21.18%**	**54.51%**	23.53%	39.21%
TG+RS+filtering	28.63%	56.86%	14.90%	34.51%
TG+RS+correction	**34.12%**	**60.39%**	20.00%	42.74%

the training corpus causes useful word association information necessary for rhyming to be lost. Surprisingly, for both PBSMT and PBSMT+RS models, the disfluency correction has a negative effect on the fluency level of the response but still falls behind TG and TG+RS models. As disfluency correction yields more fluent responses for TG and TG+RS models, the results for ISTG and ISTG+RS models in Table 1 were obtained using disfluency correction strategy.

7 Maghrebi French hip hop

We have begun to apply Freestyle to rap in languages other than English, taking advantage of the language independence and linguistics-light approach of our unsupervised transduction grammar induction methods. With no special adaption our transduction grammar based model performs surprisingly well, even with significantly smaller training data size and noisier data. These results across different languages are encouraging as they can be used to discover truly language independence assumptions. We briefly describe our initial experiments on Maghrebi French hip hop lyrics below.

7.1 Dataset

We collected freely available French hip hop lyrics of approximately 1300 songs. About 85% of the songs were by Maghrebi French artists of Algerian, Moroccan, or Tunisian cultural backgrounds, while the remaining were by artists from the rest of Francophonie. As the large majority of songs are in Maghrebi French, the lyrics are sometimes interspersed with romanized Arabic such as "De la traversée du désert au bon couscous de **Yéma**" (**Yéma** means *My mother*). Some songs also contain Berber phrases, for instance "**a yemmi ino, a thizizwith**" (which means *my son, a bee*). Furthermore, some songs also contained English phrases in the style of gangster rap such as "T'es **game over**, **game over**... Le son de **Chicken wings**". As mentioned earlier, it is complexity like this which dissuaded us from making language specific assumptions in our model.

We extracted the end-of-line words and obtained a corpus containing 120,000 tokens corresponding to potential rhyming candidates with around 29,000 unique token types which was used as the training data for the rhyme scheme detector module. For the transduction grammar induction, the training data contained about 47,000 sentence pairs selected using rhyme scheme detection.

7.2 Results

After human evaluation by native French speakers and frequent hip hop listeners, our transduction grammar based model generates about 9.2% and 14.5% of the responses that are rated *good* by the human evaluators on the criterion of fluency and rhyming respectively. About 30.2% and 38% of the responses are rated as ≥*acceptable*. These numbers are encouraging given the noisy lyrics and much smaller amount of training data. Some examples of the challenge-response pairs and learned transduction rules in French are shown in Tables 5 and 6.

From Table 5, we can see that responses generated by the system rhyme with the challenges. The first response is fluent and not only perfectly rhymes with the challenge but also semantically valid. In the second example, the model realizes a less common **AABA** rhyme scheme through the response. The re-

transduction grammar rule	*log prob.*
$A \rightarrow$ terre/la guerre	-9.4837
$A \rightarrow$ haine/peine	-9.77056
$A \rightarrow$ mal/pays natal	-10.6877
$A \rightarrow$ je frissonne/mi corazon	-11.0931
$A \rightarrow$ gratteurs/rappeurs	-11.7306

sponse in the third example, exhibits strong rhyming with the challenge and both the challenge and the response contain words like souffrance, combat and décadence which are related. Similarly in the fourth example, the challenge and response also contain semantically related tokens which also rhyme. These examples illustrate that our transduction grammar formalism coupled with our rhyme scheme detection module does capture the necessary correspondences between lines of hip hop lyrics without assuming any language specific resources.

8 Conclusion

We presented a new machine learning approach for improvising hip hop responses to challenge lyrics by inducing stochastic transduction grammars, and demonstrated that inducing the transduction rules by interpolating bottom-up token based rule induction and rule segmentation strategies outperforms a token based baseline. We compared the performance of our Freestyle model against a widely used off-the-shelf phrase-based SMT model, showing that PB-SMT falls short in tackling the noisy and highly unstructured domain of hip hop lyrics. We showed that the quality of responses improves when the training data for the transduction grammar induction is selected using a rhyme scheme detector. Several domain related oddities such as disfluencies and backing vocals have been identified and some strategies for alleviating their effects have been compared. We also reported results on Maghrebi French hip hop lyrics which indicate that our model works surprisingly well with no special adaptation for languages other than English. In the future, we plan to investigate alternative training data selection techniques, disfluency handling strategies, search heuristics, and novel transduction grammar induction models.

Modeling Scientific Impact with Topical Influence Regression

James Foulds **Padhraic Smyth**

Abstract

When reviewing scientific literature, it would be useful to have automatic tools that identify the most influential scientific articles as well as how ideas propagate between articles. In this context, this paper introduces *topical influence*, a quantitative measure of the extent to which an article tends to spread its topics to the articles that cite it. Given the text of the articles and their citation graph, we show how to learn a probabilistic model to recover both the degree of topical influence of each article and the influence relationships between articles. Experimental results on corpora from two well-known computer science conferences are used to illustrate and validate the proposed approach.

1 Introduction

Scientific articles are not created equal. Some articles generate entire disciplines or sub-disciplines of research, or revolutionize how we think about a problem, while others contribute relatively little. When we are first introduced to a new area of scientific study, it would be useful to automatically find the most important articles, and the relationships of influence between articles. Understanding the impact of scientific work is also crucial for hiring decisions, allocation of funding, university rankings and other tasks that involve the assessment of scientific merit. If scientific works stand on the shoulders of giants, we would like to be able to find the giants.

The importance of a scientific work has previously been measured chiefly through metrics derived from citation counts, such as impact factors. However, citation counts are not the whole story. Many citations are made in passing, are relevant to only one section of an article, or make no impact on a work but are referenced out of "politeness, policy or piety" (Ziman, 1968). In reality, scientific impact has many dimensions. Some articles are important because they describe scientific discoveries that alter our understanding of the world, while some develop essential tools and techniques which facilitate future research. Other articles are influential because they introduce the seeds of new ideas, which in turn inspire many other articles.

In this work we introduce *topical influence*, a quantitative metric for measuring the latter type of scientific influence, defined in the context of an unsupervised generative model for scientific corpora. The model posits that articles "coerce" the articles that cite them into having similar topical content to them. Thus, articles with higher topical influence have a larger effect on the topics of the articles that cite them. We model this influence mechanism via a regression on the parameters of the Dirichlet prior over topics in an LDA-style topic model. We show how the models can be used to recover meaningful influence scores, both for articles and for specific citations. By looking not just at the citation graph but also taking into account the content of the articles, topical influence can provide a better picture of scientific impact than simple citation counts.

2 Background

Bibliometrics, the quantitative study of scientific literature, has a long history. One example of a widely-used bibliometric measure of interest is the *impact factor* of a publication venue for a given year, defined to be the average number of times articles from

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 113–123,
Seattle, Washington, USA, 18-21 October 2013.

that venue, published in the previous two years, were cited in that year. However, the quality of articles in a given publication venue can vary wildly, and it is difficult to compare impact factors between different disciplines of study. The number of citations an article receives is an indication of importance, but this is confounded by the unknown function of each citation. Measures of importance such as PageRank (Brin and Page, 1998) can be derived recursively from the citation graph. Such graph-based measures do not in general make use of the textual content of the articles, although it is possible to apply them to graphs where the edges between articles are determined based on the similarity of their content instead of the citation graph (Lin, 2008).

A variety of methods have previously been proposed for analyzing text and citation links together, such as modeling connections between words and citations Cohn and Hofmann (2001), classifying citation function (Teufel et al., 2006), and jointly modeling citation links and document content (Chang and Blei, 2009). However, these methods do not directly measure article importance or influence relationships between articles given their citations.

More closely related to the present work, Dietz et al. (2007) proposed the citation influence model (CIM). Building on the latent Dirichlet allocation (LDA) framework, CIM assumes that each word is drawn by first selecting either (a) the distribution over topics of a cited article (with probability proportional to the influence weight of that article on the present article) or (b) a novel topic distribution, and drawing a topic from the selected distribution, then finally drawing the word from the chosen topic.[1] In their approach, every word is assigned an extra latent variable, namely the cited article whose topic distribution the topic was drawn from. For the model proposed in this paper, we do not need to introduce these additional latent variables, which leads to a simpler latent representation and fewer variables to sample during inference. Dietz et al. (2007) also assume that the citation graph is bipartite, consisting of one set of citing articles and one set of cited articles—in contrast, our proposed models can handle arbitrary citation graphs in the form of directed acyclic graphs (DAGs). While both the CIM and our approach can identify the influence of specific citations between articles, our model can also infer how influential each article is overall, and provides a flexible modeling framework which can handle different assumptions about influence.

Another related method is due to Shaparenko and Joachims (2009), who propose a mixture modeling approach for the detection of novel text content. Nallapati et al. (2011) introduced TopicFlow, a PLSA-based model for the flow of topics in a document network. In their model, citing articles "vote" on each cited article's topic distribution in retrospect, via a network flow model. Since this voting occurs in time-reversed order, it does not describe an influence mechanism and is not a generative model that can simulate or predict new documents.

Finally, the document influence model of Gerrish and Blei (2010) can be viewed as orthogonal to this work, in that it models the impact of documents on *topics* over time (specifically, how topics change over time) rather than how articles influence the specific *articles* that cite them.

3 Topical Influence Regression

Scientific research is seldom performed in a vacuum. New research builds on the research that came before it. Although there are many aspects by which the importance of a scientific article can be judged, in this work we are interested in the extent to which a given article has or will have subsequent articles that build upon it or are otherwise inspired by its ideas. We begin by defining *topical influence*, a quantitative measure for this type of influence.

3.1 Topical Influence

It is not immediately obvious how one might quantify such a notion of "idea-based" influence. However, the mechanism used in the scientific community for giving credit to prior work is citation. The presence of a citation from article b to article a therefore indicates that article b may have been influenced by the ideas in article a, to some unknown extent. We hypothesize that the extent of this influence manifests itself in the language of b. Using latent Dirichlet allocation (LDA) topics as a concrete proxy for

[1] A somewhat similar model was also proposed by He et al. (2009)

the vague notion of "ideas", we define the *topical influence* of a to be the extent to which article a coerces the documents which cite it to have similar topic distributions to it. Topical influence will be made precise in the context of a generative model for scientific corpora, conditioned on the citation graph, called *topical influence regression* (TIR).

The proposed model extends the LDA framework of Blei et al. (2003). In LDA, each word $w_i^{(d)}$ of each document d is assigned to one of K latent topics, $z_i^{(d)}$. Each topic $\Phi^{(k)}$ is a discrete distribution over words. Document d has a distribution over topics $\theta^{(d)}$, which can be viewed as a "location in topic space" summarizing its thematic content. The $\theta^{(d)}$'s have a Dirichlet prior distribution with parameters $\alpha = [\alpha_1, \alpha_2, \ldots, \alpha_K]^\intercal$. Although the α_k's are often set to be equal, representing a relatively uninformative prior over the θ's, a unique $\alpha^{(d)}$ for each document can also be used to encode prior information such as the effect of other variables on the topics of that document (Mimno and McCallum, 2008). In our case, we want to model the influence that a document has on the topic distributions of the documents that cite it. A natural way to encode such influence, then, is to allow documents to affect the value of $\alpha^{(d)}$ for each document d that cites them.

Accordingly, we model each article d as having a latent, non-negative "topical influence" value $l^{(d)}$. Let $n^{(d)}$ be number of words in article d, $n_k^{(d)}$ be the number of words assigned to topic k, and let $C^{(d)}$ be the set of articles that d cites. We model $\alpha^{(d)}$ as

$$\alpha^{(d)} = \sum_{c \in C^{(d)}} l^{(c)} \bar{z}^{(c)} + \alpha \,, \qquad (1)$$

where $\bar{z}^{(c)} = \frac{1}{n^{(c)}}[n_1^{(c)}, \ldots, n_K^{(c)}]^\intercal$ is the normalized histogram of topic counts for document c, and α is a constant for smoothing. Since the $\bar{z}^{(c)}$'s sum to one, the topical influence $l^{(c)}$ of article c can be interpreted as the number of words of precision that it adds to the prior of the topic distributions of each document that cites it. As we increase $l^{(c)}$, the articles that cite c become more likely to have similar topic proportions to it. Thus, $l^{(c)}$ encodes the degree to which article c influences the topics of each of the articles that cite it.

From another perspective, marginalizing out $\theta^{(d)}$, we can view the topic counts (in the standard LDA model) for document d as being drawn from a Polya urn scheme with $\alpha_k^{(d)}$ (possibly fractional) balls of each color $k \in \{1, \ldots, K\}$ initially in the urn. For each word, a ball is drawn randomly from the urn and the topic assignment is determined according to its color k. The ball is replaced in the urn, along with a new ball of color k. In our model, for each article c cited by article d we place $l^{(c)}$ balls, with colors distributed according to $\bar{z}^{(c)}$, into article d's urn initially. Thus, article d's topic assignments are more likely to be similar to those of the more influential articles that it cites. The total number of balls that d added to other articles' urns,

$$T^{(d)} \triangleq \sum_{b: d \in C^{(b)}} l^{(d)} = l^{(d)} \left| \{b : d \in C^{(b)}\} \right| \qquad (2)$$

measures the total impact (in a topical sense) of the article. We refer to this as *total topical influence*.

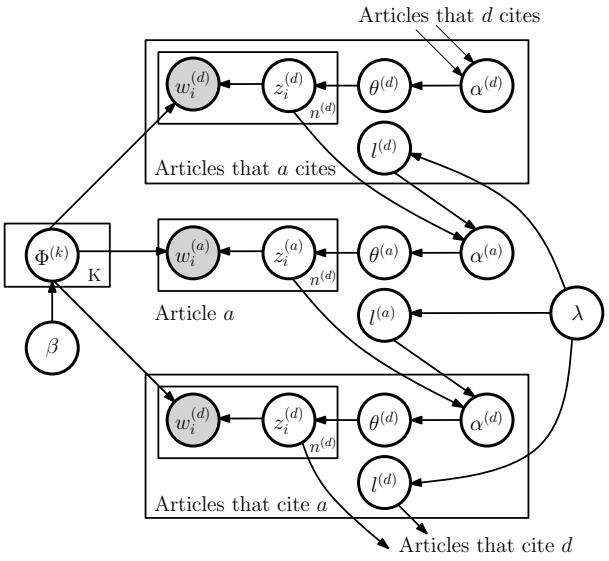

Figure 1: The graphical model for the portion of the TIR model connected to article a (the links from the z's and l's to the $\alpha^{(d)}$'s are deterministic).

3.2 Generative Model for Topical Influence Regression

The full assumed generative process for articles in this model begins with a directed acyclic citation graph $G = \{V, E\}$. Intuitively, citation graphs are typically DAGs because articles can normally only cite articles that precede them in time. We assume that G is a DAG so that influence relationships are

consistent with some temporal ordering of the articles, and so that the resulting model is a Bayesian network. Here, each vertex v_i corresponds to an article d_i, edge $e = (v_1, v_2) \in E$ IFF d_1 is cited by d_2, and vertices (articles) are numbered in a topological ordering with respect to G. Such an ordering exists because G is a DAG. We model each article d's word vector $w^{(d)}$ as being generated in topological sequence, similarly to LDA but with its prior over topic distribution being Dirichlet($\alpha^{(d)}$), as given by Equation 1. Note that each $\alpha^{(d)}$ is a function of the topics of the documents that it cites, parameterized by their topical influence values. We therefore call this model *topical influence regression* (TIR).

The TIR model provides us with topical influence scores for each article, but it does not tell us about topical influence relationships between specific pairs of cited and citing articles. To model such relationships, we can consider a hierarchical extension to TIR, with edge-wise topical influences $l^{(c,d)}$ for each edge (c, d) of the citation graph, $l^{(c,d)} \sim$ TruncGaussian($l^{(c)}, \sigma, l^{(c,d)} \geq 0$). In this case,

$$\alpha^{(d)} = \sum_{c \in C^{(d)}} l^{(c,d)} \bar{z}^{(c)} + \alpha \,. \tag{3}$$

This hierarchical setup allows us to continue to infer article-level topical influences, and provides a mechanism for sharing statistical strength between influences associated with one cited article. We shall refer to the model with influences on just the nodes (articles) as TIR, and the hierarchical extension with influences on the edges as TIRE. The graphical model for TIR is given in Figure 1, and the generative process is detailed in the following pseudocode:

- For each topic k
  - Sample the topic $\Phi^{(k)} \sim$ Dirichlet(β)
- For each document d, in topological order
  - Sample an influence weight, $l^{(d)} \sim$ Exponential(λ)
  - If using the TIRE model
    - For each cited document $c \in C^{(d)}$
      - Draw edge influence weight, $l^{(c,d)} \sim$ TruncGauss($l^{(c)}, \sigma, l^{(c,d)} \geq 0$)
  - Assign a prior over topics via $\alpha^{(d)} = \sum_{c \in C^{(d)}} l^{(c)} \bar{z}^{(c)} + \alpha$ (TIR), or $\alpha^{(d)} = \sum_{c \in C^{(d)}} l^{(c,d)} \bar{z}^{(c)} + \alpha$ (TIRE)
  - Sample a distribution over topics, $\theta^{(d)} \sim$ Dirichlet($\alpha^{(d)}$)
  - For each word i in document d
    - Sample a topic $z_i^{(d)} \sim$ Discrete($\theta^{(d)}$)
    - Sample a word $w_i^{(d)} \sim$ Discrete($\Phi^{(z_i^{(d)})}$)

3.3 Relationship to Dirichlet-Multinomial Regression

The TIR model can be viewed as an adaption of the Dirichlet-multinomial regression (DMR) framework of Mimno and McCallum (2008) to model topical influence. DMR also endows each document with its own unique $\alpha^{(d)}$, but with $\alpha_k^{(d)} = \exp(x^{(d)\intercal} \lambda_k)$ being a function of the observed feature vector $x^{(d)}$ parameterized by regression coefficients λ. The DMR model can also be applied to text corpora with citation information, by setting the feature vectors to be binary indicators of the presence of a citation to each article. TIR differs in that the functional form of the regression is parameterized in a way that directly models influence, and also differs in that the regression takes advantage of the content of the cited articles via their topic assignments.

Because an article's prior over topic distributions depends on the topic assignments of the articles that it cites, TIR induces a network of dependencies between the topic assignments of the documents. Specifically, if we collapse out Θ, the dependencies between the z's of each document form a Bayesian network whose graph is the citation graph. In contrast, DMR treats the documents as conditionally independent given their citations, and does not exploit their content in the regression.

To illustrate this, Figure 2 shows an example citation graph and the resulting Bayesian network. In the figure, an edge in (a) from c to d corresponds to a citation of c by d. Conditioned on the topics, the dependence relationships between z nodes in (b) follow the same structure as the citation graph.

4 Inference

We perform inference using a Markov chain Monte Carlo technique. We use a collapsed Gibbs sampling approach analogous to Griffiths and Steyvers (2004), integrating out Θ and

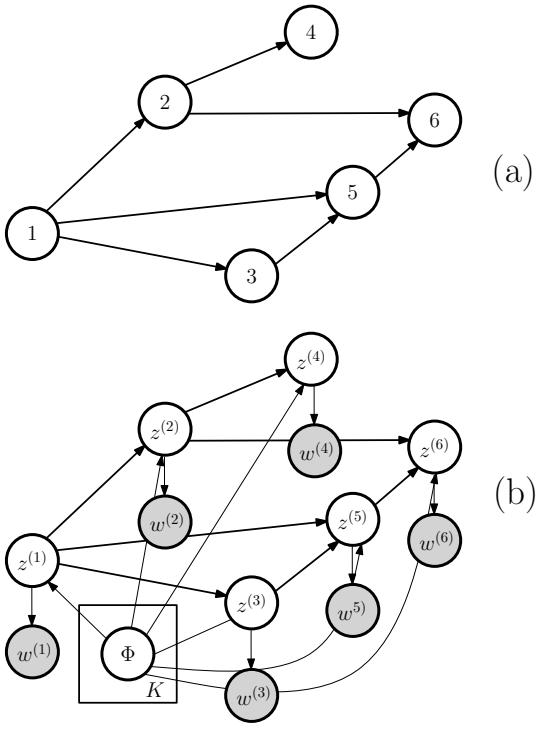

Figure 2: (a) An example citation network. (b) Graphical model for TIR on the example network, collapsing out Θ but retaining topics Φ. Influence variables and hyperparameters not shown for simplicity.

Φ. The update equation for the topic assignments is

$$Pr(z_i^{(d)} = k | z^{-(d,i)}, \ldots) \propto (n_k^{(d)-(d,i)} + \alpha_k^{(d)}) \frac{n_k^{(w_i^{(d)})-(d,i)} + \beta_{w_i^{(d)}}}{n_k^{-(d,i)} + \sum_w \beta_w} \times \prod_{d':d \in C(d')} \text{Polya}(z^{(d')} | \alpha^{(d')} : z_i^{(d)} = k, z^{-(d,i)}, l) \quad (4)$$

where the n_k's are the counts of the occurrences of topic k over all of the entries determined by the superscript. The $-(d,i)$ superscript indicates excluding the current assignment for $z_i^{(d)}$. The update equation is similar to the update equations of Griffiths and Steyvers, but with a different α for each document d, and with multiplicative weights for each document that cites it. These weights $\text{Polya}(z^{(d)}|\alpha^{(d)})$ are the likelihood for a multivariate Polya (a.k.a. Dirichlet-multinomial) distribution,

$$\text{Polya}(z^{(d)}|\alpha^{(d)}) = \frac{\Gamma(\sum_k \alpha_k^{(d)})}{\Gamma(n^{(d)} + \sum_k \alpha_k^{(d)})} \prod_k \frac{\Gamma(n_k^{(d)} + \alpha_k^{(d)})}{\Gamma(\alpha_k^{(d)})}.$$

In the case of TIR, in the collapsed model the full conditional posterior for the topical influence values l is $Pr(l|z,\lambda) \propto Pr(z|l)Pr(l|\lambda)$. Here, $Pr(z|l) = \prod_{d=1}^{D} \text{Polya}(z^{(d)}|l^{C^{(d)}}, z^{C^{(d)}})$. The topical influence values l can be sampled using Metropolis-Hastings updates, or slice sampling. An alternative is to perform stochastic EM, optimizing the likelihood or the posterior probability of l, interleaved within the Gibbs sampler, as in Mimno and McCallum (2008) and Wallach (2006). In experiments on synthetic data we found that maximum likelihood updates on l, obtained via gradient ascent, resulted in the lowest L1 error from the true l, so we use this strategy for the experimental results in this paper. The derivative of the log-likelihood with respect to the topical influence $l^{(a)}$ of article a is

$$\frac{\mathrm{d}Pr(z|l)}{\mathrm{d}l^{(a)}} = \sum_{d:a \in C(d)} \Big(\Psi(\sum_k \sum_{c \in C^{(d)}} l^{(c)} \bar{z}_k^{(c)} + K\alpha) - \Psi(\sum_k \sum_{c \in C^{(d)}} l^{(c)} \bar{z}_k^{(c)} + K\alpha + n^{(d)}) \Big) + \sum_{d:a \in C(d)} \sum_{k=1}^{K} \bar{z}_k^{(a)} \Big(\Psi(\sum_{c \in C^{(d)}} l^{(c)} \bar{z}_k^{(c)} + \alpha + n_k^{(d)}) - \Psi(\sum_{c \in C^{(d)}} l^{(c)} \bar{z}_k^{(c)} + \alpha) \Big),$$

where $\Psi(.)$ is the digamma function. For TIRE, the likelihood decomposes across documents and we can optimize the incoming edge weights for each document separately. We have

$$\frac{\mathrm{d}Pr(z^{(d)}|l)}{\mathrm{d}l^{(a,d)}} = \Psi(\sum_k \sum_{c \in C^{(d)}} l^{(c,d)} \bar{z}_k^{(c)} + K\alpha) - \Psi(\sum_k \sum_{c \in C^{(d)}} l^{(c,d)} \bar{z}_k^{(c)} + K\alpha + n^{(d)}) + \sum_{k=1}^{K} \bar{z}_k^{(a)} \Big(\Psi(\sum_{c \in C^{(d)}} l^{(c,d)} \bar{z}_k^{(c)} + \alpha + n_k^{(d)}) - \Psi(\sum_{c \in C^{(d)}} l^{(c,d)} \bar{z}_k^{(c)} + \alpha) \Big).$$

We optimize the node-level l's in TIRE via the least squares estimate (LSE), $\hat{l}^{(a)} = \frac{1}{|\{d:a \in C^{(d)}\}|} \sum_{d:a \in C^{(d)}} l^{(a,d)}$. Although the LSE for the mean of a truncated Gaussian is biased, it is widely used as it is more robust than the MLE (A'Hearn, 2004).

5 Experimental Analysis

In this section we experimentally investigate the properties of TIR and TIRE. We consider two scientific corpora: a collection of 3286 of articles from the Association for Computational Linguistics (ACL) conference[2] (Radev et al., 2009) published between 1987 and 2011, and a corpus of articles from the Neural Information Processing Systems (NIPS) conference[3] containing 1740 articles from 1987 to 1999. The corpora both contained a small number (53, and 14, respectively) of citation graph loops due to insider knowledge of simultaneous publications. Some loops were removed by manual deletion of "insider knowledge" edges, and others were removed by deleting edges in the loop uniformly at random. For computational efficiency, we performed approximate Gibbs updates where we drop the multiplicative Polya likelihood terms in Equation 4. This corresponds to only transmitting influence information downward in the citation DAG, but not transmitting "reverse influence" information upwards. Preliminary experiments on synthetic data indicated that this did not significantly impact the ability of the model to recover the topical influence weights. As one might expect, LDA is already capable of inferring topic distributions which are good enough to perform the regression on, without fully exploiting the additional feedback from the regression. This algorithm has a similar running time to the standard collapsed Gibbs sampler for LDA, as the regression step is not a bottleneck.

In all experiments, we set the hyper-parameters to $\alpha = 0.1, \beta = 0.1$ and the σ parameter for the truncated Gaussian in TIRE to be 1. We interleaved regression steps every 10 Gibbs iterations. For exploratory data analysis experiments the models were trained for 500 burn-in iterations, and the samples from the final iterations were used for the analysis.

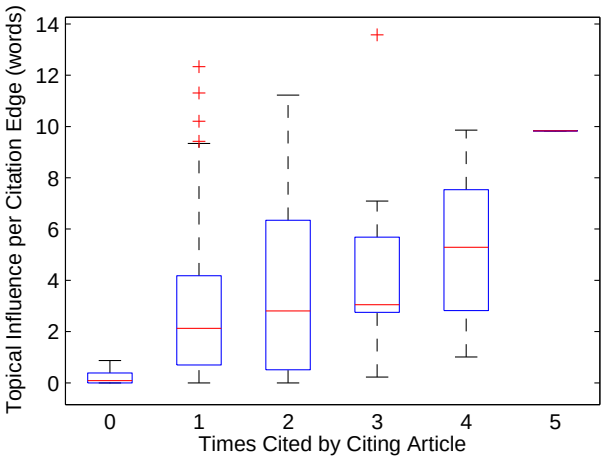

Figure 3: Topical influence per edge versus number of times cited by the citing article (NIPS). Several articles had zero in-text citations due to author or dataset errors.

5.1 Model Validation using Metadata

It is not immediately obvious how to best validate an unsupervised model of citation influence. Ground truth is not well-defined and human evaluation requires extensive knowledge of the individual papers in the corpora. With this in mind, we explore how topical influence scores relate to document metadata, which serves as a proxy for ground truth.

In many cases, if article c is repeatedly cited in the text of article d it may indicate that d builds heavily on c. We would therefore expect to see an association between repeated citations and edge-wise topical influence $l^{(c,d)}$. For each of the 106 papers in the NIPS corpus with at least three distinct references, we counted the number of repeated citations for the most influential and least influential references according to the TIRE model (Figure 3). Overall, the "most influential" references were cited 171 times in the text of their citing articles, while the "least influential" references were cited 128 times. Of the 45 articles where the counts were not tied, the most influential references had the higher citation counts 33 times. A sign test rejects the null hypothesis that the median difference in citation counts between least and most influential references is zero at $\alpha = 0.05$, with p-value $\approx 5 \times 10^{-4}$.

Self-citations, where at least one author is in common between cited and citing articles, are also informative (Figure 4). Authors often build upon their own work, so we would expect self-citations to have higher edge-wise topical influence on average. For ACL the mean topical influence for a self citation edge is 2.80 and for a non-self citation is 1.40. For NIPS the means are 5.05 (self) and 3.15 (non-self). A two-sample t-test finds these differences are both significant at $\alpha = 0.05$.

5.2 Prediction Experiments

We also used a document prediction task to explore whether the posited latent structure is predictively useful. We selected roughly 10% of the articles in each corpus (170 and 330 documents for NIPS and ACL, respectively) for testing, chosen among the articles that made at least one citation. We held out a randomly selected set of 50% of their words and evaluated the log probability of the held out partial documents under each model. This is equivalent to evaluating on a set of new documents with the same set of references as the held out set. Evaluation was performed using annealed importance sampling (Neal, 2001), as in Wallach et al. (2009) except we used multiple samples per likelihood computation.

The TIR models were compared to LDA and an "additive" version of DMR with link function $\alpha_k^{(d)} = x^{(d)\intercal}\lambda_k + \alpha$, where the λs were constrained to be positive and given an exponential prior with mean one. For DMR, binary feature vectors encoded the presence or absence of each possible citation. For each algorithm, we burned in for 250 iterations, then executed 1000 iterations, optimizing topical influence weights/DMR parameters every 10th iteration. Held-out log probability scores were computed by performing AIS with every 100th sample, and averaging the results to estimate the posterior predictive probability $Pr(\text{held out article}|\text{training set, citations, model})$.

It was found that all of the regression methods had superior predictive performance to LDA on these corpora, demonstrating that topical influence has predictive value (Table 1). Although DMR performed slightly better than TIR predictively, TIR was competitive despite the fact that it has a factor of K less regression parameters. Note that DMR does not provide an interpretable notion of influence.

5.3 Exploring Topical Influence

In this section we explore the inferred topical influence scores $l^{(d)}$, total topical influence scores $T^{(d)}$ and edgewise topical influence scores $l^{(c,d)}$ (recall their definitions in Equations 1, 2 and 3, respectively). Table 2 shows the most influential articles in the ACL corpus, according to citation counts, topical influence and total topical influence (the latter two inferred with the TIR model). The most frequently cited paper within the ACL corpus, written by Papineni et al., introduces BLEU, a technique for evaluating machine translation (MT) systems.[4] This paper is of great importance to the computational linguistics community because the method that it introduces is widely used to validate MT systems. However, the BLEU article has a relatively low *topical* influence value of 0.58, consistent with the fact that most of the papers that cite it use the technique as part of their *methodology* but do not *build upon its ideas*. We emphasize that topical influence measures a specific dimension of scientific importance, namely the tendency of an article to influence the ideas (as mediated by the topics) of citing articles; papers with low topical influence such as the BLEU article may be important for other reasons.

Ranking papers by their influence weights $l^{(d)}$ (Table 2, middle) has the opposite difficulty to ranking by citation counts — the papers with the highest topical influence were typically cited only once, by the same authors. This makes sense, given what the model is designed to do. The lone citing papers were certainly topically influenced by these articles.

A more useful metric, however, is the total topical influence $T^{(d)}$ (the bottom sub-table in Table 2). This is the total number of words of prior concentration, summed over all of its citers, that the article has contributed, and is a measure of the total corpus-wide topical influence of the paper. This metric ranks the BLEU paper at 5th place, down from 1st place by citation count. The ACL paper with the highest total topical influence, by David Chiang, won the ACL best paper award in 2005.

The behavior of the different metrics is echoed in the NIPS corpus (Table 3). The most cited paper, "Handwritten Digit Recognition," by

[4] Citations within the corpora are of course only a small fraction of the total set of citations for many of these papers.

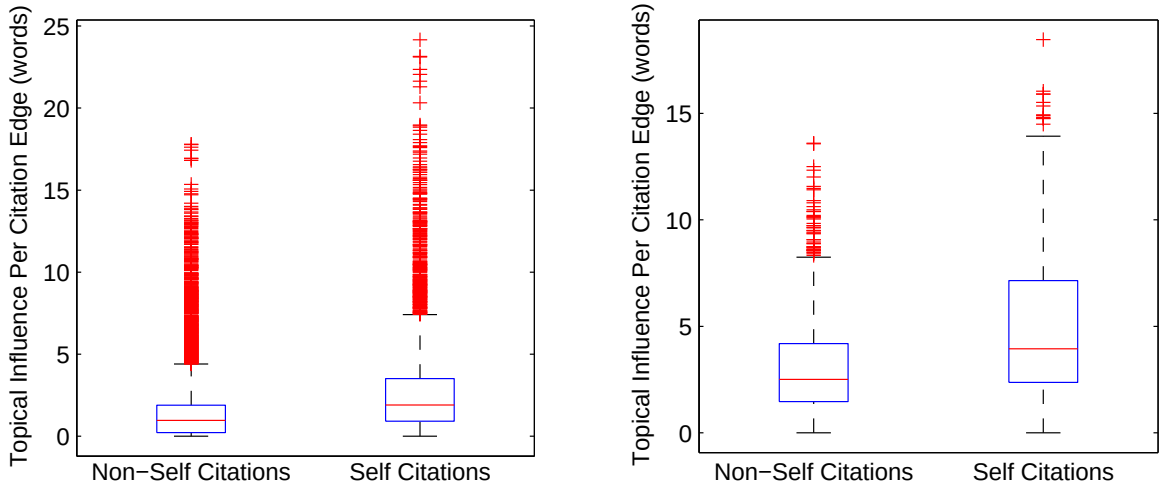

Figure 4: Topical influence for self and non-self citation edges. Left: ACL. Right: NIPS.

	ACL			NIPS		
	Wins	Losses	Average Improvement	Wins	Losses	Average Improvement
TIR	297	33	65.7	150	20	38.2
TIRE	276	54	63.0	148	22	38.7
DMR	302	28	79.1	157	13	48.4

Table 1: Wins, losses and average improvement for log probabilities of held-out articles, versus LDA. Each "Win" corresponds to the model assigning a higher log probability score for the test portion of a held-out document than LDA assigned to that document.

Le Cun et al. (1990), is an early successful application of neural networks. The paper does not introduce novel models or algorithms, but rather, in the authors' words, "show[s] that large back propagation (BP) networks can be applied to real image recognition problems." Thus, although it is has an important role as a landmark neural network success story, it does not score highly in terms of *topical* influence. This paper is ranked 13th according to total topical influence, with a score of 1.6. The top two-ranked papers according to total topical influence, on Gaussian Process Regression and POMDPs respectively, were both seminal papers that spawned large bodies of related work. An interesting case is the third-ranked paper in the NIPS corpus, by Wang et al., on the theory of early stopping. It is only referenced three times, but has a very high topical influence of 19.3 words. All three citing papers are also on the theory of early stopping, and one of the papers, by Wang and Venkatesh, directly extends a theoretical result of this paper. Although it is easy to see why this paper scores highly on topical influence, in this case the metric has perhaps overstated its importance. A limitation of topical influence is that it can potentially give more credit than is due when an article is cited by a small number of topically similar papers, due to overfitting. This is likely to be an issue for any topic-based approach for modeling scientific influence. However, topics help to absorb lexical ambiguity and author-specific idiosyncracies, mitigating the problem relative to word-based approaches.

Using the TIRE model, we can also look at influence relationships between pairs of articles. Tables 4 and 5 show the most and least topically influential references, and the most and least influenced citing papers, for three example articles from ACL and NIPS, respectively. The model correctly assigns higher influence scores along the edges to and from relevant documents. For the ACL papers, the BLEU algorithm's article is inferred to have zero topical influence on Chiang's paper, consistent with its role

in the paper as an evaluation technique. The paper most topically influenced by Chiang's paper, written by Yang and Zheng, aims to improve upon the ideas in that paper. In the NIPS corpus, the article by Bengio and Frasconi, on recurrent neural network architectures, extends previous work by the same authors, which is correctly assigned the highest topical influence. A particularly interesting case is the paper by Dayan and Hinton, which is heavily influenced by a paper by Moore, and in turn strongly influences a later paper by Moore, thus illustrating the interplay of scientific influence between authors along the citation graph. These three papers were on reinforcement learning, while the lowest scoring reference and citer were on other subjects.

6 Conclusions / Discussion

This paper introduced the notion of topical influence, a quantitative measure of scientific impact which arises from a latent variable model called topical influence regression. The model builds upon the ideas of Dirichlet-multinomial regression to encode influence relationships between articles along the citation graph. By training TIR, we can recover topical influence scores that give us insight into the impact of scientific articles. The model was applied to two scientific corpora, demonstrating the utility of the method both quantitatively and qualitatively.

In future work, the proposed framework could readily be extended to model other aspects of scientific influence, such as the effects of authors and journals on topical influence, and to exploit the context in which citations occur. From an exploratory analysis perspective, it would be instructive to compare topical influence trajectories over time for different papers. This could be further facilitated by explicitly modeling the dynamics of each article's topical influence score. The TIR framework could potentially also be applicable to other application domains such as modeling how interpersonal influence affects the spread of memes via social media.

To complement TIR, it would be useful to also have systems for identifying articles which are important for alternative reasons, such as providing methodological tools and/or demonstrating important facts. Ultimately a suite of such tools could feed into a system such as Google Scholar or Citeseer. We envision that this line of work will also be useful for building visualization tools to help researchers explore scientific corpora.

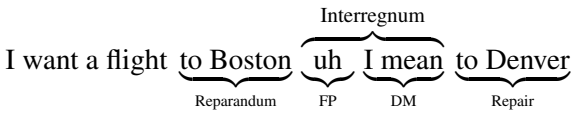
Abstract

We introduce a novel method to jointly parse and detect disfluencies in spoken utterances. Our model can use arbitrary features for parsing sentences and adapt itself with out-of-domain data. We show that our method, based on transition-based parsing, performs at a high level of accuracy for both the parsing and disfluency detection tasks. Additionally, our method is the fastest for the joint task, running in linear time.

1 Introduction

Detecting disfluencies in spontaneous speech has been widely studied by researchers in different communities including natural language processing (e.g. Qian and Liu (2013)), speech processing (e.g. Wang et al. (2013)) and psycholinguistics (e.g. Finlayson and Corley (2012)). While the percentage of spoken words which are disfluent is typically not more than ten percent (Bortfeld et al., 2001), this additional "noise" makes it much harder for spoken language systems to predict the correct structure of the sentence.

Disfluencies can be filled pauses (e.g. "uh", "um", "huh"), discourse markers (e.g. "you know", "I mean") or edited words which are repeated or corrected by the speaker. For example, in the following sentence, an edited phrase or *reparandum interval* ("to Boston") occurs with its repair ("to Denver"), a filled pause ("uh") and discourse marker ("I mean").[1]



Filled pauses and discourse markers are to some extent a fixed and closed set. The main challenge in finding disfluencies is the case where the edited phrase is neither a rough copy of its repair or has any repair phrase (i.e. discarded edited phrase). Hence, in previous work, researchers report their method performance on detecting edited phrases (reparandum) (Johnson and Charniak, 2004).

In contrast to most previous work which focuses solely on either detection or on parsing, we introduce a novel framework for jointly parsing sentences with disfluencies. To our knowledge, our work is the first model that is based on *joint dependency and disfluency detection*. We show that our model is robust enough to detect disfluencies with high accuracy, while still maintaining a high level of dependency parsing accuracy that approaches the upper bound. Additionally, our model outperforms prior work on joint parsing and disfluency detection on the disfluency detection task, and improves upon this prior work by running in linear time complexity.

The remainder of this paper is as follows. In §2, we overview some the previous work on disfluency detection. §3 describes our model. Experiments are described in §4 and Conclusions are made in §5.

* The first author worked on this project while he was a research intern in CoreNL research group, NLU lab, Nuance Communications, Sunnyvale, CA.

[1] In the literature, edited words are also known as "reparandum", and the fillers are known as "interregnum". Filled pauses are also called "Interjections".

Seattle, Washington, USA, 18-21 October 2013.

2 Related Work

Disfluency detection approaches can be divided into two different groups: text-first and speech first (Nakatani and Hirschberg, 1993). In the first approach, all prosodic and acoustic cues are ignored while in the second approach both grammatical and acoustic features are considered. For this paper, we focus on developing a text-first approach but our model is easily flexible with speech-first features because there is no restriction on the number and types of features in our model.

Among text-first approaches, the work is split between developing systems which focus specifically on disfluency detection and those which couple disfluency detection with parsing. For the former, Charniak and Johnson (2001) employ a linear classifier to predict the edited phrases in Switchboard corpus (Godfrey et al., 1992). Johnson and Charniak (2004) use a TAG-based noisy channel model to detect disfluencies while parsing with getting n-best parses from each sentence and re-ranking with a language model. The original TAG parser is not used for parsing itself and it is used just to find rough copies in the sentence. Their method achieves promising results on detecting edited words but at the expense of speed (the parser has a complexity of O(N^5). Kahn et al. (2005) use the same TAG model and add semi-automatically extracted prosodic features. Zwarts and Johnson (2011) improve the performance of TAG model by adding external language modeling information from data sets such as Gigaword in addition to using minimal expected F-loss in n-best re-ranking.

Georgila (2009) uses integer linear programming combined with CRF for learning disfluencies. That work shows that ILP can learn local and global constraints to improve the performance significantly. Qian and Liu (2013) achieve the best performance on the Switchboard corpus (Godfrey et al., 1992) without any additional data. They use three steps for detecting disfluencies using weighted Max-Margin Markov (M^3) network: detecting fillers, detecting edited words, and refining errors in previous steps.

Some text-first approaches treat parsing and disfluency detection jointly, though the models differ in the type of parse formalism employed. Lease and Johnson (2006) use a PCFG-based parser to parse sentences along with finding edited phrases. Miller and Schuler (2008) use a right-corner transform of binary branching structures on bracketed sentences but their results are much worse than (Johnson and Charniak, 2004). To date, none of the prior joint approaches have used a dependency formalism.

3 Joint Parsing Model

We model the problem using a deterministic transition-based parser (Nivre, 2008). These parsers have the advantage of being very accurate while being able to parse a sentence in linear time. An additional advantage is that they can use as many non-local and local features as needed.

Arc-Eager Algorithm We use the arc-eager algorithm (Nivre, 2004) which is a bottom-up parsing strategy that is used in greedy and k-beam transition-based parsers. One advantage of this strategy is that the words can get a head from their left side, before getting right dependents. This is particularly beneficial for our task, since we know that reparanda are similar to their repairs. Hence, a reparandum may get its head but whenever the parser faces a repair, it removes the reparandum from the sentence and continues its actions.

The actions in an arc-eager parsing algorithm are:

- **Left-arc (LA)**: The first word in the buffer becomes the head of the top word in the stack. The top word is popped after this action.
- **Right-arc (RA)**: The top word in the stack becomes the head of the first word in the buffer.
- **Reduce (R)**: The top word in the stack is popped.
- **Shift (SH)**: The first word in the buffer goes to the top of the stack.

Joint Parsing and Disfluency Detection We first extend the arc-eager algorithm by augmenting the action space with three new actions:

- **Reparandum (Rp[i;j])**: treat a phrase (words *i* to *j*) outside the look-ahead buffer as a reparandum. Remove them from the sentence and clear their dependencies.
- **Discourse Marker (Prn[i])**: treat a phrase in the look-ahead buffer (first *i* words) as a discourse marker and remove them from the sentence.

Stack	Buffer	Act.
flight	to Boston uh I mean ...	RA
flight to	Boston uh I mean to ...	RA
flight to Boston	**uh** I mean to Denver	Intj[1]
flight to Boston	**I mean** to Denver	Prn[1]
flight **to Boston**	to Denver	RP[2:3]
flight	to Denver	RA
flight to	Denver	RA
flight to Denver		R
flight to		R
flight		R

Figure 1: A sample transition sequence for the sentence "flight to Boston uh I mean to Denver". In the third column, only the underlined parse actions are learned by the parser (second classifier). The first classifier uses all instances for training (learns fluent words with "regular" label).

- **Interjection (Intj[i])**: treat a phrase in the look-ahead buffer (first *i* words) as a filled pause and remove them from the sentence.[2]

Our model has two classifiers. The first classifier decides between four possible actions and possible candidates in the current configuration of the sentence. These actions are the three new ones from above and a new action **Regular (Reg)**: which means do one of the original arc-eager parser actions.

At each configuration, there might be several candidates for being a *prn*, *intj* or *reparandum*, and one *regular* candidate. The candidates for being a *reparandum* are a set of words outside the look-ahead buffer and the candidates for being an *intj* or *prn* are a set of words beginning from the head of the look-ahead buffer. If the parser decides *regular* as the correct action, the second classifier predicts the best parsing transition, based on arc-eager parsing (Nivre, 2004).

For example, in the 4th state in Figure 1, there are multiple candidates for the first classifier: regular, "I" as *prn*[1] or *intj*[1], "I mean" as *prn*[2] or *intj*[2], "I mean to" as *prn*[3] or *intj*[3], "I mean to Denver" as *prn*[4] or *intj*[4], "Boston" as *rp*[3:3], "to Boston" as *rp*[2:3], and "flight to Boston" as *rp*[1:3].

[2]In the bracketed version of Switchboard corpus, reparandum is tagged with *EDITED* and discourse markers and paused fillers are tagged as *PRN* and *INTJ* respectively.

Training A transition-based parser action (our second-level classifier) is sensitive to the words in the buffer and stack. The problem is that we do not have gold dependencies for edited words in our data. Therefore, we need a parser to remove reparandum words from the buffer and push them into the stack. Since our parser cannot be trained on disfluent sentences from scratch, the first step is to train it on clean treebank data.

In the second step, we adapt parser weights by training it on disfluent sentences. Our assumption is that we do not know the correct dependencies between disfluent words and other words in the sentence. At each configuration, the parser updates itself with new instances by traversing all configurations in the sentences. In this case, if at the head of the buffer there is an *intj* or *prn* tag, the parser allows them to be removed from the buffer. If a reparandum word is not completely outside the buffer (the first two states in Figure 1), the parser decides between the four regular arc-eager actions (i.e. *left-arc*, *right-arc*, *shift*, and *reduce*). If the last word pushed into the stack is a reparandum and the first word in the buffer is a regular word, the parser removes all reparanda at the same level (in the case of nested edited words), removes their dependencies to other words and push their dependents into the stack. Otherwise, the parser performs the oracle action and adds that action as its new instance.[3]

With an adapted parser which is our second-level classifier, we can train our first-level classifier. The same procedure repeats, except that instances for disfluency detection are used for updating parameter weights for the first classifier for deciding the actions. In Figure 1, only the oracle actions (underlined) are added to the instances for updating parser weights but all first-level actions are learned by the first level classifier.

4 Experiments and Evaluation

For our experiments, we use the Switchboard corpus (Godfrey et al., 1992) with the same train/dev/test split as Johnson and Charniak (2004). As in that

[3]The reason that we use a parser instead of expanding all possible transitions for an edited word is that, the number of *regular* actions will increase and the other actions become sparser than natural.

work, incomplete words and punctuations are removed from data (except that we do not remove incomplete words that are not disfluent[4]) and all words are turned into lower-case. The main difference with previous work is that we use Switchboard *mrg* files for training and testing our model (since they contain parse trees) instead of the more commonly used Swithboard *dps* text files. *Mrg* files are a subset of *dps* files with about more than half of their size. Unfortunately, the disfluencies marked in the *dps* files are not exactly the same as those marked in the corresponding *mrg* files. Hence, our result is not completely comparable to previous work except for (Kahn et al., 2005; Lease and Johnson, 2006; Miller and Schuler, 2008).

We use Tsurgeon (Levy and Andrew, 2006) for extracting sentences from *mrg* files and use the Penn2Malt tool[5] to convert them to dependencies. Afterwards, we provide dependency trees with disfluent words being the dependent of nothing.

Learning For the first classifier, we use averaged structured Perceptron (AP) (Collins, 2002) with a minor modification. Since the first classifier data is heavily biased towards the "regular label", we modify the weight updates in the original algorithm to 2 (original is 1) for the cases where a "reparandum" is wrongly recognized as another label. We call the modified version "weighted averaged Perceptron (WAP)". We see that this simple modification improves the model accuracy.[6] For the second classifier (parser), we use the original averaged structured Perceptron algorithm. We report results on both AP and WAP versions of the parser.

Features Since for every state in the parser configuration, there are many candidates for being disfluent; we use local features as well as global features for the first classifier. Global features are mostly useful for discriminating between the four actions and local features are mostly useful for choosing a phrase as a candidate for being a disfluent phrase. The features are described in Figure 2. For the second classifier, we use the same features as (Zhang and Nivre, 2011, Table 1) except that we train our parser in a similar manner as the MaltParser (Nivre et al., 2007) without k-beam training.

Global Features
First n words inside/outside buffer (n=1:4)
First n POS i/o buffer (n=1:6)
Are n words i/o buffer equal? (n=1:4)
Are n POS i/o buffer equal? (n=1:4)
n last FG transitions (n=1:5)
n last transitions (n=1:5)
n last FG transitions + first POS in the buffer (n=1:5)
n last transitions + first POS in the buffer (n=1:5)
(n+m)-gram of m/n POS i/o buffer (n,m=1:4)
Refined (n+m)-gram of m/n POS i/o buffer (n,m=1:4)
Are n first words of i/o buffer equal? (n=1:4)
Are n first POS of i/o buffer equal? (n=1:4)
Number of common words i/o buffer words (n=1:6)
Local Features
First n words of the candidate phrase (n=1:4)
First n POS of the candidate phrase (n=1:6)
Distance between the candidate and first word in the buffer

Figure 2: Features used for learning the first classifier. Refined n-gram is the n-gram without considering words that are recognized as disfluent. Fine-grained (FG) transitions are enriched with parse actions (e.g. "regular:left-arc").

Parser Evaluation We evaluate our parser with both unlabeled attachment accuracy of correct words and precision and recall of finding the dependencies of correct words.[7] The second classifier is trained with 3 iterations in the first step and 3 iterations in the second step. We use the attachment accuracy of the parse tree of the correct sentences (without disfluencies) as the upper-bound attachment score and parsed tree of the disfluent sentences (without disfluency detection) as our lower-bound attachment score. As we can see in Table 1, WAP does a slightly better job parsing sentences. The upper-bound parsing accuracy shows that we do not lose too much information while jointly detecting disfluencies. Our parser is not comparable to (Johnson and Charniak, 2004) and (Miller and Schuler, 2008), since we use dependency relations for evaluation instead of constituencies.

Disfluency Detection Evaluation We evaluate our model on detecting edited words in the sentences

[4] E.g. I want t- go to school.

[5] `http://stp.lingfil.uu.se/~nivre/research/Penn2Malt.html`

[6] This is similar to WM^{3}N in (Qian and Liu, 2013).

[7] The parser is actually trained to do labeled attachment and labeled accuracy is about 1-1.5% lower than UAS.

	UAS	LB	UB	Pr.	Rec.	F2
AP	**88.6**	70.7	90.2	86.8	88.0	87.4
WAP	88.1	70.7	90.2	87.2	88.0	**87.6**

Table 1: Parsing results. UB = upperbound (parsing clean sentences), LB = lowerbound (parsing disfluent sentences without disfluency correction). UAS is unlabeled attachment score (accuracy), Pr. is precision, Rec. is recall and F1 is f-score.

	Pr.	Rec.	F1
AP	**92.9**	71.6	80.9
WAP	85.1	**77.9**	**81.4**
KL (2005)	–	–	78.2
LJ (2006)	–	–	62.4
MS (2008)	–	–	30.6
QL (2013) – Default	–	–	81.7
QL (2013) – Optimized	–	–	**82.1**

Table 2: Disfluency results. Pr. is precision, Rec. is recall and F1 is f-score. KL = (Kahn et al., 2005), LJ = (Lease and Johnson, 2006), MS = (Miller and Schuler, 2008) and QL = (Qian and Liu, 2013).

(words with "EDITED" tag in *mrg* files). As we see in Table 2, WAP works better than the original method. As mentioned before, the numbers are not completely comparable to others except for (Kahn et al., 2005; Lease and Johnson, 2006; Miller and Schuler, 2008) which we outperform. For the sake of comparing to the state of the art, the best result for this task (Qian and Liu, 2013) is replicated from their available software[8] on the portion of *dps* files that have corresponding *mrg* files. For a fairer comparison, we also optimized the number of training iterations of (Qian and Liu, 2013) for the *mrg* set based on dev data (10 iterations instead of 30 iterations). As shown in the results, our model accuracy is slightly less than the state-of-the-art (which focuses solely on the disfluency detection task and does no parsing), but we believe that the performance can be improved through better features and by changing the model. Another characteristic of our model is that it operates at a very high precision, though at the expense of some recall.

[8]We use the second version of the code: `http://code.google.com/p/disfluency-detection/`. Results from the first version are 81.4 and 82.1 for the default and optimized settings.

5 Conclusion

In this paper, we have developed a fast, yet accurate, joint dependency parsing and disfluency detection model. Such a parser is useful for spoken dialogue systems which typically encounter disfluent speech and require accurate syntactic structures. The model is completely flexible with adding other features (either text or speech features).

There are still many ways of improving this framework such as using k-beam training and decoding, using prosodic and acoustic features, using out of domain data for improving the language and parsing models, and merging the two classifiers into one through better feature engineering. It is worth noting that we put the dummy *root* word in the first position of the sentence. Ballesteros and Nivre (2013) show that parser accuracy can improve by changing that position for English.

One of the main challenges in this problem is that most of the training instances are not disfluent and thus the sample space is very sparse. As seen in the experiments, we can get further improvements by modifying the weight updates in the Perceptron learner. In future work, we will explore different learning algorithms which can help us address the sparsity problem and improve the model accuracy. Another challenge is related to the parser speed, since the number of candidates and features are much greater than the number used in classical dependency parsers.

Acknowledgements We would like to thank anonymous reviewers for their helpful comments on the paper. Additionally, we were aided by researchers by their prompt responses to our many questions: Mark Core, Luciana Ferrer, Kallirroi Georgila, Mark Johnson, Jeremy Kahn, Yang Liu, Xian Qian, Kenji Sagae, and Wen Wang. Finally, this work was conducted during the first author's summer internship at the Nuance Sunnyvale Research Lab. We would like to thank the researchers in the group for the helpful discussions and assistance on different aspects of the problem. In particular, we would like to thank Chris Brew, Ron Kaplan, Deepak Ramachandran and Adwait Ratnaparkhi.

Abstract

We present a novel vector space model for semantic co-compositionality. Inspired by Generative Lexicon Theory (Pustejovsky, 1995), our goal is a compositional model where both predicate and argument are allowed to modify each others' meaning representations while generating the overall semantics. This readily addresses some major challenges with current vector space models, notably the polysemy issue and the use of one representation per word type. We implement *co-compositionality* using *prototype projections* on predicates/arguments and show that this is effective in adapting their word representations. We further cast the model as a neural network and propose an unsupervised algorithm to jointly train word representations with co-compositionality. The model achieves the best result to date ($\rho = 0.47$) on the semantic similarity task of transitive verbs (Grefenstette and Sadrzadeh, 2011).

1 Introduction

Vector space models of words have been very successful in capturing the semantic and syntactic characteristics of individual lexical items (Turney and Pantel, 2010). Much research has addressed the question of how to construct individual word representations, for example distributional models (Mitchell and Lapata, 2010) and neural models (Collobert and Weston, 2008). These word representations are used in various natural language processing (NLP) tasks such as part-of-speech tagging, chunking, named entity recognition, and semantic role labeling (Turian et al., 2010; Collobert et al., 2011).

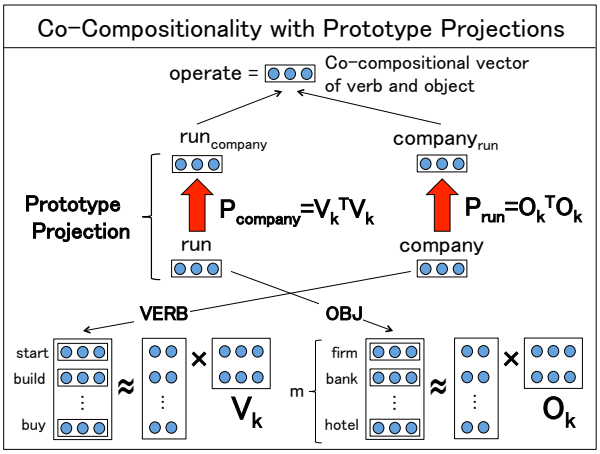

Figure 1: Here, we capture the semantics of *run* in *run company* by projecting the original word representation of *run* to the prototype space of *company* (and vice versa).

Recently, modeling of semantic compositionality (Frege, 1892) in vector space has emerged as another important line of research (Mitchell and Lapata, 2008; Mitchell and Lapata, 2010; Baroni and Zamparelli, 2010; Socher et al., 2012; Grefenstette and Sadrzadeh, 2011; Van de Cruys et al., 2013). The goal is to formulate how individual word representations ought to be combined to achieve phrasal or sentential semantics.

The main questions for semantic compositionality that we are concerned with are: (1) how can polysemy be handled by a single vector representation per word type, learned by either a distributional or neural model, and (2) how does composition resolve

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 130–140,
Seattle, Washington, USA, 18-21 October 2013.

these ambiguities. To this end, we are inspired by the idea of *type coercion* and *co-compositionality* in Generative Lexicon Theory (Pustejovsky, 1995). Co-compositionality advocates that instead of a predicate-argument view of composition, both predicate and argument influence/coerce each other to generate the overall meaning. For example, consider a polysemous word like *run*:

- (a) He runs the company.
- (b) He runs the marathon.

Run may have several senses, but the prototypical verbs that select for *company* differ from those that select for *marathon*, and thus the ambiguity at the word level is resolved at the sentence level. The same is true for the other direction, where the predicate also coerces meaning to the argument to fit expectation.

We believe that models for semantic composition ought to incorporate elements of co-compositionality. We propose such a model here, using what we call *prototype projections*. For each predicate, we transform its vector representation by projecting it into a latent space that is prototypical of its argument. This projection is performed analogously for each argument as well, and the final meaning is computed by composition of these transformed vectors (Figure 1). In addition, the model is cast as a neural network where word representations could be re-trained or fine-tuned.[1]

Our contributions are two-fold:

1. We propose a novel model for semantic co-compositionality. This model, based on prototype projections, is easy to implement and achieves state-of-the-art performance in the sentence similarity dataset developed by Grefenstette and Sadrzadeh (2011).

2. Our results empirically confirm that existing word representations (eg., SDS and NLM in Section 2) are sufficiently effective at capturing polysemy, as long as we have the proper mechanism to tease out the proper sense during composition. We further propose an unsupervised neural network training algorithm that jointly fine-tunes the word representations within the co-composition model, resulting in even better performance on the sentence similarity task.

We would like to emphasize the second contribution especially. Semantics research is divided in two strands, one focusing on learning word representations without consideration for compositionality, and the other focusing on compositional semantics using the representations only as an input. But issues are actually related from the linguistics perspective, and even more so if we adopt a Generative Lexicon perspective. Our neural network model bridges these two strands of research by modeling co-compositionality and learning word representations simultaneously. We note that methods using context effects have been explored by Erk and Padó (2008; 2009) and Thater et al. (2010; 2011), but to the best of our knowledge, ours is the first model to perform co-compositionality and learning of word representations jointly.

In the following, we first provide background to the word representations employed here (Section 2). We describe the model for co-compositionality in Section 3 and the corresponding neural network in Section 4. Evaluation and experiments are presented in Sections 5 and 6. Finally, we end with related work (Section 7) and conclusions (Section 8).

2 Word Vector Representations

2.1 Simple Distributional Semantic space (SDS) word vectors

Word meaning is often represented in a high dimensional space, where each element corresponds to some contextual element in which the word is found. Mitchell and Lapata (2010) present a co-occurrence-based semantic space called Simple Distributional Semantic space (SDS). Their SDS model uses a context window of five words on either side of the target word and 2,000 vector components, representing the most frequent context words (excluding a list of stop words). These components $v_i(t)$ were set to the ratio of the probability of the context word given the

[1] While we are inspired by co-compositionality, it is important to note that our model does not implement qualia structure and other important components of Generative Lexicon Theory. We operate within the vector space model of distributional semantics, so these ideas are implemented with matrix algebra, which is a natural fit with neural networks.

target word to the probability of the context word overall:

$$v_i(t) = \frac{p(c_i|t)}{p(c_i)} = \frac{freq_{c_i,t} \times freq_{total}}{freq_t \times freq_{c_i}} \quad (1)$$

where $freq_{c_i,t}$, $freq_{total}$, $freq_t$ and $freq_{c_i}$ are the frequencies of the context word c_i with the target word t, the total count of all word tokens, the frequency of the target word t, and the frequency of the context word c_i, respectively.

2.2 Neural Language Model (NLM) word embeddings

Another popular way to learn word representations is based on the Neural Language Model (NLM) (Bengio et al., 2003). In comparison with SDS, NLM tend to be low-dimensional (e.g. 50 dimensions) but employ dense features. These dense feature vectors are usually called word embeddings, and it has been shown that such vectors can capture interesting linear relationships, such as $king - man + woman \approx queen$ (Mikolov et al., 2013). In this work, we adopt the model by Collobert and Weston (2008). The idea is to construct a neural network based on word sequences, where one outputs high scores for n-grams that occur in a large unlabeled corpus and low scores for *nonsense* n-grams where one word is replaced by a random word. This word representation with NLM has been used to good effect, for example in (Turian et al., 2010; Collobert et al., 2011; Huang et al., 2012) where induced word representations are used with sophisticated features to improve performance in various NLP tasks.

Specifically, we first represent the word sequence as a vector $\mathbf{x} = [\mathbf{d}(w_1); \mathbf{d}(w_2); \ldots; \mathbf{d}(w_m)]$, where w_i is i_{th} word in the sequence, m is the window size, $\mathbf{d}(w)$ is the vector representation of word w (an n-dimensional column vector) and $[\mathbf{d}(w_1); \mathbf{d}(w_2); \ldots; \mathbf{d}(w_m)]$ is the concatenation of word vectors as an input of neural network. Second, we compute the score of the sequence,

$$score(\mathbf{x}) = \mathbf{s}^{\mathrm{T}}(\tanh(\mathbf{W}\mathbf{x} + \mathbf{b})) \quad (2)$$

where $\mathbf{W} \in \mathbb{R}^{h \times (mn)}$ and $\mathbf{s} \in \mathbb{R}^h$ are the first and second layer weights of the neural network, and $\mathbf{b} \in \mathbb{R}^h$ is the bias unit of hidden layer. The superscript T represents transposition, and $\tanh$ is applied element-wise. We also create a corrupted sequence $\mathbf{x}_c = [\mathbf{d}(w_1); \mathbf{d}(w_2); \ldots; \mathbf{d}(w_m{}')]$ where $w_m{}'$ is chosen randomly from the vocabulary. We compute the score of this implicit negative sequence $\mathbf{x}_c$ with the same neural network, $score(\mathbf{x}_c) = \mathbf{s}^{\mathrm{T}}(\tanh(\mathbf{W}\mathbf{x}_c + \mathbf{b}))$. Finally, we get the cost function of this training algorithm as follow.

$$J = \max(0, 1 - score(\mathbf{x}) + score(\mathbf{x}_c)) \quad (3)$$

In order to minimize this cost function, we optimize the parameters $\theta = (\mathbf{s}, \mathbf{W}, \mathbf{b}, \mathbf{x})$ via backpropagation with stochastic gradient descent (SGD).

3 The Model

3.1 Prototype Projection

Generative Lexicon Theory (Pustejovsky, 1995) makes a distinction between accidental polysemy (homonyms, e.g. *bank* as financial institution vs. as river side) and logical polysemy (e.g. figure and ground meanings of *door*). Our model handles both cases using the concept of projection to latent *prototype* space. The fundamental idea is that for each word w and a syntactic/semantic (binary) relation R (such as verb-object relation), w has a set of prototype words with which it frequently occurs in relation R. For example, if w is a word *company*, and R is the object-verb relation, prototype words should include *start*, *build*, and *buy* (Figure 1). For each word-relation pair, we pre-compute the latent semantic subspace spanned by these prototype words.

Later, when we encounter a phrase expressing a relation R between two words w_1 and w_2, each word is first projected onto a latent subspace determined by the other word and relation R. The projection operation shifts the meaning of individual words in accordance with context, and through this operation we realize coercion/co-composition. And finally, the meaning of the phrase is computed from the two projected points in the semantic space.

Let us describe how to compute the latent subspace associated with a word w_0 and a relation R. First, we collect from a corpus a set of prototype words that occur frequently in relation R with target word w_0. So for example in Figure 1, if $w_0 =$

verb	object	landmark	similarity(verb, landmark)	similarity(projected verb, landmark)
run	company	operate	0.40	0.70
meet	criterion	satisfy	0.49	0.71
spell	name	write	0.04	0.50

Table 1: Examples of verb-object pairs. Original verb and landmark verb similarity, prototype projected verb and landmark verb similarity, as measure by cosine using Collobert and Weston's word embeddings. *Meet* has a abstract meaning itself, but after prototype projection with matrix constructed by word vectors of $W(\textit{VerbOf}, \textit{criterion})$, *meet* is more close to meaning of *satisfy*.

company, and R = *VerbOf* is the object-verb relation,

$$W(\textit{VerbOf}, \textit{company}) = \{\textit{start}, \textit{build}, \ldots, \textit{buy}\}.$$

Now let $W(R, w_0) = \{w_1, w_2, \cdots, w_m\}$ be the m prototype words we collected, and let $\mathbf{d}(w)$ denote the n-dimensional (column) vector representation of word w (either by SDS or NLM representation). We make an $m \times n$ matrix $\mathbf{C}_{(R,w_0)}$ by stacking the prototype word vectors, i.e.,

$$\mathbf{C}_{(R,w_0)} = [\mathbf{d}(w_1), \mathbf{d}(w_2), \cdots, \mathbf{d}(w_m)]^{\mathrm{T}} \quad (4)$$

and then apply Singular Value Decomposition (SVD) to extract the latent space from this matrix:

$$\mathbf{C}_{(R,w_0)} \approx \mathbf{U}_k \mathbf{\Sigma}_k \mathbf{V}_k^{\mathrm{T}}. \quad (5)$$

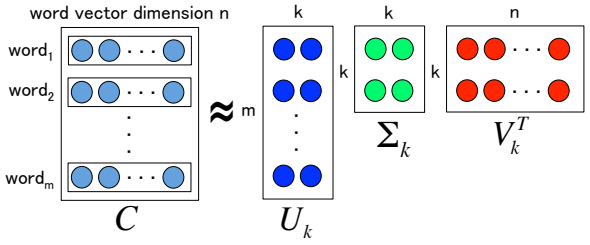

Figure 2: Graphical representation of SVD in our model.

Figure 2 shows the graphical representation of this matrix factorization. In NLP tasks, SVD is often applied to a term-document matrix, but in our model, we apply SVD to the matrix consisting of word vectors.

Intuitively, $\mathbf{\Sigma}_k \mathbf{V}_k^{\mathrm{T}}$ represents the latent subspace formed by prototypical words $W(R, w_0) = \{w_1, w_2, \cdots, w_m\}$. We call this matrix the *prototype space* of word w_0 with respect to relation R.

Note that the matrix of orthogonal projection onto this prototype space is given by $\mathbf{P}_{(R,w_0)} = (\mathbf{\Sigma}_k \mathbf{V}_k^{\mathrm{T}})^{\mathrm{T}} (\mathbf{\Sigma}_k \mathbf{V}_k^{\mathrm{T}})$. Hence, when we observe a relation $R(w_0, w)$, the projected representation of word w in this context is computed by $\mathbf{prpj}_{(R,w_0)}(w)$ defined as follows:

$$\mathbf{prpj}_{(R,w_0)}(w) = \mathbf{P}_{(R,w_0)} \mathbf{d}(w). \quad (6)$$

Table 1 shows several examples of how meanings change after prototype projection using word embeddings of Collobert and Weston (2008).[2]

3.2 Co-Compositionality

In order to model co-compositionality, we apply prototype projection to both the verb and the object. In particular, suppose verb is w_v and object is w_o, $\mathbf{C}_{(\textit{VerbOf},w_o)}$ is used to project w_v and $\mathbf{C}_{(\textit{ObjOf},w_v)}$ is used to project w_o. The vector that represents the overall meaning of verb-object with prototype projection is computed by:

$$\mathbf{cocomp}(w_v, w_o) = f(\mathbf{prpj}_{(\textit{VerbOf},w_o)}(w_v), \mathbf{prpj}_{(\textit{ObjOf},w_v)}(w_o)) \quad (7)$$

Function f can be a compositional computation like simple addition or element-wise multiplication of two vectors. This is graphically shown in Figure 1.

4 Unsupervised Learning of Co-Compositionality

In this section, we propose a new neural language model that learns word representations while jointly accounting for compositional semantics. One central assumption of our work (and many other works in compositional semantics) is that a single vector

[2] ronan.collobert.com/senna/

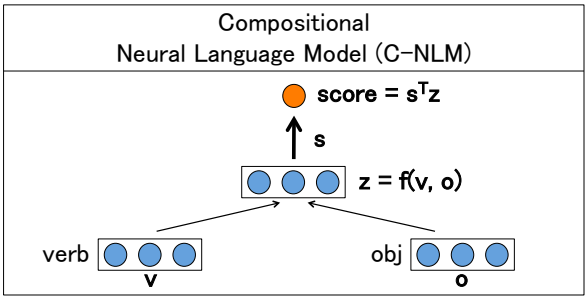

Figure 3: Compositional Neural Language Model (C-NLM).

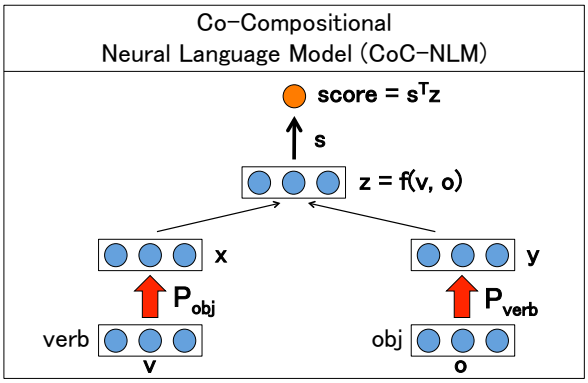

Figure 4: Co-Compositional Neural Language Model (CoC-NLM) is C-NLM with prototype projection.

per word type sufficiently represents the multiple meanings and usage patterns of a word.[3] That means that for a polysemous word, its word vector actually represents an aggregation of the distinctly different contexts it occurs in. We will show that such an assumption is quite reasonable under our model, since the prototype projections successfully tease out the proper semantics from these aggregate representations.

However, it is natural to wonder whether one can do better if one incorporates the compositional model into the training of the word representations in the first place. To do so, we formulate a novel model called *Compositional Neural Language Model* (Section 4.1). This model is a combination of an unsupervised training algorithm with basic compositionality (addition/multiplications). Then, we extend this model with the projection idea in section 3.2 to formulate a *Co-Compositional Neural Language Model* (Section 4.2).

4.1 Compositional Neural Language Model (C-NLM)

Compositional Neural Language Model (C-NLM) is a combination of a word representation learning method and compositional rule. In contrast to other compositional models based on machine learning, our model has no complex parameters for modeling composition. Composition is modeled using straightforward vector addition/multiplications; instead, what is learned is the word representation.

Figure 3 shows the C-NLM. The learning algorithm is unsupervised, and works by artificially generating negative examples in a fashion analogous to the NLM learning algorithm of (Collobert and Weston, 2008) and contrastive estimation (Smith and Eisner, 2005). First, given some initial word representations and raw sentences, we compute the compositional vector with function f (in this section, we will assume that we will be using the addition operator). Second, in order to obtain the score of compositional vector, we compute the dot product with vector $\mathbf{s} \in \mathbb{R}^n$ (n is the dimension of the word vector space): verb vector $\mathbf{v} = \mathbf{d}(w_v)$ and object vector $\mathbf{o} = \mathbf{d}(w_o)$.

$$score(\mathbf{v}, \mathbf{o}) = \mathbf{s}^{\mathrm{T}} f(\mathbf{v}, \mathbf{o}) = \mathbf{s}^{\mathrm{T}}(\mathbf{v} + \mathbf{o}) \qquad (8)$$

We also create a corrupted pair by substituting a random verb $w_{verb}{}'$. The cost function $J = \max(0, 1 - score(\mathbf{v}, \mathbf{o}) + score(\mathbf{v}_c, \mathbf{o}))$, where $\mathbf{v}_c$ is the word vector of $w_{verb}{}'$, encourages that the score of correct pair is higher than the score of the corrupt pair. Let $\mathbf{z} = \mathbf{v} + \mathbf{o}$, our model parameters are $\theta = (\mathbf{s}, \mathbf{z}, \mathbf{v})$. The optimization is divided into two steps:

1. Optimize $\mathbf{s}$ and $\mathbf{z}$ via SGD.

2. Let $\mathbf{z}_{new}$ be the updated $\mathbf{z}$ via step 1. The new verb vector $\mathbf{v}_{new}$ trained within additive compositionality is just $\mathbf{v}_{new} = \mathbf{z}_{new} - \mathbf{o}$. Note that if we also want to optimize $\mathbf{o}$, we may want to also corrupt the object and run SGD in step 2 as well.

4.2 Co-Compositional Neural Language Model (CoC-NLM)

We now add prototype projection into C-NLM, making our final model: *Co-Compositional Neural*

[3] There are works on *multiple* representations, e.g., (Reisinger and Mooney, 2010); we focus on single representation here.

Language Model (CoC-NLM). We define the score function as dot product of $\mathbf{s}$ and additional vector of prototype projected vectors (Figure 4). Let $\mathbf{P}_{obj} = \mathbf{P}_{(VerbOf,w_o)}$ and $\mathbf{P}_{verb} = \mathbf{P}_{(ObjOf,w_v)}$,

$$score(\mathbf{v}, \mathbf{o}) = \mathbf{s}^{\mathrm{T}}(\mathbf{P}_{obj}\mathbf{v} + \mathbf{P}_{verb}\mathbf{o}). \quad (9)$$

Let $\mathbf{x} = \mathbf{P}_{obj}\mathbf{v}$, $\mathbf{y} = \mathbf{P}_{verb}\mathbf{o}$ and $\mathbf{z} = \mathbf{x} + \mathbf{y}$. Our model parameters are $\theta = (\mathbf{s}, \mathbf{z}, \mathbf{v})$. The optimization algorithm of CoC-NLM is divided into three steps like C-NLM. First, we optimize $\mathbf{s}$ and $\mathbf{z}$. Second, the projected verb vector is updated as $\mathbf{x}_{new} = \mathbf{z}_{new} - \mathbf{y}$. Finally we optimize $\mathbf{v}$ to minimize the Euclidean distance between $\mathbf{x}_{new}$ and $\mathbf{P}_{obj}\mathbf{v}$, where λ is a regularization hyper-parameter:

$$J(\mathbf{v}) = \frac{1}{2}||\mathbf{x}_{new} - \mathbf{P}_{obj}\mathbf{v}||^2 + \frac{\lambda}{2}\mathbf{v}^{\mathrm{T}}\mathbf{v} \quad (10)$$

5 Evaluation

5.1 Dataset

In order to evaluate the performance of our new co-compositional model with prototype projection and word representation learning algorithm, we make use of the disambiguation task of transitive sentences developed by Grefenstette and Sadrzadeh (2011). This is an extension of the two words phrase similarity task defined in Mitchell and Lapata (2008), and constructed according to similar guidelines. The dataset consists of similarity judgments between a *landmark* verb and a triple consisting of a transitive target verb, subject and object extracted from the BNC corpus. Human judges give scores between 1 to 7, with higher scores implying higher semantic similarity. For example, Table 2 shows some examples from the data: we see that the verb *meet* with subject *system* and object *criterion* is judged similar to the landmark verb *satisfy* but not *visit*. The dataset contains a total of 2500 similarity judgements, provided by 25 participants.[4] The task is to have the model produce a score for each pair of landmark verb and verb-subject-object triple. Models are evaluated by computing the Spearman's ρ correlation between its similarity scores and that of the human judgments.

[4] http://www.cs.ox.ac.uk/people/edward.grefenstette/

verb	subj	obj	landmark	sim
meet	system	criterion	satisfy	6
meet	system	criterion	visit	1
write	student	name	spell	7
write	student	paper	spell	2

Table 2: Examples from the disambiguation task developed by Grefenstette and Sadrzadeh (2011). Human judges give scores between 1 to 7, with higher scores implying higher semantic similarity. Verb *meet* with subject *system* and object *criterion* is judged similar to the landmark verb *satisfy* but not *visit*.

5.2 Baselines

We compare our model against multiple baselines for semantic compositionality:

1. Mitchell and Lapata's (2008) additive and element-wise multiplicative model as simplest baselines.

2. Grefenstette and Sadrzadeh's (2011) model based on the abstract categorical framework (Coecke et al., 2010). This model computes the outer product of the subject and object vector, the outer product of the verb vector with itself, and then the element-wise product of both results.

3. Erk and Padó's (2008) model, which adapts the word vectors based on context and is the most similar in terms of motivation to ours.

4. Van de Cruy et al. (2013) multi-way interaction model based on matrix factorization. This achieves the best result for this task to date.

A detailed explanation of these models will be provided in Section 7. For the underlying word representations, we experiment with sparse 2000-dim SDS and dense 50-dim NLM. These are provided by Blacoe and Lapata (2012)[5] and trained on the British National Corpus (BNC). We are interested in knowing how sensitive each model is to the underlying word representation. In general, this is a challenging task: the upper-bound of $\rho = 0.62$ is the inter-annotator agreement.

[5] http://homepages.inf.ed.ac.uk/s1066731/index.php?page=resources

5.3 Implementation details

In terms of implementation detail, our model and our re-implementation of Erk and Pado's model make use of the ukWaC corpus (Baroni et al., 2009).[6] This corpus is a two billion word corpus automatically harvested from the web and parsed by the MaltParser (Nivre et al., 2006). We use ukWaC corpus to collect $W(\textit{VerbOf}, w_o)$ and $W(\textit{ObjOf}, w_v)$ for prototype projections. We also extract about 5000 verb-object pairs that relevant for testdata from this corpus to train our neural network learning algorithm. In our co-compositional model, the contribution ratio of SVD is set to 80% (i.e. automatically fixing k in SVD to include 80% of the top singular values). We set the number of prototype vectors to be $m = 20$, where $W(\textit{VerbOf}, w_o)$ is filtered with high frequency words and $W(\textit{ObjOf}, w_v)$ is filtered with both high frequency and high similarity words. In our model, we output the scores for SVO triple sentence dataset as (subject=w_s, verb=w_v, object=w_o, f = Addition/Multiplication):

$$\mathbf{cocomp}(w_s, w_v, w_o) = f(\mathbf{d}(w_s), \mathbf{cocomp}(w_v, w_o)) \quad (11)$$

6 Results and Discussion

6.1 Main Results: The Correlation

Table 3 shows the correlation scores of various models. Our observations are as follows:

1. The best reported result for this task (Van de Cruys et al., 2013) is $\rho = 0.37$. Our model (with NLM as word representation and f=Addition as operator) achieves $\rho = 0.44$, outperforming it by a large margin. To the best of our knowledge, this is now state-of-the-art result for this task.

2. Our model is not very sensitive to the underlying word representation. With f=Addition, we have $\rho = 0.41$ for SDS vs $\rho = 0.44$ for NLM. With f=Multiply, we have $\rho = 0.37$ for SDS vs. $\rho = 0.35$ for NLM. This implies that the prototype projection is robust to the underlying word representation, which is a desired characteristic of compositional models.

[6] http://wacky.sslmit.unibo.it/doku.php?id=corpora

Model	ρ
Grefenstette and Sadrzadeh (2011)	0.21
Add (SDS)	0.31
Add (NLM)	0.31
Multiply (SDS)	0.35
Multiply (NLM)	0.30
Van de Cruys et al. (2013)	0.37
Erk and Padó (SDS)	0.39
Erk and Padó (NLM)	0.03
Co-Comp with f=Add (SDS)	0.41
Co-Comp with f=Add (NLM)	**0.44**
Co-Comp with f=Multiply (SDS)	0.37
Co-Comp with f=Multiply (NLM)	0.35
Upper bound	0.62

Table 3: Results of the different compositionality models on the similarity task. The number of prototype words $m = 20$ in all our models. Our model (f=Addition and NLM) achieves the new state-of-the-art performance for this task ($\rho = 0.44$).

3. The contextual model of Erk and Padó (SDS) also performed relatively well ($\rho = 0.39$), in fact outperforming the Van de Cruy et al. (2013) result as well. This means that the general idea of adapting word representations based on context is a very powerful one. However, Erk and Padó's model using the NLM representation is extremely poor ($\rho = 0.03$). The reason is that it uses a product operation under-the-hood to adapt the vectors, which inherently assumes a sparse representation. In this sense, our projection approach is more robust.

The state-of-the-art result for our model in Table 3 does not yet make use of the training algorithm described in Section 4. It is simply implementing the co-compositionality idea using prototype projections (Section 3.2). Next in Section 6.2 we will show additional gains using unsupervised learning.

6.2 Improvements from unsupervised learning

In this experiment, we examine how much gain is possible by re-training the word representation of verbs using the unsupervised algorithm described in Section 4. We focus on the additive model of Compositional NLM, both basic and prototype projection. The initial word representation is from

model	original representation	re-trained
C-NLM	0.31	0.38
CoC-NLM	0.44	**0.47**

Table 4: Results of re-training the word representation for C-NLM and CoC-NLM. Learning rate $\alpha = 0.01$, regularization $\lambda = 10^{-4}$ and iteration = 20. One iteration is one run through the dataset of 5000 verb-object pairs which we made from the ukWaC corpus.

NLM. Table 4 shows the gains in correlation score.

This result shows that our learning model successfully captures good representation within co-compositionality of additive model. In contrast to other previous compositional models, our model does not require estimating a large number of parameters for computation of compositional vectors and word representation itself is more suitable for it. Furthermore, learning is very fast, taking about 10 minutes for C-NLM on a standard machine with Intel Core i7 2.93Ghz CPU and 8GB of RAM.

6.3 The number of prototype words

The number of prototype words (m in Figure 1) we use to generate the prototype space is one hyper-parameter that our model has. Here, we analyze the effect of the choice of m. Figure 5 shows the relation of m and the performance of co-compositional model with prototype projections using either SDS or NLM representations. In general, both NLM and SDS show relatively smooth and flat curves across m, indicating the relative robustness of the approach. Nevertheless, results do degrade for large m, due to increase in noise from non-prototype words. Further, it does appear that NLM has a slower drop in correlation with increasing m compared with SDS. This suggests that NLM is more robust, which is possibly attributable to the dense and low-dimensional distributed features.

6.4 Variations in model configuration

We have presented a compositional model of the form $\mathbf{d}(w_s) + \mathbf{cocomp}(w_v, w_o)$, where prototype projections are performed on both w_v and w_o and w_s is composed as is without projection. In general, we have the freedom to choose what to project and what not to project under this co-compositional framework. Here in Table 5 we show the results of

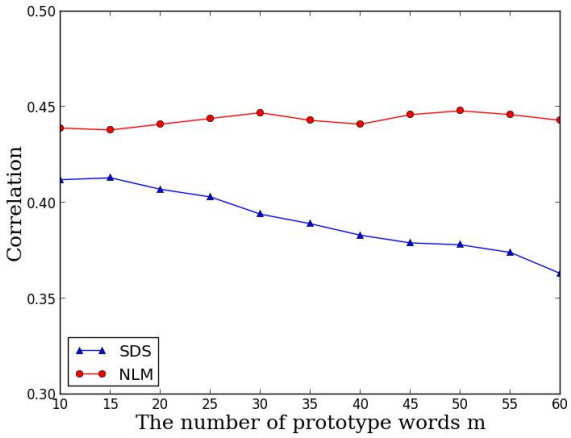

Figure 5: The relation between the number of prototype words and correlation of SDS or NLM. In general, NLM has higher correlation than SDS and is more robust across the m.

Subj	Verb	Obj	NLM ρ	SDS ρ
prpj	prpj	prpj	0.39	0.37
+	prpj	prpj	0.44	0.41
	prpj	prpj	0.45	0.41
+	prpj	+	0.43	0.38
	prpj	+	0.43	0.38
+	+	+	0.31	0.31

Table 5: Variants of the full co-compositional model, based on how subject, verb, and object vector representations are included. prpj indicates that prototype projection is used. + indicates that the vector is added without projection first. Blank indicates that the vector is not used in the final compositional score.

these variants, using f =Addition and SDS/NLM representations without re-training. We note that our positive results mainly come from the verb projections. Subject information actually does not help. We believe this best configuration is task-dependent; in this test collection, the subjects appear to have little contribution to the landmark verb.

7 Related work

In recent years, several sophisticated vector space models have been proposed for computing compositional semantics. Mitchell and Lapata (2010), Erk (2012) and Baroni et al. (2013) are recommended survey papers.

One of the first approaches is the vector addition/multiplication idea of Mitchell and Lapata (2008). The appeal of this kind of simple approach is its intuitive geometric interpretation and its robustness to various datasets. However, it may not be sufficiently expressive to represent the various factors involved in compositional semantics, such as syntax and context. To this end, Baroni and Zamparelli (2010) present a compositional model for adjectives and nouns. In their model, an adjective is a matrix operator that modifies the noun vector into an adjective-noun vector. Zanzotto et al. (2010) and Guevara (2010) also proposed linear transformation models for composition and address the issue of estimating large matrices with least squares or regression techniques. Socher et al. (2012) extend this linear transformation approach with the more powerful model of Matrix-Vector Recursive Neural Networks (MV-RNN). Each node in a parse tree is assigned both a vector and a matrix. The vector captures the actual meaning of the word itself, while the matrix is modeled as a operator that modify the meaning of neighboring words and phrases. This model captures semantic change phenomenon like *not bad* is similar to *good* due to a composition of the *bad* vector with a meaning-flipping *not* matrix. But this MV-RNN also need to optimize all matrices of words from initial value (identity plus a small amount of Gaussian noise) with supervised dataset like movie reviews. Our prototype projection model is similar to these models as a matrix-vector operation, except that the matrix is not learned and computed from prototype words. In future work, we can imagine integrating the two models, using these prototype projection matrices as initial values for MV-RNN training (Socher et al., 2012).

Another approach is exemplified by Coecke et al. (2010). In their mathematical framework unifying categorical logic and vector space models, the sentence vector is modeled as a function of the Kronecker product of its word vectors. Grefenstette and Sadrzadeh (2011) implement this based on unsupervised learning of matrices for relational words and apply them to the vectors of their arguments. Their idea is that words with relational types, such as verbs, adjectives, and adverbs are matrices that act as a filter on their arguments. They also developed a new semantic similarity task based on transitive verbs, which is the dataset we used here. The previous state-of-the-art result for this task comes from the model of Van de Cruys et al. (2013). They model compositionality as a multi-way interaction between latent factors, which are automatically constructed from corpus data via matrix factorization.

Composition Operator	Parameter
Add: $w_1 u + w_2 v$	$w_1, w_2 \in \mathbb{R}$
Multiply: $u^{w_1} \odot v^{w_2}$	$w_1, w_2 \in \mathbb{R}$
FullAdd: $W_1 u + W_2 v$	$W_1, W_2 \in \mathbb{R}^{n \times n}$
LexFunc: $A_u v$	$A_u \in \mathbb{R}^{n \times n}$
FullLex: $\sigma([W_1 A_u v, W_2 A_v u])$	$A_u, A_v \in \mathbb{R}^{n \times n}$ $W_1, W_2 \in \mathbb{R}^{n \times n}$
Ours (Add): $P_{(R,v)} u + P_{(R,u)} v$	SVD's (m, k)
Ours (Mult): $P_{(R,v)} u \odot P_{(R,u)} v$	SVD's (m, k)

Table 6: Comparison of composition operators that combine two word vector representations, $u, v \in \mathbb{R}^n$ and their learning parameters. Our model only needs two hyper-parameters: the number of prototype words m and dimensional reduction k in SVD

Comprehensive evaluation of various existing models are reported in (Blacoe and Lapata, 2012; Dinu et al., 2013). Blacoe and Lapata (2012) highlight the importance of jointly examining word representations and compositionality operators. However, two out of three composition methods they evaluate are parameter-free, so that they can side-step the issue of parameter estimation. Dinu et al. (2013) describe the relation between word vector and compositionality in more detail with free parameters. Table 6 summarizes some ways to compose the meaning of two word vectors (u, v), following (Dinu et al., 2013). These range from simple operators (e.g. Add and Multiply) to expressive models with many free parameters (e.g. LexFunc, FullLex). Many of these models need to optimize $n \times n$ parameters, which may be large. On the other hand, our model only needs two hyper-parameters: the number of prototype words m and dimensional reduction k in SVD (Table 6). Furthermore, our model performance with neural language model word embeddings is robust to variations in m.

Most closely related to our work is the work by Erk and Padó (2008; 2009) and Thater et al. (2010; 2011), which falls under the research theme of computing *word meaning in context*. Both methods are characterized by the use of selectional prefer-

ence information for subjects, verbs, and objects in context; our prototype word vectors are essentially equivalent to this idea. The main difference is in how we modify the target word representation $\mathbf{v}$ using this information: whereas we project $\mathbf{v}$ onto a latent subspace formed by collection of prototype vectors, Erk and Padó (2008; 2009) and Thater et al. (2010; 2011) use the prototype vectors to directly modify the elements of $\mathbf{v}$, i.e. by element-wise product with the centroid prototype vector. Intuitively, both our method and theirs essentially delete part of a word vector representation to adapt the meaning in context. We believe the projection is more robust to the underlying word representation (and this is shown in the results for SDS vs. NLM representations), but we note that we may be able to borrow some of more sophisticated ways to find prototype vectors from Erk and Padó (2008; 2009) and Thater et al. (2010; 2011).

8 Conclusion and Future Work

We began this work by asking how it is possible to handle polysemy issues in compositional semantics, especially when adopting distributional semantics methods that construct only one representation per word type. After all, the different senses of the same word are all conflated into a single vector representation. We found our inspiration in Generative Lexicon Theory (Pustejovsky, 1995), where ambiguity is resolved due to *co-compositionality* of the words in the sentence, i.e., the meaning of an ambiguous verb is generated by the properties the object it takes, and vice versa. We implement this idea in a novel neural network model using *prototype projections*. The advantages of this model is that it is robust to the underlying word representation used and that it enables an effective joint learning of word representations. The model achieves the current state-of-the-art performance ($\rho = 0.47$) on the semantic similarity task of transitive verbs (Grefenstette and Sadrzadeh, 2011).

Directions for future research include:

- Experiments on other semantics tasks, such as paraphrase detection, word sense induction, and word meaning in context.
- Extension to more holistic sentence-level composition using a matrix-vector recursive framework like (Socher et al., 2012).
- Explore further the potential synergy between Distributional Semantics and the Generative Lexicon.

(evamaria.vecchi|roberto.zamparelli|marco.baroni)@unitn.it

Abstract

In this study, we use compositional distributional semantic methods to investigate restrictions in adjective ordering. Specifically, we focus on properties distinguishing Adjective-Adjective-Noun phrases in which there is flexibility in the adjective ordering from those bound to a rigid order. We explore a number of measures extracted from the distributional representation of AAN phrases which may indicate a word order restriction. We find that we are able to distinguish the relevant classes and the correct order based primarily on the degree of modification of the adjectives. Our results offer fresh insight into the semantic properties that determine adjective ordering, building a bridge between syntax and distributional semantics.

1 Introduction

A prominent approach for representing the meaning of a word in Natural Language Processing (NLP) is to treat it as a numerical vector that codes the pattern of co-occurrence of that word with other expressions in a large corpus of language (Sahlgren, 2006; Turney and Pantel, 2010). This approach to semantics (sometimes called *distributional semantics*) scales well to large lexicons and does not require words to be manually disambiguated (Schütze, 1997). Until recently, however, this method had been almost exclusively limited to the level of single content words (nouns, adjectives, verbs), and had not directly addressed the problem of *compositionality* (Frege, 1892; Montague, 1970; Partee, 2004), the crucial property of natural language which allows speakers to derive the meaning of a complex linguistic constituent from the meaning of its immediate syntactic subconstituents.

Several recent proposals have strived to extend distributional semantics with a component that also generates vectors for complex linguistic constituents, using compositional operations in the vector space (Baroni and Zamparelli, 2010; Guevara, 2010; Mitchell and Lapata, 2010; Grefenstette and Sadrzadeh, 2011; Socher et al., 2012). All of these approaches construct distributional representations for novel phrases starting from the corpus-derived vectors for their lexical constituents and exploiting the geometric quality of the representation. Such methods are able to capture complex semantic information of adjective-noun (AN) phrases, such as characterizing modification (Boleda et al., 2012; Boleda et al., 2013), and can detect semantic deviance in novel phrases (Vecchi et al., 2011). Furthermore, these methods are naturally recursive: they can derive a representation not only for, e.g., *red car*, but also for *new red car*, *fast new red car*, etc. This aspect is appealing since trying to extract meaningful representations for all recursive phrases directly from a corpus will result in a problem of sparsity, since most large phrases will never occur in any finite sample.

Once we start seriously looking into recursive modification, however, the issue of modifier ordering restrictions naturally arises. Such restrictions have often been discussed in the theoretical linguistic literature (Sproat and Shih, 1990; Crisma, 1991; Scott, 2002), and have become one of the key in-

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 141–151,
Seattle, Washington, USA, 18-21 October 2013.

gredients of the 'cartographic' approach to syntax (Cinque, 2002). In this paradigm, the ordering is derived by assigning semantically different classes of modifiers to the specifiers of distinct functional projections, whose sequence is hard-wired. While it is accepted that in different languages movement can lead to a principled rearrangement of the linear order of the modifiers (Cinque, 2010; Steddy and Samek-Lodovici, 2011), one key assumption of the cartographic literature is that exactly one intonationally unmarked order for stacked adjectives should be possible in languages like English. The possibility of alternative orders, when discussed at all, is attributed to the presence of idioms (*high American building*, but *American high officer*), to asyndetic conjunctive meanings (e.g. *new creative idea* parsed as *[new & creative] idea*, rather than *[new [creative idea]]*), or to semantic category ambiguity for any adjective which appears in different orders (see Cinque (2004) for discussion).

In this study, we show that the existence of both rigid and flexible order cases is robustly attested at least for adjectival modification, and that flexible ordering is unlikely to reduce to idioms, coordination or ambiguity. Moreover, we show that at least for some recursively constructed adjective-adjective-noun phrases (AANs) we can extract meaningful representations from the corpus, approximating them reasonably well by means of compositional distributional semantic models, and that the semantic information contained in these models characterizes which AA will have rigid order (as with *rapid social change* vs. **social rapid change*), or flexible order (e.g. *total estimated population* vs. *estimated total population*). In the former case, we find that the same distributional semantic cues discriminate between correct and wrong orders.

To achieve these goals, we consider various properties of the distributional representation of AANs (both corpus-extracted and compositionally-derived), and explore their correlation with restrictions in adjective ordering. We conclude that measures that quantify the degree to which the modifiers have an impact on the distributional meaning of the AAN can be good predictors of ordering restrictions in AANs.

2 Materials and methods

2.1 Semantic space

Our initial step was to construct a *semantic space* for our experiments, consisting of a matrix where each row represents the meaning of an adjective, noun, AN or AAN as a distributional vector, each column a semantic dimension of meaning. We first introduce the source corpus, then the vocabulary of words and phrases that we represent in the space, and finally the procedure adopted to build the vectors representing the vocabulary items from corpus statistics, and obtain the semantic space matrix. We work here with a traditional, window-based semantic space, since our focus is on the effect of different composition methods given a common semantic space. In addition, Blacoe and Lapata (2012) found that a vanilla space of this sort performed best in their composition experiments, when compared to a syntax-aware space and to neural language model vectors such as those used for composition by Socher et al. (2011).

Source corpus We use as our source corpus the concatenation of the Web-derived ukWaC corpus, a mid-2009 dump of the English Wikipedia and the British National Corpus[1]. The corpus has been tokenized, POS-tagged and lemmatized with the TreeTagger (Schmid, 1995), and it contains about 2.8 billion tokens. We extract all statistics at the lemma level, meaning that we consider only the canonical form of each word ignoring inflectional information, such as pluralization and verb inflection.

Semantic space vocabulary The words/phrases in the semantic space must of course include the items that we need for our experiments (adjectives, nouns, ANs and AANs used for model training, as input to composition and for evaluation). Therefore, we first populate our semantic space with a core vocabulary containing the 8K most frequent nouns and the 4K most frequent adjectives from the corpus.

The ANs included in the semantic space are composed of adjectives with very high frequency in the corpus so that they are generally able to combine with many classes of nouns. They are composed of the 700 most frequent adjectives and 4K most frequent nouns in the corpus, which were manually

[1] http://wacky.sslmit.unibo.it, http://en.wikipedia.org, http://www.natcorp.ox.ac.uk

controlled for problematic cases – excluding adjectives such as *above*, *less*, or *very*, and nouns such as *cant*, *mph*, or *yours* – often due to tagging errors. We generated the set of ANs by crossing the filtered 663 adjectives and 3,910 nouns. We include those ANs that occur at least 100 times in the corpus in our vocabulary, which amounted to a total of 128K ANs.

Finally, we created a set of AAN phrases composed of the adjectives and nouns used to generate the ANs. Additional preprocessing of the generated A_xA_yNs includes: (i) control that both A_xN and A_yN are attested in the corpus; (ii) discard any A_xA_yN in which A_xN or A_yN are among the top 200 most frequent ANs in the source corpus (as in this case, order will be affected by the fact that such phrases are almost certainly highly lexicalized); and (iii) discard AANs seen as part of a conjunction in the source corpus (i.e., where the two adjectives appear separated by comma, *and*, or *or*; this addresses the objection that a flexible order AAN might be a hidden A(&)A conjunction: we would expect that such a conjunction should also appear overtly elsewhere). The set of AANs thus generated is then divided into two types of adjective ordering:

1. **Flexible Order** (FO): phrases where *both* orders, A_xA_yN and A_yA_xN, are attested ($f>10$ in both orders).

2. **Rigid Order** (RO): phrases with *one* order, A_xA_yN, attested ($20<f<200$)[2] and A_yA_xN unattested.

All AANs that did not meet either condition were excluded from our semantic space vocabulary. The preserved set resulted in 1,438 AANs: 621 flexible order and 817 rigid order. Note that there are almost as many flexible as rigid order cases; this speaks against the idea that free order is a marginal phenomenon, due to occasional ambiguities that reassign the adjective to a different semantic class. The existence of freely ordered stacked adjectives is a robust phenomenon, which needs to be addressed.

[2]The upper threshold was included as an additional filter against potential multiword expressions. Of course, the boundary between phrases that are at least partially compositional and those that are fully lexicalized is not sharp, and we leave it to further work to explore the interplay between the semantic factors we study here and patterns of lexicalization.

Model	ρ	*M&L*
CORP	0.41	0.43
W.ADD	0.41	0.44
F.ADD	0.40	–
MULT	0.33	0.46
LFM	0.40	–

Table 1: Correlation scores (Spearman's ρ, all significant at $p<0.001$) between cosines of corpus-extracted or model-generated AN vectors and phrase similarity ratings collected in Mitchell and Lapata (2010), as well as best reported results from Mitchell & Lapata (M&L).

Semantic vector construction For each of the items in our vocabulary, we first build 10K-dimensional vectors by recording the item's sentence-internal co-occurrence with the top 10K most frequent content lemmas (nouns, adjectives, verbs or adverbs) in the corpus. We built a rank of these co-occurrence counts, and excluded as stop words from the dimensions any element of any POS whose rank was from 0 to 300. The raw co-occurrence counts were then transformed into (positive) Pointwise Mutual Information (pPMI) scores (Church and Hanks, 1990). Next, we reduce the full co-occurrence matrix to 300 dimensions applying the Non-negative Matrix Factorization (NMF) operation (Lin, 2007). We did not tune the semantic vector construction parameters, since we found them to work best in a number of independent earlier experiments.

Corpus-extracted vectors (*corp*) were computed for the ANs and for the flexible order and attested rigid order AANs, and then mapped onto the 300-dimension NMF-reduced semantic space. As a sanity check, the first row of Table 1 reports the correlation between the AN phrase similarity ratings collected in Mitchell and Lapata (2010) and the cosines of corpus-extracted vectors in our space, for the same ANs. For the AAN vectors, which are sparser, we used human judgements to build a reliable subset to serve as our gold standard, as detailed in Section 2.4.

2.2 Composition models

We focus on four composition functions proposed in recent literature with high performance in a number of semantic tasks. We first consider methods proposed by Mitchell and Lapata (2010) in

which the model-generated vectors are simply obtained through component-wise operations on the constituent vectors. Given input vectors $\vec{u}$ and $\vec{v}$, the multiplicative model (MULT) computes a composed vector by component-wise multiplication ($\odot$) of the constituent vectors, where the i-th component of the composed vector is given by $p_i = u_i v_i$.[3] Given an $A_x A_y N$ phrase, this model extends naturally to the recursive setting of this experiment, as seen in Equation (1).

$$\vec{p} = \vec{a}_x \odot \vec{a}_y \odot \vec{n} \quad (1)$$

This composition method is order-insensitive, the formula above corresponding to the representation of both $A_x A_y N$ and $A_y A_x N$.

In the weighted additive model (W.ADD), we obtain the composed vector as a weighted sum of the two component vectors: $\vec{p} = \alpha\vec{u} + \beta\vec{v}$, where α and β are scalars. Again, we can easily apply this function recursively, as in Equation (2).

$$\vec{p} = \alpha\vec{a}_x + \beta(\alpha\vec{a}_y + \beta\vec{n}) = \alpha\vec{a}_x + \alpha\beta\vec{a}_y + \beta^2\vec{n} \quad (2)$$

We also consider the full extension of the additive model (F.ADD), presented in Guevara (2010) and Zanzotto et al. (2010), such that the component vectors are pre-multiplied by weight matrices before being added: $\vec{p} = \mathbf{W}_1\vec{u} + \mathbf{W}_2\vec{v}$. Similarly to the W.ADD model, Equation (3) describes how we apply this function recursively.

$$\begin{aligned}\vec{p} &= \mathbf{W}_1\vec{a}_x + \mathbf{W}_2(\mathbf{W}_1\vec{a}_y + \mathbf{W}_2\vec{n}) \quad (3)\\ &= \mathbf{W}_1\vec{a}_x + \mathbf{W}_2\mathbf{W}_1\vec{a}_y + \mathbf{W}_2^2\vec{n}\end{aligned}$$

Finally, we consider the lexical function model (LFM), first introduced in Baroni and Zamparelli (2010), in which attributive adjectives are treated as functions from noun meanings to noun meanings. This is a standard approach in Montague semantics (Thomason, 1974), except noun meanings here are distributional vectors, not denotations, and adjectives are (linear) functions learned from a large corpus. In this model, predicted vectors are generated by multiplying a function matrix $\mathbf{U}$ with a component vector: $\vec{p} = \mathbf{U}\vec{v}$. Given a weight matrix, $\mathbf{A}$, for each adjective in the phrase, we apply the functions in sequence recursively as shown in Equation (4).

$$\vec{p} = \mathbf{A}_x(\mathbf{A}_y\vec{n}) \quad (4)$$

Composition model estimation Parameters for W.ADD, F.ADD and LFM were estimated following the strategy proposed by Guevara (2010) and Baroni and Zamparelli (2010), recently extended to all composition models by Dinu et al. (2013b). Specifically, we learn parameter values that optimize the mapping from the noun to the AN as seen in examples of corpus-extracted N-AN vector pairs, using least-squares methods. All parameter estimations and phrase compositions were implemented using the DISSECT toolkit[4] (Dinu et al., 2013a), with a training set of 74,767 corpus-extracted N-AN vector pairs, ranging from 100 to over 1K items across the 663 adjectives. Importantly, while below we report experimental results on capturing various properties of recursive AAN constructions, no AAN was seen during training, which was based entirely on mapping from N to AN. Table 1 reports the results attained by our model implementations on the Mitchell and Lapata AN similarity data set.

2.3 Measures of adjective ordering

Our general goal is to determine which linguistically-motivated factors distinguish the two types of adjective ordering. We hypothesize that in cases of flexible order, the two adjectives will have a similarly strong effect on the noun, thus transforming the meaning of the noun equivalently in the direction of both adjectives and component ANs. For example, in the phrase *creative new idea*, the *idea* is both *new* and *creative*, so we would expect a similar impact of modification by both adjectives.

On the other hand, we predict that in rigid order cases, one adjective, the one closer to the noun, will dominate the meaning of the phrase, distorting the meaning of the noun by a significant amount. For example, the phrase *different architectural style* intuitively describes an *architectural style* that is *dif-*

[3] We conjecture that the different performance of our multiplicative model and M&L's (cf. Table 1) is due to the fact that we use log-transformed pPMI scores, making their multiplicative model more akin to our additive approach.

[4] http://clic.cimec.unitn.it/composes/toolkit

ferent, rather than a *style* that is to the same extent *architectural* and *different*.

We consider a number of measures that could capture our intuitions and quantify this difference, exploring the distance relationship between the AAN vectors and each of the AAN subparts. First, we examine how the similarity of an AAN to its component adjectives affects the ordering, using the cosine between the A_xA_yN vector and each of the component A vectors as an expression of similarity (we abbreviate this as $cosA_x$ and $cosA_y$ for the first and second adjective, respectively).[5] Our hypothesis predicts that flexible order AANs should remain similarly close to both component As, while rigid order AANs should remain systematically closer to their A_y than to their A_x.

Next, we consider the similarity between the A_xA_yN vector and its component N vector ($cosN$). This measure is aimed at verifying if the degree to which the meaning of the head noun is distorted could be a property that distinguishes the two types of adjective ordering. Again, vectors for flexible order AANs should remain closer to their component nouns in the semantic space, while rigid order AANs should distort the meaning of the head noun more notably.

We also inspect how the similarity of the AAN to its component AN vectors affects the type of adjective ordering ($cosA_xN$ and $cosA_yN$). Considering the examples above, we predict that the flexible order AAN *creative new idea* will share many properties with both *creative idea* and *new idea*, as represented in our semantic space, while rigid order AANs, like *different architectural style*, should remain quite similar to the A_yN, i.e., *architectural style*, and relatively distant from the A_xN, i.e., *different style*.

Finally, we consider a measure that does not exploit distributional semantic representations, namely the difference in PMI between A_xN and A_yN (ΔPMI). Based on our hypothesis described for the other measures, we expect the association in the corpus of A_yN to be much greater than A_xN for rigid order AANs, resulting in a large negative ΔPMI values. While flexible order AANs should have similar association strengths for both A_xN and A_yN, thus we expect ΔPMI to be closer to 0 than for rigid order AANs.

[5] In the case of LFM, we compare the similarity of the AAN with the AN centroids for each adjective, since the model does not make use of A vectors (Baroni and Zamparelli, 2010).

2.4 Gold standard

To our knowledge, this is the first study to use distributional representations of recursive modification; therefore we must first determine if the composed AAN vector representations are semantically coherent objects. Thus, for vector analysis, a *gold standard* of 320 corpus-extracted AAN vectors were selected and their quality was established by inspecting their nearest neighbors. In order to create the gold standard, we ran a crowdsourcing experiment on CrowdFlower[6] (Callison-Burch and Dredze, 2010; Munro et al., 2010), as follows.

First, we gathered a randomly selected set of 600 corpus-extracted AANs, containing 300 flexible order and 300 attested rigid order AANs. We then extracted the top 3 nearest neighbors to the corpus-extracted AAN vectors as represented in the semantic space[7]. Each AAN was then presented with each of the nearest neighbors, and participants were asked to judge "how strongly related are the two phrases?" on a scale of 1-7. The rationale was that if we obtained a good distributional representation of the AAN, its nearest neighbors should be closely related words and phrases. Each pair was judged 10 times, and we calculated a *relatedness* score for the AAN by taking the average of the 30 judgments (10 for each of the three neighbors).

The final set for the gold standard contains the 320 AANs (152 flexible order and 168 attested rigid order) which had a relatedness score over the median-split (3.9). Table 2 shows examples of gold standard AANs and their nearest neighbors. As these example indicate, the gold standard AANs reside in semantic neighborhoods that are populated by intuitively strongly related expressions, which makes them a sensible target for the compositional models to approximate.

We also find that the neighbors for the AANs represent an interesting variety of types of semantic

[6] http://www.crowdflower.com

[7] The top 3 neighbors included adjectives, nouns, ANs and AANs. The preference for ANs and AANs, as seen in Table 2, is likely a result of the dominance of those elements in the semantic space (c.f. Section 2.1).

medieval old town	*contemp. political issue*

Table 2: Examples of the nearest neighbors of the gold standard, both flexible order (left column) and rigid order (right column) AANs.

similarity. For example, the nearest neighbors to the corpus-extracted vectors for *medieval old town* and *rapid social change* include phrases which describe quite complex associations, cf. Table 2. In addition, we find that the nearest neighbors for flexible order AAN vectors are not necessarily the same for both adjective orders, as seen in the difference in neighbors of *national daily newspaper* and *daily national newspaper*. We can expect that the change in order, when acceptable and frequent, does not necessarily yield synonymous phrases, and that corpus-extracted vector representations capture subtle differences in meaning.

3 Results

3.1 Quality of model-generated AAN vectors

Our nearest neighbor analysis suggests that the corpus-extracted AAN vectors in the gold standard are meaningful, semantically coherent objects. We can thus assess the quality of AANs recursively generated by composition models by how closely they approximate these vectors. We find that the performances of most composition models in approximating the vectors for the gold AANs is quite satisfactory (cf. Table 3). To put this evaluation into perspective, note that 99% of the simulated distribution of pairwise cosines of corpus-extracted AANs is below the mean cosine of the worst-performing model (MULT), that is, a cosine of 0.424 is very significantly above what is expected by chance for two random corpus-extracted AAN vectors. Also, observe that the two more parameter-rich models are better than W.ADD, and that LFM also significantly outperforms F.ADD.

	Gold	*FO*	*RO*
W.ADD	0.565	0.572	0.558
F.ADD	0.618	0.622	0.614
MULT	0.424	0.468	0.384
LFM	0.655	0.675	0.637

Table 3: Mean cosine similarities between the corpus-extracted and model-generated gold AAN vectors. All pairwise differences between models are significant according to Bonferroni-corrected paired t-tests ($p<0.001$). For MULT and LFM, the difference between mean flexible order (FO) and rigid order (RO) cosines is also significant.

Further, the results show that the models are able to approximate flexible order AAN vectors better than rigid order AANs, significantly so for LFM and MULT. This result is quite interesting because it suggests that flexible order AANs express a more literal (or intersective) modification by both adjectives, which is what we would expect to be better captured by compositional models. Clearly, a more complex modification process is occurring in the case of rigid order AANs, as we predicted to be the case.

3.2 Distinguishing flexible vs. rigid order

In the results reported below, we test how both our baseline ΔPMI measure and the distance from the AAN and its component parts changes depending on the type of adjective ordering to which the AAN belongs. From this point forward, we only use gold standard items, where we are sure of the quality of the corpus-extracted vectors. The first block of Table 4 reports the t-normalized difference between flexible order and rigid order mean cosines for the corpus-extracted vectors.

	Measure	*t*	*sig.*

	cosA_xN	3.336	*	FO>RO
	cosA_yN	4.215	*	FO>RO
ΔPMI		8.701	*	FO>RO

Table 4: **Flexible vs. Rigid Order AANs.** t-normalized differences between flexible order (FO) and rigid order (FO) mean cosines (or mean ΔPMI values) for corpus-extracted and model-generated vectors. For significant differences ($p<0.05$ after Bonferroni correction), the last column reports whether mean cosine (or ΔPMI) is larger for flexible order (FO) or rigid order (RO) class.

These results show, in accordance with our considerations in Section 2.3 above: (i) flexible order A_xA_yNs are closer to A_xN and the component N than rigid order A_xA_yNs, and (ii) rigid order A_xA_yNs are closer to their A_y (flexible order AANs are also closer to A_x but the effect does not reach significance).[8] The results imply that the degree of modification of the A_y on the noun is a significant indicator of the type of ordering present.

[8]As an aside, the fact that mean cosines are significantly larger for the flexible order class in two cases but for the rigid order class in another addresses the concern, raised by a reviewer, that the words and phrases in one of the two classes might systematically inhabit denser regions of the space than those of the other class, thus distorting results based on comparing mean cosines.

In particular, rigid order A_xA_yNs are heavily modified by A_y, distorting the meaning of the head noun in the direction of the closest adjective quite drastically, and only undergoing a slight modification when the A_x is added. In other words, in rigid order phrases, for example *rapid social change*, the A_yN expresses a single concept (probably a "kind", in the terminology of formal semantics), strongly related to *social*, *social change*, which is then modified by the A_x. Thus, the *change* is not both *social* and *rapid*, rather, the *social change* is *rapid*. On the other hand, flexible order AANs maintain the semantic value of the head noun while being modified only slightly by both adjectives, almost equivalently. For example, in the phrase *friendly helpful staff*, one is saying that the *staff* is both *friendly* and *helpful*. Most importantly, the corpus-extracted distributional representations are able to model this phenomenon inherently and can significantly distinguish the two adjective orders.

The results of the composition models (cf. Table 4) show that for all models at least some properties do distinguish flexible and rigid order AANs, although only MULT and LFM capture the two properties that show the largest effect for the corpus-extracted vectors, namely the asymmetry in similarity to the noun and the A_xN (flexible order AANs being more similar to both).

It is worth remarking that MULT approximated the patterns observed in the corpus vectors quite well, despite producing order-insensitive representations of recursive structures. For flexible order AANs, order is indeed only slightly affecting the meaning, so it stands to reason that MULT has no problems modeling this class. For rigid order AANs, where we consider here the attested-order only, evidently the order-insensitive MULT representation is sufficient to capture their relations to their constituents.

Finally, we see that the ΔPMI measure is the best at distinguishing between the two classes of AAN ordering. This confirms our hypothesis that a lot has to do with how integrated A_y and N are. While it is somewhat disappointing that ΔPMI outperforms all distributional semantic cues, note that this measure conflates semantic and lexical factors, as the high PMI of A_yN in at least some rigid order AANs might be also a cue of the fact that the latter bigram is a lexicalized phrase (as discussed in footnote 2, it

is unlikely that our filtering strategies sifted out all multiword expressions). Moreover, ΔPMI does not produce a semantic representation of the phrase (see how composed distributional vectors approximate of high quality AAN vectors in Table 3). Finally, this measure will not scale up to cases where the ANs are not attested, whereas measures based on composition only need corpus-harvested representations of adjectives and nouns.

3.3 Properties of the correct adjective order

Having shown that flexible order and rigid order AANs are significantly distinguished by various properties, we proceed now to test whether those same properties also allow us to distinguish between correct (corpus-attested) and wrong (unattested) adjective ordering in rigid AANs (recall that we are working with cases where the attested-order occurs more than 20 times in the corpus, and both adjectives modify the nouns at least 10 times, so we are confident that there is a true asymmetry).

We expect that the fundamental property that distinguishes the orders is again found in the degree of modification of both component adjectives. We predict that the single concept created by the A_yN in attested-order rigid AANs, such as *legal status* in *formal legal status*, is an effect of the modification strength of the A_y on the head noun, and when seen in the incorrect ordering, i.e., $^?$*legal formal status*, the strong modification of *legal* will still dominate the meaning of the AAN. Composition models should be able to capture this effect based on the distance from both the component adjectives and ANs.

Clearly, we cannot run these analyses on corpus-extracted vectors since the unattested order, by definition, is not seen in our corpus, and therefore we cannot collect co-occurrence statistics for the AAN phrase. Thus, we test our measures of adjective ordering on the model-generated AAN vectors, for all gold rigid order AANs in both orders.

We also consider the ΔPMI measure which was so effective in distinguishing flexible vs. rigid order AANs. We expect that the greater association with A_yN for attested-order AANs will again lead to large, negative differences in PMI scores, while the expectation that unattested-order AANs will be highly associated with their A_xN will correspond to large, positive differences in PMI.

	cosA_yN	0.774		
ΔPMI		-11.448	*	U>A

Table 5: **Attested- vs. unattested-order rigid order AANs.** t-normalized mean paired cosine (or ΔPMI) differences between attested (A) and unattested (U) AANs with their components. For significant differences (paired t-test $p<0.05$ after Bonferroni correction), last column reports whether cosines (or ΔPMI) are on average larger for A or U.

Across all composition models, we find that the distance between the model-generated AAN and its component adjectives, A_x and A_y, are significant indicators of attested vs. unattested adjective ordering (cf. Table 5). Specifically, we find that rigid order AANs in the correct order are closest to their A_y, while we can detect the unattested order when the rigid order AAN is closer to its A_x. This finding is quite interesting, since it shows that the order in which the composition functions are applied does not alter the fact that the modification of one adjective in rigid order AANs (the A_y in the case of attested-order rigid order AANs) is much stronger than the other. Unlike the measures that differentiated flexible and rigid order AANs, here we see that the distance from the component N is not an indicator of the correct adjective ordering (trivially so for MULT, where attested and unattested AANs are identical).

Next, we find that for W.ADD, F.ADD and LFM,

the distance from the component A_xN is a strong indicator of attested- vs. unattested-order rigid order AANs. Specifically, attested-order AANs are further from their A_xN than unattested-order AANs. This finding is in line with our predictions and follows the findings of the impact of the distance from the component adjectives.

ΔPMI, as seen in the ability to distinguish flexible vs. rigid order AANs, is the strongest indicator of correct vs wrong adjective ordering. This measure confirms that the association of one adjective (the A_y in attested-order AANs) with the head noun is indeed the most significant factor distinguishing these two classes. However, as we mentioned before, this measure has its limitations and is likely not to be entirely sufficient for future steps in modeling recursive modification.

4 Conclusion

While AN constructions have been extensively studied within the framework of compositional distributional semantics (Baroni and Zamparelli, 2010; Boleda et al., 2012; Boleda et al., 2013; Guevara, 2010; Mitchell and Lapata, 2010; Turney, 2012; Vecchi et al., 2011), for the first time, we extended the investigation to recursively built AAN phrases.

First, we showed that composition functions applied recursively can approximate corpus-extracted AAN vectors that we know to be of high semantic quality.

Next, we looked at some properties of the same high-quality corpus-extracted AAN vectors, finding that the distinction between "flexible" AANs, where the adjective order can be flipped, and "rigid" ones, where the order is fixed, is reflected in distributional cues. These results all derive from the intuition that the most embedded adjective in a rigid AAN has a very strong effect on the distributional semantic representation of the AAN. Most compositional models were able to capture at least some of the same cues that emerged in the analysis of the corpus-extracted vectors.

Finally, similar cues were also shown to distinguish (compositional) representations of rigid AANs in the "correct" (corpus-attested) and "wrong" (unattested) orders, again pointing to the degree to which the (attested-order) closest adjective affects the overall AAN meaning as an important factor.

Comparing the composition functions, we find that the linguistically motivated LFM approach has the most consistent performance across all our tests. This model significantly outperformed all others in approximating high-quality corpus-extracted AAN vectors, it provided the closest approximation to the corpus-observed patterns when distinguishing flexible and rigid AANs, and it was one of the models with the strongest cues distinguishing attested and unattested orders of rigid AANs.

From an applied point of view, a natural next step would be to use the cues we proposed as features to train a classifier to predict the preferred order of adjectives, to be tested also in cases where neither order is found in the corpus, so direct corpus evidence cannot help. For a full account of adjectival ordering, non-semantic factors should also be taken into account. As shown by the effectiveness in our experiments of PMI, which is a classic measure used to harvest idioms and other multiword expressions (Church and Hanks, 1990), ordering is affected by arbitrary lexicalization patterns. Metrical effects are also likely to play a role, like they do in the well-studied case of "binomials" such as *salt and pepper* (Benor and Levy, 2006; Copestake and Herbelot, 2011). In a pilot study, we found that indeed word length (roughly quantified by number of letters) is a significant factor in predicting adjective ordering (the shorter adjective being more likely to occur first), but its effect is not nearly as strong as that of the semantic measures we considered here. In our future work, we would like to develop an order model that exploits semantic, metrical and lexicalization features jointly for maximal classification accuracy.

Adjectival ordering information could be useful in parsing: in English, it could tell whether an AANN sequence should be parsed as A[[AN]N] or A[A[NN]]; in languages with pre- and post-N adjectives, like Italian or Spanish, it could tell whether ANA sequences should be parsed as A[NA] or [AN]A. The ability to detect ordering restrictions could also help Natural Language Generation tasks (Malouf, 2000), especially for the generation of unattested combinations of As and Ns.

From a theoretical point of view, we would like to extend our analysis to adjective coordination (what's

the difference between *new and creative idea* and *new creative idea*?). Additionally, we could go more granular, looking at whether compositional models can help us to understand why certain classes of adjectives are more likely to precede or follow others (why is size more likely to take scope over color, so that *big red car* sounds more natural than *red big car*?) or studying the behaviour of specific adjectives (can our approach capture the fact that *strong alcoholic drink* is preferable to *alcoholic strong drink* because *strong* pertains to the alcoholic properties of the drink?).

In the meantime, we hope that the results we reported here provide convincing evidence of the usefulness of compositional distributional semantics in tackling topics, such as recursive adjectival modification, that have been of traditional interest to theoretical linguists from a new perspective.

Abstract

Domain adaptation has been popularly studied on exploiting labeled information from a source domain to learn a prediction model in a target domain. In this paper, we develop a novel representation learning approach to address domain adaptation for text classification with automatically induced discriminative latent features, which are generalizable across domains while informative to the prediction task. Specifically, we propose a hierarchical multinomial Naive Bayes model with latent variables to conduct supervised word clustering on labeled documents from both source and target domains, and then use the produced cluster distribution of each word as its latent feature representation for domain adaptation. We train this latent graphical model using a simple expectation-maximization (EM) algorithm. We empirically evaluate the proposed method with both cross-domain document categorization tasks on Reuters-21578 dataset and cross-domain sentiment classification tasks on Amazon product review dataset. The experimental results demonstrate that our proposed approach achieves superior performance compared with alternative methods.

1 Introduction

Supervised prediction models typically require a large amount of labeled data for training. However, manually collecting data annotations is expensive in many real-world applications such as document categorization or sentiment classification. Recently, domain adaptation has been proposed to exploit existing labeled data in a related source domain to assist the prediction model training in the target domain (Ben-David et al., 2006; Blitzer et al., 2006; Daumé III, 2007; Blitzer et al., 2011; Chen et al., 2012). As an effective tool to reduce annotation effort, domain adaptation has achieved success in various cross-domain natural language processing (NLP) systems such as document categorization (Dai et al., 2007), sentiment classification (Blitzer et al., 2007; Chen et al., 2012; Mejova and Srinivasan, 2012; Chen et al., 2011), email spam detection (Jiang and Zhai, 2007), and a number of other NLP tasks (Blitzer et al., 2011; Daumé III, 2007).

One primary challenge of domain adaptation lies in the distribution divergence of the two domains in the original feature representation space. For example, documents about *books* may contain very different high-frequency words and discriminative words from documents about *kitchen*. A good cross-domain feature *representation* thus has been viewed as critical for bridging the domain divergence gap and facilitating domain adaptation in the NLP area (Ben-David et al., 2006, 2010). Many domain adaptation works have been proposed to learn new cross-domain feature representations (Blitzer et al., 2006, 2011). Though demonstrated good performance on certain problems, these works mostly induce new feature representations in an unsupervised way, without taking the valuable label information into account.

In this work, we present a novel supervised representation learning approach to discover a latent representation of words which is not only generalizable across domains but also informative to the classification task. Specifically, we propose a hier-

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 152–162,
Seattle, Washington, USA, 18-21 October 2013.

archical multinomial Naive Bayes model with latent word cluster variables to perform supervised word clustering on labeled documents from both domains. Our model directly models the relationships between the observed document label variables and the latent word cluster variables. The induced cluster representation of each word thus will be informative for the classification labels, and hence discriminative for the target classification task. We train this directed graphical model using an expectation-maximization (EM) algorithm, which maximizes the log-likelihood of the observations of labeled documents. The induced cluster distribution of each word can then be used as its generalizable representation to construct new cluster-based representation of each document. For domain adaptation, we train a supervised learning system with labeled data from both domains in the new representation space and apply it to categorize test documents in the target domain. In order to evaluate the proposed technique, we conduct extensive experiments on the Reuters-21578 dataset for cross-domain document categorization and on Amazon product review dataset for cross-domain sentiment classification. The experimental results show the proposed approach can produce more effective representations than the comparison domain adaptation methods.

2 Related Work

Domain adaptation has recently been popularly studied in natural language processing and a variety of domain adaptation approaches have been developed, including instance weighting adaptation methods and feature representation learning methods.

Instance weighting adaptation methods improve the transferability of a prediction model by training an instance weighted learning system. Much work in this category has been developed to address different weighting schemas (Sugiyama et al., 2007; Wan et al., 2011). Jiang and Zhai (2007) applied instance weighting algorithms to tackle cross-domain NLP tasks and proposed to remove misleading source training data and assign less weights to labeled data from the source domain than labeled data from the target domain. Dai et al. (2007) proposed to increase the weights of mistakenly predicted instances from the target domain and decrease the weights of incorrectly predicted instances from the source domain during an iterative training process.

Representation learning methods bridge domain divergence either by differentiating domain-invariant features from domain-specific features (Daumé III, 2007; Daumé III et al., 2010; Blitzer et al., 2011; Finkel and Manning, 2009) or seeking generalizable latent features across domains (Blitzer et al., 2006, 2007; Prettenhofer and Stein, 2010). Daumé III (2007); Daumé III et al. (2010) proposed a simple heuristic feature replication method to represent common, source specific and target specific features. Finkel and Manning (2009) proposed a former version of it based on the use of a hierarchical Bayesian prior. Blitzer et al. (2011) proposed a coupled subspace learning method, which learns two projectors, one for each domain, to project the original features into domain-sharing and domain-specific features. Blitzer et al. (2006) proposed a structural correspondence learning (SCL) method to model the correlation between pivot features and non-pivot features. It uses the correlation to induce latent domain-invariant features as augmenting features for supervised learning. Extensions of this work include improving pivot feature selection (Blitzer et al., 2007; Prettenhofer and Stein, 2010), and improving the correlation modeling between pivot and non-pivot features (Tan, 2009).

The proposed approach in this paper belongs to representation learning methods. However, unlike the unsupervised representation learning methods reviewed above, our proposed approach learns generalizable feature representations of words by exploiting data labels from the two domains.

3 Learning Latent Word Representations using Supervised Word Clustering

In this paper, we address domain adaptation for text classification. Given a source domain $\mathcal{D}_{\mathcal{S}}$ with plenty of labeled documents, and a target domain $\mathcal{D}_{\mathcal{T}}$ with a very few labeled documents, the task is to learn a classifier from the labeled documents in both domains, and use it to classify the unlabeled documents in the target domain. The documents in the two domains share the same universal vocabulary $\mathcal{V} = \{w_1, w_2, \cdots, w_n\}$, but the word distributions in the two domains are typically different.

Therefore, training the classification model directly from the original word feature space $\mathcal{V}$ may not generalize well in the target domain.

We propose to address this problem by first learning a supervised mapping function $\phi : \mathcal{V} \longrightarrow \mathcal{Z}$ from the labeled documents in both domains, which maps the input word features in the large vocabulary set $\mathcal{V}$ into a low dimensional latent feature space $\mathcal{Z}$. By filtering out unimportant details and noises, we expect the low dimensional mapping can capture the intrinsic structure of the input data that is discriminative for the classification task and generalizable across domains. In particular, we learn such a mapping function by conducting supervised word clustering on the labeled documents using a hierarchical multinomial Naive Bayes model. Below, we will first introduce this supervised word clustering model and then use the mapping function produced to transform documents in different domains into the same low-dimensional space for training cross domain text classification systems.

3.1 Supervised Word Clustering

Given all labeled documents from the source and target domains, $D = \{(\mathbf{w}_t, y_t)\}_{t=1}^{T}$, where the t-th labeled document is expressed as a bag of words, $\mathbf{w}_t = \{w_{t1}, w_{t2}, \cdots, w_{tN_t}\}$, and its label value is $y_t \in \mathcal{Y}$ for $\mathcal{Y} = \{1, \cdots, K\}$, we propose to perform supervised word clustering by modeling the document-label pair distribution using a hierarchical multinomial Naive Bayes model given in Figure 1, which has a middle layer of latent cluster variables.

In this plate model, the variable Y_t denotes the observed class label for the t-th document, and all the label variables, $\{Y_t\}_{t=1}^{T}$, share the same multinomial distribution θ_Y across documents. The latent variable $C_{t,i}$ denotes the cluster membership of the word $W_{t,i}$, and all the cluster variables, $\{C_{t,i}\}_{t=1,i=1}^{T,N_t}$, share the same set of conditional distributions $\{\theta_{C|y}\}_{y=1}^{K}$ across documents and words. The variable $W_{t,i}$ denotes the i-th observed word in the t-th document, and all the word variables, $\{W_{t,i}\}_{t=1,i=1}^{T,N_t}$, share the same set of conditional distributions $\{\theta_{W|c}\}_{c=1}^{m}$. Here we assume the number of word clusters is m. For simplicity, we do not show the distribution parameter variables in the Figure.

Following the *Markov property* of directed graphical models, we can see that given the cluster variable values, the document label variables will be completely independent of the word variables. By learning this latent directed graphical model, we thus expect the important classification information expressed in the input observation words can be effectively summarized into the latent cluster variables. This latent model is much simpler than the supervised topic models (Blei and McAuliffe, 2007), but we will show later that it can suitably produce a generalizable feature mapping function for domain adaptation.

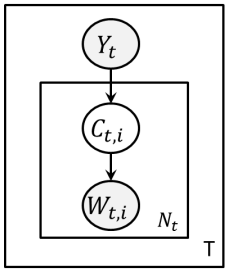

Figure 1: Supervised word clustering model.

To train the latent graphical model in Figure 1 on labeled documents D, we use a standard expectation-maximization (EM) algorithm (Dempster et al., 1977) to maximize the marginal log-likelihood of the observations:

$$LL(D; \boldsymbol{\theta}) = \sum_{t} \log P(y_t, \mathbf{w}_t | \boldsymbol{\theta}) \qquad (1)$$

The EM algorithm is an iterative procedure. In each iteration, it takes an alternative E-step and M-step to maximize the lower bound of the marginal log-likelihood function. In our experiments, we start from a random initialization of the model parameters and the latent variable values, and then perform iterative EM updates until converge to a local optimal solution.

3.2 Induced Word Representation

After training the supervised clustering model using EM algorithm, a set of local optimal model parameters $\boldsymbol{\theta}^*$ will be returned, which define a joint distribution over the three groups of variables in the directed graphical model. Next we define a supervised latent feature mapping function ϕ from this trained

model to map each word w in the vocabulary $\mathcal{V}$ into a conditional distribution vector over the word cluster variable, such as

$$\phi(w) = [P(c=1|w, \boldsymbol{\theta}^*), \cdots, P(c=m|w, \boldsymbol{\theta}^*)]. \quad (2)$$

The conditional distributions involved in this mapping function can be computed as

$$P(c|w, \boldsymbol{\theta}^*) = \frac{\sum_{y \in \mathcal{Y}} P(w|c, \boldsymbol{\theta}^*) P(c|y, \boldsymbol{\theta}^*) P(y|\boldsymbol{\theta}^*)}{P(w)} \quad (3)$$

where $P(w|c, \boldsymbol{\theta}^*) = \boldsymbol{\theta}^*_{w|c}$ $P(c|y, \boldsymbol{\theta}^*) = \boldsymbol{\theta}^*_{c|y}$ and $P(y|\boldsymbol{\theta}^*) = \boldsymbol{\theta}^*_y$ can be determined from the model parameters directly, and $p(w)$ can be computed as the empirical frequency of word w among all the other words in all the training documents.

We then define a transformation matrix $\Pi \in \mathbb{R}^{n \times m}$ based on the mapping function ϕ defined in Eq. (2), such that $\Pi_{i:} = \phi(w_i)$ where w_i is the i-th word in the vocabulary $\mathcal{V}$. That is, each row of Π is the induced representation vector for one word. Π can be viewed as a soft word clustering matrix, and $\Pi_{i,j}$ denotes the probability of word w_i belongs to the j-th cluster. Given the original document-word frequency matrix $X_{tr} \in \mathbb{R}^{T \times n}$ for the labeled training documents from the two domains, we can construct its representations $Z_{tr} \in \mathbb{R}^{T \times m}$ in the predictive latent clustering space by performing the following transformation:

$$Z_{tr} = X_{tr} \Pi. \quad (4)$$

Similarly, we can construct the new representation matrix Z_{ts} for the test data X_{ts} in the target domain. We then train a classification model on the labeled data Z_{tr} and apply it to classify the test data Z_{ts}.

4 Experiments

We evaluate the proposed approach with experiments on cross domain document categorization of Reuters data and cross domain sentiment classification of Amazon product reviews, comparing to a number of baseline and existing domain adaptation methods. In this section, we report the experimental setting and results on these two data sets.

4.1 Approaches

We compared our proposed supervised word clustering approach (*SWC*) with the following five comparison methods for domain adaptation:

(1) *BOW*: This is a bag-of-word baseline method, which trains a SVM classifier with labeled data from both domains using the original bag-of-word features.

(2) *PLSA*: This is an unsupervised word clustering method, which first applies the probabilistic latent semantic analysis (PLSA) (Hofmann, 1999) to obtain word clusterings with both labeled and unlabeled data from the two domains and then uses the soft word clusterings as augmenting features to train SVM classifiers.

(3) *FDLDA*: This is an alternative supervised word clustering method we built by training the Fast-Discriminative Latent Dirichlet Allocation model (Shan et al., 2009) with all labeled data from the two domains. After training the model, we used the learned topic distribution $p(z)$ and the conditional word distributions $p(w|z)$ to compute the conditional distribution over topics $p(z|w)$ for each word as the soft clustering of the word. We then used the soft word clusterings as augmenting features to train SVM classifiers.

(4) *SCL*: This is the structural correspondence learning based domain adaptation method (Blitzer et al., 2006). It first induces generalizable features with all data from both domains by modeling the correlations between pivot features and non-pivot features, and then uses the produced generalizable features as augmenting features to train SVM classifiers.

(5) *CPSP*: This is coupled subspace learning based domain adaptation method (Blitzer et al., 2011). It first learns two domain projectors using all data from the two domains by approximating multi-view dimensionality reduction, and then projects the labeled data to low dimensional latent feature space to train SVM Classifiers.

We used the LIBSVM package (Chang and Lin, 2011) with its default parameter setting to train linear SVM classifiers as the base classification model for all comparison methods.

Table 1: Average results (accuracy±standard deviation) for three cross-domain document categorization tasks on Reuters-21578 dataset.

Task	BOW	PLSA	FDLDA	SCL	CPSP	SWC
Orgs vs People	76.07±0.39	76.50±0.10	76.95±0.23	78.71±0.20	77.58±0.21	**81.27±0.23**
Orgs vs Places	73.88±0.58	74.68±0.20	74.87±0.29	76.71±0.23	75.76±0.28	**78.33±0.64**
People vs Places	61.80±0.44	63.36±0.40	63.46±0.40	64.65±0.40	62.73±0.53	**67.48±0.20**

4.2 Experiments on Reuters Data Set

We used the popularly studied Reuters-21578 dataset (Dai et al., 2007), which contains three cross-domain document categorization tasks, *Orgs vs People, Orgs vs Places, People vs Places*. The source and target domains of each task contain documents sampled from different non-overlapping subcategories. From example, the task of *Orgs vs People* assigns a document into one of the two top categories (*Orgs, People*), and the source domain documents and the target domain documents are sampled from different subcategories of *Orgs* and *People*. There are 1237 source documents and 1208 target documents for the task of *Orgs vs People*, 1016 source documents and 1043 target documents for the task of *Orgs vs Places*, and 1077 source documents and 1077 target documents for the task of*People vs Places*. For each task, we built a unigram vocabulary based on all the documents from the two domains and represented each document as a feature vector containing term frequency values.

4.2.1 Experimental Results for Cross-Domain Document Categorization

For each of the three cross-domain document categorization tasks on Reuters-21578 dataset, we used all the source documents as labeled training data while randomly selecting 100 target documents as labeled training data and setting the rest as unlabeled test data. For the BOW baseline method, we used the term-frequency features. The other five approaches are based on representation learning, and we selected the dimension size of the representation learning, i.e., the cluster number in our proposed approach, from $\{5, 10, 20, 50, 100\}$ according to the average classification results over 3 runs on the task of *Orgs vs People*. The dimension sizes of the induced representations for the five approaches, *PLSA, FDLDA, SCL, CPSP* and *SWC* are *20, 20, 100, 100* and *20* respectively.

We then repeated each experiment 10 times on each task with different random selections of the 100 labeled target documents to compare the six comparison approaches. The average classification results in terms of accuracy and standard deviations are reported in Table 1. We can see that by simply combining labeled documents from the two domains without adaptation, the *BOW* method performs poorly across the three tasks. The *PLSA* method outperforms the *BOW* method over all the three tasks with small improvements. The supervised word clustering method *FDLDA*, though performing slightly better than the unsupervised clustering method *PLSA*, produces poor performance comparing to the proposed *SWC* method. One possible reason is that the *FDLDA* model is not specialized for supervised word clustering, and it uses a logistic regression model to predict the labels from the word topics, while the final soft word clustering is computed from the learned distribution $p(z)$ and $p(w|z)$. That is, in the FDLDA model the labels only influence the word clusterings indirectly and hence its influence can be much smaller than the influence of labels as direct parent variables of the word cluster variables in the *SWC* model. The two domain adaptation approaches, *SCL* and *CPSP*, both produce significant improvements over *BOW*, *PLSA* and *FDLDA* on the two tasks of *Orgs vs People* and *Orgs vs Places*, while the *CPSP* method produces slightly inferior performance than *PLSA* and *FDLDA* on the task of *People vs Places*. The proposed method *SWC* on the other hand consistently and significantly outperforms all the other comparison methods across all the three tasks.

We also studied the sensitivity of the proposed approach with respect to the number of clusters,

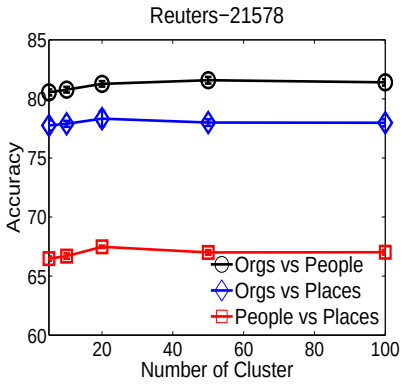

Figure 2: Sensitivity analysis of the proposed approach w.r.t. the number of clusters for the three cross-domain document categorization tasks on Reuters-21578 dataset.

i.e., the dimension size of the learned representation. We experimented with a set of different values $m \in \{5, 10, 20, 50, 100\}$ as the number of clusters. For each m value, we used the same experimental setting as above and repeated the experiments 10 times to obtain the average comparison results. The classification accuracy results on the three tasks are reported in Figure 2. We can see that the proposed method is not very sensitive to the number of clusters, across the set of increasing values we considered, and its performance becomes very stable after the cluster number reaches 20.

4.2.2 Document Categorization Accuracy vs Label Complexity in Target Domain

We next conducted experiments to compare the six approaches by varying the amount of the labeled data from the target domain. We tested a set of different values, $s \in \{100, 200, 300, 400, 500\}$, as the number of labeled documents from the target domain. For each different s value, we repeated the experiments 10 times by randomly selecting s labeled documents from the target domain using the same experimental setting as before. The comparison results across the set of s values are plotted in Figure 3. We can see that in general the performance of each method improves with the increase of the number of labeled documents from the target domain. The proposed method *SWC* and the domain adaptation method *SCL* clearly outperform the other four methods. Moreover, the proposed method *SWC* not only maintains consistent and significant advantages over all other methods across the range of different s values, its performance with 300 labeled target instances is even superior to the other methods with 500 labeled target instances. All these results suggest the proposed approach is very effective for adapting data across domains.

4.3 Experiments on Amazon Product Reviews

We conducted cross-domain sentiment classification on the widely used Amazon product reviews (Blitzer et al., 2007), which contains review documents distributed in four categories: *Books(B)*, *DVD(D)*, *Electronics(E)* and *Kitchen(K)*. Each category contains 1000 positive and 1000 negative reviews. We constructed 12 cross-domain sentiment classification tasks, one for each source-target domain pair, *B2D*, *B2E*, *B2K*, *D2B*, *D2E*, *D2K*, *E2B*, *E2D*, *E2K*, *K2B*, *K2D*, *K2E*. For example, the task *B2D* means that we use the *Books* reviews as the source domain and the *DVD* reviews as the target domain. For each pair of domains, we built a vocabulary with both unigram and bigram features extracted from all the documents of the two domains, and then represented each review document as a feature vector with term frequency values.

4.3.1 Experimental Results for Cross-Domain Sentiment Classification

For each of the twelve cross-domain sentiment classification tasks on Amazon product reviews, we used all the source reviews as labeled data and randomly selected 100 target reviews as labeled data while treating the rest as unlabeled test data. For the baseline method *BOW*, we used binary indicator values as features, which has been shown to work better than the term-frequency features for sentiment classification tasks (Pang et al., 2002; Na et al., 2004). For all the other representation learning based methods, we selected the dimension size of learned representation according to the average results over 3 runs on the *B2D* task. The dimension sizes selected for the methods *PLSA*, *FDLDA*, *SCL*, *CPSP*, and *SWC* are 10, 50, 50, 100 and 10, respectively.[1]

[1] 50 and 100 are also the suggested values for SCL (Blitzer et al., 2007) and CPSP (Blitzer et al., 2011) respectively on this cross-domain sentiment classification dataset.

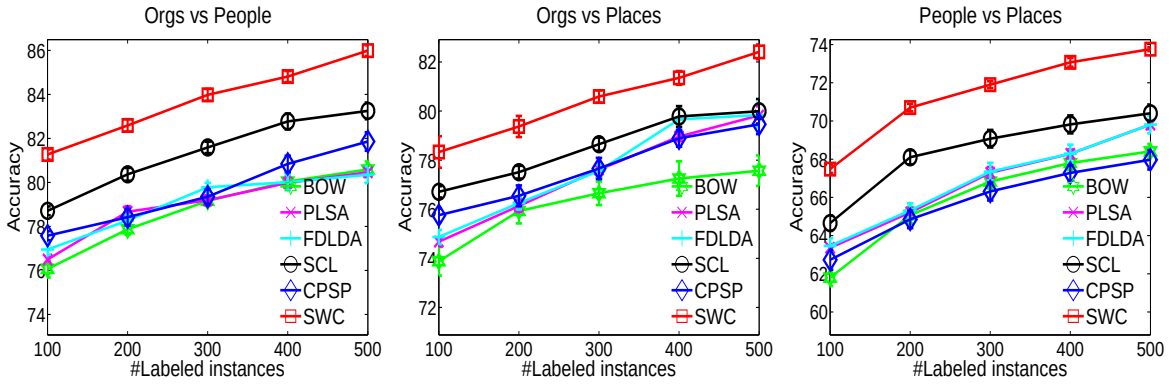

Figure 3: Average classification results for three cross-domain document categorization tasks on Reuters-21578 dataset by varying the amount of labeled training data from the target domain.

Table 2: Average results (accuracy±standard deviation) for twelve cross-domain sentiment classification tasks on Amazon product reviews.

Task	**BOW**	**PLSA**	**FDLDA**	**SCL**	**CPSP**	**SWC**
B2D	76.58±0.14	76.01±0.10	75.95±0.16	80.17±0.16	77.53±0.14	**81.66**±0.23
B2K	75.48±0.34	74.68±0.20	74.87±0.15	78.13±0.21	76.38±0.15	**82.26**±0.20
B2E	72.92±0.37	73.36±0.19	73.46±0.21	74.79±0.19	73.31±0.17	**77.04**±0.64
D2B	74.10±0.29	74.04±0.20	74.08±0.18	78.73±0.23	77.07±0.15	**79.95**±0.25
D2K	75.19±0.33	75.37±0.31	75.44±0.31	76.98±0.19	76.77±0.10	**82.13**±0.20
D2E	73.01±0.34	74.21±0.30	74.09±0.31	75.69±0.25	73.83±0.21	**76.98**±0.54
E2B	67.58±0.24	68.48±0.15	68.44±0.17	70.21±0.16	70.47±0.16	**72.11**±0.46
E2D	70.15±0.27	70.16±0.23	70.06±0.22	72.83±0.25	71.76±0.20	**73.81**±0.59
E2K	82.23±0.12	82.24±0.18	82.26±0.19	84.69±0.11	81.31±0.14	**85.33**±0.16
K2B	70.67±0.18	72.18±0.21	72.18±0.16	73.91±0.21	72.18±0.19	**75.78**±0.55
K2D	71.51±0.26	72.00±0.18	72.05±0.19	74.82±0.26	72.59±0.18	**76.88**±0.49
K2E	80.81±0.12	80.39±0.18	80.46±0.18	82.96±0.11	80.81±0.14	**84.78**±0.19

We then repeated each experiment 10 times based on different random selections of 100 labeled reviews from the target domain to compare the six methods on the twelve tasks. The average classification results are reported in Table 2. We can see that the *PLSA* and *FDLDA* methods do not show much advantage over the baseline method *BOW*. *CPSP* performs better than *PLSA* and *BOW* on many of the twelve tasks, but with small advantages, while *SCL* outperforms *CPSP* on most tasks. The proposed method *SWC* however demonstrates a clear advantage over all the other methods and produces the best results on all the twelve tasks.

We also conducted sensitivity analysis over the proposed approach regarding the number of clusters on the twelve cross-domain sentiment classification tasks, by testing a set of cluster number values $m = \{5, 10, 20, 50, 100\}$. The average results are plotted in Figure 5. Similar as before, we can see the proposed approach has stable performance across the set of different cluster numbers. Moreover, these results also clearly show that domain adaptation is not a symmetric process, as we can see it is easier to conduct domain adaptation from the source domain *Books* to the target domain *Kitchen* (with an accuracy around 82%), but it is more difficult to make domain adaptation from the source domain *Kitchen* to the target domain *Books* (with an ac-

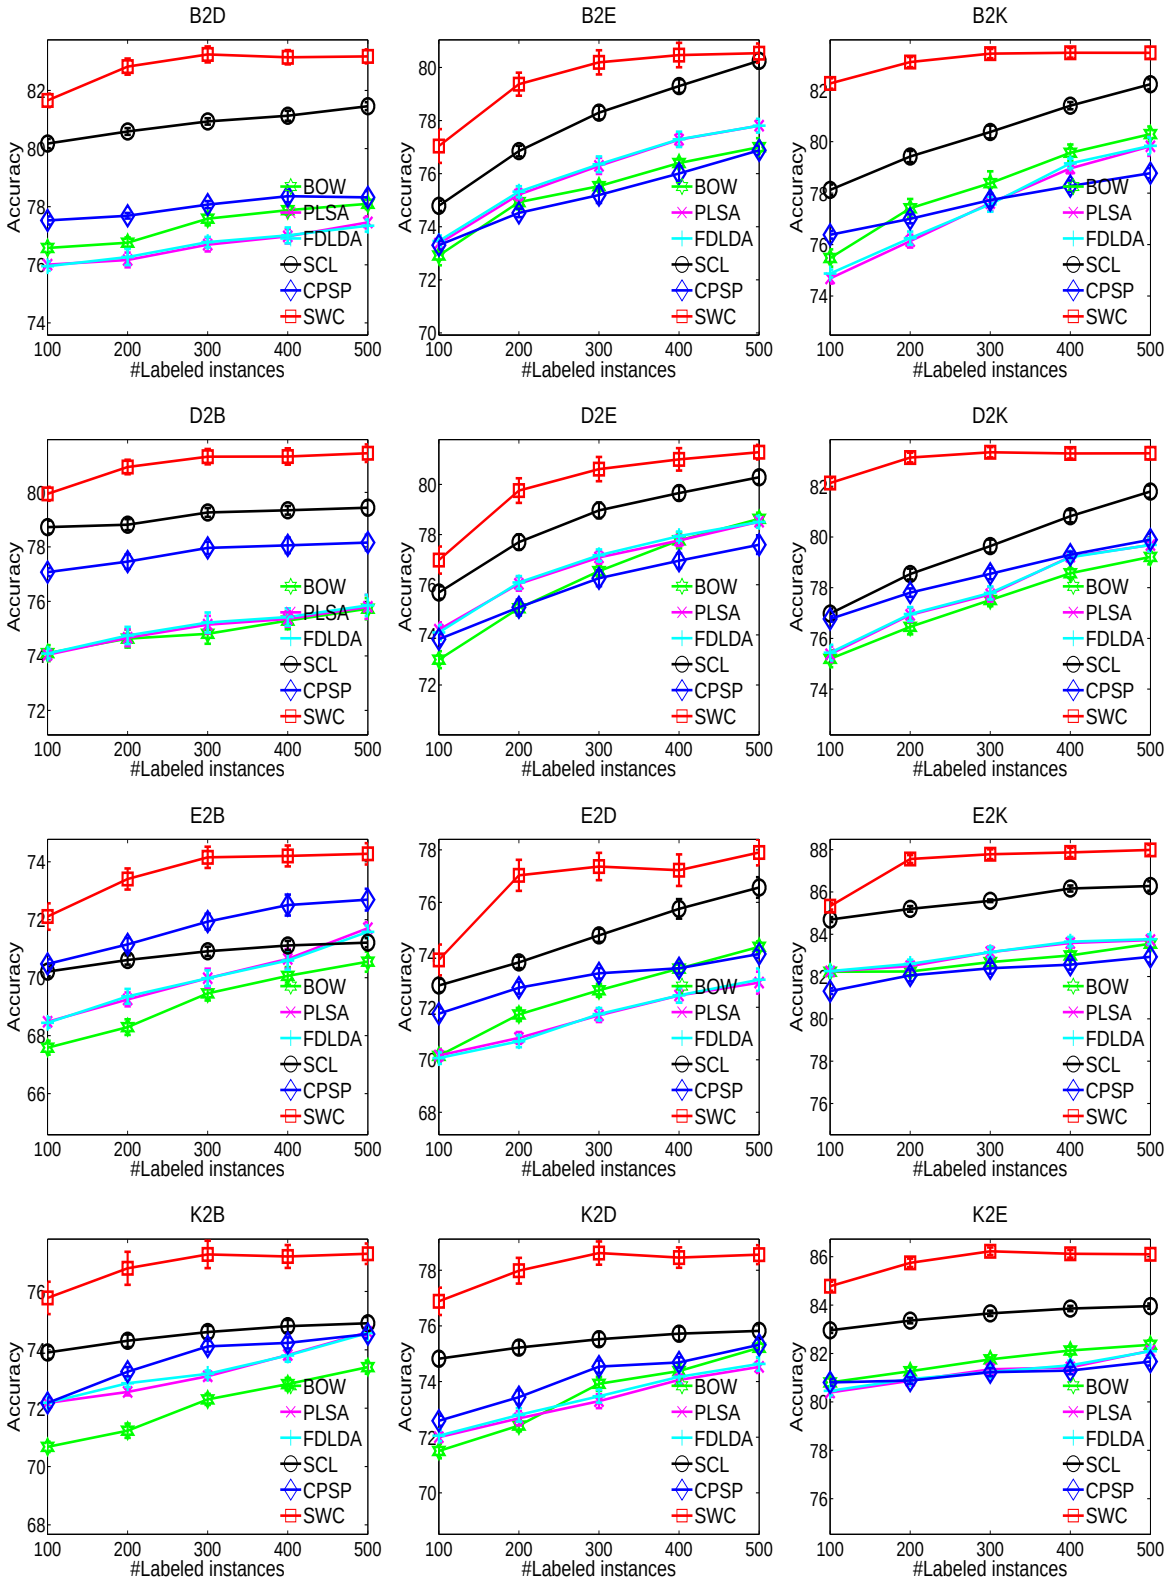

Figure 4: Average results (accuracy±standard deviation) for the 12 cross-domain sentiment classification tasks on Amazon product reviews with different numbers of labeled training data from the target domain.

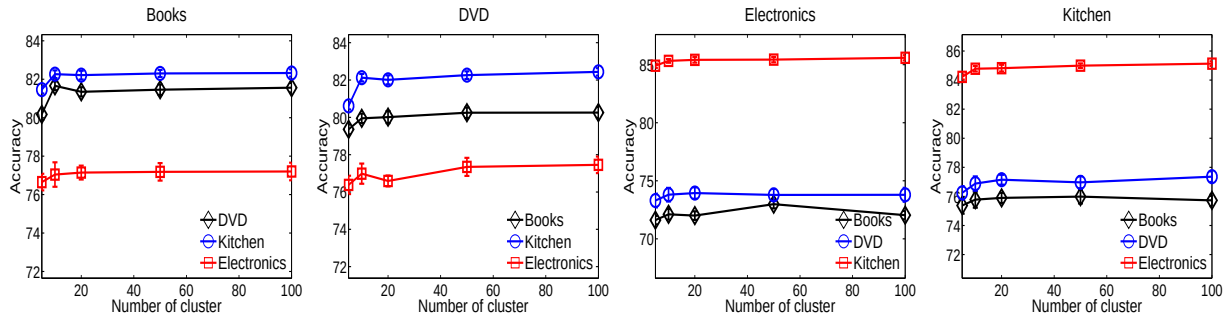

Figure 5: Sensitivity analysis of the proposed approach wrt the number of clusters for the twelve cross-domain sentiment classification tasks. Each figure shows experimental results for three tasks with the same source domain.

curacy around 75%). It also shows that the degree of relatedness of the two domains is an important factor for the effectiveness of knowledge adaptation. For example, one can see that it is much easier to conduct domain adaptation from *Kitchen* to *Electronics* (with an accuracy around 84%) than from *Kitchen* to *Books* (with an accuracy around 75%), as *Kitchen* is more closely related to *Electronics* than *Books*.

4.3.2 Sentiment Classification Accuracy vs Label Complexity in Target Domain

Similar as before, we tested the proposed approach using a set of different values $s \in \{100, 200, 300, 400, 500\}$ as the number of labeled reviews from the target domain. For each given s value, we conducted the comparison experiments using the same setting above. The average results are reported in Figure 4. We can see that the performance of each approach in general improves with the increase of the number of labeled reviews from the target domain. The proposed approach maintains a clear advantage over all the other methods on all the twelve tasks across different label complexities. All those empirical results demonstrate the effectiveness of the proposed approach for cross-domain sentiment classification.

4.3.3 Illustration of the Word Clusters

Finally, we would also like to demonstrate the *hard* word clusters produced by the proposed supervised word clustering method. We assign a word into the cluster it most likely belongs to according to its soft clustering representation, such as $c^* = \arg\max_c P(c|w, \boldsymbol{\theta}^*)$. Table 3 presents the top representative words (i.e., the most frequent words) of the 10 word clusters produced on the task of *B2K*. We can see that the first three clusters (C1, C2, and C3) contain words with *positive* sentiment polarity in different degrees. The two clusters (C4 and C5) contain words used to express the degree of opinions. The next four clusters (C6, C7, C8, and C9) contain content words related to *Books* or *Kitchen*. The last cluster (C10) contains words of *negative* sentiment polarity. These results demonstrate that the proposed supervised word clustering can produce task meaningful word clusters and hence label-informative latent features, which justifies its effectiveness.

5 Conclusion

In this paper, we proposed a novel supervised representation learning method to tackle domain adaptation by inducing predictive latent features based on supervised word clustering. With the soft word clustering produced, we can transform all documents from the two domains into a unified low-dimensional feature space for effective training of cross-domain NLP prediction system. We conducted extensive experiments on cross-domain document categorization tasks on Reuters-21578 dataset and cross-domain sentiment classification tasks on Amazon product reviews. Our empirical results demonstrated the efficacy of the proposed approach.

Appropriately Incorporating Statistical Significance in PMI

Om P. Damani and Shweta Ghonge
IIT Bombay
India
{damani,shwetaghonge}@cse.iitb.ac.in

Abstract

Two recent measures incorporate the notion of statistical significance in basic PMI formulation. In some tasks, we find that the new measures perform worse than the PMI. Our analysis shows that while the basic ideas in incorporating statistical significance in PMI are reasonable, they have been applied slightly inappropriately. By fixing this, we get new measures that improve performance over not just PMI but on other popular co-occurrence measures as well. In fact, the revised measures perform reasonably well compared with more resource intensive non co-occurrence based methods also.

1 Introduction

The notion of *word association* is used in many language processing and information retrieval applications and it is important to have low-cost, high-quality association measures. Lexical co-occurrence based word association measures are popular because they are computationally efficient and they can be applied to any language easily. One of the most popular co-occurrence measure is Pointwise Mutual Information (PMI) (Church and Hanks, 1989).

One of the limitations of PMI is that it only works with relative probabilities and ignores the absolute amount of evidence. To overcome this, recently two new measures have been proposed that incorporate the notion of statistical significance in basic PMI formulation. In (Washtell and Markert, 2009), statistical significance is introduced in PMI_{sig} by multiplying PMI value with the square root of the evidence. In contrast, in (Damani, 2013), cPMId is introduced by bounding the probability of observing a given deviation between a given word pair's co-occurrence count and its expected value under a null model where with each word a global unigram generation probability is associated. In Table 1, we give the definitions of PMI, PMI_{sig}, and cPMId.

While these new measures perform better than PMI on some of the tasks, on many other tasks, we find that the new measures perform worse than the PMI. In Table 3, we show how these measures perform compared to PMI on four different tasks. We find that PMI_{sig} degrades performance in three out of these four tasks while cPMId degrades performance in two out of these four tasks. The experimental details and discussion are given in Section 4.2.

Our analysis shows that while the basic ideas in incorporating statistical significance are reasonable, they have been applied slightly inappropriately. By fixing this, we get new measures that improve performance over not just PMI, but also on other popular co-occurrence measures on most of these tasks. In fact, the revised measures perform reasonably well compared with more resource intensive non co-occurrence based methods also.

2 Adapting PMI for Statistical Significance

In (Washtell and Markert, 2009), it is assumed that the statistical significance of a word pair association is proportional to the square root of the evidence. The question of what constitutes the evidence is answered by taking the lesser of the frequencies of the two words in the word pair, since at most that many pairings are possible. Hence the PMI value is multi-

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 163–169,
Seattle, Washington, USA, 18-21 October 2013.

Method	Formula	Revised Formula
PMI (Church and Hanks, 1989)	$log\frac{f(x,y)}{f(x)*f(y)/W}$	
PMI_{sig} (Washtell and Markert, 2009)	$log\frac{f(x,y)}{f(x)*f(y)/W} * \sqrt{\mathbf{min(f(x),f(y))}}$	PMIs: $log\frac{f(x,y)}{f(x)*f(y)/W} * \sqrt{\mathbf{max(f(x),f(y))}}$
cPMId (Damani, 2013)	$log\frac{d(x,y)}{\mathbf{d(x)*d(y)}/D+\sqrt{\mathbf{d(x)}}*\sqrt{\frac{\ln\delta}{(-2.0)}}}$	sPMId: $log\frac{d(x,y)}{\mathbf{max(d(x),d(y))*min(d(x),d(y))}/D+\sqrt{\mathbf{max(d(x),d(y))}}*\sqrt{\frac{\ln\delta}{(-2.0)}}}$

Terminology:

W	Total number of words in the corpus	D	Total number of documents in the corpus
$f(x), f(y)$	unigram frequencies of x, y respectively in the corpus	$d(x), d(y)$	Total number of documents in the corpus containing at least one occurrence of x and y respectively
$f(x,y)$	Span-constrained (x,y) word pair frequency in the corpus	$d(x,y)$	Total number of documents in the corpus having at-least one span-constrained occurrence of the word pair (x,y)
δ	a parameter varying between 0 and 1		

Table 1: Definitions of PMI and its statistically significant adaptations. The sub-parts in bold represent the changes between the original formulas and the revised formulas. The product $max(d(x),d(y)) * min(d(x),d(y))$ in sPMId formula can be simplified to $f(x) * f(y)$, however, we left it this way to emphasize the transformation from cPMId.

plied by $\sqrt{min(f(x),f(y))}$ to get PMI_{sig}.

In (Damani, 2013), statistical significance is introduced by bounding the probability of observing a given number of word-pair occurrences in the corpus, just by chance, under a null model of independent unigram occurrences. For this computation, one needs to decide what constitutes a random trial when looking for a word-pair occurrence. Is it the occurrence of the first word (say x) in the pair, or the second (say y). In (Damani, 2013), occurrences of x are arbitrarily chosen to represent the sites of the random trial. Using Hoeffdings Inequality:

$$P[f(x,y) \geq f(x) * f(y)/W + f(x) * t] \leq \exp(-2 * f(x) * t^2)$$

By setting $t = \sqrt{\ln\delta/(-2 * f(x))}$, we get δ as an upper bound on probability of observing more than $f(x) * f(y)/W + f(x) * t$ bigram occurrences in the corpus, just by chance. Based on this *Corpus Level Significant PMI*(cPMI) is defined as:

$$cPMI(x,y) = log\frac{f(x,y)}{f(x) * f(y)/W + f(x) * t}$$
$$= log\frac{f(x,y)}{f(x) * f(y)/W + \sqrt{f(x)} * \sqrt{\ln\delta/(-2)}}$$

In (Damani, 2013), several variants of cPMI are introduced that incorporate different notions of statistical significance. Of these *Corpus Level Significant PMI based on Document count*(cPMId - defined in Table 1) is found to be the best performing, and hence we consider this variant only in this work.

2.1 Choice of Random Trial

While considering statistical significance, one has to decide what constitutes a random trial. When looking for a word-pair (x,y)'s occurrences, y can potentially occur near each occurrence of x, or x can potentially occur near each occurrence of y. Which of these two set of occurrences should be considered the sites of random trial. We believe that the occurrences of the more frequent of x and y should be considered, since near each of these occurrences the other word could have occurred. Hence $f(x)$ and $f(y)$ in cPMI definition should be replaced with $max(f(x),f(y))$ and $min(f(x),f(y))$ respectively. Similarly, $d(x)$ and $d(y)$ in cPMId formula should be replaced with $max(d(x),d(y))$ and $min(d(x),d(y))$ respectively to give a new measure *Significant PMI based on Document count*(sPMId).

Using the same logic, $\sqrt{min(f(x),f(y))}$ in PMI_{sig} formula should be replaced with $\sqrt{max(f(x),f(y))}$ to give the formula for a new measure *PMI-significant*(PMIs). The definitions of sPMId and PMIs are also given in Table 1.

3 Related Work

There are three main types of word association measures: Knowledge based, Distributional Similarity based, and Lexical Co-occurrence based.

Based on Firth's *You shall know a word by the company it keeps* (Firth, 1957), distributional similarity based measures characterize a word by the distribution of other words around it and compare

Method	Formula
ChiSquare (χ^2)	$\sum_{i,j} \frac{(f(i,j)-Ef(i,j))^2}{Ef(i,j)}$
Dice (Dice, 1945)	$\frac{f(x,y)}{f(x)+f(y)}$
GoogleDistance (L.Cilibrasi and Vitany, 2007)	$\frac{max(\log d(x), \log d(y)) - \log d(x,y)}{\log D - min(\log d(x), \log d(y))}$
Jaccard (Jaccard, 1912)	$\frac{f(x,y)}{f(x)+f(y)-f(x,y)}$
LLR (Dunning, 1993)	$\sum_{\substack{x' \in \{x, \neg x\} \\ y' \in \{y, \neg y\}}} f(x', y') log \frac{f(x', y')}{f(x')f(y')}$
nPMI (Bouma, 2009)	$\frac{log \frac{f(x,y)}{f(x)*f(y)/W}}{log \frac{1}{f(x,y)/W}}$
Ochiai (Janson and Vegelius, 1981)	$\frac{f(x,y)}{\sqrt{f(x)f(y)}}$
PMI^2 (Daille, 1994)	$log \frac{\frac{f(x,y)}{f(x)*f(y)/W}}{\frac{1}{f(x,y)/W}} = log \frac{f(x,y)^2}{f(x)*f(y)}$
Simpson (Simpson, 1943)	$\frac{f(x,y)}{min(f(x), f(y))}$
SCI (Washtell and Markert, 2009)	$\frac{f(x,y)}{f(x)\sqrt{f(y)}}$
T-test	$\frac{f(x,y)-Ef(x,y)}{\sqrt{f(x,y)\left(1-\frac{f(x,y)}{W}\right)}}$

Table 2: Definition of other co-occurrence measures being compared in this work. The terminology used here is same as that in Table 1, except that E in front of a variable name means the expected value of that variable.

Table 3: 5-fold cross-validation results for different co-occurrence measures. The results for the best, and second best co-occurrence measures for each data-set is shown in bold and underline respectively. Except GoogleDistance and LLR, all results for all co-occurrence measures are statistically significant at $p = .05$. For each task, the best known result for different non co-occurrence based methods is also shown.

two words for distributional similarity (Agirre et al., 2009; Wandmacher et al., 2008; Bollegala et al., 2007; Chen et al., 2006). They are also used for modeling the meaning of a phrase or a sentence (Grefenstette and Sadrzadeh, 2011; Wartena, 2013; Mitchell, 2011; G. Dinu and Baroni, 2013; Kartsaklis et al., 2013).

Knowledge-based measures use knowledge-sources like thesauri, semantic networks, or taxonomies (Milne and Witten, 2008; Hughes and Ramage, 2007; Gabrilovich and Markovitch, 2007; Yeh et al., 2009; Strube and Ponzetto, 2006; Finkelstein et al., 2002; Liberman and Markovitch, 2009).

Co-occurrence based measures (Pecina and Schlesinger, 2006) simply rely on unigram and bigram frequencies of the words in a pair. In this work, our focus is on the co-occurrence based measures, since they are resource-light and can easily be used for resource-scarce languages.

3.1 Co-occurrence Measures being Compared

Co-occurrence based measures of association between two entities are used in several domains like ecology, psychology, medicine, language processing, etc. To compare the performance of our newly introduced measures with other co-occurrence measures, we have selected a number of popular co-occurrence measures like ChiSquare (χ^2), Dice (Dice, 1945), GoogleDistance (L.Cilibrasi and Vitany, 2007), Jaccard (Jaccard, 1912), LLR (Dunning, 1993), Simpson (Simpson, 1943), and T-test from these domains.

In addition to these popular measures, we also experiment with other known variations of PMI like nPMI (Bouma, 2009), PMI^2 (Daille, 1994), Ochiai (Janson and Vegelius, 1981), and SCI (Washtell and Markert, 2009). Since PMI^2 is a monotonic transformation of Ochiai, we present their results together. In Table 2, we present the definitions of these measures. While the motivation given for SCI in (Washtell and Markert, 2009) is slightly different, in light of the discussion in Section 2.1, we can assume that SCI is PMI adapted for statistical significance (multiplied by $\sqrt{\mathbf{f(y)}}$), where the site of random trial is taken to be the occurrences of the second word y, instead of the less frequent word, as in the case of PMI_{sig}.

When counting co-occurrences, we only consider the non-overlapping *span*-constrained occurrences. The span of a word-pair's occurrence is the direction-independent distance between the occurrences of the members of the pair. We consider only those co-occurrences where span is less than a given threshold. Therefore, span threshold is a parameter for all the co-occurrence measures being considered.

4 Performance Evaluation

Having introduced the revised measures PMIs and sPMId, we need to evaluate the performance of these measures compared to PMI and the original measures introducing significance. In addition, we also wish to compare the performance of these measures with other co-occurrence measures. To compare the performance of these measures with more resource heavy non co-occurrence based measures, we have chosen those tasks and datasets on which published results exist for distributional similarity and knowledge based word association measures.

4.1 Task Details

We evaluate these measures on three tasks: Sentence Similarity(65 sentence-pairs from (Li et al., 2006)), Synonym Selection(50 questions ESL (Turney, 2001) and 80 questions TOEFL (Landauer and Dutnais, 1997) datasets), and, Semantic Relatedness(353 words Wordsim (Finkelstein et al., 2002) dataset).

For each of these tasks, gold standard human judgment results exist. For sentence similarity, following (Li et al., 2006), we evaluate a measure by the Pearsons correlation between the ranking produced by the measure and the human ranking. For synonym selection, we compute the percentage of correct answers, since there is a unique answer for each challenge word in the datasets. Semantic relatedness has been evaluated by Spearman's rank correlation with human judgment instead of Pearsons correlation in literature and we follow the same practice to make results comparable.

For sentence similarity detection, the algorithm used by us (Li et al., 2006) assumes that the association scores are between 0 and 1. Hence we normalize the value produced by each measure using

Challenge x	Option y (correct)	Option z (incorrect)	$f(x)$	$f(y)$	$f(z)$	$f(x,y)$	$f(x,z)$	PMI$_{sig}$ (x,y)	PMI$_{sig}$ (x,z)	PMIs (x,y)	PMIs (x,z)
brass	metal	plastic	15923	125088	24985	228	75	14	24	40	30
twist	intertwine	curl	11407	153	2047	1	9	7	17	61	41
saucer	dish	frisbee	2091	12453	1186	5	1	9	14	21	18
mass	lump	element	90398	1595	43321	14	189	4	10	29	15
applause	approval	friends	1998	19673	11689	8	6	9	11	29	28
confession	statement	plea	7687	47299	5232	76	12	18	22	45	26
swing	sway	bounce	33580	2994	4462	13	17	7	8	24	21
sheet	leaf	book	20470	20979	586581	20	194	7	2	7	12

Table 4: Details of ESL word-pairs, correctness of whose answers changes between PMI$_{sig}$ and PMIs. Except for the gray-row, for all other questions, incorrect answers becomes correct on using PMIs instead of PMI$_{sig}$, and vice-versa for the gray-row. The association values have been suitably scaled for readability. To save space, of the four choices, options not selected by either of the methods have been omitted. These results are for a 10 word span.

max-min normalization:

$$v' = \frac{v - min}{max - min}$$

where *max and* min are computed over all association scores for the entire task for a given measure.

4.2 Experimental Results

We use a 1.24 Gigawords Wikipedia corpus for getting co-occurrence statistics. Since co-occurrence methods have span-threshold as a parameter, we follow the standard methodology of five-fold cross validation. Note that, in addition to span-threshold, cPMId and sPMId have an additional parameter δ.

In Table 3, we present the performance of all the co-occurrence measures considered on all the tasks. Note that, except GoogleDistance and LLR, all results for all co-occurrence measures are statistically significant at p = .05. For completeness of comparison, we also include the best known results from literature for different non co-occurrence based word association measures on these tasks.

4.3 Performance Analysis and Conclusions

We find that on average, PMI$_{sig}$ and cPMId, the recently introduced measures that incorporate significance in PMI, do not perform better than PMI on the given datasets. Both of them perform worse than PMI on three out of four datasets. By appropriately incorporating significance, we get new measures PMIs and sPMId that perform better than PMI(also PMI$_{sig}$ and cPMId respectively) on most datasets. PMIs improves performance over PMI on three out of four datasets, while sPMId improves performance on all four datasets.

The performance improvement of PMIs over PMI$_{sig}$ and of sPMId over cPMId, is not random. For example, on the ESL dataset, while the percentage of correct answers increases from 58 to 66 from PMI$_{sig}$ to PMIs, it is not the case that on moving from PMI$_{sig}$ to PMIs, several correct answers become incorrect and an even larger number of incorrect answers become correct. As shown in Table 4, only one correct answers become incorrect while seven incorrect answers get corrected. The same trend holds for most parameters values, and for moving from cPMId to sPMId. This substantiates the claim that the improvement is not random, but due to the appropriate incorporation of significance, as discussed in Section 2.1.

PMIs and sPMId perform better than not just PMI, but they perform better than all popular co-occurrence measures on most of these tasks. When compared with any other co-occurrence measure, on three out of four datasets each, both PMIs and sPMId perform better than that measure. In fact, PMIs and sPMId perform reasonably well compared with more resource intensive non co-occurrence based methods as well. Note that different non co-occurrence based measures perform well on different tasks. We are comparing the performance of a single measure (say sPMId or PMIs) against the best measure for each task.

Growing Multi-Domain Glossaries from a Few Seeds using Probabilistic Topic Models

Stefano Faralli and **Roberto Navigli**
Dipartimento di Informatica
Sapienza Università di Roma
{faralli,navigli}@di.uniroma1.it

Abstract

In this paper we present a minimally-supervised approach to the multi-domain acquisition of wide-coverage glossaries. We start from a small number of hypernymy relation seeds and bootstrap glossaries from the Web for dozens of domains using Probabilistic Topic Models. Our experiments show that we are able to extract high-precision glossaries comprising thousands of terms and definitions.

1 Introduction

Dictionaries, thesauri and glossaries are useful sources of information for students, scholars and everyday readers, who use them to look up words of which they either do not know, or have forgotten, the meaning. With the advent of the Web an increasing number of dictionaries and technical glossaries has been made available online, thereby speeding up the definition search process. However, finding definitions is not always immediate, especially if the target term pertains to a specialized domain. Indeed, not even well-known services such as Google Define are able to provide definitions for scientific or technical terms such as *taxonomy learning* or *distant supervision* in AI or *figure-four leglock* and *suspended surfboard* in wrestling.

Domain-specific knowledge of a definitional nature is not only useful for humans, it is also useful for machines (Hovy et al., 2013). Examples include Natural Language Processing tasks such as Question Answering (Cui et al., 2007), Word Sense Disambiguation (Duan and Yates, 2010; Faralli and Navigli, 2012) and ontology learning (Velardi et al., 2013). Unfortunately, most of the Web dictionaries and glossaries available online comprise just a few hundred definitions, and they therefore provide only a partial view of a domain. This is also the case with manually compiled glossaries created by means of collaborative efforts, such as Wikipedia.[1] The coverage issue is addressed by online aggregation services such as Google Define, which bring together definitions from several online dictionaries. However, these services do not classify textual definitions by domain: they just present the collected definitions for all the possible meanings of a given term.

In order to automatically obtain large domain glossaries, in recent years computational approaches have been developed which extract textual definitions from corpora (Navigli and Velardi, 2010; Reiplinger et al., 2012) or the Web (Velardi et al., 2008; Fujii and Ishikawa, 2000). The methods involving corpora start from a given set of terms (possibly automatically extracted from a domain corpus) and then harvest textual definitions for these terms from the input corpus using a supervised system. Web-based methods, instead, extract text snippets from Web pages which match pre-defined lexical patterns, such as "X is a Y", along the lines of Hearst (1992). These approaches typically perform with high precision and low recall, because they fall short of detecting the high variability of the syntactic structure of textual definitions. To address the low-recall issue, recurring cue terms occurring

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 170–181,
Seattle, Washington, USA, 18-21 October 2013.

within dictionary and encyclopedic resources can be automatically extracted and incorporated into lexical patterns (Saggion, 2004). However, this approach is term-specific and does not scale to arbitrary terminologies and domains.

The goal of the new approach outlined in this paper is to enable the automatic harvesting of large-scale, full-fledged domain glossaries for dozens of domains, an outcome which should be very useful for both human activities and automatic tasks. We present ProToDoG (Probabilistic Topics for multi-Domain Glossaries), a framework for growing multi-domain glossaries which has three main novelties:

i) **minimal human supervision:** a small set of hypernymy relation seeds for each domain is used to bootstrap the multi-domain acquisition process;

ii) **jointness:** our approach harvests terms and glosses at the same time;

iii) **probabilistic topic models** are leveraged for a simultaneous, high-precision multi-domain classification of the extracted definitions, with substantial performance improvements over our previous work on glossary bootstrapping, i.e., GlossBoot (De Benedictis et al., 2013).

ProToDog is able to harvest definitions from the Web and thus drop the requirement of large corpora for each domain. Moreover, apart from the need to select a few seeds, it avoids the use of training data or manually defined sets of lexical patterns. It is thus applicable to virtually any language of interest.

2 ProToDoG

Given a set of domains $D = \{d_1, ..., d_n\}$, for each domain $d \in D$ ProToDoG harvests a domain glossary G_d containing pairs of the kind (t, g) where t is a domain term and g is its textual definition, i.e., gloss. We show the pseudocode of ProToDoG in Algorithm 1.

Step 1. Initial seed selection: Algorithm 1 takes as input a set of domains D and, for each domain $d \in D$, a small set of hypernymy relation seeds $S_d = \{(t_1, h_1), \ldots, (t_{|S_d|}, h_{|S_d|})\}$, where the seed pair (t_j, h_j) contains a term t_j and its generalization h_j (e.g., (*linux*, *operating system*)). This is the only human input to the entire glossary acquisition process. The selection of the input seeds plays a key role in the bootstrapping process, in that the pattern and gloss extraction process will be driven by them. The chosen hypernymy relations thus have to be as topical and representative as possible for the domain of interest (e.g., (*compiler*, *computer program*) is an appropriate pair for computer science, while (*byte*, *unit of measurement*) is not, as it might cause the extraction of out-of-domain glossaries of units and measures).

Algorithm 1 ProToDoG

Input: the set of domains D,
a set S_d of hypernymy seeds for each domain $d \in D$
Output: a multi-domain glossary G

1: $k \leftarrow 1$
2: **repeat**
3: **for each** domain $d \in D$ **do**
4: $G_d^k \leftarrow \emptyset$
5: **for each** seed $(t_j, h_j) \in S_d$ **do**
6: $pages \leftarrow webSearch(t_j, h_j, \text{“}glossary\text{”})$
7: $G_d^k \leftarrow G_d^k \cup extractGlossary(pages)$
8: **end for**
9: **end for**
10: *create* a topic model using glossaries from previous iterations
11: *infer* topic assignments for iteration-k glosses
12: *filter out* non-domain glosses for each domain
13: **for each** $d \in D$ **do**
14: $S_d \leftarrow seedSelectionForNextIteration(G_d^k)$
15: **end for**
16: $k \leftarrow k + 1$
17: **until** $k > max$
18: **for each** domain $d \in D$ **do**
19: *recover* filtered glosses into G_d^{max+1}
20: $G_d \leftarrow \bigcup_{j=1,\ldots,max+1} G_d^j$
21: **end for**
22: **return** $G = \{(G_d, d) : d \in D\}$

The algorithm first sets the iteration counter k to 1 (line 1) and starts the first iteration of the glossary bootstrapping process (lines 2-17), each involving steps 2-4, described below. After each iteration k, for each domain d we keep track of the set of glosses G_d^k acquired during that iteration. After the last iteration, we perform step (5) of gloss recovery (lines 18-21).

Step 2. Web search and glossary extraction (lines 3-9): For each domain d, we first initialize the domain glossary for iteration k: $G_d^k := \emptyset$ (line 4). Then, for each seed pair $(t_j, h_j) \in S_d$, we submit the following query to a Web search engine: "t_j" "h_j" `glossary` and collect the top-ranking results for each query (line 6).[2] Each resulting page is a candidate glossary for the domain d.

We then call the $extractGlossary$ function (line 7) which extracts terms and glosses from the retrieved pages as follows. From each candidate page, we harvest all the text snippets s starting with t_j and ending with h_j (e.g., "*linux* – an *operating system*"), i.e., $s = t_j \ldots h_j$. For each such text snippet s, we extract the following pattern instance:

$$p_L\ t_j\ p_M\ gloss_s(t_j)\ p_R,$$

where:

- p_M is the longest sequence of HTML tags and non-alphanumeric characters between t_j and the glossary definition (e.g., " –" between "linux" and "an" in the above example);
- $gloss_s(t_j)$ is the gloss of t_j obtained by moving to the right of p_M until we reach a non-formatting tag element (e.g., , ,), while ignoring formatting elements such as , and <a> which are typically included within a definition sentence;
- p_L and p_R are the longest sequences of HTML tags on the left of t_j and the right of $gloss_s(t_j)$, respectively.

For instance, given the HTML snippet "... linux – an operating system developed by Linus Torvalds ..." we extract the following pattern instance: p_L = " ", t_j = "*linux*", p_M = " –", $gloss_s(t_j)$ = "an *operating system* developed by Linus Torvalds", p_R =" ".

Then we generalize the above pattern instance by replacing t_j and $gloss_s(t_j)$ with *, obtaining:

$$p_L\ *\ p_M\ *\ p_R,$$

For the above example, we obtain the following pattern:

 * – * .

We add the first sentence of the retrieved gloss $gloss_s(t_j)$ to our glossary G_d^k, i.e., $G_d^k := G_d^k \cup \{(t_j, first(gloss_s(t_j)))\}$, where $first(g)$ returns the first sentence of gloss g. Finally, we look for additional pairs of terms/glosses in the Web page containing the snippet s by matching the page against the generalized pattern $p_L\ *\ p_M\ *\ p_R$, and adding them to G_d^k.

As a result of step (2), for each domain $d \in D$ we obtain a glossary G_d^k for the terms discovered at iteration k.

Step 3. Topic modeling and gloss filtering (lines 10-12): Unfortunately, not all (term, gloss) pairs in a glossary G_d^k will pertain to the domain d. For instance, we might end up retrieving interdisciplinary or even unrelated glossaries. In order to address this fuzziness, we model domains with a Probabilistic Topic Model (PTM) (Blei et al., 2003; Steyvers and Griffiths, 2007). PTMs model a given text document as a mixture of topics. In our case topics are domains and we, first, create a topic model from the domain glossaries acquired before the current iteration k, then, second, use the topic model to estimate the domain assignment of each new pair (term, gloss) in our glossaries G_d^k, i.e., obtained at iteration k, third, filter out non-domain glosses.

Creating the topic model (line 10): For a given iteration k and domain d, we first define the terminology accumulated up until iteration $k-1$ for that domain as the set $T_d^{1,k-1} := \bigcup_{j=1}^{k-1} T_d^j$, where T_d^j is the set of terms acquired at iteration j, i.e., $T_d^j := \{t : \exists (t, g) \in G_d^j\}$.[3] Then we define:

- $W := \bigcup_{d \in D} T_d^{1,k-1}$ as the entire terminology acquired up until iteration $k-1$ for all domains, i.e., the full set of terms independently of their domain;
- $M := \bigcup_{d \in D} \bigcup_{j=1}^{k-1} G_d^j$ as the multi-domain glossary acquired up until iteration $k-1$, i.e., the full set of pairs (term, gloss) independently of their domain;[4]

[2] We use the Google Ajax API, which returns the 64 top-ranking search results.

[3] For the first iteration, i.e., when $k = 1$, we define $T_d^{1,0} := \{t : \exists (t, g) \in G_d^1\}$, i.e., we use the terminology resulting from step (2) of the first iteration.

[4] For $k = 1$, $M := \bigcup_{d \in D} G_d^1$.

- Two count matrices, i.e., the word-domain matrix C^{WD} and the gloss-domain matrix C^{MD}, such that: $C^{WD}_{w,d}$ counts the number of times $w \in W$ is assigned to domain $d \in D$, i.e., it occurs in the glosses of domain d; $C^{MD}_{(t,g),d}$ counts the number of words in g assigned to domain d.

At this point, as shown by Steyvers and Griffiths (2007), we can estimate the probability $\phi^{(d)}_w$ for word w, and the probability $\theta^{(t,g)}_d$ for a term/gloss pair (t, g), of belonging to domain d:

$$\phi^{(d)}_w = \frac{C^{WD}_{w,d} + \beta}{\sum_{w'=1}^{|W|} C^{WD}_{w',d} + |W|\beta}; \quad (1)$$

$$\theta^{(t,g)}_d = \frac{C^{MD}_{(t,g),d} + \alpha}{\sum_{d'=1}^{|D|} C^{MD}_{(t,g),d'} + |D|\alpha} \quad (2)$$

where α and β are smoothing factors.[5] The two above probabilities represent the core of our topic model of the domain knowledge acquired up until iteration $k-1$.

Probabilistic modeling of iteration-k glosses (line 11): We now utilize the above topic model to estimate the probabilities in Formulas 1 and 2 for the newly acquired glosses at iteration k. To this end we define $M' := \bigcup_{d \in D} G^k_d$ as the union of the (term, gloss) pairs at iteration k and $W' := \bigcup_{d \in D} T^k_d \bigcap W$ as the union of terms acquired at iteration k, but also occurring in W (i.e., the entire terminology up until iteration $k-1$). Then we apply Gibbs sampling (Blei et al., 2003; Phan et al., 2008) to estimate the probability of each pair $(t, g) \in M'$ of pertaining to a domain d by computing:

$$\theta'^{(t,g)}_d = \frac{R^{M'D}_{(t,g),d} + \alpha}{\sum_{d'=1}^{|D|} R^{M'D}_{(t,g),d'} + |D|\alpha} \quad (3)$$

where the gloss-domain matrix $R^{M'D}$ is initially defined by counting random domain assignments for each word w' in the bag of words of each (term, gloss) pair $\in M'$. Next, the domain assignment counts in $R^{M'D}$ are iteratively updated using Gibbs sampling.[6]

Filtering out non-domain glosses (line 12): Now, for each domain $d \in D$, for each pair $(t, g) \in G^k_d$ we have a probability $\theta'^{(t,g)}_d$ of belonging to d. We mark (t, g) as a non-domain item if $\theta'^{(t,g)}_d < \delta$, where δ is a confidence threshold, or if $\theta'^{(t,g)}_d$ is not maximum among all domains in D. Non-domain pairs are removed from G^k_d and stored into a set A_d for possible recovery after the last iteration (see step (5)).

Step 4. Seed selection for next iteration (lines 13-15): For each domain $d \in D$, we now select the new set of hypernymy relation seeds to be used to start the next iteration. First, for each newly-acquired term/gloss pair $(t, g) \in G^k_d$, we automatically extract a candidate hypernym h from the textual gloss g. To do this we use a simple heuristic which just selects the first content term in the gloss.[7] Then we sort all the glosses in G^k_d by the number of seed terms found in each gloss. In the case of ties (i.e., glosses with the same number of seed terms), we further sort the glosses by $\theta'^{(t,g)}_d$. Finally we select the (term, hypernym) pairs corresponding to the $|S_d|$ top-ranking glosses as the new set of seeds for the next iteration.

Next, we increment k (line 16 of Algorithm 1) and if the maximum number of iterations is reached we jump to step (5). Otherwise, we go back to step (2) of our glossary bootstrapping algorithm with the new set of seeds S_d.

Step 5. Gloss recovery (line 19): After all iterations, the entire multi-domain terminology W (cf. step (3)) may contain several new terms which were not present when a given gloss g was filtered out. So, thanks to the last-iteration topic model, the gloss g might come back into play because its words are now important cues for a domain. To reassess the domain pertinence of (term, gloss) pairs in A_d for each d, we just reapply the entire step (3) by setting $G^{max+1}_d := A_d$ for each $d \in D$. As a result, we

[5] As experienced by Steyvers and Griffiths (2007), the values of $\alpha = 50/|D|$ and $\beta = 0.01$ work well with many different text collections.

[6] For the PTM part of ProToDoG we used the JGibbLDA library, a Java Implementation of Latent Dirichlet Allocation (LDA) using Gibbs Sampling for Parameter Estimation and Inference, available at: `http://jgibblda.sourceforge.net/`

[7] While more complex strategies could be devised, e.g., lattice-based hypernym extraction (Navigli and Velardi, 2010), we found that this heuristic works well because, even when it is not a hypernym, the first term acts as a cue word for the defined term.

obtain an updated glossary G_d^{max+1} which contains all the recovered glosses.

Final output: For each domain $d \in D$ the final output of ProToDoG is a domain glossary $G_d := \bigcup_{j=1,...,max+1} G_d^j$. Finally the algorithm aggregates all glossaries G_d into a multi-domain glossary G (line 22).

3 Experimental Setup

3.1 Domains

For our experiments we selected 30 different domains ranging from Arts to Warfare, mostly following the domain classification of Wikipedia featured articles (full list at `http://lcl.uniroma1.it/protodog`). The set includes several technical domains, such as Chemistry, Geology, Meteorology, Mathematics, some of which are highly interdisciplinary. For instance, the Environment domain covers terms from fields such as Chemistry, Biology, Law, Politics, etc.

3.2 Gold Standard

Since our evaluations required considerable human effort, in what follows we calculated all performances on a random set of 10 domains, shown in the top row of Table 1. For each of these 10 domains we selected well-reputed glossaries on the Web as gold standards, including the Reuters glossary of finance, the Utah computing glossary and many others (full list at the above URL). We show the size of our 10 gold-standard datasets in Table 1.

3.3 Evaluation measures

We evaluated the quality of both terms and glosses, as jointly extracted by ProToDoG.

3.3.1 Terms

For each domain we calculated coverage, extra-coverage and precision of the acquired terms T. **Coverage** is the ratio of extracted terms in T also contained in the gold standard $\hat{T}$ over the size of $\hat{T}$. **Extra-coverage** is calculated as the ratio of the additional extracted terms in $T \setminus \hat{T}$ over the number of gold standard terms $\hat{T}$. Finally, **precision** is the ratio of extracted terms in T deemed to be within the domain. To calculate precision we randomly sampled 5% of the retrieved terms and asked two human annotators to manually tag their domain pertinence (with adjudication in case of disagreement; $\kappa = .62$, indicating substantial agreement). Note that by randomly sampling on the entire set T we calculate the precision of both terms in $T \cap \hat{T}$, i.e., in the gold standard, and terms in $T \setminus \hat{T}$, i.e., not in the gold standard, but which are not necessarily outside the domain.

3.3.2 Glosses

We calculated the precision of the extracted glosses as the ratio of glosses which were both well-formed textual definitions and specific to the target domain. Precision was determined on a random sample of 5% of the acquired glosses for each domain. The annotation was made by two annotators, with $\kappa = .675$, indicating substantial agreement. The annotators were provided with specific guidelines available on the ProToDoG Web site (see URL above).

3.4 Comparison

We compared ProToDog against:

- **BoW**: a bag-of-words variant in which step (3) is replaced by a simple bag-of-words scoring approach which assigns a score to each term/gloss pair $(t, g) \in G_d^k$ as follows:

$$score(g) = \frac{|Bag(g) \cap T_d^{1,k-1}|}{|Bag(g)|}. \quad (4)$$

  where $Bag(g)$ contains all content words in g. At iteration k, we filter out those glosses whose $score(g) < \sigma$, where σ is a threshold tuned in the same manner as δ (see Section 3.5). This approach essentially implements GlossBoot, our previous work on domain glossary bootstrapping (De Benedictis et al., 2013).

- **Wikipedia**: since Wikipedia is the largest collaborative resource, covering hundreds of fields of knowledge, we devised a simple heuristic for producing multi-domain glossaries from Wikipedia, so as to compare their performance against our gold standards. For each target domain we manually selected one

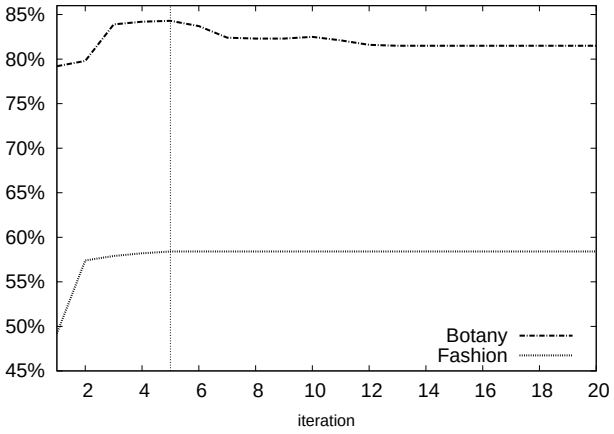

Figure 1: Harmonic mean of precision and coverage for Botany and Fashion (tuning domains) over 20 iterations ($|S_d|$=5, δ=0.03).

or more Wikipedia categories representing the domain (for instance, `Category:Arts` for Arts, `Category:Business` for Finance, etc.). Then, for each domain d, we picked out all the Wikipedia pages tagged either with the categories selected for d or their direct subcategories (e.g., `Category:Creative works`) or subsubcategories (e.g., `Category:Genres`). From each page we extracted a (page title, gloss) pair, where the gloss was obtained by extracting the first sentence of the Wikipedia page, as done, e.g., in BabelNet (Navigli and Ponzetto, 2012). Since subcategories might have more parents and might thus belong to multiple domains, we discarded pages assigned to more than 2 domains.

3.5 Parameter tuning

In order to choose the optimal values of the parameters of ProToDoG (number $|S_d|$ of seeds per domain, number max of iterations, and filtering threshold δ) and BoW (σ threshold) we selected two extra domains, i.e., Botany and Fashion, not used in our tests, together with the corresponding gold standard Web glossaries.

As regards the number of seeds, we defined an initial pool of 10 seeds for each of the two tuning domains and studied the average performance of 5 random sets of x seeds (from the initial pool), when $x = 1, 3, 5, 7, 9$. As regards the number of iterations, we explored all values between 1 and 20. Finally, for the filtering thresholds δ and σ for ProToDoG PTM and its BoW variant, we tried values of $\delta \in \{0, 0.03, 0.06, \ldots, 0.6\}$ and $\sigma \in \{0, 0.05, 0.1, \ldots, 1.0\}$, respectively.

Given the high number of possible parameter value configurations, we first explored the entire search space automatically by calculating the coverage of ProToDoG PTM (and BoW) with each configuration against our tuning gold standards. Then we identified as optimal candidates those "frontier" configurations for which, when moving from a lower-coverage configuration, coverage reached a maximum. We then calculated the precision of each optimal candidate configuration by manually validating a 3% random sample of the resulting glossaries for the two tuning domains. The optimal configuration for ProToDoG was $|S_d| = 5$, $max = 5$, $\delta = 0.03$, while for BoW was $\sigma = 0.1$.

In Figure 1 we show the performance trend over iterations for our two tuning domains when $|S_d| = 5$ and $\delta = 0.03$. Performance is calculated as the harmonic mean of precision and coverage of the acquired glossary after each iteration, from 1 to 20. We can see that after 5 iterations performance decreases for Botany (a highly interdisciplinary domain) due to lower precision, while it remains stable for Fashion due to the lack of newly-acquired glosses.

3.6 Seed Selection

For each domain d we manually selected five seed hypernymy relations as the seed sets S_d input to Algorithm 1 (see Section 3.5). The seeds were selected by the authors on the basis of just two conditions: i) the seeds should cover different aspects of the domain and, indeed, should identify the domain implicitly; ii) at least 10,000 results should be returned by the search engine when querying it with the seeds plus the `glossary` keyword (see line 6 of Algorithm 1). The seed selection was not fine-tuned (i.e., it was not adjusted to improve performance), so it might well be that better seeds would provide better results (see (Kozareva and Hovy, 2010a)). However, such a study is beyond the scope of this paper.

		Art	Business	Chemistry	Computing	Environment	Food	Law	Music	Physics	Sport

Table 1: Size of the gold standard and the automatically-acquired glossaries for 10 of the 30 selected domains (t: number of terms, g: number of glosses).

4 Results and Discussion

4.1 Terms

The size of the extracted terminologies for the 10 domains after five iterations is reported in Table 1 (the output for all 30 domains is available at the above URL, cf. Section 3.1). ProToDoG PTM and its BoW variant extract thousands of terms and glosses for each domain, whereas the number of glosses obtained from Wikipedia (cf. Section 3.4) varies depending upon the domain, from thousands to hundreds of thousands. Note that there is no overlap between the glossaries extracted by ProToDoG and the set of Wikipedia articles, since the latter are not organized as glossaries.

In Table 2 we show the percentage results in terms of precision (P), coverage (C), and extra-coverage (X, see Section 3.3 for definitions) for ProToDoG PTM and its BoW variant and for the Wikipedia glossary. With the exception of the Food domain, ProToDoG achieves the best precision. The Wikipedia glossary has fluctuating precision values, ranging between 25% and 90%, due to the heterogeneous nature of subcategories. ProToDog achieves the best coverage of gold standard terms on 6 of the 10 domains, with the BoW variant obtaining slightly higher coverage on 3 domains and +10% on the Food domain. The coverage of Wikipedia glossaries, instead, with the sole exception of Sport, is much lower, despite the use of (sub)subcategories (cf. Section 3.4). Both ProToDoG PTM and BoW achieve very high extra-coverage percentages, meaning that they are able to go substantially beyond our domain gold standards, but it is the Wikipedia glossary which achieves the highest extra-coverage values. To get a better insight into the quality of extra-coverage we calculated the percentage of named entities (i.e., encyclopedic) among the terms extracted by each of the different approaches. Comparing results across the (E) columns of Table 2 it can be seen that high percentages of the terms extracted by Wikipedia are named entities, which is in marked contrast to the 0%-1% extracted by ProToDog. This is as should be expected for an encyclopedia, whose coverage focuses on people, places, brands, etc. rather than concepts.

To summarize, ProToDoG PTM outperforms both BoW and Wikipedia in terms of precision, while at the same time achieving both competitive coverage and extra-coverage. The Wikipedia glossary suffers from fluctuating precision values across domains and overly encyclopedic coverage of terms.

4.2 Glosses

We show the results of gloss evaluation in Table 2 (last two columns) for ProToDoG PTM and BoW (we do not report the precision values for Wikipedia, as they are slightly lower than those obtained for terms). Precision ranges between 89% and 99% for ProToDoG PTM and between 82% and 97% for BoW. We observe that these results are strongly correlated with the precision of the extracted terms (cf. Table 2), because the retrieved glosses of domain terms are usually in-domain too, and follow a definitional style since they come from glossaries. Note, however, that the gloss precision could also be

higher than term precision, thanks to many pertinent glosses being extracted for the same term (cf. Table 1).

In Table 4 we show an excerpt of the multi-domain glossary extracted by ProToDoG for the Art, Business and Sport domains.

5 Comparative Evaluation

5.1 Comparison with Google Define

We performed a comparison with Google Define,[8] a state-of-the-art definition search service. This service inputs a term query and outputs a list of glosses. First, we randomly sampled 100 terms from our gold standard for each domain. Next, for each domain, we manually calculated the fraction of terms for which at least one in-domain definition was provided by Google Define and ProToDoG. Table 3 shows the coverage results. In this experiment, Google Define outperforms our system on 9 of the 10 analyzed domains. However, we note that when searching for domain-specific knowledge only, Google Define: i) needs to know the domain term to be defined in advance, while ProToDoG jointly acquires domain terms and glosses starting from just a few seeds; ii) does not discriminate between glosses pertaining to the target domain and glosses pertaining to other fields or senses, whereas ProToDog extracts terms and glosses specific to each domain of interest.

5.2 Comparison with TaxoLearn

We also compared ProToDoG with the output of a state-of-the-art taxonomy learning framework, called TaxoLearn (Navigli et al., 2011). We did this because i) TaxoLearn extracts terms and glosses from domain corpora in order to create a domain taxonomy; ii) it is one of the few systems which extracts both terms and glosses from specialized corpora; iii) the extracted glossaries are available online.[9] Therefore we compared the performance of ProToDoG on two domains for which glossaries were extracted by TaxoLearn, i.e. AI and Finance. The glossaries were harvested from large collections of scholarly articles. For ProToDoG we selected 10 seeds to cover all the fields of AI, while for the financial domain we selected the same 5 seeds used in the Business

[8] Accessible from Google search with the `define:` keyword.

Art	
rock art	includes pictographs (designs painted on stone surfaces) and petroglyphs (designs pecked or incised on stone surfaces).
impressionism	Late 19th-century French school dedicated to defining transitory visual impressions painted directly from nature, with light and color of primary importance.
point	Regarding paper, a unit of thickness equating 1/1000 inch.
Business	
hyperinflation	Extremely rapid or out of control inflation.
interbank rate	The rate of interest charged by a bank on a loan to another bank.
points	Amount of discount on a mortgage loan stated as a percentage; one point equals one percent of the face amount of the loan; a discount of one point raises the net yield on the loan by one-eighth of one percent.
Sport	
gross score	The actual number of strokes taken by a player for hole or round before the player's handicap is deducted.
obstructing	preventing the opponent from going around a player by standing in the path of movement.
points	a team statistic indicating its degree of success, calculated as follows: 2 points for a win (3 in the 1994 World Cup), 1 point for a tie, 0 points for a loss.

Table 4: An excerpt of the resulting multi-domain glossary obtained with ProToDoG.

domain of our experiments above (cf. Section 3).

We show the number of extracted terms and glosses for ProToDoG and TaxoLearn in Table 5. We also show the precision values calculated on a random sample of 5% of terms and glosses. As can be clearly seen, on both domains ProToDoG extracts a number of terms and glosses which is an order of magnitude greater than those obtained by TaxoLearn, while at the same time obtaining considerably higher precision.

6 Related Work

Current approaches to automatic glossary acquisition suffer from two main issues: i) the poor availability of large domain-specific corpora from which terms and glosses are extracted at different times; ii) the focus on individual domains. ProToDog addresses both issues by providing a joint multi-domain approach to term and glossary extraction.

Among the approaches which extract unrestricted textual definitions from open text, Fujii and Ishikawa (2000) determine the definitional nature of text fragments by using an n-gram model, whereas Klavans and Muresan (2001) apply pattern matching techniques at the lexical level guided by cue phrases such as "is called" and "is defined as". More recently, a domain-independent supervised approach, named Word-Class Lattices (WCLs), was presented which learns lattice-based definition classifiers applied to candidate sentences containing the input terms (Navigli and Velardi, 2010). To avoid the burden of manually creating a training dataset, definitional patterns can be extracted automatically. Faralli and Navigli (2013) utilized Wikipedia as a huge source of definitions and simple, yet effective heuristics to automatically annotate them. Reiplinger et al. (2012) experimented with two different approaches for the acquisition of lexical-syntactic patterns. The first approach bootstraps patterns from a domain corpus and then manually refines the acquired patterns. The second approach, instead, automatically acquires definitional sentences by using a more sophisticated syntactic and semantic processing. The results show high precision in both cases. However, all the above approaches need large domain corpora, the poor availability of which hampers the creation of wide-coverage glossaries for several domains. To avoid the need to use a large corpus, domain terminologies can be obtained by using Doubly-Anchored Patterns (DAPs)

	AI				Finance			
	# terms	P	# glosses	P	# terms	P	# glosses	P
ProToDoG	4983	83%	5326	84%	7370	95%	9795	96%
TaxoLearn	427	77%	834	79%	2348	86%	1064	88%

Table 5: Number and precision of terms and glosses extracted by ProToDoG and TaxoLearn in the Artificial Intelligence (AI) and Finance domains.

which, given a (term, hypernym) pair, extract from the Web sentences matching manually-defined patterns like "<hypernym> such as <term>, and *" (Kozareva and Hovy, 2010b). This term extraction process is further extended by harvesting new hypernyms using the corresponding inverse patterns (called DAP^{-1}) like "* such as <term$_1$>, and <term$_2$>". Similarly to ProToDoG, this approach drops the requirement of a domain corpus and starts from a small number of (term, hypernym) seeds. However, while DAPs have proven useful in the induction of domain taxonomies (Kozareva and Hovy, 2010b), they cannot be applied to the glossary learning task because the extracted sentences are not formal definitions. In contrast, ProToDoG performs the novel task of multi-domain glossary acquisition from the Web by bootstrapping the extraction process with a few (term, hypernym) seeds. Bootstrapping techniques (Brin, 1998; Agichtein and Gravano, 2000; Paşca et al., 2006) have been successfully applied to several tasks, including learning semantic relations (Pantel and Pennacchiotti, 2006), extracting surface text patterns for open-domain question answering (Ravichandran and Hovy, 2002), semantic tagging (Huang and Riloff, 2010) and unsupervised Word Sense Disambiguation (Yarowsky, 1995). ProToDoG synergistically integrates bootstrapping with probabilistic topic models so as to keep the glossary acquisition process within the target domains as much as possible.

7 Conclusions

In this paper we have presented ProToDoG, a new, minimally-supervised approach to multi-domain glossary acquisition. Starting from a small set of hypernymy seeds which identify each domain of interest, we apply a bootstrapping approach which iteratively obtains generalized patterns from Web glossaries and then applies them to the extraction of term/gloss pairs. To our knowledge, ProToDoG is the first approach to large-scale probabilistic glossary learning which jointly acquires thousands of terms and glosses for dozens of domains with minimal supervision.

At the core of ProToDoG lies our glossary bootstrapping approach, thanks to which we can drop the requirements of existing techniques such as the ready availability of domain corpora, which often do not contain enough definitions (cf. Table 5), and the manual definition of lexical patterns, which typically extract sentence snippets instead of formal glosses.

ProToDoG will be made available to the research community. Beyond the immediate usability of the output glossaries (we show an excerpt in Table 4), we also wish to show the benefit of ProToDoG in gloss-driven approaches to taxonomy learning (Navigli et al., 2011; Velardi et al., 2013) and Word Sense Disambiguation (Duan and Yates, 2010; Faralli and Navigli, 2012). The 30-domain glossaries and gold standards created for our experiments are available from `http://lcl.uniroma1.it/protodog`.

We remark that the terminologies covered with ProToDoG are not only precise, but are also one order of magnitude greater than those covered in individual online glossaries. As future work, we plan to study the ability of ProToDoG to acquire domain glossaries at different levels of specificity (i.e., domains vs. subdomains). Finally, we will adapt ProToDoG to other languages, by translating the `glossary` keyword used in step (2), along the lines of (De Benedictis et al., 2013).

Abstract

The creation of a pronunciation lexicon remains the most inefficient process in developing an Automatic Speech Recognizer (ASR). In this paper, we propose an unsupervised alternative – requiring no language-specific knowledge – to the conventional manual approach for creating pronunciation dictionaries. We present a hierarchical Bayesian model, which jointly discovers the phonetic inventory and the Letter-to-Sound (L2S) mapping rules in a language using only transcribed data. When tested on a corpus of spontaneous queries, the results demonstrate the superiority of the proposed joint learning scheme over its sequential counterpart, in which the latent phonetic inventory and L2S mappings are learned separately. Furthermore, the recognizers built with the automatically induced lexicon consistently outperform grapheme-based recognizers and even approach the performance of recognition systems trained using conventional supervised procedures.

1 Introduction

Modern automatic speech recognizers require a few essential ingredients such as a signal representation of the speech signal, a search component, and typically a set of stochastic models that capture 1) the acoustic realizations of the basic sounds of a language, for example, phonemes, 2) the realization of words in terms of these sounds, and 3) how words are combined in spoken language. When creating a speech recognizer for a new language the usual requirements are: first, a large speech corpus with word-level annotations; second, a pronunciation dictionary that essentially defines a phonetic inventory for the language as well as word-level pronunciations, and third, optional additional text data that can be used to train the language model. Given these data and some decision about the signal representation, e.g., centi-second Mel-Frequency Cepstral Coefficients (MFCCs) (Davis and Mermelstein, 1980) with various derivatives, as well as the nature of the acoustic and language model such as 3-state HMMs and n-grams, iterative training methods can be used to effectively learn the model parameters for the acoustic and language models. Although the details of the components have changed through the years, this basic ASR formulation was well established by the late 1980's, and has not really changed much since then.

One of the interesting aspects of this formulation is the inherent dependence on the dictionary, which defines both the phonetic inventory of a language, and the pronunciations of all the words in the vocabulary. The dictionary is arguably the cornerstone of a speech recognizer as it provides the essential transduction from sounds to words. Unfortunately, the dependency on this resource is a significant impediment to the creation of speech recognizers for new languages, since they are typically created by experts, whereas annotated corpora can be relatively more easily created by native speakers of a language.

The existence of an expert-derived dictionary in the midst of stochastic speech recognition models is somewhat ironic, and it is natural to ask why it continues to receive special status after all these years. Why can we not learn the inventory of sounds of a language and associated word pronunciations automatically, much as we learn our acoustic model parameters? If successful, we would move one step forward towards breaking the language barrier that

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 182–192,
Seattle, Washington, USA, 18-21 October 2013.

limits us from having speech recognizers for all languages of the world, instead of the less than 2% that currently exist.

In this paper, we investigate the problem of inferring a pronunciation lexicon from an annotated corpus without exploiting any language-specific knowledge. We formulate our approach as a hierarchical Bayesian model, which jointly discovers the acoustic inventory and the latent encoding scheme between the letters and the sounds of a language. We evaluate the quality of the induced lexicon and acoustic model through a series of speech recognition experiments on a conversational weather query corpus (Zue et al., 2000). The results demonstrate that our model consistently generates close performance to recognizers that are trained with expert-defined phonetic inventory and lexicon. Compared to grapheme-based recognizers, our model is capable of improving the Word Error Rates (WERs) by at least 15.3%. Finally, the joint learning framework proposed in this paper is proven to be much more effective than modeling the acoustic units and the letter-to-sound mappings separately, as shown in a 45% WER deduction our model achieves compared to a sequential approach.

2 Related Work

Various algorithms for learning sub-word based pronunciations were proposed in (Lee et al., 1988; Fukada et al., 1996; Bacchiani and Ostendorf, 1999; Paliwal, 1990). In these previous approaches, spoken samples of a word are gathered, and usually only one single pronunciation for the word is derived based on the acoustic evidence observed in the spoken samples. The major difference between our work and these previous works is that our model learns word pronunciations in the context of letter sequences. More specifically, our model learns letter pronunciations first and then concatenates the pronunciation of each letter in a word to form the word pronunciation. The advantage of our approach is that pronunciation knowledge learned for a particular letter in some arbitrary word can subsequently be used to help learn the letter's pronunciation in other words. This property allows our model to potentially learn better pronunciations for less frequent words.

The more recent work by Garcia and Gish (2006) and Siu et al. (2013) has made extensive use of self-organizing units for keyword spotting and other tasks for languages with limited linguistic resources. Others who have more recently explored the unsupervised space include (Varadarajan et al., 2008; Jansen and Church, 2011; Lee and Glass, 2012). The latter work introduced a non-parametric Bayesian inference procedure for automatically learning acoustic units that is most similar to our current work except that our model also infers word pronunciations simultaneously.

The concept of creating a speech recognizer for a language with only orthographically annotated speech data has also been explored previously by means of graphemes. This approach has been shown to be effective for alphabetic languages with relatively straightforward grapheme to phoneme transformations and does not require any unsupervised learning of units or pronunciations (Killer et al., 2003; Stüker and Schultz, 2004). As we explain in later sections, grapheme-based systems can actually be regarded as a special case of our model; therefore, we expect our model to have greater flexibilities for capturing pronunciation rules of graphemes.

3 Model

The goal of our model is to induce a word pronunciation lexicon from spoken utterances and their corresponding word transcriptions. No other language-specific knowledge is assumed to be available, including the phonetic inventory of the language. To achieve the goal, our model needs to solve the following two tasks:

- Discover the phonetic inventory.
- Reveal the latent mapping between the letters and the discovered phonetic units.

We propose a hierarchical Bayesian model for jointly discovering the two latent structures from an annotated speech corpus. Before presenting our model, we first describe the key latent and observed variables of the problem.

Letter (l_i^m) We use l_i^m to denote the i^{th} letter observed in the word transcription of the m^{th} training sample. To be sure, a training sample involves a speech utterance and its

corresponding text transcription. The letter sequence composed of l_i^m and its context, namely $l_{i-\kappa}^m, \cdots, l_{i-1}^m, l_i^m, l_{i+1}^m, \cdots, l_{i+\kappa}^m$, is denoted as $\vec{l}_{i,\kappa}^m$. Although l_i^m is referred to as a *letter* in this paper, it can represent any *character* observed in the text data, including space and symbols indicating sentence boundaries. The set of unique characters observed in the data set is denoted as G. For notation simplicity, we use $\mathcal{L}_\kappa$ to denote the set of letter sequences of length $2\kappa + 1$ that appear in the dataset and use $\vec{l}_\kappa$ to denote the elements in $\mathcal{L}_\kappa$. Finally, $\mathbb{P}(\vec{l}_\kappa)$ is used to represent the *parent* of $\vec{l}_\kappa$, which is a substring of $\vec{l}_\kappa$ with the first and the last characters truncated.

Number of Mapped Acoustic Units (n_i^m) Each letter l_i^m in the transcriptions is assumed to be mapped to a certain number of phonetic units. For example, the letter *x* in the word *fox* is mapped to 2 phonetic units /k/ and /s/, while the letter *e* in the word *lake* is mapped to 0 phonetic units. We denote this number as n_i^m and limit its value to be 0, 1 or 2 in our model. The value of n_i^m is always unobserved and needs to be inferred by the our model.

Identity of the Acoustic Unit ($c_{i,p}^m$) For each phonetic unit that l_i^m maps to, we use $c_{i,p}^m$, for $1 \leq p \leq n_i^m$, to denote the identity of the phonetic unit. Note that the phonetic inventory that describes the data set is unknown to our model, and the identities of the phonetic units are associated with the acoustic units discovered automatically by our model.

Speech Feature x_t^m The observed speech data in our problem are converted to a series of 25 ms 13-dimensional MFCCs (Davis and Mermelstein, 1980) and their first- and second-order time derivatives at a 10 ms analysis rate. We use $x_t^m \in \mathbb{R}^{39}$ to denote the t^{th} feature frame of the m^{th} utterance.

3.1 Generative Process

We present the generative process for a single training sample (i.e., a speech utterance and its corresponding text transcription); to keep notation simple, we discard the index variable m in this section.

For each l_i in the transcription, the model generates n_i, given $\vec{l}_{i,\kappa}$, from the 3-dimensional categorical distribution $\phi_{\vec{l}_{i,\kappa}}(n_i)$. Note that for every unique $\vec{l}_{i,\kappa}$ letter sequence, there is an associated $\phi_{\vec{l}_{i,\kappa}}(n_i)$

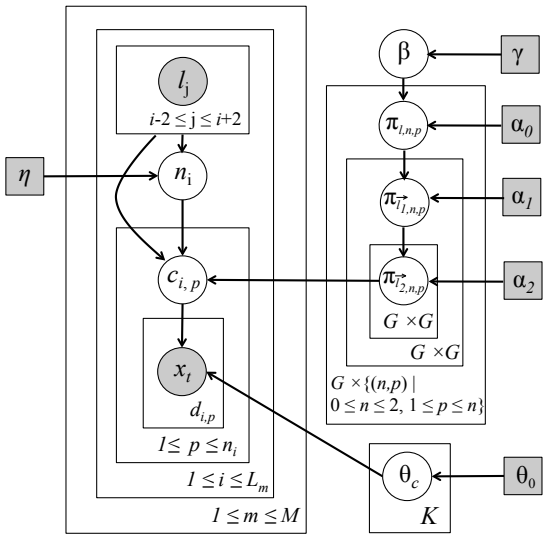

Figure 1: The graphical representation of the proposed hierarchical Bayesian model. The shaded circle denotes the observed text and speech data, and the squares denote the hyperparameters of the priors in our model. See Sec. 3 for a detailed explanation of the generative process of our model.

distribution, which captures the fact that the number of phonetic units a letter maps to may depend on its context. In our model, we impose a Dirichlet distribution prior $Dir(\eta)$ on $\phi_{\vec{l}_{i,\kappa}}(n_i)$.

If $n_i = 0$, l_i is not mapped to any acoustic units and the generative process stops for l_i; otherwise, for $1 \leq p \leq n_i$, the model generates $c_{i,p}$ from:

$$c_{i,p} \sim \pi_{\vec{l}_{i,\kappa},n_i,p} \tag{1}$$

where $\pi_{\vec{l}_{i,\kappa},n_i,p}$ is a K-dimensional categorical distribution, whose outcomes correspond to the phonetic units discovered by the model from the given speech data. Eq. 1 shows that for each combination of $\vec{l}_{i,\kappa}$, n_i and p, there is an unique categorical distribution. An important property of these categorical distributions is that they are coupled together such that their outcomes point to a consistent set of phonetic units. In order to enforce the coupling, we construct $\pi_{\vec{l}_{i,\kappa},n_i,p}$ through a hierarchical process.

$$\beta \sim Dir(\gamma) \tag{2}$$

$$\pi_{\vec{l}_{i,\kappa},n_i,p} \sim Dir(\alpha_\kappa \beta) \text{ for } \kappa = 0 \tag{3}$$

$$\pi_{\vec{l}_{i,\kappa},n_i,p} \sim Dir(\alpha_\kappa \pi_{\vec{l}_{i,\kappa-1},n_i,p}) \text{ for } \kappa \geq 1 \tag{4}$$

To interpret Eq. 2 to Eq. 4, we envision that the observed speech data are generated by a K-component mixture model, of which the components correspond to the phonetic units in the language. As a result, β in Eq. 2 can be viewed as the mixture weight over the components, which indicates how likely we are to observe each acoustic unit in the data overall. By adopting this point of view, we can also regard the mapping between l_i and the phonetic units as a mixture model, and $\pi_{l_i,n_i,p}$[1] represents how probable l_i is mapped to each phonetic unit given n_i and p. We apply a Dirichlet distribution prior parametrized by $\alpha_0\beta$ to $\pi_{l_i,n_i,p}$ as shown in Eq. 3. With this parameterization, the mean of $\pi_{l_i,n_i,p}$ is the global mixture weight β, and α_0 controls how similar $\pi_{l_i,n_i,p}$ is to the mean. More specifically, for large $\alpha_0 \gg K$, the Dirichlet distribution is highly peaked around the mean; on the contrary, for $\alpha_0 \ll K$, the mean lies in a valley. The parameters of a Dirichlet distribution can also be viewed as pseudo-counts for each category. Eq. 4 shows that the prior for $\pi_{\vec{l}_{i,\kappa},n_i,p}$ is seeded by pseudo-counts that are proportional to the mapping weights over the phonetic units of l_i in a shorter context. In other words, the mapping distribution of l_i in a shorter context can be thought of as a back-off distribution of l_i's mapping weights in a longer context.

Each component of the K-dimensional mixture model is linked to a 3-state Hidden Markov Model (HMM). These K HMMs are used to model the phonetic units in the language (Jelinek, 1976). The emission probability of each HMM state is modeled by a diagonal Gaussian Mixture Model (GMM). We use θ_c to represent the set of parameters that define the c^{th} HMM, which includes the state transition probability and the GMM parameters of each state emission distribution. The conjugate prior of θ_c is denoted as $H(\theta_0)$[2].

Finally, to finish the generative process, for each $c_{i,p}$ we use the corresponding HMM $\theta_{c_{i,p}}$ to generate the observed speech data x_t, and the generative process of the HMM determines the duration, $d_{i,p}$, of the speech segment. The complete generative model, with κ set to 2, is depicted in Fig. 1; M is the total number of transcribed utterances in the corpus, and L_m is the number of letters in utterance m. The shaded circles denote the observed data, and the squares denote the hyperparameters of the priors used in our model. Lastly, the unshaded circles denote the latent variables of our model, for which we derive inference algorithms in the next section.

[1] An abbreviation of $\pi_{\vec{l}_{i,0},n_i,p}$

[2] $H(\theta_0)$ includes a Dirichlet prior for the transition probability of each state, and a Dirichlet prior for each mixture weight of the three GMMs, and a normal-Gamma distribution for the mean and precision of each Gaussian mixture in the 3-state HMM.

4 Inference

We employ Gibbs sampling (Gelman et al., 2004) to approximate the posterior distribution of the latent variables in our model. In the following sections, we first present a message-passing algorithm for block-sampling n_i and $c_{i,p}$, and then describe how we leverage acoustic cues to accelerate the computation of the message-passing algorithm. Note that the block-sampling algorithm for n_i and $c_{i,p}$ can be parallelized across utterances. Finally, we briefly discuss the inference procedures for $\phi_{\vec{l}_\kappa}$, $\pi_{\vec{l}_\kappa,n,p}$, β, θ_c.

4.1 Block-sampling n_i and $c_{i,p}$

To understand the message-passing algorithm in this study, it is helpful to think of our model as a simplified Hidden Semi-Markov Model (HSMM), in which the letters represent the states and the speech features are the observations. However, unlike in a regular HSMM, where the state sequence is hidden, in our case, the state sequence is fixed to be the given letter sequence. With this point of view, we can modify the message-passing algorithms of Murphy (2002) and Johnson and Willsky (2013) to compute the posterior information required for block-sampling n_i and $c_{i,p}$.

Let $\mathbb{L}(x_t)$ be a function that returns the index of the letter from which x_t is generated; also, let $F_t = 1$ be a tag indicating that a new phone segment starts at $t+1$. Given the constraint that $0 \leq n_i \leq 2$, for $0 \leq i \leq L_m$ and $0 \leq t \leq T_m$, the backwards messages $B_t(i)$ and $B^*_t(i)$ for the m^{th} training sample can be defined and computed as in Eq. 5 and Eq. 7. Note that for clarity we discard the index variable m in the derivation of the algorithm.

$$
\begin{aligned}
B_t(i) &\triangleq p(x_{t+1:T}|\mathbb{L}(x_t) = i, F_t = 1) \\
&= \sum_{j=i+1}^{\min\{L,i+1+U\}} B_t^*(j) \prod_{k=i+1}^{j-1} p(n_k = 0|\vec{l}_{i,\kappa}) \\
&= \sum_{j=i+1}^{\min\{L,i+1+U\}} B_t^*(j) \prod_{k=i+1}^{j-1} \phi_{\vec{l}_{i,\kappa}}(0) \qquad (5)
\end{aligned}
$$

$$
\begin{aligned}
&B_t^*(i) \triangleq p(x_{t+1:T}|\mathbb{L}(x_{t+1}) = i, F_t = 1) \\
&= \sum_{d=1}^{T-t} p(x_{t+1:t+d}|\vec{l}_{i,\kappa}) B_{t+d}(i) \qquad (6) \\
&= \sum_{d=1}^{T-t} \{ \sum_{c_{i,1}=1}^{K} \phi_{\vec{l}_{i,\kappa}}(1) \pi_{\vec{l}_{i,\kappa},1,1}(c_{i,1}) p(x_{t+1:t+d}|\theta_{c_{i,1}}) \\
&+ \sum_{v=1}^{d-1} \sum_{c_{i,1}}^{K} \sum_{c_{i,2}}^{K} \phi_{\vec{l}_{i,\kappa}}(2) \pi_{\vec{l}_{i,\kappa},2,1}(c_{i,1}) \pi_{\vec{l}_{i,\kappa},2,2}(c_{i,2}) \\
&\times p(x_{t+1:t+v}|\theta_{c_{i,1}}) p(x_{t+v+1:t+d}|\theta_{c_{i,2}}) \} B_{t+d}(i) \qquad (7)
\end{aligned}
$$

We use $x_{t_1:t_2}$ to denote the segment consisting of $x_{t_1}, \cdots, x_{t_2}$. Our inference algorithm only allows up to U letters to emit 0 acoustic units in a row. The value of U is set to 2 for our experiments. $B_t(i)$ represents the total probability of all possible alignments between $x_{t+1:T}$ and $l_{i+1:L}$. $B_t^*(i)$ contains the probability of all the alignments between $x_{t+1:T}$ and $l_{i+1:L}$ that map x_{t+1} to l_i particularly. This alignment constraint between x_{t+1} and l_i is explicitly shown in the first term of Eq. 6, which represents how likely the speech segment $x_{t+1:t+d}$ is generated by l_i given l_i's context. This likelihood is simply the marginal probability of $p(x_{t+1:t+d}, n_i, c_{i,p}|\vec{l}_{i,\kappa})$ with n_i and $c_{i,p}$ integrated out, which can be expanded and computed as shown in the last three rows of Eq. 7. The index v specifies where the phone boundary is between the two acoustic units that l_i is aligned with when $n_i = 2$. Eq. 8 to Eq. 10 are the boundary conditions of the message passing algorithm. $B_0(0)$ carries the total probably of all possible alignments between $l_{1:L}$ and $x_{1:T}$. Eq. 9 specifies that at most U letters at the end of an sentence can be left unaligned with any speech features, while Eq. 10 indicates that all of the speech features in an utterance must be assigned to a letter.

Algorithm 1 Block-sample n_i and $c_{i,p}$ from $B_t(i)$ and $B_t^*(i)$

```
1:  i ← 0
2:  t ← 0
3:  while i < L ∧ t < T do
4:      next_i ← SampleFromB_t(i)
5:      if next_i > i + 1 then
6:          for k = i + 1 to k = next_i − 1 do
7:              n_k ← 0
8:          end for
9:      end if
10:     d, n_i, ⟨c_{i,p}⟩, v ← SampleFromB*_t(next_i)
11:     t ← t + d
12:     i ← next_i
13: end while
```

$$
B_0(0) = \sum_{j=1}^{\min\{L,U+1\}} B_0^*(j) \prod_{k=1}^{j-1} \phi_{\vec{l}_{i,\kappa}}(0) \qquad (8)
$$

$$
B_T(i) \triangleq \begin{cases} 1 & \text{if } i = L \\ \prod_{j=i+1}^{L} \phi_{\vec{l}_{i,\kappa}}(0) & \text{if } L - U \leq i < L \\ 0 & \text{if } i < L - U \end{cases} \qquad (9)
$$

$$
B_t(L) \triangleq \begin{cases} 1 & \text{if } t = T \\ 0 & \text{otherwise} \end{cases} \qquad (10)
$$

Given $B_t(i)$ and $B_t^*(i)$, n_i and $c_{i,p}$ for each letter in the utterance can be sampled using Alg. 1. The $SampleFromB_t(i)$ function in line 4 returns a random sample from the relative probability distribution composed by entries of the summation in Eq. 5. Line 5 to line 9 check whether l_i (and maybe l_{i+1}) is mapped to zero phonetic units. $next_i$ points to the letter that needs to be aligned with 1 or 2 phone segments starting from x_t. The number of phonetic units that l_{next_i} maps to and the identities of the units are sampled in $SampleFromB_t^*(i)$. This subroutine generates a tuple of d, n_i, $\langle c_{i,p} \rangle$ as well as v (if $n_i = 2$) from all the entries of the summation shown in Eq. 7[3].

[3]We use $\langle c_{i,p} \rangle$ to denote that $\langle c_{i,p} \rangle$ may consist of two numbers, $c_{i,1}$ and $c_{i,2}$, when $n_i = 2$.

4.2 Heuristic Phone Boundary Elimination

The variables d and v in Eq. 7 enumerate through every frame index in a sentence, treating each feature frame as a potential boundary between acoustic units. However, it is possible to exploit acoustic cues to avoid checking feature frames that are unlikely to be phonetic boundaries. We follow the presegmentation method described in Glass (2003) to skip roughly 80% of the feature frames and greatly speed up the computation of $B_t^*(i)$.

Another heuristic applied to our algorithm to reduce the search space for d and v is based on the observation that the average duration of phonetic units is usually no longer than 300 ms. Therefore, when computing $B_t^*(i)$, we only consider speech segments that are shorter than 300 ms to avoid aligning letters to speech segments that are too long to be phonetic units.

4.3 Sampling $\phi_{\vec{l}_\kappa}$, $\pi_{\vec{l}_\kappa,n_i,p}$, β and θ_c

Sampling $\phi_{\vec{l}_\kappa}$ To compute the posterior distribution of $\phi_{\vec{l}_\kappa}$, we count how many times $\vec{l}_\kappa$ is mapped to 0, 1 and 2 phonetic units from n_i^m. More specifically, we define $\mathcal{N}_{\vec{l}_\kappa}(j)$ for $0 \leq j \leq 2$ as follows:

$$\mathcal{N}_{\vec{l}_\kappa}(j) = \sum_{m=1}^{M}\sum_{i=1}^{L_m} \delta(n_i^m, j)\delta(\vec{l}_{i,\kappa}^m, \vec{l}_\kappa)$$

where we use $\delta(\cdot)$ to denote the discrete Kronecker delta. With $\mathcal{N}_{\vec{l}_\kappa}$, we can simply sample a new value for $\phi_{\vec{l}_\kappa}$ from the following distribution:

$$\phi_{\vec{l}_\kappa} \sim Dir(\eta + \mathcal{N}_{\vec{l}_\kappa})$$

Sampling $\pi_{\vec{l}_\kappa,n,p}$ and β The posterior distributions of $\pi_{\vec{l}_\kappa,n,p}$ and β are constructed recursively due to the hierarchical structure imposed on $\pi_{\vec{l}_\kappa,n,p}$ and β. We start with gathering counts for updating the π variables at the lowest level, i.e., $\pi_{\vec{l}_2,n,p}$ given that κ is set to 2 in our model implementation, and then sample pseudo-counts for the π variables at higher hierarchies as well as β. With the pseudo-counts, a new β can be generated, which allows $\pi_{\vec{l}_\kappa,n,p}$ to be re-sampled sequentially.

More specifically, we define $\mathcal{C}_{\vec{l}_2,n,p}(k)$ to be the number of times that $\vec{l}_2$ is mapped to n units and the unit in position p is the k^{th} phonetic unit. This value can be counted from the current values of $c_{i,p}^m$ as follows.

$$\mathcal{C}_{\vec{l}_2,n,p}(k) = \sum_{m=1}^{M}\sum_{i=1}^{L_m} \delta(\vec{l}_{i,2}, \vec{l}_2)\delta(n_i^m, n)\delta(c_{i,p}^m, k)$$

To derive the posterior distribution of $\pi_{\vec{l}_1,n,p}$ analytically, we need to sample pseudo-counts $\mathcal{C}_{\vec{l}_1,n,p}$, which is defined as follows.

$$\mathcal{C}_{\vec{l}_1,n,p}(k) = \sum_{\vec{l}_2 \in \mathcal{U}_{\vec{l}_1}} \sum_{i=1}^{\mathcal{C}_{\vec{l}_2,n,p}(k)} \mathbb{I}[\nu_i < \frac{\alpha_2 \pi_{\vec{l}_1,n,p}(k)}{i + \alpha_2 \pi_{\vec{l}_1,n,p}(k)}] \tag{11}$$

We use $\mathcal{U}_{\vec{l}_1} = \{\vec{l}_2 | \mathbb{P}(\vec{l}_2) = \vec{l}_1\}$ to denote the set of $\vec{l}_2$ whose parent is $\vec{l}_1$ and ν_i to represent random variables sampled from a uniform distribution between 0 and 1. Eq. 11 can be applied recursively to compute $\mathcal{C}_{\vec{l}_0,n,p}(k)$ and $\mathcal{C}_{\_,n,p}(k)$, the pseudo-counts that are applied to the conjugate priors of $\pi_{\vec{l}_0,n,p}$ and β. With the pseudo-count variables computed, new values for β and $\pi_{\vec{l}_\kappa,n,p}$ can be sampled sequentially as shown in Eq. 12 to Eq. 14.

$$\beta \sim Dir(\gamma + \mathcal{C}_{\_,n,p}) \tag{12}$$

$$\pi_{\vec{l}_\kappa,n,p} \sim Dir(\alpha_\kappa \beta + \mathcal{C}_{\vec{l}_\kappa,n,p}) \text{ for } \kappa = 0 \tag{13}$$

$$\pi_{\vec{l}_\kappa,n,p} \sim Dir(\alpha_\kappa \pi_{\vec{l}_{\kappa-1},n,p} + \mathcal{C}_{\vec{l}_\kappa,n,p}) \text{ for } \kappa \geq 1 \tag{14}$$

5 Experimental Setup

To test the effectiveness of our model for joint learning phonetic units and word pronunciations from an annotated speech corpus, we construct speech recognizers out of the training results of our model. The performance of the recognizers is evaluated and compared against three baselines: first, a grapheme-based speech recognizer; second, a recognizer built by using an expert-crafted lexicon, which is referred to as an expert lexicon in the rest of the paper for simplicity; and third, a recognizer built by discovering the phonetic units and L2S pronunciation rules *sequentially* without using a lexicon. In this section, we provide a detailed description of the experimental setup.

η	γ	α_0	α_1	α_2	θ_0	κ	K
$\langle 0.1 \rangle_3$	$\langle 10 \rangle_{100}$	1	0.1	0.2	*	2	100

Table 1: The values of the hyperparameters of our model. We use $\langle a \rangle_D$ to denote a D-dimensional vector with all entries being a. *We follow the procedure reported in (Lee and Glass, 2012) to set up the HMM prior θ_0.

5.1 Dataset

All the speech recognition experiments reported in this paper are performed on a weather query dataset, which consists of narrow-band, conversational telephone speech (Zue et al., 2000). We follow the experimental setup of McGraw et al. (2013) and split the corpus into a training set of 87,351 utterances, a dev set of 1,179 utterances and a test set of 3,497 utterances. A subset of 10,000 utterances is randomly selected from the training set. We use this subset of data for training our model to demonstrate that our model is able to discover the phonetic composition and the pronunciation rules of a language even from just a few hours of data.

5.2 Building a Recognizer from Our Model

The values of the hyperparameters of our model are listed in Table 1. We run the inference procedure described in Sec. 4 for 10,000 times on the randomly selected 10,000 utterances. The samples of $\phi_{\vec{l}_\kappa}$ and $\pi_{\vec{l}_\kappa n,p}$ from the last iteration are used to decode n_i^m and $c_{i,p}^m$ for each sentence in the entire training set by following the block-sampling algorithm described in Sec. 4.1. Since $c_{i,p}^m$ is the phonetic mapping of l_i^m, by concatenating the phonetic mapping of every letter in a word, we can obtain a pronunciation of the word represented in the labels of discovered phonetic units. For example, assume that word w appears in sentence m and consists of $l_3 l_4 l_5$ (the sentence index m is ignored for simplicity). Also, assume that after decoding, $n_3 = 1$, $n_4 = 2$ and $n_5 = 1$. A pronunciation of w is then encoded by the sequence of phonetic labels $c_{3,1} c_{4,1} c_{4,2} c_{5,1}$. By repeating this process for each word in every sentence for the training set, a list of word pronunciations can be compiled and used as a stochastic lexicon to build a speech recognizer.

In theory, the HMMs inferred by our model can be directly used as the acoustic model of a monophone speech recognizer. However, if we regard the $c_{i,p}$ labels of each utterance as the phone transcription of the sentence, then a new acoustic model can be easily re-trained on the entire data set. More conveniently, the phone boundaries corresponding to the $c_{i,p}$ labels are the by-products of the block-sampling algorithm, which are indicated by the values of d and v in line 10 of Alg. 1 and can be easily saved during the sampling procedure. Since these data are readily available, we re-build a context-independent model on the entire data set. In this new acoustic model, a 3-state HMM is used to model each phonetic unit, and the emission probability of each state is modeled by a 32-mixture GMM.

Finally, a trigram language model is built by using the word transcriptions in the full training set. This language model is utilized in all speech recognition experiments reported in this paper. Finite State Transducers (FSTs) are used to build all the recognizers used in this study. With the language model, the lexicon and the context-independent acoustic model constructed by the methods described in this section, we can build a speech recognizer from the learning output of the proposed model without the need of a pre-defined phone inventory and any expert-crafted lexicons.

5.2.1 Pronunciation Mixture Model Retraining

McGraw et al. (2013) presented the Pronunciation Mixture Model (PMM) for composing stochastic lexicons that outperform pronunciation dictionaries created by experts. Although the PMM framework was designed to incorporate and augment expert lexicons, we found that it can be adapted to polish the pronunciation list generated by our model.

In particular, the training procedure for PMMs includes three steps. First, train a L2S model from a manually specified expert-pronunciation lexicon; second, generate a list of pronunciations for each word in the dataset using the L2S model; and finally, use an acoustic model to re-weight the pronunciations based on the acoustic scores of the spoken examples of each word.

To adapt this procedure for our purposes, we simply plug in the word pronunciations and the acoustic model generated by our model. Once we obtain the re-weighted lexicon, we re-generate forced

phone alignments and retrain the acoustic model, which can be utilized to repeat the PMM lexicon reweighting procedure. For our experiments, we iterate through this model refining process until the recognition performance converges.

5.2.2 Triphone Model

Conventionally, to train a context-dependent acoustic model, a list of questions based on the linguistic properties of phonetic units is required for growing decision tree classifiers (Young et al., 1994). However, such language-specific knowledge is not available for our training framework; therefore, our strategy is to compile a question list that treats each phonetic unit as a unique linguistic class. In other words, our approach to training a context-dependent acoustic model for the automatically discovered units is to let the decision trees grow fully based on acoustic evidence.

5.3 Baselines

We compare the recognizers trained by following the procedures described in Sec. 5.2 against three baselines. The first baseline is a grapheme-based speech recognizer. We follow the procedure described in Killer et al. (2003) and train a 3-state HMM for each grapheme, which we refer to as the *monophone grapheme* model. Furthermore, we create a *singleton question set* (Killer et al., 2003), in which each grapheme is listed as a question, to train a *triphone grapheme* model. Note that to enforce better initial alignments between the graphemes and the speech data, we use a pre-trained acoustic model to identify the non-speech segments at the beginning and the end of each utterance before starting training the monophone grapheme model.

Our model jointly discovers the phonetic inventory and the L2S mapping rules from a set of transcribed data. An alternative of our approach is to learn the two latent structures sequentially. We follow the training procedure of Lee and Glass (2012) to learn a set of acoustic models from the speech data and use these acoustic models to generate a phone transcription for each utterance. The phone transcriptions along with the corresponding word transcriptions are fed as inputs to the L2S model proposed in Bisani and Ney (2008). A stochastic lexicon can be learned by applying the L2S model and the discovered acoustic models to PMM. This two-stage approach for training a speech recognizer without an expert lexicon is referred to as the *sequential model* in this paper.

unit(%)	Monophone
Our model	17.0
Oracle	13.8
Grapheme	32.7
Sequential model	31.4

Table 2: Word error rates generated by the four monophone recognizers described in Sec. 5.2 and Sec. 5.3 on the weather query corpus.

Finally, we compare our system against a recognizer trained from an *oracle* recognition system. We build the oracle recognizer on the same weather query corpus by following the procedure presented in McGraw et al. (2013). This oracle recognizer is then applied to generate forced-aligned phone transcriptions for the training utterances, from which we can build both monophone and triphone acoustic models. The expert-crafted lexicon used in the oracle recognizer is also used in this baseline. Note that for training the triphone model, we compose a singleton question list (Killer et al., 2003) that has every expert-defined phonetic unit as a question. We use this singleton question list instead of a more sophisticated one to ensure that this baseline and our system differ only in the acoustic model and the lexicon used to generate the initial phone transcriptions. We call this baseline the *oracle* baseline.

6 Results and Analysis

6.1 Monophone Systems

Table 2 shows the WERs produced by the four monophone recognizers described in Sec. 5.2 and Sec. 5.3. It can be seen that our model outperforms the grapheme and the sequential model baselines significantly while approaching the performance of the supervised oracle baseline. The improvement over the sequential baseline demonstrates the strength of the proposed joint learning framework. More specifically, unlike the sequential baseline, in which the acoustic units are discovered independently from the text data, our model is able to exploit the L2S mapping constraints provided by the word transcriptions to cluster speech segments.

By comparing our model to the grapheme baseline, we can see the advantage of modeling the pronunciations of a letter using a mixture model, especially for a language like English which has many pronunciation irregularities. However, even for languages with straightforward pronunciation rules, the concept of modeling letter pronunciations using mixture models still applies. The main difference is that the mixture weights for letters of languages with simple pronunciation rules will be sparser and spikier. In other words, in theory, our model should always perform comparable to, if not better than, grapheme recognizers.

Last but not least, the recognizer trained with the automatically induced lexicon performs similarly to the recognizer initialized by an oracle recognition system, which demonstrates the effectiveness of the proposed model for discovering the phonetic inventory and a pronunciation lexicon from an annotated corpus. In the next section, we provide some insights into the quality of the learned lexicon and into what could have caused the performance gap between our model and the conventionally trained recognizer.

6.2 Pronunciation Entropy

The major difference between the recognizer that is trained by using our model and the recognizer that is seeded by an oracle recognition system is that the former uses an automatically discovered lexicon, while the latter exploits an expert-defined pronunciation dictionary. In order to quantify, as well as to gain insights into, the difference between these two lexicons, we define the average pronunciation entropy, $\hat{H}$, of a lexicon as follows.

$$\hat{H} \equiv \frac{-1}{|V|} \sum_{w \in V} \sum_{b \in \mathcal{B}(w)} p(b) \log p(b) \qquad (15)$$

where V denotes the vocabulary of a lexicon, $\mathcal{B}(w)$ represents the set of pronunciations of a word w and $p(b)$ stands for the weight of a certain pronunciation b. Intuitively, we can regard $\hat{H}$ as an indicator of how much pronunciation variation that each word in a lexicon has on average. Table 3 shows that the $\hat{H}$ values of the lexicon induced by our model and the expert-defined lexicon as well as their respective PMM-refined versions[4]. In Table 3, we can see that the automatically-discovered lexicon and its PMM-reweighted versions have much higher $\hat{H}$ values than their expert-defined counterparts. These higher $\hat{H}$ values imply that the lexicon induced by our model contains more pronunciation variation than the expert-defined lexicon. Therefore, the lattices constructed during the decoding process for our recognizer tend to be larger than those constructed for the oracle baseline, which explains the performance gap between the two systems in Table 2 and Table 3.

Our model (Discovered lexicon)	*PMM iterations*		
	0	1	2
$\hat{H}$ (bit)	4.58	3.47	3.03
WER (%)	17.0	16.6	15.9
Oracle (Expert lexicon)	*PMM iterations*		
	0	1	2
$\hat{H}$ (bit)	0.69	0.90	0.92
WER (%)	13.8	12.8	12.4

Table 3: The upper-half of the table shows the average pronunciation entropies, $\hat{H}$, of the lexicons induced by our model and refined by PMM as well as the WERs of the monophone recognizers built with the corresponding lexicons for the weather query corpus. The definition of $\hat{H}$ can be found in Sec. 6.2. The first row of the lower-half of the table lists the average pronunciation entropies, $\hat{H}$, of the expert-defined lexicon and the lexicons generated and weighted by the L2P-PMM framework described in McGraw et al. (2013). The second row of the lower-half of the table shows the WERs of the recognizers that are trained with the expert-lexicon and its PMM-refined versions.

As shown in Table 3, even though the lexicon induced by our model is noisier than the expert-defined dictionary, the PMM retraining framework consistently refines the induced lexicon and improves the performance of the recognizers[5]. To the best of our knowledge, we are the first to apply PMM to lexicons that are created by a fully unsu-

[4]We build the PMM-refined version of the expert-defined lexicon by following the L2P-PMM framework described in McGraw et al. (2013).

[5]The recognition results all converge in $2 \sim 3$ PMM retraining iterations.

pronunciations	*pronunciation probabilities*		
	Our model	1 PMM	2 PMM
93 56 87 39 19	0.125	-	-
93 56 61 87 73 99	0.125	-	-
11 56 61 87 73 99	0.125	0.400	0.419
93 20 75 87 17 27 52	0.125	0.125	0.124
55 93 56 61 87 73 84 19	0.125	0.220	0.210
93 26 61 87 49	0.125	0.128	0.140
63 83 86 87 73 53 19	0.125	-	-
93 26 61 87 61	0.125	0.127	0.107

Table 4: Pronunciation lists of the word *Burma* produced by our model and refined by PMM after 1 and 2 iterations.

pervised method. Therefore, in this paper, we provide further analysis on how PMM helps enhance the performance of our model.

We compare the pronunciation lists for the word *Burma* generated by our model and refined iteratively by PMM in Table 4. The first column of Table 4 shows all the pronunciations of *Burma* discovered by our model, to which our model assigns equal probabilities to create a stochastic list[6]. As demonstrated in the third and the fourth columns of Table 4, the PMM framework is able to iteratively re-distribute the pronunciation weights and filter out less-likely pronunciations, which effectively reduces both the size and the entropy of the stochastic lexicon generated by our model. The benefits of using the PMM to refine the induced lexicon are twofold. First, the search space constructed during the recognition decoding process with the refined lexicon is more constrained, which is the main reason why the PMM is capable of improving the performance of the monophone recognizer that is trained with the output of our model. Secondly, and more importantly, the refined lexicon can greatly reduce the size of the FST built for the triphone recognizer of our model. These two observations illustrate why the PMM framework can be an useful tool for enhancing the lexicon discovered automatically by our model.

6.3 Triphone Systems

The best monophone systems of the grapheme baseline, the oracle baseline and our model are used to generate forced-aligned phone transcriptions, which are used to train the triphone models described in Sec. 5.2.2 and Sec. 5.3. Table 5 shows the WERs of the triphone recognition systems. Note that if a more conventional question list, for example, a list that contains rules to classify phones into different broad classes, is used to build the oracle triphone system, the WER can be reduced to 6.5%. However, as mentioned earlier, in order to gain insights into the quality of the induced lexicon and the discovered phonetic set, we compare our model against an oracle triphone system that is built by using a singleton question set.

Unit(%)	Triphone
Our model	13.4
Oracle	10.0
Grapheme	15.7

Table 5: Word error rates of the triphone recognizers. The triphone recognizers are all built by using the phone transcriptions generated by their best monohpone system. For the oracle initialized baseline and for our model, the PMM-refined lexicons are used to build the triphone recognizers.

By comparing Table 2 and Table 5, we can see that the grapheme triphone improves by a large margin compared to its monophone counterpart, which is consistent with the results reported in (Killer et al., 2003). However, even though the grapheme baseline achieves a great performance gain with context-dependent acoustic models, the recognizer trained using the lexicon learned by our model and subsequently refined by PMM still outperforms the grapheme baseline. The consistently better performance our model achieves over the grapheme baseline demonstrates the strength of modeling the pronunciation of each letter with a mixture model that is presented in this paper.

Last but not least, by comparing Table 2 and Table 5, it can be seen that the relative performance gain achieved by our model is similar to that obtained by the oracle baseline. Both Table 2 and Table 5 show that even without exploiting any language-specific knowledge during training, our recognizer is able to perform comparably with the recognizer trained using an expert lexicon. The ability of our model to obtain such similar performance

[6]It is also possible to assign probabilities proportional to the decoding scores of the word tokens.

further supports the effectiveness of the joint learning framework proposed in this paper for discovering the phonetic inventory and the word pronunciations from simply an annotated speech corpus.

7 Conclusion

We present a hierarchical Bayesian model for simultaneously discovering acoustic units and learning word pronunciations from transcribed spoken utterances. Both monophone and triphone recognizers can be built on the discovered acoustic units and the inferred lexicon. The recognizers trained with the proposed unsupervised method consistently outperforms grapheme-based recognizers and approach the performance of recognizers trained with expert-defined lexicons. In the future, we plan to apply this technology to develop ASRs for more languages.

Acknowledgements

The authors would like to thank Ian McGraw and Ekapol Chuangsuwanich for their advice on the PMM and recognition experiments presented in this paper. Thanks to the anonymous reviewers for helpful comments. Finally, the authors would like to thank Stephen Shum for proofreading and editing the early drafts of this paper.

Abstract

We present MCTest, a freely available set of stories and associated questions intended for research on the machine comprehension of text. Previous work on machine comprehension (e.g., semantic modeling) has made great strides, but primarily focuses either on limited-domain datasets, or on solving a more restricted goal (e.g., open-domain relation extraction). In contrast, MCTest requires machines to answer multiple-choice reading comprehension questions about fictional stories, directly tackling the high-level goal of open-domain machine comprehension. Reading comprehension can test advanced abilities such as causal reasoning and understanding the world, yet, by being multiple-choice, still provide a clear metric. By being fictional, the answer typically can be found only in the story itself. The stories and questions are also carefully limited to those a young child would understand, reducing the world knowledge that is required for the task. We present the scalable crowd-sourcing methods that allow us to cheaply construct a dataset of 500 stories and 2000 questions. By screening workers (with grammar tests) and stories (with grading), we have ensured that the data is the same quality as another set that we manually edited, but at one tenth the editing cost. By being open-domain, yet carefully restricted, we hope MCTest will serve to encourage research and provide a clear metric for advancement on the machine comprehension of text.

1 Reading Comprehension

A major goal for NLP is for machines to be able to understand text as well as people. Several research disciplines are focused on this problem: for example, information extraction, relation extraction, semantic role labeling, and recognizing textual entailment. Yet these techniques are necessarily evaluated individually, rather than by how much they advance us towards the end goal. On the other hand, the goal of semantic parsing is the machine comprehension of text (MCT), yet its evaluation requires adherence to a specific knowledge representation, and it is currently unclear what the best representation is, for open-domain text.

We believe that it is useful to directly tackle the top-level task of MCT. For this, we need a way to measure progress. One common method for evaluating someone's understanding of text is by giving them a multiple-choice reading comprehension test. This has the advantage that it is objectively gradable (vs. essays) yet may test a range of abilities such as causal or counterfactual reasoning, inference among relations, or just basic understanding of the world in which the passage is set.

Therefore, we propose a multiple-choice reading comprehension task as a way to evaluate progress on MCT. We have built a reading comprehension dataset containing 500 fictional stories, with 4 multiple choice questions per story. It was built using methods which can easily scale to at least 5000 stories, since the stories were created, and the curation was done, using crowd sourcing almost entirely, at a total of $4.00 per story. We plan to periodically update the dataset to ensure that methods are not overfitting to the existing data. The dataset is open-domain, yet restricted to concepts and words that a 7 year old is expected to understand. This task is still beyond the capability of today's computers and algorithms.

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 193–203,
Seattle, Washington, USA, 18-21 October 2013.

By restricting the concept space, we gain the difficulty of being an open-domain problem, without the full complexity of the real world (for example, there will be no need for the machine to understand politics, technology, or to have any domain specific expertise). The multiple choice task avoids ambiguities (such as when the task is to find a sentence that best matches a question, as in some early reading comprehension tasks: see Section 2), and also avoids the need for additional grading, such as is needed in some TREC tasks. The stories were chosen to be fictional to focus work on finding the answer in the story itself, rather than in knowledge repositories such as Wikipedia; the goal is to build technology that actually understands stories and paragraphs on a deep level (as opposed to using information retrieval methods and the redundancy of the web to find the answers).

We chose to use crowd sourcing, as opposed to, for example, contracting teachers or paying for existing standardized tests, for three reasons, namely: (1) scalability, both for the sizes of datasets we can provide, and also for the ease of regularly refreshing the data; (2) for the variety in story-telling that having many different authors brings; and (3) for the free availability that can only result from providing non-copyrighted data. The content is freely available at http://research.microsoft.com/mct, and we plan to use that site to track published results and provide other resources, such as labels of various kinds.

2 Previous Work

The research goal of mapping text to meaning representations in order to solve particular tasks has a long history. DARPA introduced the Airline Travel Information System (ATIS) in the early 90's: there the task was to slot-fill flight-related information by modeling the intent of spoken language (see Tur et al., 2010, for a review). This data continues to be a used in the semantic modeling community (see, for example, Zettlemoyer and Collins, 2009). The Geoquery database contains 880 geographical facts about the US and has played a similar role for written (as opposed to spoken) natural language queries against a database (Zelle and Mooney, 1996) and it also continues to spur research (see for example Goldwasser et al., 2011), as does the similar Jobs database, which provides mappings of 640 sentences to a listing of jobs (Tang and Mooney, 2001). More recently, Zweig and Burges (2012) provided a set of 1040 sentences that comprise an SAT-style multiple choice sentence completion task.

The idea of using story-based reading comprehension questions to evaluate methods for machine reading itself goes back over a decade, when Hirschmann et al. (1999) showed that a bag of words approach, together with some heuristic linguistic modeling, could achieve 40% accuracy for the task of picking the sentence that best matches the query for "who / what / when / where / why" questions, on a small reading comprehension dataset from Remedia. This dataset spurred several research efforts, for example using reinforcement learning (Grois and Wilkins, 2005), named entity resolution (Harabagiu et al., 2003) and mapping questions and answers to logical form (Wellner et al., 2006). Work on story understanding itself goes back much further, to 1972, when Charniak proposed using a background model to answer questions about children's stories. Similarly, the TREC (and TAC) Question Answering tracks (e.g., Voorhees and Tice, 1999) aim to evaluate systems on their ability to answer factual questions such as "Where is the Taj Mahal". The QA4MRE task also aims to evaluate machine reading systems through question answering (e.g., Clark et al., 2012). Earlier work has also aimed at controlling the scope by limiting the text to children's stories: Breck et al. (2001) collected 75 stories from the Canadian Broadcasting Corporation's web site for children, and generated 650 questions for them manually, where each question was answered by a sentence in the text. Leidner et al. (2003) both enriched the CBC4kids data by adding several layers of annotation (such as semantic and POS tags), and measured QA performance as a function of question difficulty. For a further compendium of resources related to the story comprehension task, see Mueller (2010).

The task proposed here differs from the above work in several ways. Most importantly, the data collection is scalable: if the dataset proves sufficiently useful to others, it would be straightforward to gather an order of magnitude more. Even the dataset size presented here is an order of magnitude larger than the Remedia or the CBC4kids data and many times larger than QA4MRE. Second, the multiple choice task presents less ambiguity (and is consequently easier to collect data for) than the

James the Turtle was always getting in trouble. Sometimes he'd reach into the freezer and empty out all the food. Other times he'd sled on the deck and get a splinter. His aunt Jane tried as hard as she could to keep him out of trouble, but he was sneaky and got into lots of trouble behind her back.
One day, James thought he would go into town and see what kind of trouble he could get into. He went to the grocery store and pulled all the pudding off the shelves and ate two jars. Then he walked to the fast food restaurant and ordered 15 bags of fries. He didn't pay, and instead headed home.
His aunt was waiting for him in his room. She told James that she loved him, but he would have to start acting like a well-behaved turtle.
After about a month, and after getting into lots of trouble, James finally made up his mind to be a better turtle.

1) What is the name of the trouble making turtle?
A) Fries
B) Pudding
C) James
D) Jane

2) What did James pull off of the shelves in the grocery store?
A) pudding
B) fries
C) food
D) splinters

3) Where did James go after he went to the grocery store?
A) his deck
B) his freezer
C) a fast food restaurant
D) his room

4) What did James do after he ordered the fries?
A) went to the grocery store
B) went home without paying
C) ate them
D) made up his mind to be a better turtle

Figure 1. Sample Story and Questions (chosen randomly from MC500 train set).

task of finding the most appropriate sentence, and may be automatically evaluated. Further, our stories are fictional, which means that the information to answer the question is contained only in the story itself (as opposed to being able to directly leverage knowledge repositories such as Wikipedia). This design was chosen to focus the task on the machine understanding of short passages, rather than the ability to match against an existing knowledge base. In addition, while in the CBC4kids data each answer was a sentence from the story, here we required that approximately half of the questions require at least two sentences from the text to answer; being able to control complexity in this way is a further benefit of using multiple choice answers. Finally, as explained in Section 1, the use of free-form input makes the problem open domain (as opposed to the ATIS, Geoquery and Jobs data), leading to the hope that solutions to the task presented here will be easier to apply to novel, unrelated tasks.

3 Generating the Stories and Questions

Our aim was to generate a corpus of fictional story sets[1] that could be scaled with as little expert input as possible. Thus, we designed the process to be gated by cost, and keeping the costs low was a high priority. Crowd-sourcing seemed particularly appropriate, given the nature of the task, so we opted to use Amazon Mechanical Turk[2] (AMT). With over 500,000 workers[3], it provides the work force required to both achieve scalability and, equally importantly, to provide diversity in the stories and types of questions. We restricted our task to AMT workers (*workers*) residing in the United States. The average worker is 36 years old, more educated than the United States population in general (Paolacci et al., 2010), and the majority of workers are female.

3.1 The Story and Questions

Workers were instructed to write a short (150-300 words) fictional story, and to write as if for a child in grade school. The choice of 150-300 was made to keep the task an appropriate size for workers while still allowing for complex stories and questions. The workers were free to write about any topic they desired (as long as it was appropriate for a young child), and so there is a wide range, including vacations, animals, school, cars, eating, gardening, fairy tales, spaceships, and cowboys.

[1] We use the term "story set" to denote the fictional story together with its multiple choice questions, hypothetical answers, and correct answer labels.

[2] http://www.mturk.com

[3] https://requester.mturk.com/tour

Workers were also asked to provide four reading comprehension questions pertaining to their story and, for each, four multiple-choice answers. Coming up with incorrect alternatives (*distractors*) is a difficult task (see, e.g., Agarwal, 2011) but workers were requested to provide "reasonable" incorrect answers that at least include words from the story so that their solution is not trivial. For example, for the question "*What is the name of the dog?*", if only one of the four answers occurs in the story, then that answer must be the correct one.

Finally, workers were asked to design their questions and answers such that at least two of the four questions required multiple sentences from the story to answer them. That is, for those questions it should not be possible to find the answer in any individual sentence. The motivation for this was to ensure that the task could not be fully solved using lexical techniques, such as word matching, alone. Whilst it is still possible that a sophisticated lexical analysis could completely solve the task, requiring that answers be constructed from at least two different sentences in the story makes this much less likely; our hope is that the solution will instead require some inference and some form of limited reasoning. This hope rests in part upon the observation that standardized reading comprehension tests, whose goal after all is to test comprehension, generally avoid questions that can be answered by reading a single sentence.

3.2 Automatic Validation

Besides verifying that the story and all of the questions and answers were provided, we performed the following automatic validation before allowing the worker to complete the task:

Limited vocabulary: The lowercase words in the story, questions, and answers were stemmed and checked against a vocabulary list of approximately 8000 words that a 7-year old is likely to know (Kuperman et al., 2012). Any words not on the list were highlighted in red as the worker typed, and the task could not be submitted unless all of the words satisfied this vocabulary criterion. To allow the use of arbitrary proper nouns, capitalized words were not checked against the vocabulary list.

Multiple-sentence questions: As described earlier, we required that at least two of the questions need multiple sentences to answer. Workers were simply asked to mark whether a question needs one or multiple sentences and we required that at least two are marked as *multiple*.

3.3 The Workers

Workers were required to reside in the United States and to have completed 100 HITs with an over 95% approval rate[4]. The median worker took 22 minutes to complete the task. We paid workers $2.50 per story set and allowed each to do a maximum of 8 tasks (5 in MC500). We did not experiment with paying less, but this rate amounts to $6.82/hour, which is approximately the rate paid by other writing tasks on AMT at the time, though is also significantly higher than the median wage of $1.38 found in 2010 (Horton and Chilton, 2010). Workers could optionally leave feedback on the task, which was overwhelmingly positive – the most frequent non-stopword in the comments was "*fun*" and the most frequent phrase was "*thank you*". The only negative comments (in <1% of submissions) were when the worker felt that a particular word should have been on the allowed vocabulary list. Given the positive feedback, it may be possible to pay less if we collect more data in the future. We did not enforce story length constraints, but some workers interpreted our suggestion that the story be 150-300 words as a hard constraint, and some asked to be able to write a longer story.

The MCTest corpus contains two sets of stories, named MC160 and MC500, and containing 160 and 500 stories respectively. MC160 was gathered first, then some improvements were made before gathering MC500. We give details on the differences between these two sets below.

3.4 MC160: Manually Curated for Quality

In addition to the details described above, MC160 workers were given a target elementary grade school level (1-4) and a sample story matching that grade level[5]. The intent was to produce a set of stories and questions that varied in difficulty so that research work can progress grade-by-grade if needed. However, we found little difference between grades in the corpus..

After gathering the stories, we manually curated the MC160 corpus by reading each story set and

[4] The latter two are the default AMT requirements.

[5] From http://www.englishforeveryone.org/.

1. We went to visit the Smith's at their house.
2. I altered their suits for them.
3. You're car is very old.
4. Jim likes to run, hike, and going kayaking.
5. He should of come to work on time.
6. I think its best to wash lots of apples.
7. Are people who write "ping" thinking of submarines?
8. Smoke filled the room, making it hard to breathe.
9. Alert yet aloof - that's you.
10. They wanted they're money back.
11. Hawks and eagles like to fly high in the sky.
12. Don't let her wear them down.
13. The cat particularly liked the greasy plate.
14. The company is less successful because we have less employees.
15. The hamster belongs to Sam and I.
16. No one landed on the air strip today.
17. He was very effected by her tears.
18. You are a tired piece of toast, metaphorically speaking.
19. Anne plays bass and sings.
20. Him and me met at the park.

Figure 2. Grammar test for qualifying workers.

correcting errors. The most common mistakes were grammatical, though occasionally questions and/or answers needed to be fixed. 66% of the stories have at least one correction. We provide both the curated and original corpuses in order to allow research on reading comprehension in the presence of grammar, spelling, and other mistakes.

3.5 MC500: Adding a Grammar Test

Though the construction of MC160 was successful, it requires a costly curation process which will not scale to larger data sets (although the curation was useful, both for improving the design of MC500, and for assessing the effectiveness of automated curation techniques). To more fully automate the process, we added two more stages: (1) A grammar test that automatically pre-screens workers for writing ability, and (2) a second Mechanical Turk task whereby new workers take the reading comprehension tests and rate their quality. We will discuss stage (2) in the next section.

The grammar test consisted of 20 sentences, half of which had one grammatical error (see Figure 2). The incorrect sentences were written using common errors such as *you're* vs. *your*, using *'s* to indicate plurality, incorrect use of tense, *it's* vs. *its*, *less* vs. *fewer*, *I* vs. *me*, etc. Workers were required to indicate for each sentence whether it was grammatically correct or not, and had to pass with at least 80% accuracy in order to qualify for the task. The 80% threshold was chosen to trade off worker quality with the rate at which the tasks would be completed; initial experiments using a threshold of 90% indicated that collecting 500 stories would take many weeks instead of days. Note that each worker is allowed to write at most 5 stores, so we required at least 100 workers to pass the qualification test.

	Quality (1-5)	About animals
No Grammar Test	3.2	73%
Grammar Test	**4.3**	**30%**

Table 1. Pre-screening workers using a grammar test improves both quality and diversity of stories. Both differences are significant using the two-tailed t-test ($p<0.05$ for quality and $p<0.01$ for animals).

To validate the use of the qualification test, we gathered 30 stories requiring the test (*qual*) and 30 stories without. We selected a random set of 20 stories (10 from each), hid their origin, and then graded the overall quality of the story and questions from 1-5, meaning *do not attempt to fix*, *bad but rescuable*, *has non-minor problems*, *has only minor problems*, and *has no problems*, respectively. Results are shown in Table 1. The difference is statistically significant ($p<0.05$, using the two-tailed t-test). The *qual* stories were also more diverse, with fewer of them about animals (the most common topic).

Additional Modifications: Based on our experience curating MC160, we also made the following modifications to the task. In order to eliminate trivially-answerable questions, we required that each answer be unique, and that either the correct answer did not appear in the story or, if it did appear, that at least two of the incorrect answers also appeared in the story. This is to prevent questions that are trivially answered by checking which answer appears in the story. The condition on whether the correct answer appears is to allow questions such as "*How many candies did Susan eat?*", where the total may never appear in the story, even though the information needed to derive it does. An answer is considered to appear in the story if at least half (rounded down) of its non-stopword

terms appear in the story (ignoring word endings). This check is done automatically and must be satisfied before the worker is able to complete the task. Workers could also bypass the check if they felt it was incorrect, by adding a special term to their answer.

We were also concerned that the sample story might bias the workers when writing the story set, particularly when designing questions that require multiple sentences to answer. So, we removed the sample story and grade level from the task.

Finally, in order to encourage more diversity of stories, we added *creativity terms*, a set of 15 nouns chosen at random from the allowed vocabulary set. Workers were asked to "*please consider*" using one or more of the terms in their story, but use of the words was strictly optional. On average, workers used 3.9 of the creativity terms in their stories.

4 Rating the Stories and Questions

In this section we discuss the crowd-sourced rating of story sets. We wished to ensure story set quality despite the fact that MC500 was only minimally manually curated (see below). Pre-qualifying workers with a grammar test was one step of this process. The second step was to have additional workers on Mechanical Turk both evaluate each story and take its corresponding test. Each story was evaluated in this way by 10 workers, each of whom provided scores for each of age-appropriateness (*yes/maybe/no*), grammaticality (*few/some/many* errors), and story clarity (*excellent/reasonable/poor*). When answering the four reading comprehension questions, workers could also mark a question as "unclear". Each story set was rated by 10 workers who were each paid $0.15 per set.

Since we know the purportedly correct answer, we can estimate worker quality by measuring what fraction of questions that worker got right. Workers with less than 80% accuracy (ignoring those questions marked as unclear) were removed from the set. This constituted just 4.1% of the raters and 4.2% of the judgments (see Figure 3). Only one rater appeared to be an intentional spammer, answering 1056 questions with only 29% accuracy. The others primarily judged only one story. Only one worker fell between, answering 336 questions with just 75% accuracy.

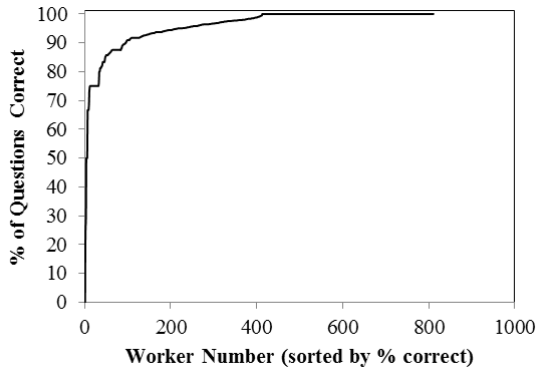

Figure 3. Just 4.1% of raters had an accuracy below 80% (constituting 4.2% of the judgments).

For the remaining workers (those who achieved at least 80% accuracy), we measured median story appropriateness, grammar, and clarity. For each category, stories for which less than half of the ratings were the best possible (e.g., *excellent* story clarity) were inspected and optionally removed from the data set. This required inspecting 40 (<10%) of the stories, only 2 of which were deemed poor enough to be removed (both of which had over half of the ratings all the way at the bottom end of the scale, indicating we could potentially have inspected many fewer stories with the same results). We also inspected questions for which at least 5 workers answered incorrectly, or answered "unclear". In total, 29 questions (<2%) were inspected. 5 were fixed by changing the question, 8 by changing the answers, 2 by changing both, 6 by changing the story, and 8 were left unmodified.

Note that while not fully automated, this process of inspecting stories and repairing questions took one person one day, so is still scalable to at least an order of magnitude more stories.

5 Dataset Analysis

In Table 2, we present results demonstrating the value of the grammar test and curation process. As expected, manually curating MC160 resulted in increased grammar quality and percent of questions answered correctly by raters. The goal of MC500 was to find a more scalable method to achieve the same quality as the curated MC160. As Table 2 shows, the grammar test improved story grammar quality from 1.70 to 1.77 (both uncurated). The rating and one-day curation process in-

Set	AgeAp	Clarity	Grammar	Correct
160	1.88	1.63	1.70	95.3
500	1.92	1.65	1.77	95.3
500 curated	1.94	**1.71**	1.79	**96.9**
160 curated	1.91	1.67	**1.84**‡	**97.7**

Table 2. Average age appropriateness, story clarity, grammar quality (0-2, with 2 being best), and percent of questions answered correctly by raters, for the original and curated versions of the data. Bold indicates statistical significance vs. the original version of the same set, using the two-sample t-test with unequal variance. The ‡ indicates the only statistical difference between 500 curated and 160 curated.

Corpus	Stories	Median writing time	Average Words Per:		
			Story	Question	Answer
MC160	160	26 min	204	8.0	3.4
MC500	500	20 min	212	7.7	3.4

Table 3. Corpus statistics for MC160 and MC500.

creases this to 1.79, whereas a fully manual curation results in a score of 1.84. Curation also improved the percent of questions answered correctly for both MC160 and MC500, but, unlike with grammar, there is no significant difference between the two curated sets. Indeed, the only statistically significant difference between the two is in grammar. So, the MC500 grammar test and curation process is a very scalable method for collecting stories of nearly the quality of the costly manual curation of MC160.

We also computed correlations between these measures of quality and various factors such as story length and time spent writing the story. On MC500, there is a mild correlation between a worker's grammar test score and the judged grammar quality of that worker's story (correlation of 0.24). Interestingly, this relation disappeared once MC500 was curated, likely due to repairing the stories with the worst grammar. On MC160, there is a mild correlation between the clarity and the number of words in the question and answer (0.20 and 0.18). All other correlations were below 0.15. These factors could be integrated into an estimate for age-appropriateness, clarity, and grammar, potentially reducing the need for raters.

Table 3 provides statistics on each corpus. MC160 and MC500 are similar in average number of words per story, question, and answer, as well as the median writing time. The most commonly used

Baseline Algorithms

Require: Passage P, set of passage words PW, i^{th} word in passage P_i, set of words in question Q, set of words in hypothesized answers $A_{1..4}$, and set of stop words U,

nouns in MC500 are: *day*, *friend*, *time*, *home*, *house*, *mother*, *dog*, *mom*, *school*, *dad*, *cat*, *tree*, and *boy*. The stories vary widely in theme. The first 10 stories of the randomly-ordered MC500 set are about: travelling to Miami to visit friends, waking up and saying hello to pets, a bully on a schoolyard, visiting a farm, collecting insects at Grandpa's house, planning a friend's birthday party, selecting clothes for a school dance, keeping animals from eating your ice cream, animals ordering food, and adventures of a boy and his dog.

MC160	Train and Dev: 400 Q's		Test: 240 Q's	
	SW	SW+D	SW	SW+D
Single	59.46	68.11	64.29	75.89
Multi	59.53	67.44	48.44	57.81
All	*59.50*	*67.75*	*55.83*	*66.25*

Table 4. Percent correct for the multiple choice questions for MC160. SW: sliding window algorithm. SW+D: combined results with sliding window and distance based algorithms. Single/Multi: questions marked by worker as requiring a single/multiple sentence(s) to answer. All differences between SW and SW+D are significant ($p<0.01$ using the two-tailed paired t-test).

MC500	Train and Dev: 1400 Q's		Test: 600 Q's		All
	SW	SW+D	SW	SW+D	SW+D
Single	55.13	61.77	51.10	57.35	60.44
Multi	49.80	55.28	51.83	56.10	55.53
All	*52.21*	*58.21*	*51.50*	*56.67*	*57.75*

Table 5. Percent correct for the multiple choice questions for MC500, notation as above. All differences between SW and SW+D are significant ($p<0.01$, tested as above).

We randomly divided MC160 and MC500 into train, development, and test sets of 70, 30, and 60 stories and 300, 50, and 150 stories, respectively.

6 Baseline System and Results

We wrote two baseline systems, both using only simple lexical features. The first system used a sliding window, matching a bag of words constructed from the question and hypothesized answer to the text. Since this ignored long range dependencies, we added a second, word-distance based algorithm. The distance-based score was simply subtracted from the window-based score to arrive at the final score (we tried scaling the distance score before subtraction but this did not improve results on the MC160 train set). The algorithms are summarized in Figure 4. A coin flip is used to break ties. The use of inverse word counts was inspired by TF-IDF.

Results for MC160 and MC500 are shown in Table 4 and Table 5. The MC160 train and development sets were used for tuning. The baseline algorithm was authored without seeing any portion of MC500, so both the MC160 test set and all of MC500 were used for testing (although we nevertheless report results on the train/test split). Note that adding the distance based algorithm improved accuracy by approximately 10% absolute on MC160 and approximately 6% on MC500. Overall, error rates on MC500 are higher than on MC160, which agrees with human performance (see Table 2), suggesting that MC500's questions are more difficult.

	MC160 Test	MC500 Test
Baseline (SW+D)	66.25	56.67
RTE	59.79‡	53.52
Combined	67.60	60.83‡

Table 6. Percent correct for MC160 and MC500 test sets. The ‡ indicates statistical significance vs. baseline ($p<0.01$ using the two-tailed paired t-test). MC160 combined vs. baseline has p-value 0.063.

7 Recognizing Textual Entailment Results

We also tried using a "recognizing textual entailment" (RTE) system to answer MCTest questions. The goal of RTE (Dagan et al., 2005) is to determine whether a given statement can be inferred from a particular text. We can cast MCTest as an RTE task by converting each question-answer pair into a statement, and then selecting the answer whose statement has the highest likelihood of being entailed by the story. For example, in the sample story given in Figure 1, the second question can be converted into four statements (one for each answer), and the RTE system should select the statement "James pulled pudding off of the shelves in the grocery store" as the most likely one.

For converting question-answer pairs to statements, we used the rules employed in a web-based question answering system (Cucerzan and Agichtein, 2005). For RTE, we used BIUTEE (Stern and Dagan, 2011), which performs better than the median system in the past four RTE competitions. We ran BIUTEE both in its default configuration, as well as with its optional additional data sources (FrameNet, ReVerb, DIRT, and others as found on the BIUTEE home page). The default configuration performed better so we present its results here. The results in Table 6 show that the RTE method performed worse than the baseline.

We also combined the baseline and RTE system by training BIUTEE on the train set and using the development set to optimize a linear combination of BIUTEE with the baseline; the combined system outperforms either component system on MC500.

It is possible that with some tuning, an RTE system will outperform our baseline system. Nevertheless, these RTE results, and the performance of the baseline system, both suggest that the reading comprehension task described here will not be trivially solved by off-the-shelf techniques.

8 Making Data and Results an Ongoing Resource

Our goal in constructing this data is to encourage research and innovation in the machine comprehension of text. Thus, we have made both MC160 and MC500 freely available for download at http://research.microsoft.com/mct. To our knowledge, these are the largest copyright-free reading comprehension data sets publicly available. To further encourage research on these data, we will be continually updating the webpage with the best-known published results to date, along with pointers to those publications.

One of the difficulties in making progress on a particular task is implementing previous work in order to apply improvements to it. To mitigate this difficulty, we are encouraging researchers who use the data to (optionally) provide per-answer scores from their system. Doing so has three benefits: (a) a new system can be measured in the context of the errors made by the previous systems, allowing each research effort to incrementally add useful functionality without needing to also re-implement the current state-of-the-art; (b) it allows system performance to be measured using paired statistical testing, which will substantially increase the ability to determine whether small improvements are significant; and (c) it enables researchers to perform error analysis on any of the existing systems, simplifying the process of identifying and tackling common sources of error. We will also periodically ensemble the known systems using standard machine learning techniques and make those results available as well (unless the existing state-of-the-art already does such ensembling).

The released data contains the stories and questions, as well as the results from workers who rated the stories and took the tests. The latter may be used, for example, to measure machine performance vs. human performance on a per-question basis (i.e., does your algorithm make similar mistakes to humans?), or vs. the judged clarity of each story. The ratings, as well as whether a question needs multiple sentences to answer, should typically only be used in evaluation, since such information is not generally available for most text. We will also provide an anonymized author id for each story, which could allow additional research such as using other works by the same author when understanding a story, or research on authorship attribution (e.g., Stamatatos, 2009).

9 Future Work

We plan to use this dataset to evaluate approaches for machine comprehension, but are making it available now so that others may do the same. If MCTest is used we will collect more story sets and will continue to refine the collection process. One interesting research direction is ensuring that the questions are difficult enough to challenge state-of-the-art techniques as they develop. One idea for this is to apply existing techniques automatically during story set creation to see whether a question is too easily answered by a machine. By requiring authors to create difficult questions, each data set will be made more and more difficult (but still answerable by humans) as the state-of-the-art methods advance. We will also experiment with timing the raters as they answer questions to see if we can find those that are too easy for people to answer. Removing such questions may increase the difficulty for machines as well. Additionally, any divergence between how easily a person answers a question vs. how easily a machine does may point toward new techniques for improving machine comprehension; we plan to conduct research in this direction as well as make any such data available for others.

10 Conclusion

We present the MCTest dataset in the hope that it will help spur research into the machine comprehension of text. The metric (the accuracy on the question sets) is clearly defined, and on that metric, lexical baseline algorithms only attain approximately 58% correct on test data (the MC500 set) as

opposed to the 100% correct that the majority of crowd-sourced judges attain. A key component of MCTest is the scalable design: we have shown that data whose quality approaches that of expertly curated data can be generated using crowd sourcing coupled with expert correction of worker-identified errors. Should MCTest prove useful to the community, we will continue to gather data, both to increase the corpus size, and to keep the test sets fresh. The data is available at http://research.microsoft.com/mct and any submitted results will be posted there too. Because submissions will be requested to include the score for each test item, researchers will easily be able to compare their systems with those of others, and investigation of ensembles comprised of components from several different teams will be straightforward. MCTest also contains supplementary material that researchers may find useful, such as worker accuracies on a grammar test and crowd-sourced measures of the quality of their stories.

Acknowledgments

We would like to thank Silviu Cucerzan and Lucy Vanderwende for their help with converting questions to statements and other useful discussions.

Abstract

This paper proposes a novel noise-aware character alignment method for bootstrapping statistical machine transliteration from automatically extracted phrase pairs. The model is an extension of a Bayesian many-to-many alignment method for distinguishing non-transliteration (noise) parts in phrase pairs. It worked effectively in the experiments of bootstrapping Japanese-to-English statistical machine transliteration in patent domain using patent bilingual corpora.

1 Introduction

Transliteration is used for providing translations for source language words that have no appropriate counterparts in target language, such as some technical terms and named entities. Statistical machine transliteration (Knight and Graehl, 1998) is a technology to solve it in a statistical manner. Bilingual dictionaries can be used to train its model, but many of their entries are actually *translation* but not *transliteration*. Such non-transliteration pairs hurt the transliteration model and should be eliminated beforehand.

Sajjad et al. (2012) proposed a method to identify such non-transliteration pairs, and applied it successfully to *noisy* word pairs obtained from automatic word alignment on bilingual corpora. It enables the statistical machine transliteration to be bootstrapped from bilingual corpora. This approach is beneficial because it does not require carefully-developed bilingual transliteration dictionaries and it can learn domain-specific transliteration patterns from bilingual corpora in the target domain. However, their transliteration mining approach is sample-wise; that is, it makes a decision whether a bilingual phrase pair is transliteration or not. Suppose that a compound word in a language A is transliterated into two words in another language B. Their correspondence may not be fully identified by automatic word alignment and a wrong alignment between the compound word in A and only one component word in B is found. The sample-wise mining cannot make a correct decision of *partial transliteration* on the aligned candidate, and may introduces noise to the statistical transliteration model.

This paper proposes a novel transliteration mining method for such partial transliterations. The method uses a noise-aware character alignment model that distinguish non-transliteration (noise) parts from transliteration (signal) parts. The model is an extension of a Bayesian alignment model (Finch and Sumita, 2010) and can be trained by a sampling algorithm extended for a constraint on noise. Our experiments of Japanese-to-English transliteration achieved 16% relative error reduction in transliteration accuracy from the sample-wise method. The main contribution of this paper is two-fold:

- we formulate alignment over string pairs with partial noise and present a solution with a noise-aware alignment model;
- we proved its effectiveness by experiments with frequent unknown words in actual Japanese-to-English patent translation data.

2 Bayesian many-to-many alignment

We briefly review a Bayesian many-to-many character alignment proposed by Finch and Sumita (2010) on which our model is based. The model is based on a generative process of bilingual substring pairs $\langle \bar{s}, \bar{t} \rangle$ by the following Dirichlet process (DP):

$$\begin{aligned} G|_{\alpha, G_0} &\sim \mathrm{DP}(\alpha, G_0) \\ \langle \bar{s}, \bar{t} \rangle | G &\sim G, \end{aligned}$$

where G is a probability distribution over substring pairs according to a DP prior with base measure G_0 and hyperparameter α. G_0 is modeled as a joint spelling model as follows:

$$G_0\left(\langle \bar{s}, \bar{t} \rangle\right) = \frac{\lambda_s^{|\bar{s}|}}{|\bar{s}|!} e^{-\lambda_s} v_s^{-|\bar{s}|} \times \frac{\lambda_t^{|\bar{t}|}}{|\bar{t}|!} e^{-\lambda_t} v_t^{-|\bar{t}|}. \quad (1)$$

This is a simple joint probability of the spelling models, in which each alphabet appears based on a uniform distribution over the vocabulary (of size v_s and v_t) and each string length follows a Poisson distribution (with the average length λ_s and λ_t).

The model handles infinite number of substring pairs according to the Chinese Restaurant Process (CRP). The probability of a substring pair $\langle \bar{s}_k, \bar{t}_k \rangle$ is based on the counts of all other substring pairs as follows:

$$\begin{aligned} &p\left(\langle \bar{s}_k, \bar{t}_k \rangle | \left\{\langle \bar{s}, \bar{t} \rangle\right\}_{-k}\right) \\ &\qquad = \frac{N\left(\langle \bar{s}_k, \bar{t}_k \rangle\right) + \alpha G_0\left(\langle \bar{s}_k, \bar{t}_k \rangle\right)}{\sum_i N\left(\langle \bar{s}_i, \bar{t}_i \rangle\right) + \alpha}. \quad (2) \end{aligned}$$

Here $\left\{\langle \bar{s}, \bar{t} \rangle\right\}_{-k}$ means a set of substring pairs excluding $\langle \bar{s}_k, \bar{t}_k \rangle$, and $N\left(\langle \bar{s}_k, \bar{t}_k \rangle\right)$ is the number of $\langle \bar{s}_k, \bar{t}_k \rangle$ in the current sample space. This alignment model is suitable for representing very sparse distribution over arbitrary substring pairs, thanks to reasonable CRP-based smoothing for unseen pairs based on the spelling model.

3 Proposed method

We propose an extended many-to-many alignment model that can handle partial noise. We extend the model in the previous section by introducing a noise symbol and state-based probability calculation.

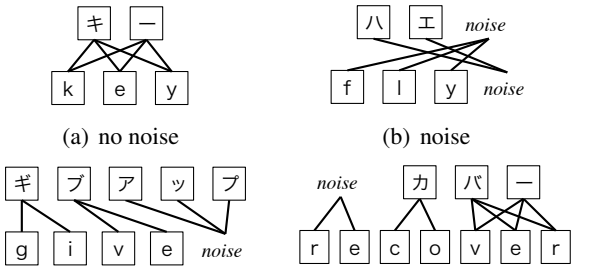

Figure 1: Three types of noise in transliteration data. Solid lines are correct many-to-many alignment links.

3.1 Partial noise in transliteration data

Figure 1 shows transliteration examples with "no noise," "noise," and "partial noise." Solid lines in the figure show correct many-to-many alignment links. The examples (a) and (b) can be distinguished effectively by Sajjad et al. (2012). We aim to do alignment as in the examples (c) and (d) by distinguishing its non-transliteration (noise) part, which cannot be handled by the existing methods.

3.2 Noise-aware alignment model

We introduce a *noise symbol* to handle partial noise in the many-to-many alignment model. Htun et al. (2012) extended the many-to-many alignment for the sample-wise transliteration mining, but its noise model only handles the sample-wise noise and cannot distinguish partial noise. We model partial noise in the CRP-based joint substring model.

Partial noise in transliteration data typically appears in compound words as mentioned earlier, because their counterparts consisting of two or more words may not be fully covered in automatically extracted words and phrases as shown in Figure 1(c). Another type of partial noise is derived from morphological differences due to inflection, which usually appear in the sub-word level as prefixes and suffixes as shown in Figure 1(d). According to this intuition, we assume that partial noise appears in the beginning and/or end of transliteration data (in case of sample-wise noise, we assume the noise is in the beginning). This assumption derives a constraint between signal and noise parts that helps to avoid a welter of transliteration and non-transliteration parts. It also has a shortcoming that it is generally

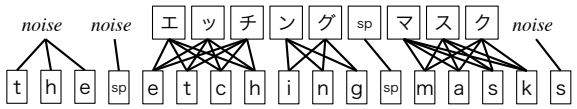

Figure 2: Example of many-to-many alignment with partial noise in the beginning and end. "*noise*" stands for the noise symbol and "sp" stands for a white space.

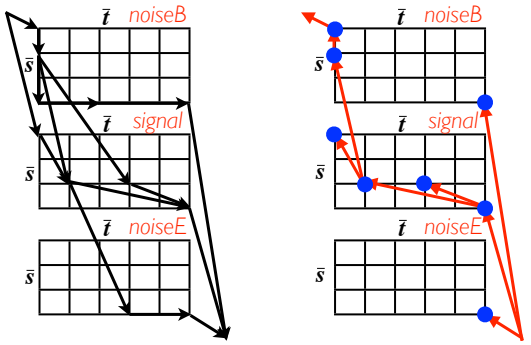
not appropriate for noise in the middle, but handling arbitrary number of noise parts increases computational complexity and sparseness. We rely on this simple assumption in this paper and consider a more complex mid-noise problem as future work.

Figure 2 shows a partial noise example in both the beginning and end. This example is actually correct translation but includes noise in a sense of transliteration; an article "the" is wrongly included in the phrase pair (no articles are used in Japanese) and a plural noun "masks" is transliterated into "マスク"(mask). These non-transliteration parts are aligned to noise symbols in the proposed model. The noise symbols are treated as zero-length substrings in the model, same as other substrings.

3.3 Constrained Gibbs sampling

Finch and Sumita (2010) used a blocked Gibbs sampling algorithm with forward-filtering backward-sampling (FFBS) (Mochihashi et al., 2009). We extend their algorithm for our noise-aware model using a state-based calculation over the three states: non-transliteration part in the beginning (noiseB), transliteration part (signal), non-transliteration part in the end (noiseE).

Figure 3 illustrates our FFBS steps. At first in the forward filtering, we begin with transition to noiseB and signal. The calculation of forward probabilities itself is almost the same as Finch and Sumita (2010) except for state transition constraints: from noiseB to signal, from signal to noiseE. The backward-sampling traverses a path by probability-based sampling with true posteriors, starting from the choice of the ending state among noiseB (means full noise), signal, and noiseE. This algorithm increases the computational cost by three times to consider three different states, compared to that of Finch and Sumita (2010).



(a) Forward filtering (b) Backward sampling

Figure 3: State-based FFBS for the proposed model.

4 Experiments

We conducted experiments comparing the proposed method with the conventional sample-wise method for the use in bootstrapping statistical machine transliteration using Japanese-to-English patent translation dataset (Goto et al., 2013).

4.1 Training data setup

First, we trained a phrase table on the 3.2M parallel sentences by a standard training procedure using Moses, with Japanese tokenization using MeCab[1]. We obtained 591,840 phrase table entries whose Japanese side was written in *katakana* (Japanese phonogram) only[2]. Then, we iteratively ran the method of Sajjad et al. (2012) on these entries and eliminate non-transliteration pairs, until the number of pairs converged. Finally we obtain 104,563 *katakana*-English pairs after 10 iterations; they were our *baseline training set* mined by sample-wise method. We used Sajjad et al.'s method as preprocessing for filtering sample-wise noise while the proposed method could also do that, because the proposed method took much more training time for all phrase table entries.

4.2 Transliteration experiments

The transliteration experiment used a translation-based implementation with Moses, using a

[1]http://code.google.com/p/mecab/

[2]This *katakana*-based filtering is a language dependent heuristic for choosing potential transliteration candidate, because transliterations in Japanese are usually written in *katakana*.

character-based 7-gram language model trained on 300M English patent sentences. We compared three transliteration models below.

The test set was top-1000 unknown (in the Japanese-to-English translation model) *katakana* words appeared in 400M Japanese patent sentences. They covered 15.5% of all unknown *katakana* words and 8.8% of all unknown words (excluding numbers); that is, more than a half of unknown words were *katakana* words.

4.2.1 Sample-wise method (BASELINE)

We used the baseline training set to train statistical machine transliteration model for our baseline. The training procedure was based on Moses: MGIZA++ word alignment, grow-diag-final-and alignment symmetrization and phrase extraction with the maximum phrase length of 7.

4.2.2 Proposed method (PROPOSED)

We applied the proposed method to the baseline training set with 30 sampling iterations and eliminated partial noise. The transliteration model was trained in the same manner as BASELINE after eliminating noise.

The hyperparameters, α, λ_s, and λ_t, were optimized using a held-out set of 2,000 *katakana*-English pairs that were randomly chosen from a general-domain bilingual dictionary. The hyperparameter optimization was based on F-score values on the held-out set with varying α among 0.01, 0.02, 0.05, 0.1, 1.0, and λs among 1, 2, 3, 5.

Table 1 compares the statistics on the training sets of BASELINE and PROPOSED. Note that we applied the proposed method to BASELINE data (the sample-wise method was already applied until convergence). The proposed method eliminated only two transliteration candidates in sample-wise but also eliminated 5,714 (0.64%) *katakana* and 55,737 (4.1%) English characters[3].

4.2.3 Proposed method using aligned joint substrings as phrases (PROPOSED-JOINT)

The many-to-many character alignment actually induces substring pairs, which can be used as phrases in statistical machine transliteration and improved transliteration performance (Finch and Sumita, 2010). We extracted them by: 1) generate many-to-many word alignment, in which all possible word alignment links in many-to-many correspondences (e.g., 0-0 0-1 0-2 1-0 1-1 1-2 for ⟨コ ン, c o m⟩), 2) run phrase extraction and scoring same as a standard Moses training. This procedure extracts longer phrases satisfying the many-to-many alignment constraints than the simple use of extracted joint substring pairs as phrases.

[3]The reason of larger number of partial noise in English side would be a syntactic difference as shown in Figure 2 and the *katakana*-based filtering heuristics.

Table 1: Statistics of the training sets.

Method	#pairs	#Ja chars.	#En chars.
BASELINE	104,563	899,080	1,372,993
PROPOSED	104,561	893,366	1,317,256

4.3 Results

Table 2 shows the results. We used three evaluation metrics: ACC, F-score, and BLEU_c. ACC is a sample-wise accuracy and F-score is a character-wise F-measure-like score (Li et al., 2010). BLEU_c is BLEU (Papineni et al., 2002) in the character level with n=4.

PROPOSED achieved 63% in ACC (16% relative error reduction from BASELINE), and 94.6% in F-score (25% relative error reduction from BASELINE). These improvements clearly showed an advantage of the proposed method over the sample-wise mining. BLEU_c showed a similar improvements. Recall that BASELINE and PROPOSED had a small difference in their training data, actually 0.64% (*katakana*) and 4.1% (English) in the number of characters. The results suggest that the partial noise can hurt transliteration models.

PROPOSED-JOINT showed similar performance as PROPOSED with a slight drop in BLEU_c, although many-to-many substring alignment was expected to improve transliteration as reported by Finch and Sumita (2010). The difference may be due to the difference in coverage of the phrase tables; PROPOSED-JOINT retained relatively long substrings by the many-to-many alignment constraints in contrast to the less-constrained grow-diag-final-and alignments in PROPOSED. Since the training data in our bootstrapping experiments con-

Table 2: Japanese-to-English transliteration results for top-1000 unknown *katakana* words. ACC and F-score stand for the ones used in NEWS workshop, BLEU_c is character-wise BLEU.

Method	ACC	F-score	BLEU_c
BASELINE	0.56	0.929	0.864
PROPOSED	0.63	0.946	0.897
PROPOSED-JOINT	0.63	0.943	0.888

tained many similar phrases unlike dictionary-based data in Finch and Sumita (2010), the phrase table of PROPOSED-JOINT may have a small coverage due to long and sparse substring pairs with large probabilities even if the many-to-many alignment was good. This sparseness problem is beyond the scope of this paper and worth further study.

4.4 Alignment Examples

Figure 4 shows examples of the alignment results in the training data. As expected, partial noise both in Japanese and English was identified correctly in (a), (b), and (c). There were some alignment errors in the signal part in (b), in which characters in boundary positions were aligned incorrectly to adjacent substrings. These alignment errors did not directly degrade the partial noise identification but may cause a negative effect on overall alignment performance in the sampling-based optimization. (d) is a negative example in which partial noise was incorrectly aligned. (c) and (d) have similar partial noise in their English word endings, but it could not be identified in (d). One possible reason for that is the sparseness problem mentioned above, as shown in erroneous long character alignments in (d).

5 Conclusion

This paper proposed a noise-aware many-to-many alignment model that can distinguish partial noise in transliteration pairs for bootstrapping statistical machine transliteration model from automatically extracted phrase pairs. The model and training algorithm are straightforward extension of those by Finch and Sumita (2010). The proposed method was proved to be effective in Japanese-to-English transliteration experiments in patent domain.

Future work will investigate the proposed method

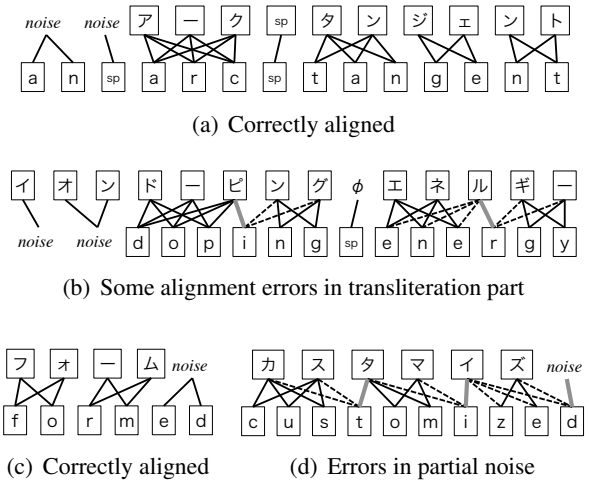


Figure 4: Examples of noise-aware many-to-many alignment in the training data. ϕ stands for a zero-length substring. Dashed lines show incorrect alignments, and bold grey lines mean their corrections.

in other domains and language pairs. The partial noise would appear in other language pairs, typically between agglutinative and non-agglutinative languages. It is also worth extending the approach into word alignment in statistical machine translation.

Abstract

Beam search is a fast and empirically effective method for translation decoding, but it lacks formal guarantees about search error. We develop a new decoding algorithm that combines the speed of beam search with the optimal certificate property of Lagrangian relaxation, and apply it to phrase- and syntax-based translation decoding. The new method is efficient, utilizes standard MT algorithms, and returns an exact solution on the majority of translation examples in our test data. The algorithm is 3.5 times faster than an optimized incremental constraint-based decoder for phrase-based translation and 4 times faster for syntax-based translation.

1 Introduction

Beam search (Koehn et al., 2003) and cube pruning (Chiang, 2007) have become the *de facto* decoding algorithms for phrase- and syntax-based translation. The algorithms are central to large-scale machine translation systems due to their efficiency and tendency to produce high-quality translations (Koehn, 2004; Koehn et al., 2007; Dyer et al., 2010). However despite practical effectiveness, neither algorithm provides any bound on possible decoding error.

In this work we present a variant of beam search decoding for phrase- and syntax-based translation. The motivation is to exploit the effectiveness and efficiency of beam search, but still maintain formal guarantees. The algorithm has the following benefits:

- In theory, it can provide a certificate of optimality; in practice, we show that it produces optimal hypotheses, with certificates of optimality, on the vast majority of examples.
- It utilizes well-studied algorithms and extends off-the-shelf beam search decoders.
- Empirically it is very fast, results show that it is 3.5 times faster than an optimized incremental constraint-based solver.

While our focus is on fast decoding for machine translation, the algorithm we present can be applied to a variety of dynamic programming-based decoding problems. The method only relies on having a constrained beam search algorithm and a fast unconstrained search algorithm. Similar algorithms exist for many NLP tasks.

We begin in Section 2 by describing constrained hypergraph search and showing how it generalizes translation decoding. Section 3 introduces a variant of beam search that is, in theory, able to produce a certificate of optimality. Section 4 shows how to improve the effectiveness of beam search by using weights derived from Lagrangian relaxation. Section 5 puts everything together to derive a fast beam search algorithm that is often optimal in practice.

Experiments compare the new algorithm with several variants of beam search, cube pruning, A* search, and relaxation-based decoders on two translation tasks. The optimal beam search algorithm is able to find exact solutions with certificates of optimality on 99% of translation examples, significantly more than other baselines. Additionally the optimal

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 210–221,
Seattle, Washington, USA, 18-21 October 2013.

beam search algorithm is much faster than other exact methods.

2 Background

The focus of this work is decoding for statistical machine translation. Given a source sentence, the goal is to find the target sentence that maximizes a combination of translation model and language model scores. In order to analyze this decoding problem, we first abstract away from the specifics of translation into a general form, known as a hypergraph. In this section, we describe the hypergraph formalism and its relation to machine translation.

2.1 Notation

Throughout the paper, scalars and vectors are written in lowercase, matrices are written in uppercase, and sets are written in script-case, e.g. $\mathcal{X}$. All vectors are assumed to be column vectors. The function $\delta(j)$ yields an indicator vector with $\delta(j)_j = 1$ and $\delta(j)_i = 0$ for all $i \neq j$.

2.2 Hypergraphs and Search

A directed hypergraph is a pair $(\mathcal{V}, \mathcal{E})$ where $\mathcal{V} = \{1 \dots |\mathcal{V}|\}$ is a set of vertices, and $\mathcal{E}$ is a set of directed hyperedges. Each hyperedge $e \in \mathcal{E}$ is a tuple $\left\langle \langle v_2, \dots, v_{|v|} \rangle, v_1 \right\rangle$ where $v_i \in \mathcal{V}$ for $i \in \{1 \dots |v|\}$. The *head* of the hyperedge is $h(e) = v_1$. The *tail* of the hyperedge is the ordered sequence $t(e) = \langle v_2, \dots, v_{|v|} \rangle$. The size of the tail $|t(e)|$ may vary across different hyperedges, but $|t(e)| \geq 1$ for all edges and is bounded by a constant. A directed graph is a directed hypergraph with $|t(e)| = 1$ for all edges $e \in \mathcal{E}$.

Each vertex $v \in \mathcal{V}$ is either a *non-terminal* or a *terminal* in the hypergraph. The set of non-terminals is $\mathcal{N} = \{v \in \mathcal{V} : h(e) = v \text{ for some } e \in \mathcal{E}\}$. Conversely, the set of terminals is defined as $\mathcal{T} = \mathcal{V} \setminus \mathcal{N}$.

All directed hypergraphs used in this work are acyclic: informally this implies that no hyperpath (as defined below) contains the same vertex more than once (see Martin et al. (1990) for a full definition). Acyclicity implies a partial topological ordering of the vertices. We also assume there is a distinguished *root* vertex 1 where for all $e \in \mathcal{E}$, $1 \notin t(e)$.

Next we define a hyperpath as $x \in \{0, 1\}^{|\mathcal{E}|}$ where $x(e) = 1$ if hyperedge e is used in the hyperpath, $x(e) = 0$ otherwise. The set of valid hyperpaths is defined as

$$\mathcal{X} = \left\{ x : \begin{array}{l} \displaystyle\sum_{e \in \mathcal{E}: h(e) = 1} x(e) = 1, \\ \\ \displaystyle\sum_{e: h(e) = v} x(e) = \sum_{e: v \in t(e)} x(e) \quad \forall\, v \in \mathcal{N} \setminus \{1\} \end{array} \right\}$$

The first problem we consider is *unconstrained* hypergraph search. Let $\theta \in R^{|\mathcal{E}|}$ be the weight vector for the hypergraph and let $\tau \in \mathbb{R}$ be a weight offset.[1] The unconstrained search problem is to find

$$\max_{x \in \mathcal{X}} \sum_{e \in \mathcal{E}} \theta(e) x(e) + \tau = \max_{x \in \mathcal{X}} \theta^\top x + \tau$$

This maximization can be computed for any weights and directed acyclic hypergraph in time $O(|\mathcal{E}|)$ using dynamic programming. Figure 1 shows this algorithm which is simply a version of the CKY algorithm.

procedure BESTPATHSCORE(θ, τ)
  $\pi[v] \leftarrow 0$ for all $v \in \mathcal{T}$
  for $e \in \mathcal{E}$ in topological order **do**
    $\langle \langle v_2, \dots, v_{|v|} \rangle, v_1 \rangle \leftarrow e$
    $s \leftarrow \theta(e) + \sum_{i=2}^{|v|} \pi[v_i]$
    if $s > \pi[v_1]$ **then** $\pi[v_1] \leftarrow s$
  return $\pi[1] + \tau$

Figure 1: Dynamic programming algorithm for unconstrained hypergraph search. Note that this version only returns the highest score: $\max_{x \in \mathcal{X}} \theta^\top x + \tau$. The optimal hyperpath can be found by including back-pointers.

Next consider a variant of this problem: *constrained* hypergraph search. Constraints will be necessary for both phrase- and syntax-based decoding. In phrase-based models, the constraints will ensure that each source word is translated exactly once. In syntax-based models, the constraints will be used to intersect a translation forest with a language model.

In the constrained hypergraph problem, hyperpaths must fulfill additional linear hyperedge constraints. Define the set of constrained hyperpaths as

$$\mathcal{X}' = \{x \in \mathcal{X} : Ax = b\}$$

[1] The purpose of the offset will be clear in later sections. For this section, the value of τ can be taken as 0.

where we have a constraint matrix $A \in \mathbb{R}^{|b| \times |\mathcal{E}|}$ and vector $b \in R^{|b|}$ encoding $|b|$ constraints. The optimal constrained hyperpath is $x^* = \arg\max_{x \in \mathcal{X}'} \theta^\top x + \tau$.

Note that the constrained hypergraph search problem may be NP-Hard. Crucially this is true even when the corresponding unconstrained search problem is solvable in polynomial time. For instance, phrase-based decoding is known to be NP-Hard (Knight, 1999), but we will see that it can be expressed as a polynomial-sized hypergraph with constraints.

Example: Phrase-Based Machine Translation Consider translating a source sentence $w_1 \dots w_{|w|}$ to a target sentence in a language with vocabulary Σ. A simple phrase-based translation model consists of a tuple $(\mathcal{P}, \omega, \sigma)$ with

- $\mathcal{P}$; a set of pairs (q, r) where $q_1 \dots q_{|q|}$ is a sequence of source-language words and $r_1 \dots r_{|r|}$ is a sequence of target-language words drawn from the target vocabulary Σ.
- $\omega : \mathbb{R}^{|\mathcal{P}|}$; parameters for the translation model mapping each pair in $\mathcal{P}$ to a real-valued score.
- $\sigma : \mathbb{R}^{|\Sigma \times \Sigma|}$; parameters of the language model mapping a bigram of target-language words to a real-valued score.

The translation decoding problem is to find the best derivation for a given source sentence. A derivation consists of a sequence of *phrases* $p = p_1 \dots p_n$. Define a phrase as a tuple (q, r, j, k) consisting of a span in the source sentence $q = w_j \dots w_k$ and a sequence of target words $r_1 \dots r_{|r|}$, with $(q, r) \in \mathcal{P}$. We say the source words $w_j \dots w_k$ are *translated* to r.

The score of a derivation, $f(p)$, is the sum of the translation score of each phrase plus the language model score of the target sentence

$$f(p) = \sum_{i=1}^{n} \omega(q(p_i), r(p_i)) + \sum_{i=0}^{|u|+1} \sigma(u_{i-1}, u_i)$$

where u is the sequence of words in Σ formed by concatenating the phrases $r(p_1) \dots r(p_n)$, with boundary cases $u_0 = \texttt{<s>}$ and $u_{|u|+1} = \texttt{</s>}$.

Crucially for a derivation to be valid it must satisfy an additional condition: it must translate every source word *exactly* once. The decoding problem for phrase-based translation is to find the highest-scoring derivation satisfying this property.

We can represent this decoding problem as a constrained hypergraph using the construction of Chang and Collins (2011). The hypergraph weights encode the translation and language model scores, and its structure ensures that the count of source words translated is $|w|$, i.e. the length of the source sentence. Each vertex will remember the preceding target-language word and the count of source words translated so far.

The hypergraph, which for this problem is also a directed graph, takes the following form.

- Vertices $v \in \mathcal{V}$ are labeled (c, u) where $c \in \{1 \dots |w|\}$ is the count of source words translated and $u \in \Sigma$ is the last target-language word produced by a partial hypothesis at this vertex. Additionally there is an initial terminal vertex labeled $(0, \texttt{<s>})$.
- There is a hyperedge $e \in \mathcal{E}$ with head (c', u') and tail $\langle (c, u) \rangle$ if there is a valid corresponding phrase (q, r, j, k) such that $c' = c + |q|$ and $u' = r_{|r|}$, i.e. c' is the count of words translated and u' is the last word of target phrase r. We call this phrase $p(e)$.

  The weight of this hyperedge, $\theta(e)$, is the translation model score of the pair plus its language model score

$$\theta(e) = \omega(q, r) + \left(\sum_{i=2}^{|r|} \sigma(r_{i-1}, r_i) \right) + \sigma(u, r_1)$$

- To handle the end boundary, there are hyperedges with head 1 and tail $\langle (|w|, u) \rangle$ for all $u \in \Sigma$. The weight of these edges is the cost of the stop bigram following u, i.e. $\sigma(u, \texttt{</s>})$.

While any valid derivation corresponds to a hyperpath in this graph, a hyperpath may not correspond to a valid derivation. For instance, a hyperpath may translate some source words more than once or not at all.

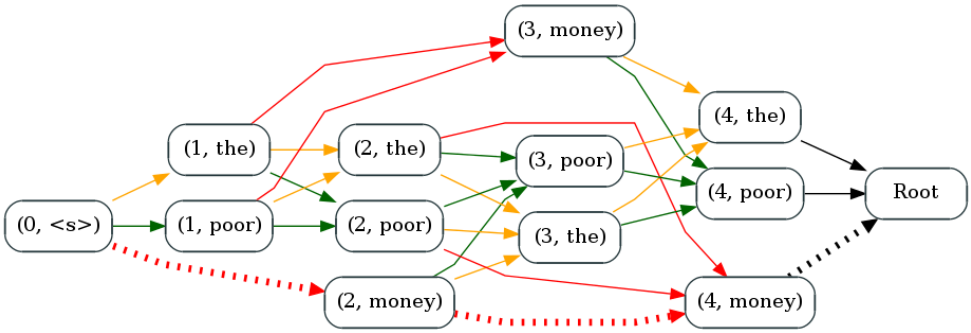

Figure 2: Hypergraph for translating the sentence $w = \texttt{les}_1\ \texttt{pauvres}_2\ \texttt{sont}_3\ \texttt{demunis}_4$ with set of pairs $\mathcal{P} = \{(\texttt{les}, \texttt{the}), (\texttt{pauvres}, \texttt{poor}), (\texttt{sont demunis}, \texttt{don't have any money})\}$. Hyperedges are color-coded by source words translated: orange for $\texttt{les}_1$, green for $\texttt{pauvres}_2$, and red for $\texttt{sont}_3\ \texttt{demunis}_4$. The dotted lines show an invalid hyperpath x that has signature $Ax = \langle 0, 0, 2, 2 \rangle \neq \langle 1, 1, 1, 1 \rangle$.

We handle this problem by adding additional constraints. For all source words $i \in \{1 \dots |w|\}$, define ρ as the set of hyperedges that translate w_i

$$\rho(i) = \{e \in \mathcal{E} : j(p(e)) \leq i \leq k(p(e))\}$$

Next define $|w|$ constraints enforcing that each word in the source sentence is translated exactly once

$$\sum_{e \in \rho(i)} x(e) = 1 \quad \forall\, i \in \{1 \dots |w|\}$$

These linear constraints can be represented with a matrix $A \in \{0, 1\}^{|w| \times |\mathcal{E}|}$ where the rows correspond to source indices and the columns correspond to edges. We call the product Ax the *signature*, where in this case $(Ax)_i$ is the number of times word i has been translated. The full set of constrained hyperpaths is $\mathcal{X}' = \{x \in \mathcal{X} : Ax = \mathbf{1}\}$, and the best derivation under this phrase-based translation model has score $\max_{x \in \mathcal{X}'} \theta^\top x + \tau$.

Figure 2.2 shows an example hypergraph with constraints for translating the sentence `les pauvres sont demunis` into English using a simple set of phrases. Even in this small example, many of the possible hyperpaths violate the constraints and correspond to invalid derivations.

Example: Syntax-Based Machine Translation Syntax-based machine translation with a language model can also be expressed as a constrained hypergraph problem. For the sake of space, we omit the definition. See Rush and Collins (2011) for an in-depth description of the constraint matrix used for syntax-based translation.

3 A Variant of Beam Search

This section describes a variant of the beam search algorithm for finding the highest-scoring constrained hyperpath. The algorithm uses three main techniques: (1) dynamic programming with additional signature information to satisfy the constraints, (2) beam pruning where some, possibly optimal, hypotheses are discarded, and (3) branch-and-bound-style application of upper and lower bounds to discard provably non-optimal hypotheses.

Any solution returned by the algorithm will be a valid constrained hyperpath and a member of $\mathcal{X}'$. Additionally the algorithm returns a certificate flag opt that, if true, indicates that no beam pruning was used, implying the solution returned is optimal. Generally it will be hard to produce a certificate even by reducing the amount of beam pruning; however in the next section we will introduce a method based on Lagrangian relaxation to tighten the upper bounds. These bounds will help eliminate most solutions before they trigger pruning.

3.1 Algorithm

Figure 3 shows the complete beam search algorithm. At its core it is a dynamic programming algorithm filling in the chart π. The beam search chart indexes hypotheses by vertex $v \in \mathcal{V}$ as well as a signature $sig \in \mathbb{R}^{|b|}$ where $|b|$ is the number of constraints. A new hypothesis is constructed from each hyperedge and all possible signatures of tail nodes. We define the function SIGS to take the tail of an edge and re-

turn the set of possible signature combinations

$$\textsc{Sigs}(v_2, \dots v_{|v|}) = \prod_{i=2}^{|v|} \{sig : \pi[v_i, sig] \neq -\infty\}$$

where the product is the Cartesian product over sets. Line 8 loops over this entire set.[2] For hypothesis x, the algorithm ensures that its signature sig is equal to Ax. This property is updated on line 9.

The signature provides proof that a hypothesis is still valid. Let the function $\textsc{Check}(sig)$ return true if the hypothesis can still fulfill the constraints. For example, in phrase-based decoding, we will define $\textsc{Check}(sig) = (sig \leq \mathbf{1})$; this ensures that each word has been translated 0 or 1 times. This check is applied on line 11.

Unfortunately maintaining all signatures is inefficient. For example we will see that in phrase-based decoding the signature is a bit-string recording which source words have been translated; the number of possible bit-strings is exponential in the length of the sentence. The algorithm includes two methods for removing hypotheses, bounding and pruning.

Bounding allows us to discard provably non-optimal solutions. The algorithm takes as arguments a lower bound on the optimal score $\mathrm{lb} \leq \theta^\top x^* + \tau$, and computes upper bounds on the outside score for all vertices v: $\mathrm{ubs}[v]$, i.e. an overestimate of the score for completing the hyperpath from v. If a hypothesis has score s, it can only be optimal if $s + \mathrm{ubs}[v] \geq \mathrm{lb}$. This bound check is performed on line 11.

Pruning removes weak partial solutions based on problem-specific checks. The algorithm invokes the black-box function, PRUNE, on line 13, passing it a pruning parameter β and a vertex-signature pair. The parameter β controls a threshold for pruning. For instance for phrase-based translation, it specifies a hard-limit on the number of hypotheses to retain. The function returns true if it prunes from the chart. Note that pruning may remove optimal hypotheses, so we set the certificate flag opt to false if the chart is modified.

[2]For simplicity we write this loop over the entire set. In practice it is important to use data structures to optimize lookup. See Tillmann (2006) and Huang and Chiang (2005).

1: **procedure** BEAMSEARCH($\theta, \tau, \mathrm{lb}, \beta$)
2: $\mathrm{ubs} \leftarrow \textsc{Outside}(\theta, \tau)$
3: $\mathrm{opt} \leftarrow \mathrm{true}$
4: $\pi[v, sig] \leftarrow -\infty$ for all $v \in \mathcal{V}, sig \in \mathbb{R}^{|b|}$
5: $\pi[v, 0] \leftarrow 0$ for all $v \in \mathcal{T}$
6: **for** $e \in \mathcal{E}$ in topological order **do**
7: $\langle \langle v_2, \dots, v_{|v|} \rangle, v_1 \rangle \leftarrow e$
8: **for** $sig^{(2)} \dots sig^{(|v|)} \in \textsc{Sigs}(v_2, \dots, v_{|v|})$ **do**
9: $sig \leftarrow A\delta(e) + \sum_{i=2}^{|v|} sig^{(i)}$
10: $s \leftarrow \theta(e) + \sum_{i=2}^{|v|} \pi[v_i, sig^{(i)}]$
11: **if** $\begin{pmatrix} s > \pi[v_1, sig] \wedge \\ \textsc{Check}(sig) \wedge \\ s + \mathrm{ubs}[v_1] \geq \mathrm{lb} \end{pmatrix}$ **then**
12: $\pi[v_1, sig] \leftarrow s$
13: **if** $\textsc{Prune}(\pi, v_1, sig, \beta)$ **then** $\mathrm{opt} \leftarrow \mathrm{false}$
14: $\mathrm{lb}' \leftarrow \pi[1, c] + \tau$
15: **return** $\mathrm{lb}', \mathrm{opt}$

Input:

$(\mathcal{V}, \mathcal{E}, \theta, \tau)$	hypergraph with weights
(A, b)	matrix and vector for constraints
$\mathrm{lb} \in \mathbb{R}$	lower bound
β	a pruning parameter

Output:

lb'	resulting lower bound score
opt	certificate of optimality

Figure 3: A variant of the beam search algorithm. Uses dynamic programming to produce a lower bound on the optimal constrained solution and, possibly, a certificate of optimality. Function OUTSIDE computes upper bounds on outside scores. Function SIGS enumerates all possible tail signatures. Function CHECK identifies signatures that do not violate constraints. Bounds lb and ubs are used to remove provably non-optimal solutions. Function PRUNE, taking parameter β, returns true if it prunes hypotheses from π that could be optimal.

This variant on beam search satisfies the following two properties (recall x^* is the optimal constrained solution)

Property 3.1 (Primal Feasibility)**.** *The returned score* lb' *lower bounds the optimal constrained score, that is* $\mathrm{lb}' \leq \theta^\top x^* + \tau$.

Property 3.2 (Dual Certificate)**.** *If beam search returns with* $\mathrm{opt} = \mathrm{true}$*, then the returned score is optimal, i.e.* $\mathrm{lb}' = \theta^\top x^* + \tau$.

An immediate consequence of Property 3.1 is that the output of beam search, lb', can be used as the input lb for future runs of the algorithm. Furthermore,

procedure PRUNE(π, v, sig, β)
  $\mathcal{C} \leftarrow \{(v', sig') : ||sig'||_1 = ||sig||_1, \pi[v', sig'] \neq -\infty\}$
  $\mathcal{D} \leftarrow \mathcal{C} \setminus \text{mBEST}(\beta, \mathcal{C}, \pi)$
  $\pi[v', sig'] \leftarrow -\infty$ for all $v', sig' \in \mathcal{D}$
  if $\mathcal{D} = \emptyset$ **then return** true
  else return false

Input: (v, sig) the last hypothesis added to the chart
$\beta \in \mathbb{Z}$ # of hypotheses to retain
Output: true, if π is modified

Figure 4: Pruning function for phrase-based translation. Set $\mathcal{C}$ contains all hypotheses with $||sig||_1$ source words translated. The function prunes all but the top-β scoring hypotheses in this set.

if we loosen the amount of beam pruning by adjusting the pruning parameter β we can produce tighter lower bounds and discard more hypotheses. We can then iteratively apply this idea with a sequence of parameters $\beta_1 \dots \beta_K$ producing lower bounds $\text{lb}^{(1)}$ through $\text{lb}^{(K)}$. We return to this idea in Section 5.

Example: Phrase-based Beam Search. Recall that the constraints for phrase-based translation consist of a binary matrix $A \in \{0,1\}^{|w| \times |\mathcal{E}|}$ and vector $b = \mathbf{1}$. The value sig_i is therefore the number of times source word i has been translated in the hypothesis. We define the predicate CHECK as CHECK$(sig) = (sig \leq \mathbf{1})$ in order to remove hypotheses that already translate a source word more than once, and are therefore invalid. For this reason, phrase-based signatures are called *bit-strings*.

A common beam pruning strategy is to group together items into a set $\mathcal{C}$ and retain a (possibly complete) subset. An example phrase-based beam pruner is given in Figure 4. It groups together hypotheses based on $||sig_i||_1$, i.e. the number of source words translated, and applies a hard pruning filter that retains only the β highest-scoring items $(v, sig) \in \mathcal{C}$ based on $\pi[v, sig]$.

3.2 Computing Upper Bounds

Define the set $\mathcal{O}(v, x)$ to contain all outside edges of vertex v in hyperpath x (informally, hyperedges that do not have v as an ancestor). For all $v \in \mathcal{V}$, we set the upper bounds, ubs, to be the best unconstrained outside score

$$\text{ubs}[v] = \max_{x \in \mathcal{X}: v \in x} \sum_{e \in \mathcal{O}(v,x)} \theta(e) + \tau$$

This upper bound can be efficiently computed for all vertices using the standard outside dynamic programming algorithm. We will refer to this algorithm as OUTSIDE(θ, τ).

Unfortunately, as we will see, these upper bounds are often quite loose. The issue is that unconstrained outside paths are able to violate the constraints without being penalized, and therefore greatly overestimate the score.

4 Finding Tighter Bounds with Lagrangian Relaxation

Beam search produces a certificate only if beam pruning is never used. In the case of phrase-based translation, the certificate is dependent on all groups $\mathcal{C}$ having β or less hypotheses. The only way to ensure this is to bound out enough hypotheses to avoid pruning. The effectiveness of the bounding inequality, $s + \text{ubs}[v] < \text{lb}$, in removing hypotheses is directly dependent on the tightness of the bounds.

In this section we propose using Lagrangian relaxation to improve these bounds. We first give a brief overview of the method and then apply it to computing bounds. Our experiments show that this approach is very effective at finding certificates.

4.1 Algorithm

In Lagrangian relaxation, instead of solving the constrained search problem, we relax the constraints and solve an unconstrained hypergraph problem with modified weights. Recall the constrained hypergraph problem: $\max_{x \in \mathcal{X}: Ax = b} \theta^\top x + \tau$. The Lagrangian dual of this optimization problem is

$$\begin{aligned} L(\lambda) &= \max_{x \in \mathcal{X}} \theta^\top x + \tau - \lambda^\top (Ax - b) \\ &= \left(\max_{x \in \mathcal{X}} (\theta - A^\top \lambda)^\top x \right) + \tau + \lambda^\top b \\ &= \max_{x \in \mathcal{X}} \theta'^\top x + \tau' \end{aligned}$$

where $\lambda \in R^{|b|}$ is a vector of dual variables and define $\theta' = \theta - A^\top \lambda$ and $\tau' = \tau + \lambda^\top b$. This maximization is over $\mathcal{X}$, so for any value of λ, $L(\lambda)$ can be calculated as `BestPathScore`(θ', τ').

Note that for all valid constrained hyperpaths $x \in \mathcal{X}'$ the term $Ax - b$ equals 0, which implies that these hyperpaths have the same score under the modified weights as under the original weights, $\theta^\top x + \tau = \theta'^\top x + \tau'$. This leads to the following two properties,

procedure LRROUND(α_k, λ)
$x \leftarrow \arg\max_{x \in \mathcal{X}} \theta^\top x + \tau - \lambda^\top (Ax - b)$
$\lambda' \leftarrow \lambda - \alpha_k (Ax - b)$
$\text{opt} \leftarrow Ax = b$
$\text{ub} \leftarrow \theta^\top x + \tau$
return $\lambda', \text{ub}, \text{opt}$
procedure LAGRANGIANRELAXATION(α)
$\lambda^{(0)} \leftarrow 0$
for k in $1 \dots K$ **do**
$\lambda^{(k)}, \text{ub}, \text{opt} \leftarrow \text{LRROUND}(\alpha_k, \lambda^{(k-1)})$
if opt **then return** $\lambda^{(k)}, \text{ub}, \text{opt}$
return $\lambda^{(K)}, \text{ub}, \text{opt}$

Input: $\alpha_1 \dots \alpha_K$ sequence of subgradient rates

Output:
- λ final dual vector
- ub upper bound on optimal constrained solution
- opt certificate of optimality

Figure 5: Lagrangian relaxation algorithm. The algorithm repeatedly calls LRROUND to compute the subgradient, update the dual vector, and check for a certificate.

where $x \in \mathcal{X}$ is the hyperpath computed within the max,

Property 4.1 (Dual Feasibility). *The value $L(\lambda)$ upper bounds the optimal solution, that is $L(\lambda) \geq \theta^\top x^* + \tau$*

Property 4.2 (Primal Certificate). *If the hyperpath x is a member of $\mathcal{X}'$, i.e. $Ax = b$, then $L(\lambda) = \theta^\top x^* + \tau$.*

Property 4.1 states that $L(\lambda)$ always produces some upper bound; however, to help beam search, we want as tight a bound as possible: $\min_\lambda L(\lambda)$.

The Lagrangian relaxation algorithm, shown in Figure 5, uses subgradient descent to find this minimum. The subgradient of $L(\lambda)$ is $Ax - b$ where x is the argmax of the modified objective $x = \arg\max_{x \in \mathcal{X}} \theta'^\top x + \tau'$. Subgradient descent iteratively solves unconstrained hypergraph search problems to compute these subgradients and updates λ. See Rush and Collins (2012) for an extensive discussion of this style of optimization in natural language processing.

Example: Phrase-based Relaxation. For phrase-based translation, we expand out the Lagrangian to

$$L(\lambda) = \max_{x \in \mathcal{X}} \theta^\top x + \tau - \lambda^\top (Ax - b) =$$
$$\max_{x \in \mathcal{X}} \sum_{e \in \mathcal{E}} \left(\theta(e) - \sum_{i=j(p(e))}^{k(p(e))} \lambda_i \right) x(e) + \tau + \sum_{i=1}^{|s|} \lambda_i$$

The weight of each edge $\theta(e)$ is modified by the dual variables λ_i for each source word translated by the edge, i.e. if $(q, r, j, k) = p(e)$, then the score is modified by $\sum_{i=j}^{k} \lambda_i$. A solution under these weights may use source words multiple times or not at all. However if the solution uses each source word exactly once ($Ax = \mathbf{1}$), then we have a certificate and the solution is optimal.

4.2 Utilizing Upper Bounds in Beam Search

For many problems, it may not be possible to satisfy Property 4.2 by running the subgradient algorithm alone. Yet even for these problems, applying subgradient descent will produce an improved estimate of the upper bound, $\min_\lambda L(\lambda)$.

To utilize these improved bounds, we simply replace the weights in beam search and the outside algorithm with the modified weights from Lagrangian relaxation, θ' and τ'. Since the result of beam search must be a valid constrained hyperpath $x \in \mathcal{X}'$, and for all $x \in \mathcal{X}'$, $\theta^\top x + \tau = \theta'^\top x + \tau'$, this substitution does not alter the necessary properties of the algorithm; i.e. if the algorithm returns with opt equal to true, then the solution is optimal.

Additionally the computation of upper bounds now becomes

$$\text{ubs}[v] = \max_{x \in \mathcal{X}: v \in x} \sum_{e \in \mathcal{O}(v,x)} \theta'(e) + \tau'$$

These outside paths may still violate constraints, but the modified weights now include penalty terms to discourage common violations.

5 Optimal Beam Search

The optimality of the beam search algorithm is dependent on the tightness of the upper and lower bounds. We can produce better lower bounds by varying the pruning parameter β; we can produce better upper bounds by running Lagrangian relaxation. In this section we combine these two ideas and present a complete optimal beam search algorithm.

Our general strategy will be to use Lagrangian relaxation to compute modified weights and to use beam search over these modified weights to attempt to find an optimal solution. One simple method for doing this, shown at the top of Figure 6, is to run

in stages. The algorithm first runs Lagrangian relaxation to compute the best λ vector. The algorithm then iteratively runs beam search using the parameter sequence β_k. These parameters allow the algorithm to loosen the amount of beam pruning. For example in phrase based pruning, we would raise the number of hypotheses stored per group until no beam pruning occurs.

A clear disadvantage of the staged approach is that it needs to wait until Lagrangian relaxation is completed before even running beam search. Often beam search will be able to quickly find an optimal solution even with good but non-optimal λ. In other cases, beam search may still improve the lower bound lb.

This motivates the alternating algorithm OPTBEAM shown Figure 6. In each round, the algorithm alternates between computing subgradients to tighten ubs and running beam search to maximize lb. In early rounds we set β for aggressive beam pruning, and as the upper bounds get tighter, we loosen pruning to try to get a certificate. If at any point either a primal or dual certificate is found, the algorithm returns the optimal solution.

procedure OPTBEAMSTAGED(α, β)
  $\lambda, \mathrm{ub}, \mathrm{opt} \leftarrow$LAGRANGIANRELAXATION($\alpha$)
  if opt **then return** ub
  $\theta' \leftarrow \theta - A^\top \lambda$
  $\tau' \leftarrow \tau + \lambda^\top b$
  $\mathrm{lb}^{(0)} \leftarrow -\infty$
  for k in $1 \dots K$ **do**
    $\mathrm{lb}^{(k)}, \mathrm{opt} \leftarrow$ BEAMSEARCH($\theta', \tau', \mathrm{lb}^{(k-1)}, \beta_k$)
    if opt **then return** $\mathrm{lb}^{(k)}$
  return $\max_{k \in \{1 \dots K\}} \mathrm{lb}^{(k)}$

procedure OPTBEAM(α, β)
  $\lambda^{(0)} \leftarrow 0$
  $\mathrm{lb}^{(0)} \leftarrow -\infty$
  for k in $1 \dots K$ **do**
    $\lambda^{(k)}, \mathrm{ub}^{(k)}, \mathrm{opt} \leftarrow$ LRROUND($\alpha_k, \lambda^{(k-1)}$)
    if opt **then return** $\mathrm{ub}^{(k)}$
    $\theta' \leftarrow \theta - A^\top \lambda^{(k)}$
    $\tau' \leftarrow \tau + \lambda^{(k)\top} b$
    $\mathrm{lb}^{(k)}, \mathrm{opt} \leftarrow$ BEAMSEARCH($\theta', \tau', \mathrm{lb}^{(k-1)}, \beta_k$)
    if opt **then return** $\mathrm{lb}^{(k)}$
  return $\max_{k \in \{1 \dots K\}} \mathrm{lb}^{(k)}$

Input: $\begin{bmatrix} \alpha_1 \dots \alpha_K & \text{sequence of subgradient rates} \\ \beta_1 \dots \beta_K & \text{sequence of pruning parameters} \end{bmatrix}$
Output: optimal constrained score or lower bound

Figure 6: Two versions of optimal beam search: staged and alternating. Staged runs Lagrangian relaxation to find the optimal λ, uses λ to compute upper bounds, and then repeatedly runs beam search with pruning sequence $\beta_1 \dots \beta_k$. Alternating switches between running a round of Lagrangian relaxation and a round of beam search with the updated λ. If either produces a certificate it returns the result.

6 Related Work

Approximate methods based on beam search and cube-pruning have been widely studied for phrase-based (Koehn et al., 2003; Tillmann and Ney, 2003; Tillmann, 2006) and syntax-based translation models (Chiang, 2007; Huang and Chiang, 2007; Watanabe et al., 2006; Huang and Mi, 2010).

There is a line of work proposing exact algorithms for machine translation decoding. Exact decoders are often slow in practice, but help quantify the errors made by other methods. Exact algorithms proposed for IBM model 4 include ILP (Germann et al., 2001), cutting plane (Riedel and Clarke, 2009), and multi-pass A* search (Och et al., 2001). Zaslavskiy et al. (2009) formulate phrase-based decoding as a traveling salesman problem (TSP) and use a TSP decoder. Exact decoding algorithms based on finite state transducers (FST) (Iglesias et al., 2009) have been studied on phrase-based models with limited reordering (Kumar and Byrne, 2005). Exact decoding based on FST is also feasible for certain hierarchical grammars (de Gispert et al., 2010). Chang and Collins (2011) and Rush and Collins (2011) develop Lagrangian relaxation-based approaches for exact machine translation.

Apart from translation decoding, this paper is closely related to work on column generation for NLP. Riedel et al. (2012) and Belanger et al. (2012) relate column generation to beam search and produce exact solutions for parsing and tagging problems. The latter work also gives conditions for when beam search-style decoding is optimal.

7 Results

To evaluate the effectiveness of optimal beam search for translation decoding, we implemented decoders for phrase- and syntax-based models. In this section we compare the speed and optimality of these

decoders to several baseline methods.

7.1 Setup and Implementation

For phrase-based translation we used a German-to-English data set taken from Europarl (Koehn, 2005). We tested on 1,824 sentences of length at most 50 words. For experiments the phrase-based systems uses a trigram language model and includes standard distortion penalties. Additionally the unconstrained hypergraph includes further derivation information similar to the graph described in Chang and Collins (2011).

For syntax-based translation we used a Chinese-to-English data set. The model and hypergraphs come from the work of Huang and Mi (2010). We tested on 691 sentences from the newswire portion of the 2008 NIST MT evaluation test set. For experiments, the syntax-based model uses a trigram language model. The translation model is tree-to-string syntax-based model with a standard context-free translation forest. The constraint matrix A is based on the constraints described by Rush and Collins (2011).

Our decoders use a two-pass architecture. The first pass sets up the hypergraph in memory, and the second pass runs search. When possible the baselines share optimized construction and search code.

The performance of optimal beam search is dependent on the sequences α and β. For the step-size α we used a variant of Polyak's rule (Polyak, 1987; Boyd and Mutapcic, 2007), substituting the unknown optimal score for the last computed lower bound: $\alpha_k \leftarrow \frac{\text{ub}^{(k)} - \text{lb}^{(k)}}{||Ax^{(k)} - b||_2^2}$. We adjust the order of the pruning parameter β based on a function μ of the current gap: $\beta_k \leftarrow 10^{\mu(\text{ub}^{(k)} - \text{lb}^{(k)})}$.

Previous work on these data sets has shown that exact algorithms do not result in a significant increase in translation accuracy. We focus on the efficiency and model score of the algorithms.

7.2 Baseline Methods

The experiments compare optimal beam search (OPTBEAM) to several different decoding methods. For both systems we compare to: BEAM, the beam search decoder from Figure 3 using the original weights θ and τ, and $\beta \in \{100, 1000\}$; LR-TIGHT, Lagrangian relaxation followed by incremental tightening constraints, which is a reimplementation of Chang and Collins (2011) and Rush and Collins (2011).

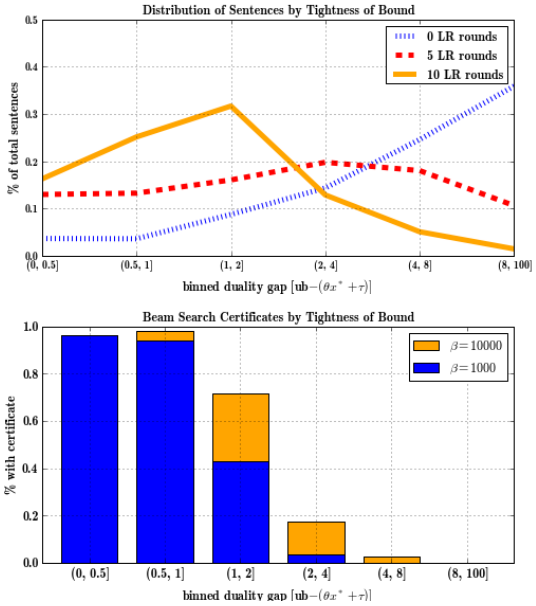

Figure 7: Two graphs from phrase-based decoding. Graph (a) shows the duality gap distribution for 1,824 sentences after 0, 5, and 10 rounds of LR. Graph (b) shows the % of certificates found for sentences with differing gap sizes and beam search parameters β. Duality gap is defined as, ub - $(\theta^\top x^* + \tau)$.

For phrase-based translation we compare with: MOSES-GC, the standard Moses beam search decoder with $\beta \in \{100, 1000\}$ (Koehn et al., 2007); MOSES, a version of Moses without gap constraints more similar to BEAM (see Chang and Collins (2011)); ASTAR, an implementation of A* search using original outside scores, i.e. OUTSIDE(θ, τ), and capped at 20,000,000 queue pops.

For syntax-based translation we compare with: ILP, a general-purpose integer linear programming solver (Gurobi Optimization, 2013) and CUBEPRUNING, an approximate decoding method similar to beam search (Chiang, 2007), tested with $\beta \in \{100, 1000\}$.

7.3 Experiments

Table 1 shows the main results. For phrase-based translation, OPTBEAM decodes the optimal translation with certificate in 99% of sentences with an average time of 17.27 seconds per sentence. This

Table 1: Experimental results for translation experiments. Column *time* is the mean time per sentence in seconds, *cert* is the percentage of sentences solved with a certificate of optimality, *exact* is the percentage of sentences solved exactly, i.e. $\theta^\top x + \tau = \theta^\top x^* + \tau$. Results are grouped by sentence length (group 1-10 is omitted for space).

is seven times faster than the decoder of Chang and Collins (2011) and 3.5 times faster then our reimplementation, LR-TIGHT. ASTAR performs poorly, taking lots of time on difficult sentences. BEAM runs quickly, but rarely finds an exact solution. MOSES without gap constraints is also fast, but less exact than OPTBEAM and unable to produce certificates.

For syntax-based translation. OPTBEAM finds a certificate on 98.8% of solutions with an average time of 1.75 seconds per sentence, and is four times faster than LR-TIGHT. CUBE (100) is an order of magnitude faster, but is rarely exact on longer sentences. CUBE (1000) finds more exact solutions, but is comparable in speed to optimal beam search. BEAM performs better than in the phrase-based model, but is not much faster than OPTBEAM.

Figure 7.2 shows the relationship between beam search optimality and duality gap. Graph (a) shows how a handful of LR rounds can significantly tighten the upper bound score of many sentences. Graph (b) shows how beam search is more likely to find optimal solutions with tighter bounds. BEAM effectively uses 0 rounds of LR, which may explain why it finds so few optimal solutions compared to OPTBEAM.

Table 2 breaks down the time spent in each part of the algorithm. For both methods, beam search has the most time variance and uses more time on longer sentences. For phrase-based sentences, Lagrangian relaxation is fast, and hypergraph construction dominates. If not for this cost, OPTBEAM might be comparable in speed to MOSES (1000).

		≥ 30		all	
		mean	median	mean	median
PB	Hypergraph	56.6%	69.8%	59.6%	69.6%
	Lag. Relaxation	10.0%	5.5%	9.4%	7.6%
	Beam Search	33.4%	24.6%	30.9%	22.8%
SB	Hypergraph	0.5%	1.6%	0.8%	2.4%
	Lag. Relaxation	15.0%	35.2%	17.3%	41.4%
	Beam Search	84.4%	63.1%	81.9 %	56.1%

Table 2: Distribution of time within optimal beam search, including: hypergraph construction, Lagrangian relaxation, and beam search. *Mean* is the percentage of total time. *Median* is the distribution over the median values for each row.

8 Conclusion

In this work we develop an optimal variant of beam search and apply it to machine translation decoding. The algorithm uses beam search to produce constrained solutions and bounds from Lagrangian relaxation to eliminate non-optimal solutions. Results show that this method can efficiently find exact solutions for two important styles of machine translation.

Abstract

Ngram language models tend to increase in size with inflating the corpus size, and consume considerable resources. In this paper, we propose an efficient method for implementing $n$gram models based on double-array structures. First, we propose a method for representing backwards suffix trees using double-array structures and demonstrate its efficiency. Next, we propose two optimization methods for improving the efficiency of data representation in the double-array structures. Embedding probabilities into unused spaces in double-array structures reduces the model size. Moreover, tuning the word IDs in the language model makes the model smaller and faster. We also show that our method can be used for building large language models using the division method. Lastly, we show that our method outperforms methods based on recent related works from the viewpoints of model size and query speed when both optimization methods are used.

1 Introduction

Ngram language models (F. Jelinek, 1990) are widely used as probabilistic models of sentence in natural language processing. The wide use of the Internet has entailed a dramatic increase in size of the available corpora, which can be harnessed to obtain a significant improvement in model quality. In particular, Brants et al. (2007) have shown that the performance of statistical machine translation systems is monotonically improved with the increasing size of training corpora for the language model. However, models using larger corpora also consume more resources. In recent years, many methods for improving the efficiency of language models have been proposed to tackle this problem (Pauls and Klein, 2011; Kenneth Heafield, 2011). Such methods not only reduce the required memory size but also raise query speed.

In this paper, we propose the double-array language model (DALM) which uses double-array structures (Aoe, 1989). Double-array structures are widely used in text processing, especially for Japanese. They are known to provide a compact representation of tries (Fredkin, 1960) and fast transitions between trie nodes. The ability to store and manipulate tries efficiently is expected to increase the performance of language models (i.e., improving query speed and reducing the model size in terms of memory) because tries are one of the most common representations of data structures in language models. We use double-array structures to implement a language model since we can utilize their speed and compactness when querying the model about an $n$gram.

In order to utilize of double-array structures as language models, we modify them to be able to store probabilities and backoff weights. We also propose two optimization methods: `embedding` and `ordering`. These methods reduce model size and increase query speed. `Embedding` is an efficient method for storing $n$gram probabilities and backoff weights, whereby we find vacant spaces in the double-array language model structure and populate them with language model information, such as probabilities and backoff weights. `Ordering` is

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 222–232,
Seattle, Washington, USA, 18-21 October 2013.

a method for compacting the double-array structure. DALM uses word IDs for all words of the $n$gram, and `ordering` assigns a word ID to each word to reduce the model size. These two optimization methods can be used simultaneously and are also expected to work well.

In our experiments, we use a language model based on corpora of the NTCIR patent retrieval task (Atsushi Fujii et al., 2007; Atsushi Fujii et al., 2005; Atsushi Fujii et al., 2004; Makoto Iwayama et al., 2003). The model size is 31 GB in the ARPA file format. We conducted experiments focusing on query speed and model size. The results indicate that when the abovementioned optimization methods are used together, DALM outperforms state-of-the-art methods on those points.

2 Related Work

2.1 Tries and Backwards Suffix Trees

Tries (Fredkin, 1960) are one of the most widely used tree structures in $n$gram language models since they can reduce memory requirements by sharing common prefix. Moreover, since the query speed for tries depends only on the number of input words, the query speed remains constant even if the $n$gram model increases in size.

Backwards suffix trees (Bell et al., 1990; Stolcke, 2002; Germann et al., 2009) are among the most efficient representations of tries for language models. They contain $n$grams in reverse order of history words.

Figure 1 shows an example of a backwards suffix tree representation. In this paper, we denote an $n$gram: by the form $w_1, w_2, \cdots, w_n$ as $\boldsymbol{w}_1^n$. In this example, word lists (represented as rectangular tables) contain target words (here, w_n) of $n$grams, and circled words in the tree denote history words (here, $\boldsymbol{w}_1^{n-1}$) associated with target words. The history words "I eat," "you eat", and "do you eat" are stored in reverse order. Querying this trie about an $n$gram is simple: just trace history words in reverse and then find the target word in a list. For example, consider querying about the trigram "I eat fish". First, simply trace the history in the trie in reverse order ("eat" → "I"); then, find "fish" in list <1>. Similarly, querying a backwards suffix tree about unknown $n$grams is also efficient, because the backwards suffix tree

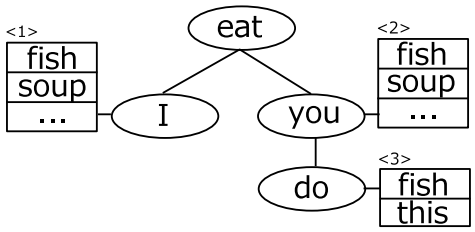

Figure 1: Example of a backwards suffix tree. There are two branch types in a backwards suffix tree: history words and target words. History words are shown in circles and target words are stored in word lists.

representation is highly suitable for the backoff calculation. For example, in querying about the 4gram "do you eat soup", we first trace "eat" → "you" → "do" in a manner similar to above. However, searching for the word "soup" in list <3> fails because list <3> does not contain the word "soup". In this case, we return to the node "you" to search the list <2>, where we find "soup". This means that the trigram "you eat soup" is contained in the tree while the 4gram "do you eat soup" is not. This behavior can be efficiently used for backoff calculation.

SRILM (Stolcke, 2002) is a widely used language model toolkit. It utilizes backwards suffix trees for its data structures. In SRILM, tries are implemented as 64-bit pointer links, which wastes a lot of memory. On the other hand, the access speed for $n$gram probabilities is relatively high.

2.2 Efficient Language Models

In recent years, several methods have been proposed for storing language models efficiently in memory.

Talbot and Osborne (2007) have proposed an efficient method based on bloom filters. This method modifies bloom filters to store count information about training sets. In prior work, bloom filters have been used for checking whether certain data are contained in a set. To store the count information, pairs from <$n$gram,1> to <$n$gram,count> are all added to the set for each $n$gram. To query this language model about the probability of an $n$gram, probabilities are calculated during querying by using these counts. Talbot and Brants (2008) have proposed a method based on perfect hash functions and bloomier filters. This method uses perfect hash functions to store $n$grams and encode values (for exam-

ple, probabilities or counts of $n$grams in the training corpus) to a large array. Guthrie and Hepple (2010) have proposed a language model called ShefLM that uses minimal perfect hash functions (Belazzougui et al., 2009), which can store $n$grams without vacant spaces. Furthermore, values are compressed by *simple dense coding* (Fredriksson and Nikitin, 2007). ShefLM achieves a high compression ratio when it stores counts of $n$grams in the training corpus. However, when this method stores probabilities of $n$grams, the advantage of using compression is limited because floating-point numbers are difficult to compress. Generally, compression is performed by combining the same values but, two floating-point numbers are rarely the same, especially in the case of probability values[1]. These methods implement lossy language models, meaning that, we can reduce the model size at the expense of model quality. These methods also reduce the model performance (perplexity).

Pauls and Klein (2011) have proposed BerkeleyLM which is based on an *implicit encoding* structure, where $n$grams are separated according to their order, and are sorted by word ID. The sorted $n$grams are linked to each other like a trie structure. BerkeleyLM provides rather efficient methods. Variable-length coding and block compression are used if small model size is more important than query speed. In addition, Heafield (2011) has proposed an efficient language model toolkit called KenLM that has been recently used in machine translation systems, for which large language models are often needed. KenLM has two different main structure types: `trie` and `probing`. The `trie` structure is compact but relatively slower to query, whereas the `probing` structure is relatively larger but faster to query.

In this paper, we propose a language model structure based on double-array structures. As we describe in Section 3, double-array structures can be used as fast and compact representations of tries. We propose several techniques for maximizing the performance of double-array structures from the perspective of query speed and model size.

[1]In our experience, it is considerably easier to compress backoff weights than to compress probabilities, although both are represented with floating-point numbers. We use this knowledge in our methods.

3 Double-Array

3.1 Double-Array Structure

In DALM, we use a double-array structure (Aoe, 1989) to represent the trie of a language model. Double-array structures are trie representations consisting of two parallel arrays: $BASE$ and $CHECK$. They are not only fast to query, but also provide a compact way to store tries. In the structure, nodes in the trie are represented by slots with the same index in both arrays. Before proposing several efficient language model representation techniques in Section 4, we introduce double-array themselves. In addition, the construction algorithms for double-arrays are described in Section 3.2 and Section 3.3.

The most naive implementation of a trie will have a two-dimensional array $NEXT$. Let WORDID (w) be a function that returns a word ID as a number corresponding to its argument word w; then $NEXT[n]$[WORDID (w)] (that presents the $WORDID(w)$-th slot of the nth row in the $NEXT$ array) stores the node number which can be transit from the node number n by the word w, and we can traverse the trie efficiently and easily to serialize the array in memory. This idea is simple but wastes the most of the used memory because almost all of the slots are unused and this results in occupying memory space. The double-array structures solve this problem by taking advantage of the sparseness of the $NEXT$ array. The two-dimensional array $NEXT$ is merged into a one-dimensional array $BASE$ by shifting the entries of each row of the $NEXT$ array and combining the set of resulting arrays. We can store this result in much less memory than the serialization of the naive implementation above. Additionally, a $CHECK$ array is introduced to check whether the transition is valid or not because we cannot distinguish which node the information in a particular slot comes from. Using a $CHECK$ array, we can avoid transition errors and move safely to the child node of any chosen node.

As a definition, a node link from a node n_s with a word w to the next node n_{next}in the trie is defined as follows:

$$\begin{aligned} next \quad &\leftarrow \quad BASE[s] + \text{WORDID}\,(w) \\ &if \quad CHECK[next] == s \end{aligned}$$

where s denotes the index of the slot in the double-

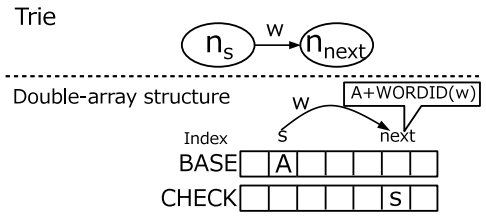

Figure 2: A trie and a corresponding double-array structure. Node n_s is represented by the slots $BASE[s]$ and $CHECK[s]$. A link from a node n_s with a word w is indicated by $CHECK[next] == s$.

array structure which represents n_s. The trie transition from a node n_s with a word w is applied according to the following steps:

Step 1 Calculating the "$next$" destination and

Step 2 Checking whether the transition is correct.

Step 2 specifically means the following:

1. If $CHECK[next] == s$, then we can "move" to the node n_{next};

2. otherwise, we can detect that the transition from the node n_s with the word w is not contained in the trie.

Figure 2 shows an example of a transition from a parent node n_s with a word w.

Next, we describe how the existence of an $n$gram history can be determined (Aoe, 1989). We can iterate over the nodes by the transitions shown above and may find the node representing an $n$gram history. But we should check that it is valid because nodes except for leaf nodes possiblly represent a fragment of some total $n$gram history. We can use *endmarker* symbols to determine whether an $n$gram history is in the trie. We add nodes meaning the *endmarker* symbol after the last node of each $n$gram history. When querying about $\boldsymbol{w}_1^{n-1}$, we transit repeatedly; in other words, we set $s = 0$ and start by applying Step 1 and 2 repeatedly for each word. When we reach the node w_{n-1}, we continue searching for an *endmarker* symbol. If the symbol is found, we know that the $n$gram history $\boldsymbol{w}_1^{n-1}$ is in the trie.

The double-array structure consumes 8 bytes per node because the $BASE$ and $CHECK$ arrays are 4 byte array variables. Therefore, the structure can store nodes compactly in case of a high filling rate. Moreover, node transitions are very fast because they require only one addition and one comparison per transition. We use a double-array structure in DALM, which can maximize its potential.

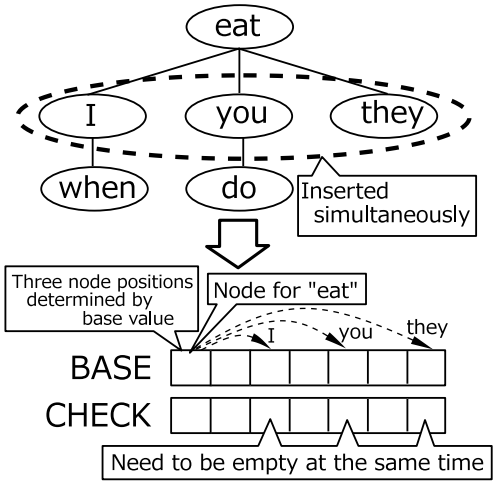

Figure 3: Greedy insertion of trie elements. The children of a node are collectively inserted into the double-array when the $BASE$ value of the node is fixed.

3.2 Greedy Construction

Greedy algorithms are widely used for constructing static double-array structures[2]. The construction steps are as follows:

1. Define the root node of a trie to correspond to index 0 of the double-array structure and

2. Find the $BASE$ value greedily (i.e., in order $1, 2, 3, \cdots$) for all nodes which have fixed their indices in the double-array structure.

In practice, once the $BASE$ value of a node is fixed, the positions of its children are fixed at the same time, and we can find the $BASE$ values for each child recursively.

Figure 3 shows an example of such construction. In this example, three nodes ("I", "you" and "they") are inserted at the same time. This is because the above three node positions are fixed by the $BASE$ value of the node "eat". To insert nodes

[2]We were unable to find an original source for this technique. However, this method is commonly used in double-array implementations.

"I", "you" and "they", the following three slots must be empty (i.e., the slots must not be used by other nodes.):

- $BASE[s]$ + WORDID("I")
- $BASE[s]$ + WORDID("you")
- $BASE[s]$ + WORDID("they")

where s is the index of the node "eat". At the construction step, we need to find $BASE[s]$ which satisfies the above conditions.

3.3 Efficient Construction Algorithm

The construction time for a double-array structure poses the greatest challenge. We use a more efficient method (Nakamura and Mochizuki, 2006) instead of the naive method for constructing a double-array structure because the naive method requires a long time. We call the method "empty doubly-linked list". This algorithm is one of the most efficient construction methods devised to date. Figure 4 shows an example of an empty doubly-linked list. We can efficiently define the $BASE$ value of each node by using the $CHECK$ array to store the next empty slot. In this example, in searching the $BASE$ value of a node, the first child node can be set to position 1, and if that fails, we can successively try positions $3, 4, 6, 8, \cdots$ by tracing the list instead of searching all $BASE$ values $0, 1, 2, 3, 4, 5, \cdots$.

As analyzed by Nakamura and Mochizuki(2006), the computational cost of a node insertion is less than in the naive method. The original naive method requires $O(NM)$ time for a node insertion, where M is a number of unique word types and N is a number of nodes of the trie; the algorithm using an empty double-linked list requires $O(UM)$, where U is the number of unused slots.

As described in Section 5, we divide the trie into several smaller tries and apply the efficient method for constructing our largest models. This is because it is not feasible to wait several weeks for the large language model structure to be built. The dividing method is currently the only method allowing us to build them.

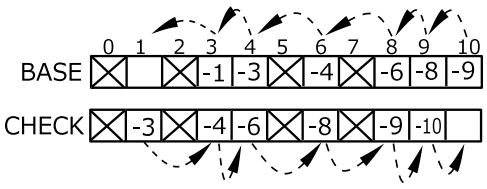

Figure 4: Empty doubly-linked list. Unused $CHECK$ slots are used to indicate the next unused slots, and unused $BASE$ slots are used to indicate previous unused slots. Thus, the $BASE$ and $CHECK$ arrays are used as a doubly-linked list which can reduce the number of ineffective trials.

4 Proposed Methods

4.1 DALM

In this section, we present the application of the double-array structure to backwards suffix trees. As this is the most basic structure based on double-array structures, we refer to it as the `simple` structure and improve its performance as described in the following sections.

To represent a backwards suffix tree as a double-array structure, we should modify the tree because it has two types of branches (target words and history nodes), which must be distinguished in the double-array structure. Instead, we should distinguish the branch type which indicates whether the node is a target word or a history word. We use the *endmarker* symbol (<#>) for branch discrimination. In prior work, the *endmarker* symbol has been used to indicate whether an $n$gram is in the trie. However, there is no need to distinguish whether the node of the tree is included in the language model because all nodes of a backwards suffix tree which represents $n$grams surely exist in the model. We use the *endmarker* symbol to indicate nodes which are end-of-history words. Therefore, target words of $n$grams are children of the *endmarker* symbols that they follow.

By using the *endmarker* symbol, target words can be treated the same as ordinary nodes because all target words are positioned after <#>. Figure 5 shows an example of such construction. We can clearly distinguish target words and history words in the backwards suffix tree.

Querying in the tree is rather simple. For example, consider the case of a query trigram "I eat fish" in the trie of Figure 5. We can trace this trigram in

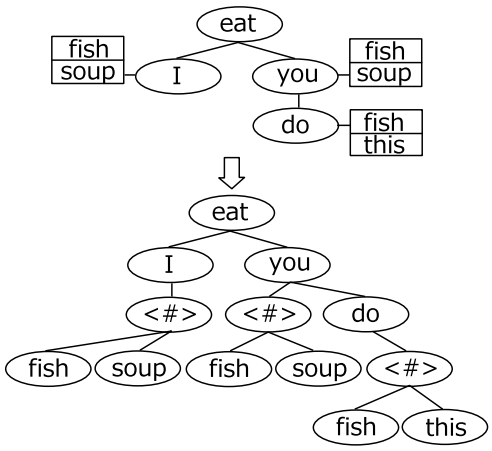

Figure 5: An example of converting a backwards suffix tree. We introduce *endmarker* symbols to distinguish the two branch types. We can treat the tree as an ordinary trie that can be represented by a double-array structure while retaining the advantages of the tree structure.

the same way as the original backwards suffix tree. First, we trace "eat" → "I", then trace that to the *endmarker* symbol <#> and finally find the word "fish".

Next, we describe the procedure for storing probabilities and backoff weights. We prepare a $VALUE$ array to store the probabilities and backoff weights of $n$grams. Figure 6 shows the `simple` DALM structure. The backwards suffix tree stores a backoff weight for each node and a probability for each target word. In `simple` DALM, each value is stored for the respective position of the corresponding node.

4.2 `Embedding`

`Embedding` is a method for reducing model size. In the `simple` DALM structure, there are many vacant spaces in the $BASE$ and $CHECK$ arrays. We use these vacant spaces to store backoff weights and probabilities. Figure 7 shows vacant spaces in the `simple` DALM structure.

First, the $BASE$ array slots of target word nodes are unused because target words are always in leaf positions in the backwards suffix tree and do not have any children nodes. In the example of Figure 7, $BASE[9]$ is not used, and therefore can be used for storing a probability value. This method can reduce the model size because all probabilities are stored into the $BASE$ array. As a result, the $VALUE$ array

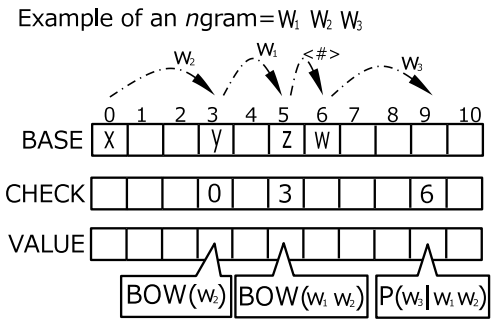

Figure 6: The `simple` DALM data structure. The $BASE$ and $CHECK$ arrays are used in the same way as in a double-array structure. To return probabilities and backoff weights, a $VALUE$ array is introduced.

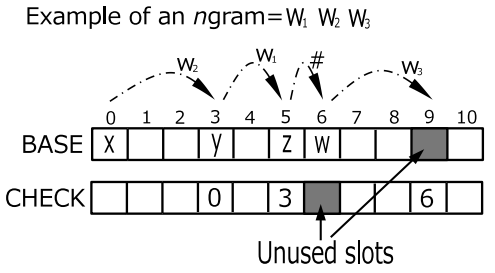

Figure 7: Unused slots in the `simple` DALM structure used for other types of information, such as probabilities.

contains only backoff weights.

Next, the $CHECK$ array slots of *endmarker* symbols are also vacant. We do not need to check for *endmarker* symbol transition because the *endmarker* symbol <#> is seen for all nodes except target word nodes. This means that all *endmarker* symbol transitions are ensured to be correct and the $CHECK$ array slots of *endmarker* symbols do not need to be used. We use this space to store backoff weights.

In order to avoid false positives, we cannot store backoff weights directly. Instead, we store the positions of the backoff weights in the $VALUE$ array as negative numbers. When a query for an unknown $n$gram encounters an *endmarker* symbol node, the value of the $CHECK$ array is never matched because the corresponding value stored there is negative. The same values in the $VALUE$ array can be unified to reduce the memory requirements. Figure 8 illustrates an example of the `embedding` method.

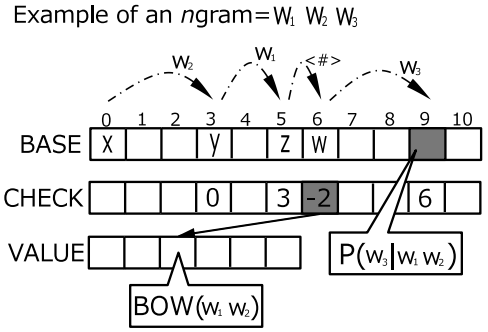

Figure 8: Implementation of the `embedding` method. We use vacant spaces in the $VALUE$ array to store the probabilities and indices of backoff weights. The indices of backoff weights are taken with a negative sign to avoid false positives. Backoff weights are stored in the $VALUE$ array, and the same values in the $VALUE$ array can be unified.

4.3 `Ordering`

`Ordering` is a method for shortening the double-array structure and increasing the query speed. In `ordering`, word IDs are assigned in order of unigram probability. This is done at a preprocessing stage, before the DALM is built.

Before explaining the reasons why this method is effective, we present an *interpretation* of double-array construction in Figure 9 which corresponds to the case presented in Figure 3. In the previous section, we pointed out that the insertion problem is equivalent to the problem of finding the $BASE$ value of the parent node. Here, we expand this further into the idea that finding the $BASE$ value is equivalent to the problem of finding the shift length of an *insertion array*. We can create an *insertion array* which is an array of flag bits set to 1 at the positions of word IDs of children nodes' words. Moreover, we prepare a *used array* which is also a flag bit array denoting whether the original slots in the double-array structure are occupied. In this situation, finding the shift length is equivalent to the problem of finding the $BASE$ value of the slot for the node "eat", and the combined *used array* denotes the size of the double-array structure after insertion.

Figure 10 shows an intuitive example illustrating the efficiency of the `ordering` method. When word IDs are assigned in order of unigram probability, 1s in the *insertion array* are gathered toward

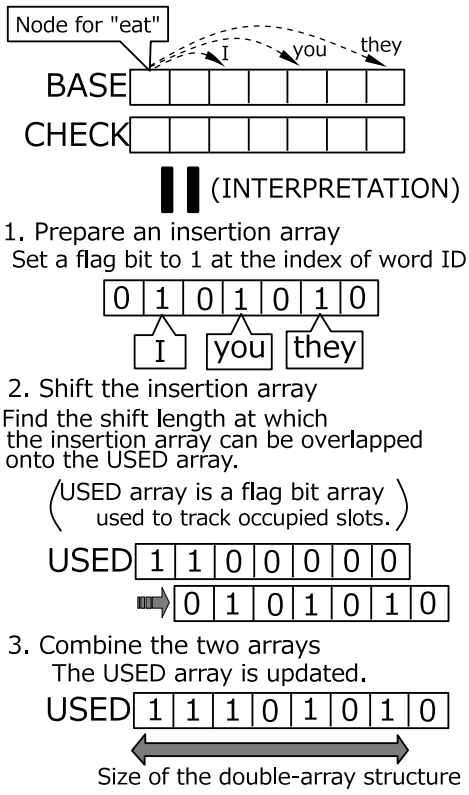

Figure 9: Interpretation of a double-array construction. The insertion problem for the double-array structure is interpreted as a finding problem of a shift length of the insertion array. We can measure the size of the double-array structure in the *used array*.

the beginning of the array. This means that 1s in the *insertion array* form clusters, which makes insertion easier than for unordered *insertion arrays*. This shortens the shift lengths for each insertion array: a shorter double-array structure results.

5 Experiment

5.1 Experimental Setup

To compare the performance of DALM with other methods, we conduct experiments on two $n$gram models built from small and large training corpora. Table 1 shows the specifications of the model.

Training data are extracted from the *Publication of unexamined Japanese patent applications*, which is distributed with the NTCIR 3,4,5,6 patent retrieval task (Atsushi Fujii et al., 2007; Atsushi Fujii et al., 2005; Atsushi Fujii et al., 2004; Makoto Iwayama et al., 2003). We used data for the period from

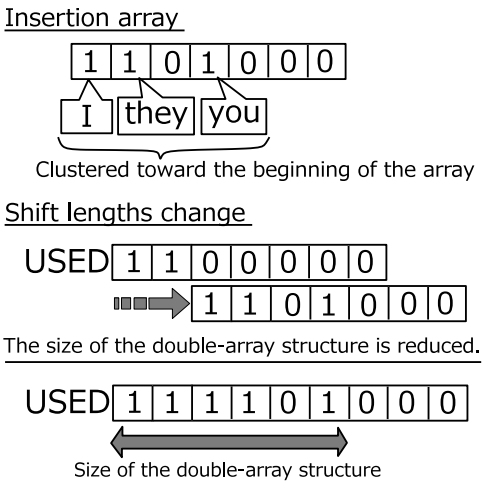

Figure 10: An example of word ID `ordering` efficiency. Word IDs in the insertion array are packed to the front in advance. Therefore, shift lengths for ordered arrays are often shorter than unordered ones. The resulting size of the double-array structure is expected to be smaller than that of an unordered array.

Table 1: Corpus and model specifications.

Model	Corpus Size (words)	Unique Type (words)	Ngram Type (1-5gram)
100 Mwords	100 M	195 K	31 M
5 Gwords	5 G	2,140 K	936 M
Test set	100 M	198 K	-

1,993 to 2,002 and extracted paragraphs containing "background" and "example". This method is similar to the NTCIR 7 Patent Translation Task(Fujii et al., 2008). The small and large training data sets contained 100 Mwords and 5 Gwords, respectively. Furthermore, we sampled another 100 Mwords as a test set to measure the access speed for extracting $n$gram probabilities. We used an Intel® Xeon® X5675 (3.07 GHz) 24-core server with 142 GB of RAM.

Our experiments were performed from the viewpoints of speed and model size. We executed each program twice, and the results of the second run were taken as the final performance.

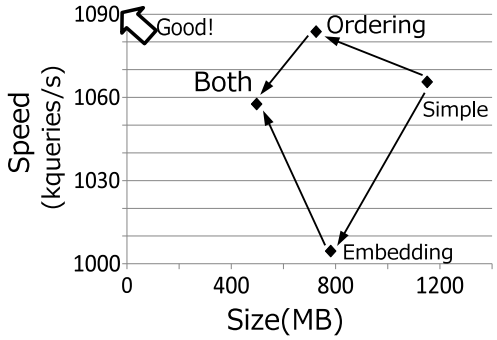

Figure 11: Comparison between tuned and non-tuned double-array structures.

Table 2: Comparison between tuned and non-tuned double-array structures.

Method	Size (MB)	Speed (queries/s)
`Simple`	1,152	1,065,536
`Embedding`	782	1,004,555
`Ordering`	726	1,083,703
`Both`	498	1,057,607

5.2 Optimization Methods

We compared the performance of the DALMs proposed here, namely `simple`, `embedding`, `ordering` and `both`, where `both` indicates that the language model uses both `embedding` and `ordering`. We conducted experiments examining how these methods affect the size of the double-array structures and the query speeds. We used the 100 Mwords model in the comparison because it was difficult to build a DALM using the 5 Gwords model.

The results are shown in Figure 11 and Table 2. While both `ordering` and `embedding` decreased the model size, the query speed was increased by the former and decreased by the latter. `Both` was the smallest and most balanced method.

5.3 Divided Double-Array Structure

Building a double-array structure requires a long time, which can sometimes be impractical. In fact, as mentioned above, waiting on construction of the double-array structure of the 5 Gwords model is infeasible.

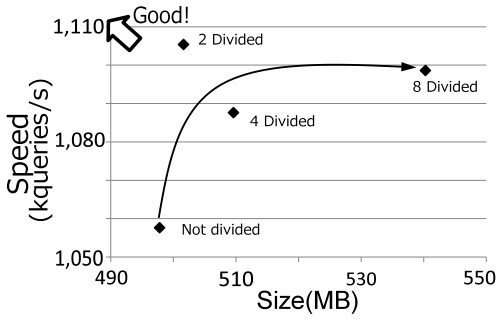

Figure 12: Comparison between divided and original double-array structures.

As described in Section 3.3, the efficient algorithm requires $O(UM)$ time to insert one node and the insertion is iterated N (the total number of insertions) times. If we assume that the number of unused slots at the ith insertion, U_i, is proportional to i, or that $U_i = c \times i$ where c is a proportionality constant, we can calculate the building time as follows: $\sum_{i=1}^{N} U_i M = O\left(MN^2\right)$.

To shorten the build time, we divided the original trie into several parts. Building parts of the original trie is possible because N is reduced. Moreover, these double-array structures can be built in parallel. Note that query results for both original and divided tries are completely equivalent because divided tries hold all the $n$gram statistics of the original trie. This method is similar to that used in *randomized language models* (Talbot and Brants, 2008).

We compared the differences between the methods using the original and divided double-array structures. In the comparison, we also used the 100 Mwords model with the `both` optimization method described in the previous section (Figure 12 and Table 3).

Although dividing the trie increased the size of the DALM slightly, the model size was still smaller than that without optimization. Query speed increased as the number of parts was increased. We attributed this to the divided DALM consisting of several double-array structures, each smaller than the undivided structure which results in an increase. Figure 12 shows that there is a trade-off relation between model size and query speed.

Below, we use the 5 Gwords model in our experiments. In our environment, building a 5 Gwords double-array structure required about 4 days when the double-array structures were divided into 8 parts, even though we used the more efficient algorithm described in Section 3.3. The time required for building the model when the original structure was divided into less than 8 parts was too long. Thus, a more efficient building algorithm is essential for advancing this research further.

Table 3: Comparison between divided and original double-array structures.

Number of parts	Size (MB)	Speed (queries/s)
1	498	1,057,607
2	502	1,105,358
4	510	1,087,619
8	540	1,098,594

5.4 Comparison with Other Methods

Using the 100 Mwords and 5 Gwords models, we compared DALM with other methods (KenLM (Kenneth Heafield, 2011) and SRILM (Stolcke, 2002)). In this experiment, we used the `both` method (which is mentioned above) for DALM and divided the original trie into 8 parts and built double-array structures.

The results are shown in Figure 13 and Table 4; the group on the left shows the results for the 100 Mwords model and the group on the right shows the results for the 5 Gwords model.

The experimental results clearly indicate that DALM is the fastest of all the compared methods and that the model size is nearly the same or slightly smaller than that of KenLM (`Probing`). Whereas KenLM (`Trie`) is the smallest model, it is slower than DALM.

The differences between the 5 Gwords versions of DALM and KenLM (`Probing`) are smaller in comparison with the 100 Mwords models. This is because hash-based language models have an advantage when storing higher-order $n$grams. Large language models have more 5grams, which leads to shorter backoff times. On the other hand, trie-based language models have to trace higher-order $n$grams for every query, which requires more time.

Finally, we discuss practical situations. We con-

Table 4: Comparison between DALM and other methods.

LM	100 Mwords Model		5 Gwords Model	
	Size (MB)	Speed (queries/s)	Size (MB)	Speed (queries/s)
SRILM	1,194	894,138	31,747	729,447
KenLM (`Probing`)	665	1,002,489	18,685	913,208
KenLM (`Trie`)	340	804,513	9,606	635,300
DALM (8 parts)	540	1,098,594	15,345	953,186

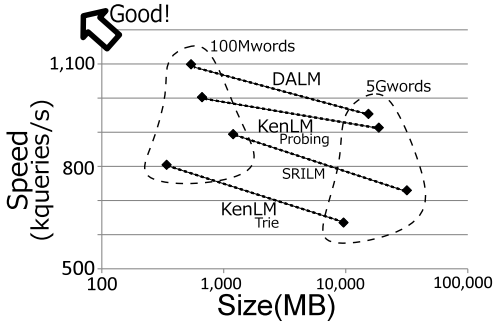

Figure 13: Comparison between DALM and other language model systems.

ducted this study's experiments using test set text written by humans. In some applications such as statistical machine translations, language model systems should compute probabilities of many unnatural $n$grams which will be unknown. This may affect query speed because querying unknown and unnatural $n$grams generate many backoffs. They may results in trie-based LM being slightly faster, because traversing the trie can stop immediately when it detects that a queried $n$gram history is not contained in the trie. On the other hand, hash-based LM such as KenLM probing would repeat queries until finding truncated $n$gram histories in the trie.

6 Conclusion

We proposed a method for implementing language models based on double-array structures. We call this method DALM. Moreover, we proposed two methods for optimizing DALM: `embedding` and `ordering`. `Embedding` is a method whereby empty spaces in arrays are used to store $n$gram probabilities and backoff weights, and `ordering` is a method for numbering word IDs; these methods reduce model size and increase query speed. These two optimization methods work well independently, but even better performance can be achieved if they are combined.

We also used a division method to build the model structure in several parts in order to speed up the construction of double-array structures. Although this procedure results in a slight increase in model size, the divided double-array structures mostly retained the compactness and speed of the original structure. The time required for building double-array structures is the bottleneck of DALM as it is sometimes too long to be practical, even though the model structure itself achieves high performance. In future work, we will develop a faster algorithm for building double-array structures.

While DALM has outperformed state-of-the-art language model implementations methods in our experiments, we should continue to consider ways to optimize the method for higher-order $n$grams.

Abstract

Language models can be formalized as log-linear regression models where the input features represent previously observed contexts up to a certain length m. The complexity of existing algorithms to learn the parameters by maximum likelihood scale linearly in nd, where n is the length of the training corpus and d is the number of observed features. We present a model that grows logarithmically in d, making it possible to efficiently leverage longer contexts. We account for the sequential structure of natural language using tree-structured penalized objectives to avoid overfitting and achieve better generalization.

1 Introduction

Language models are crucial parts of advanced natural language processing pipelines, such as speech recognition (Burget et al., 2007), machine translation (Chang and Collins, 2011), or information retrieval (Vargas et al., 2012). When a sequence of symbols is observed, a language model predicts the probability of occurrence of the next symbol in the sequence. Models based on so-called back-off smoothing have shown good predictive power (Goodman, 2001). In particular, Kneser-Ney (KN) and its variants (Kneser and Ney, 1995) are still achieving state-of-the-art results for more than a decade after they were originally proposed. Smoothing methods are in fact clever heuristics that require tuning parameters in an ad-hoc fashion. Hence, more principled ways of learning language models have been proposed based on maximum entropy (Chen and Rosenfeld, 2000) or conditional random fields (Roark et al., 2004), or by adopting a Bayesian approach (Wood et al., 2009).

In this paper, we focus on penalized maximum likelihood estimation in log-linear models. In contrast to language models based on *unstructured* norms such as ℓ_2 (quadratic penalties) or ℓ_1 (absolute discounting), we use *tree-structured* norms (Zhao et al., 2009; Jenatton et al., 2011). Structured penalties have been successfully applied to various NLP tasks, including chunking and named entity recognition (Martins et al., 2011), but not language modelling. Such penalties are particularly well-suited to this problem as they mimic the nested nature of word contexts. However, existing optimizing techniques are not scalable for large contexts m.

In this work, we show that structured tree norms provide an efficient framework for language modelling. For a special case of these tree norms, we obtain an memory-efficient learning algorithm for log-linear language models. Furthermore, we aslo give the first efficient learning algorithm for structured ℓ_∞ tree norms with a complexity nearly linear in the number of training samples. This leads to a memory-efficient *and* time-efficient learning algorithm for generalized linear language models.

The paper is organized as follows. The model and other preliminary material is introduced in Section 2. In Section 3, we review unstructured penalties that were proposed earlier. Next, we propose structured penalties and compare their memory and time requirements. We summarize the characteristics of the proposed algorithms in Section 5 and experimentally validate our findings in Section 6.

Subfigure (c) shows vector after proximal projection for ℓ_2^T-norm (which cannot be collapsed), and Subfigure (d) that of ℓ_∞^T-norm proximal projection which can be collapsed.

2 Log-linear language models

Multinomial logistic regression and Poisson regression are examples of log-linear models (McCullagh and Nelder, 1989), where the likelihood belongs to an exponential family and the predictor is linear. The application of log-linear models to language modelling was proposed more than a decade ago (Della Pietra et al., 1997) and it was shown to be competitive with state-of-the-art language modelling such as Knesser-Ney smoothing (Chen and Rosenfeld, 2000).

2.1 Model definition

Let V be a set of words or more generally a set of symbols, which we call vocabulary. Further, let xy be a sequence of $n+1$ symbols of V, where $x \in V^n$ and $y \in V$. We model the probability that symbol y succeeds x as

$$P(y = v|x) = \frac{e^{w_v^\top \phi_m(x)}}{\sum_{u \in V} e^{w_u^\top \phi_m(x)}}, \qquad (1)$$

where $W = \{w_v\}_{v \in V}$ is the set of parameters, and $\phi_m(x)$ is the vector of features extracted from x, the sequence preceding y. We will describe the features shortly.

Let $x_{1:i}$ denote the subsequence of x starting at the first position up to the i^{th} position and y_i the next symbol in the sequence. Parameters are estimated by minimizing the penalized log-loss:

$$W^* \in \operatorname*{argmin}_{W \in \mathcal{K}} f(W) + \lambda \Omega(W), \qquad (2)$$

where $f(W) := -\sum_{i=1}^n \ln p(y_i|x_{1:i}; W)$ and $\mathcal{K}$ is a convex set representing the constraints applied on the parameters. Overfitting is avoided by adjusting the regularization parameter λ, e.g., by cross-validation.

2.2 Suffix tree encoding

Suffix trees provide an efficient way to store and manipulate discrete sequences and can be constructed in linear time when the vocabulary is fixed (Giegerich and Kurtz, 1997). Recent examples include language models based on a variable-length Markovian assumption (Kennington et al., 2012) and the sequence memoizer (Wood et al., 2011). The suffix tree data structure encodes all the unique suffixes observed in a sequence up to a maximum given length. It exploits the fact that the set of observed contexts is a small subset of all possible contexts. When a series of suffixes of increasing lengths are

Algorithm 1 $W^* := \operatorname{argmin} \{f(X, Y; W) + \lambda\Omega(W)\}$ Stochastic optimization algorithm (Hu et al., 2009)

Input: λ regularization parameter , L Lipschitz constant of ∇f , μ coefficient of strong-convexity of $f + \lambda\Omega$, X design matrix, Y label set
Initialize: $\overline{W} = Z = 0$, $\tau = \delta = 1$, $\rho = L + \mu$
repeat until maximum iterations
  #estimate point for gradient update
  $\overline{W} = (1 - \tau)W + \tau Z$
  #use mini-batch $\{X_\vartheta, Y_\vartheta\}$ for update
  W = ParamUpdate$(X_\vartheta, Y_\vartheta, \overline{W}, \lambda, \rho)$
  #weighted combination of estimates
  $Z = \frac{1}{\rho\tau + \mu}\big((1 - \mu)Z + (\mu - \rho)\overline{W} + \rho W\big)$
  #update constants
  $\rho = L + \mu/\delta$, $\tau = \frac{\sqrt{4\delta + \delta^2} - \delta}{2}$, $\delta = (1 - \tau)\delta$

Procedure: $W :=$ ParamUpdate$(X_\vartheta, Y_\vartheta, \overline{W}, \lambda, \rho)$
  $W' = \overline{W} - \frac{1}{\rho}\nabla f(X_\vartheta, Y_\vartheta, \overline{W})$ #gradient step
  $W = [W]_+$ #projection to non-negative orthant
  $W = \Pi_\Omega(w, \kappa)$ #proximal step

always observed in the same context, the successive suffixes are collapsed into a single node. The uncollapsed version of the suffix tree T is called a suffix *trie*, which we denote S. A suffix trie also has a tree structure, but it potentially has much larger number of nodes. An example of a suffix trie S and the associated suffix tree T are shown in Figures 1(a) and 1(b) respectively. We use $|S|$ to denote the number of nodes in the trie S and $|T|$ for the number of nodes in the tree T.

Suffix tree encoding is particularly helpful in applications where the resulting hierarchical structures are thin and tall with numerous non-branching paths. In the case of text, it has been observed that the number of nodes in the tree grows slower than that of the trie with the length of the sequence (Wood et al., 2011; Kennington et al., 2012). This is a significant gain in the memory requirements and, as we will show in Section 4, can also lead to important computational gains when this structure is exploited.

The feature vector $\phi_m(x)$ encodes suffixes (or contexts) of increasing length up to a maximum length m. Hence, the model defined in (1) is similar to m-gram language models. Naively, the feature vector $\phi_m(x)$ corresponds to one path of length m starting at the root of the suffix trie S. The entries in W correspond to weights for each suffix. We thus have a trie structure S on W (see Figure 1(a)) constraining the number of free parameters. In other words, there is one weight parameter per node in the trie S and the matrix of parameters W is of size $|S|$.

In this work, however, we consider models where the number of parameters is equal to the size of the suffix tree T, which has much fewer nodes than S. This is achieved by ensuring that all parameters corresponding to suffixes at a node share the same parameter value (see Figure 1(b)). These parameters correspond to paths in the suffix trie that do not branch *i.e.* sequence of words that always appear together in the same order.

2.3 Proximal gradient algorithm

The objective function (2) involves a smooth convex loss f and a possibly non-smooth penalty Ω. Subgradient descent methods for non-smooth Ω could be used, but they are unfortunately very slow to converge. Instead, we choose proximal methods (Nesterov, 2007), which have fast convergence rates and can deal with a large number of penalties Ω, see (Bach et al., 2012).

Proximal methods iteratively update the current estimate by making a generalized gradient update at each iteration. Formally, they are based on a linearization of the smooth function f around a parameter estimate $\overline{W}$, adding a quadratic penalty term to keep the updated estimate in the neighborhood of $\overline{W}$. At iteration t, the update of the parameter W is given by

$$W^{t+1} = \operatorname*{argmin}_{W \in \mathcal{K}} \Big\{ f(\overline{W}) + (W - \overline{W})^\top \nabla f(\overline{W}) + \Omega(W) + \frac{L}{2}\|W - \overline{W}\|_2^2 \Big\}, \quad (3)$$

where $L > 0$ is an upper-bound on the Lipschitz constant of the gradient ∇f. The matrix $\overline{W}$ could either be the current estimate W^t or its weighted combination with the previous estimate for accelerated convergence depending on the specific algorithm used (Beck and Teboulle, 2009). Equation (3) can be rewritten to be solved in two independent steps: a gradient update from the smooth part followed by a projection depending only on the non-smooth penalty:

$$W' = \overline{W} - \frac{1}{L}\nabla f(\overline{W}), \quad (4)$$

$$W^{t+1} = \operatorname*{argmin}_{W \in \mathcal{K}} \frac{1}{2} \left\| W - W' \right\|_2^2 + \frac{\lambda \Omega(W)}{L}. \quad (5)$$

Update (5) is called the proximal operator of W' with parameter $\frac{\lambda}{L}$ that we denote $\Pi_\Omega \left(W', \frac{\lambda}{L} \right)$. Efficiently computing the proximal step is crucial to maintain the fast convergence rate of these methods.

2.4 Stochastic proximal gradient algorithm

In language modelling applications, the number of training samples n is typically in the range of 10^5 or larger. Stochastic version of the proximal methods (Hu et al., 2009) have been known to be well adapted when n is large. At every update, the stochastic algorithm estimates the gradient on a mini-batch, that is, a subset of the samples. The size of the mini-batches controls the trade-off between the variance in the estimate of gradient and the time required for compute it. In our experiments we use mini-batches of size 400. The training algorithm is summarized in Algorithm 1. The acceleration is obtained by making the gradient update at a specific weighted combination of the current and the previous estimates of the parameters. The weighting is shown in step 6 of the Algorithm 1.

2.5 Positivity constraints

Without constraining the parameters, the memory required by a model scales linearly with the vocabulary size $|V|$. Any symbol in V observed in a given context is a positive example, while any symbols in V that does not appear in this context is a negative example. When adopting a log-linear language model, the negative examples are associated with a small negative gradient step in (4), so that the solution is not sparse accross multiple categories in general. By constraining the parameters to be positive (i.e., the set of feasible solutions $\mathcal{K}$ is the positive orthant), the projection step 2 in Algorithm 1 can be done with the same complexity, while maintaining sparse parameters accross multiple categories. More precisely, the weights for the category k associated to a given context x, is always zeros if the category k never occured after context x. A significant gain in memory (nearly $|V|$-fold for large context lengths) was obtained without loss of accuracy in our experiments.

3 Unstructured penalties

Standard choices for the penalty function $\Omega(W)$ include the ℓ_1-norm and the squared ℓ_2-norm. The former typically leads to a solution that is sparse and easily interpretable, while the latter leads to a non-sparse, generally more stable one. In particular, the squared ℓ_2 and ℓ_1 penalties were used in the context of log-linear language models (Chen and Rosenfeld, 2000; Goodman, 2004), reporting performances competitive with bi-gram and tri-gram interpolated Kneser-Ney smoothing.

3.1 Proximal step on the suffix trie

For squared ℓ_2 penalties, the proximal step $\Pi_{\ell_2^2}(w^t, \frac{\kappa}{2})$ is the element-wise rescaling operation:

$$w_i^{(t+1)} \leftarrow w_i^{(t)} (1 + \kappa)^{-1} \quad (6)$$

For ℓ_1 penalties, the proximal step $\Pi_{\ell_1}(w^t, \kappa)]$ is the soft-thresholding operator:

$$w_i^{(t+1)} \leftarrow \max(0, w_i^{(t)} - \kappa). \quad (7)$$

These projections have linear complexity in the number of features.

3.2 Proximal step on the suffix tree

When feature values are identical, the corresponding proximal (and gradient) steps are identical. This can be seen from the proximal steps (7) and (6), which apply to single weight entries. This property can be used to group together parameters for which the feature values are equal. Hence, we can collapse successive nodes that always have the same values in a suffix trie (as in Figure 1(b)), that is to say we can directly work on the suffix tree. This leads to a proximal step with complexity that scales linearly with the number of symbols seen in the corpus (Ukkonen, 1995) and logarithmically with context length.

4 Structured penalties

The ℓ_1 and squared ℓ_2 penalties do not account for the sequential dependencies in the data, treating suffixes of different lengths equally. This is inappropriate considering that longer suffixes are typically observed less frequently than shorter ones. Moreover, the fact that suffixes might be nested is disregarded. Hence, we propose to use the tree-structured

Algorithm 2 $w := \Pi_{\ell_2^T}(w, \kappa)$ Proximal projection step for ℓ_2^T on grouping $\mathcal{G}$.

Input: T suffix tree, w trie-structured vector, κ threshold
Initialize: $\{\gamma_i\} = 0$, $\{\eta_i\} = 1$
η = UpwardPass(η, γ, κ, w)
w = DownwardPass(η, w)

Procedure: η := UpwardPass(η, γ, κ, w)
for $x \in$ DepthFirstSuffixTraversal(T, *PostOrder*)
  $\gamma_x = w_x^2 + \sum_{h \in children(x)} \gamma_h$
  $\eta_x = [1 - \kappa/\sqrt{\gamma_x}]_+$
  $\gamma_x = \eta_x^2 \gamma_x$

Procedure: w := DownwardPass(η, w)
for $x \in$ DepthFirstSuffixTraversal(T, *PreOrder*)
  $w_x = \eta_x w_x$
  for $h \in children(x)$
    $\eta_h = \eta_x \eta_h$

a DepthFirstSuffixTraversal(T,*Order*) returns observed suffixes from the suffix tree T by depth-first traversal in the order prescribed by *Order*.
b w_x is the weights corresponding to the suffix x from the weight vector w and $children(x)$ returns all the immediate children to suffix x in the tree.

Algorithm 3 $w := \Pi_{\ell_\infty^T}(w, \kappa)$ Proximal projection step for ℓ_∞^T on grouping $\mathcal{G}$.

Input: T suffix tree, w=[v c] tree-structured vector v with corresponding number of suffixes collapsed at each node in c, κ threshold
for $x \in$ DepthFirstNodeTraversal(T, *PostOrder*)
  $g(v, x) := \pi_{\ell_\infty^T}(\, g(v, x), c_x \kappa\,)$

Procedure: $q := \pi_{\ell_\infty}(q, \kappa)$
Input: $q = [v\ c],\ q_i = [v_i\ c_i],\ i = 1, \cdots, |q|$
Initialize: $U = \{\}, L = \{\}, I = \{1, \cdots, |q|\}$
while $I \neq \varnothing$
  pick random $\rho \in I$ #choose pivot
  $U = \{j | v_j \geq v_\rho\}$ #larger than v_ρ
  $L = \{j | v_j < v_\rho\}$ #smaller than v_ρ
  $\delta S = \sum_{i \in U} v_i \cdot c_i,\ \delta C = \sum_{i \in U} c_i$
  if $(S + \delta S) - (C + \delta C)\rho < \kappa$
    $S := (S + \delta S),\ C := (C + \delta C),\ I := L$
  else $I := U \backslash \{\rho\}$
$r = \frac{S - \kappa}{C}$, $v_i := v_i - \max(0, v_i - r)$ #take residuals

a DepthFirstNodeTraversal(T,*Order*) returns nodes x from the suffix tree T by depth-first traversal in the order prescribed by *Order*.

norms (Zhao et al., 2009; Jenatton et al., 2011), which are based on the suffix trie or tree, where subtrees correspond to contexts of increasing lengths. As will be shown in the experiments, this prevents the model to overfit unlike the ℓ_1- or squared ℓ_2-norm.

4.1 Definition of tree-structured ℓ_p^T norms

Definition 1. *Let x be a training sequence. Group $g(w, j)$ is the subvector of w associated with the subtree rooted at the node j of the suffix trie $S(x)$.*

Definition 2. *Let $\mathcal{G}$ denote the ordered set of nodes of the tree $T(x)$ such that for $r < s$, $g(w, r) \cap g(w, s) = \emptyset$ or $g(w, r) \subset g(w, s)$. The tree-structured ℓ_p-norm is defined as follows:*

$$\ell_p^T(w) = \sum_{j \in \mathcal{G}} \|g(w, j)\|_p \,. \tag{8}$$

We specifically consider the cases $p = 2, \infty$ for which efficient optimization algorithms are available. The ℓ_p^T-norms can be viewed as a group sparsity-inducing norms, where the groups are organized in a tree. This means that when the weight associated with a parent in the tree is driven to zero, the weights associated to all its descendants should also be driven to zero.

For structured ℓ_p^T-norm, the proximal step amounts to residuals of recursive projections on the ℓ_q-ball in the order defined by $\mathcal{G}$ (Jenatton et al., 2011), where ℓ_q-norm is the dual norm of ℓ_p-norm[1]. In the case ℓ_2^T-norm this comes to a series of projections on the ℓ_2-ball. For ℓ_∞^T-norm it is instead projections on the ℓ_1-ball. The order of projections defined by $\mathcal{G}$ is generated by an upward pass of the suffix trie. At each node through the upward pass, the subtree below is projected on the dual norm ball of size κ, the parameter of proximal step. We detail the projections on the norm ball below.

4.2 Projections on ℓ_q-ball for $q = 1, 2$

Each of the above projections on the dual norm ball takes one of the following forms depending on the choice of the norm. Projection of vector w on the ℓ_2-ball is equivalent to thresholding the magnitude of w by κ units while retaining its direction:

$$w \leftarrow [||w||_2 - \kappa]_+ \frac{w}{||w||_2}. \tag{9}$$

This can be performed in time linear in size of w, $O(|w|)$. Projection of a non-negative vector w on the ℓ_1-ball is more involved and requires thresholding

[1] ℓ_p-norm and ℓ_q-norm are dual to each other if $\frac{1}{p} + \frac{1}{q} = 1$. ℓ_2-norm is self-dual while the dual of ℓ_∞-norm is the ℓ_1-norm.

by a value such that the entries in the resulting vector add up to κ, otherwise w remains the same:

$$w \leftarrow [w - \tau]_+ \text{ s.t. } ||w||_1 = \kappa \text{ or } \tau = 0. \quad (10)$$

$\tau = 0$ is the case where w lies inside the ℓ_1-ball of size κ with $||w||_1 < \kappa$, leaving w intact. In the other case, the threshold τ is to be computed such that after thresholding, the resulting vector has an ℓ_1-norm of κ. The simplest way to achieve this is to sort by descending order the entries $\overline{w} = \text{sort}(w)$ and pick the k largest values such that the $(k+1)^{th}$ largest entry is smaller than τ:

$$\sum_{i=1}^{k} \overline{w}_i - \tau = \kappa \text{ and } \tau > \overline{w}_{k+1}. \quad (11)$$

We refer to $\overline{w}_k$ as the pivot and are only interested in entries larger than the pivot. Given a sorted vector, it requires looking up to exactly k entries, however, sorting itself take $O(|w| \log |w|)$.

4.3 Proximal step

Naively employing the projection on the ℓ_2-ball described above leads to an $O(d^2)$ algorithm for ℓ_2^T proximal step. This could be improved to a linear algorithm by aggregating all necessary scaling factors while making an upward pass of the trie S and applying them in a single downward pass as described in (Jenatton et al., 2011). In Algorithm 2, we detail this procedure for trie-structured vectors.

The complexity of ℓ_∞^T-norm proximal step depends directly on that of the pivot finding algorithm used within its ℓ_1-projection method. Naively sorting vectors to find the pivot leads to an $O(d^2 \log d)$ algorithm. Pivot finding can be improved by randomly choosing candidates for the pivot and the best known algorithm due to (Bruckner, 1984) has amortized linear time complexity in the size of the vector. This leaves us with $O(d^2)$ complexity for ℓ_∞^T-norm proximal step. (Duchi et al., 2008) proposes a method that scales linearly with the number of non-zero entries in the gradient update (s) but logarithmically in d. But recursive calls to ℓ_1-projection over subtrees will fail the sparsity assumption (with $s \approx d$) making proximal step quadratic. Procedure for $\Pi_{\ell_\infty^T}$ on trie-structured vectors using randomized pivoting method is described in Algorithm 3.

We next explain how the number of ℓ_1-projections can be reduced by switching to the tree T instead of trie S which is possible due to the good properties of ℓ_∞^T-norm. Then we present a pivot finding method that is logarithmic in the feature size for our application.

4.4 ℓ_∞^T-norm with suffix trees

We consider the case where all parameters are initialized with the same value for the optimization procedure, typically with zeros. The condition that the parameters at any given node continue to share the same value requires that both the gradient update (4) and proximal step (5) have this property. We modify the tree structure to ensure that after gradient updates parameters at a given node continue to share a single value. Nodes that do not share a value after gradient update are split into multiple nodes where each node has a single value. We formally define this property as follows:

Definition 3. *A **constant value non-branching path** is a set of nodes $P \in \mathcal{P}(T, w)$ of a tree structure T w.r.t. vector w if P has $|P|$ nodes with $|P| - 1$ edges between them and each node has at most one child and all nodes $i, j \in P$ have the same value in vector w as $w_i = w_j$.*

The nodes of Figure 1(b) correspond to constant value non-branching paths when the values for all parameters at each of the nodes are the same. Next we show that this tree structure is retained after proximal steps of ℓ_∞^T-norm.

Proposition 1. *Constant value non-branching paths $\mathcal{P}(T, w)$ of T structured vector w are preserved under the proximal projection step $\Pi_{\ell_\infty^T}(w, \kappa)$.*

Figure 1(d) illustrates this idea showing ℓ_∞^T projection applied on the collapsed tree. This makes it memory efficient but the time required for the proximal step remains the same since we must project each subtree of S on the ℓ_1-ball. The sequence of projections at nodes of S in a non-branching path can be rewritten into a single projection step using the following technique bringing the number of projections from $|S|$ to $|T|$.

Proposition 2. *Successive projection steps for subtrees with root in a constant value non-branching path $P = \{g_1, \cdots, g_{|P|}\} \in \mathcal{P}(T, w)$ for $\Pi_{\ell_\infty^T}(w, \kappa)$*

is $\pi_{g_{|P|}} \circ \cdots \circ \pi_{g_1}(w, \kappa)$ applied in bottom-up order defined by $\mathcal{G}$. The composition of projections can be rewritten into a single projection step with κ scaled by the number of projections $|P|$ as,

$$\pi_{g_{|P|}}(w, \kappa|P|) \equiv \pi_{g_{|P|}} \circ \cdots \circ \pi_{g_1}(w, \kappa).$$

The above propositions show that ℓ_∞^T-norm can be used with the suffix tree with fewer projection steps. We now propose a method to further improve each of these projection steps.

4.5 Fast proximal step for ℓ_∞^T-norm

Let k be the cardinality of the set of values larger than the pivot in a vector to compute the threshold for ℓ_1-projection as referred in (11). This value varies from one application to another, but for language applications, our experiments on 100K english words (APNews dataset) showed that k is generally small: its value is on average 2.5, and its maximum is around 10 and 20, depending on the regularization level. We propose using a max-heap data structure (Cormen et al., 1990) to fetch the k-largest values necessary to compute the threshold. Given the heap of the entries the cost of finding the pivot is $O(k \log(d))$ if the pivot is the k^{th} largest entry and there are d features. This operation is performed d times for ℓ_∞^T-norm as we traverse the tree bottom-up. The heap itself is built on the fly during this upward pass. At each subtree, the heap is built by merging those of their children in constant time by using Fibonacci heaps. This leaves us with a $O(dk \log(d))$ complexity for the proximal step. This procedure is detailed in Algorithm 4.

Algorithm 4 $w := \Pi_{\ell_\infty^T}(w, \kappa)$ Proximal projection step for ℓ_∞^T on grouping $\mathcal{G}$ using heap data structure.

Input: T suffix tree, w=[v c] tree-structured vector v with corresponding number of suffixes collapsed at each node in c, κ threshold
Initialize $\mathcal{H}$ = {} # empty set of heaps
1 **for** $x \in$ DepthFirstNodeTraversal(T, *PostOrder*)
  $g(v, x) := \pi_{\ell_\infty^T}(w, x, c_x\kappa, \mathcal{H})$

Procedure: $q := \pi_{\ell_\infty}(w, x, \kappa, \mathcal{H})$
1 $\mathcal{H}_x = \text{NewHeap}(v_x, c_x, v_x)$
2 **for** $j \in \text{children}(x)$ # merge with child heaps
  $\tau_x = \tau_x + \tau_j$ # update ℓ_1-norm
  $\mathcal{H}_x = \text{Merge}(\mathcal{H}_x, \mathcal{H}_j), \mathcal{H} = \mathcal{H} \backslash \mathcal{H}_j$
3 $\mathcal{H} = \mathcal{H} \cup H_x, S = 0, C = 0, J = \{\}$
4 **if** $\mathcal{H}_x(\tau) < \kappa$, **set** $\mathcal{H}_x = 0$ **return**
5 **for** $j \in \text{OrderedIterator}(\mathcal{H}_x)$ # get max values
  if $v_j > \frac{S+(v_j c_j)-\kappa}{C+c_j}$
    $S = S + (v_j \cdot c_j), C = C + c_j, J = J \cup \{j\}$
  else break
6 $r = \frac{S-\kappa}{C}, \delta = 0$ # compute threshold
7 **for** $j \in J$ # apply threshold
  $\nu = \min(v_j, r), \delta = \delta + (v_j - \nu)$
  $\mathcal{H}_j(v) = \nu$
8 $\mathcal{H}_x(\tau) = \mathcal{H}_j(\tau) - \delta$ # update ℓ_1-norm

a. Heap structure on vector w holds three values (v, c, τ) at each node. v, c being value and its count, τ is the ℓ_1-norm of the sub-vector below. Tuples are ordered by decreasing value of v and $\mathcal{H}_j$ refers to heap with values in sub-tree rooted at j. Merge operation merges the heaps passed. OrderedIterator returns values from the heap in decreasing order of v.

5 Summary of the algorithms

Table 1 summarizes the characteristics of the algorithms associated to the different penalties:

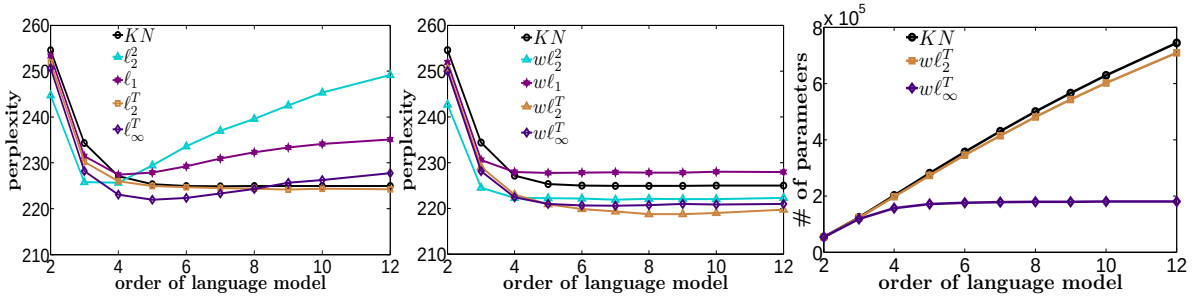
1. The unstructured norms ℓ_p do not take into account the varying sparsity level with context length. For p=1, this leads to a sparse solution and for p=2, we obtain the classical quadratic penalty. The suffix tree representation leads to an efficient memory usage. Furthermore, to make the training algorithm time efficient, the parameters corresponding to contexts which always occur in the same larger context are grouped. We will illustrate in the experiments that these penalties do not lead to good predictive performances.

2. The ℓ_2^T-norm nicely groups features by subtrees which concurs with the sequential structure of sequences. This leads to a powerful algorithm in terms of generalization. But it can only be applied on the uncollapsed tree since there is no closure property of the *constant value non-branching path* for its proximal step making it less amenable for larger tree depths.

3. The ℓ_∞^T-norm groups features like the ℓ_2^T-norm while additionally encouraging numerous feature groups to share a single value, leading to a substantial reduction in memory usage. The generalization properties of this algorithm is as good as the generalization obtained with the ℓ_2^T penalty, if not better. However, it has the *constant value non-branching path* property, which

Penalty			good generalization	memory efficient	time efficient
unstructured ℓ_1 and ℓ_2^2			no	yes $_{O(\|T\|)}$	yes $_{O(\|T\|)}$
struct.	ℓ_2^T		yes	no $_{O(\|S\|)}$	no $_{O(\|S\|)}$
	ℓ_∞^T	rand. pivot	yes	yes $_{O(\|T\|)}$	no $_{O(\|T\|^2)}$
	ℓ_∞^T	heap	yes	yes $_{O(\|T\|)}$	yes $_{O(\|T\|\log\|T\|)}$

Table 1: Properties of the algorithms proposed in this paper. Generalization properties are as compared by their performance with increasing context length. Memory efficiency is measured by the number of free parameters of W in the optimization. Note that the suffix tree is much smaller than the trie (uncollapsed tree): $|T| << |S|$. Time complexities reported are that of one proximal projection step.



(a) Unweighted penalties. (b) Weighted penalties. (c) Model complexity for structured penalties.

Figure 2: (a) compares average perplexity (lower is better) of different methods from 2-gram through 12-gram on four different 100K-20K train-test splits. (b) plot compares the same with appropriate feature weighting. (c) compares model complexity for weighted structured penalties $w\ell_2^T$ and $w\ell_\infty^T$ measure by then number of parameters.

means that the proximal step can be applied directly to the suffix tree. There is thus also a significant gain of performances.

6 Experiments

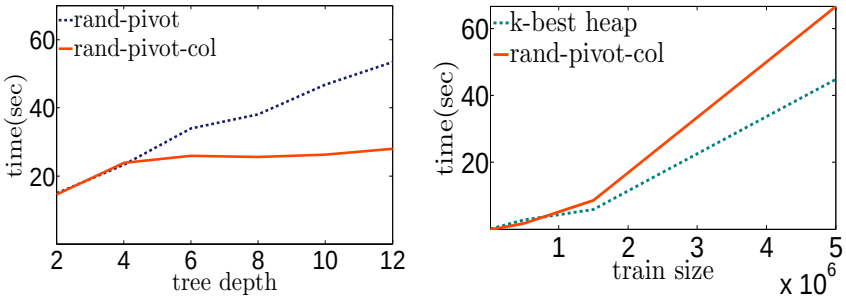
In this section, we demonstrate empirically the properties of the algorithms summarized in Table 1. We consider four distinct subsets of the Associated Press News (AP-news) text corpus with train-test sizes of 100K-20K for our experiments. The corpus was preprocessed as described in (Bengio et al., 2003) by replacing proper nouns, numbers and rare words with special symbols "⟨proper_noun⟩", "#n" and "⟨unknown⟩" respectively. Punctuation marks are retained which are treated like other normal words. Vocabulary size for each of the training subsets was around 8,500 words. The model was reset at the start of each sentence, meaning that a word in any given sentence does not depend on any word in the previous sentence. The regularization parameter λ is chosen for each model by cross-validation on a smaller subset of data. Models are fitted to training sequence of 30K words for different values of λ and validated against a sequence of 10K words to choose λ.

We quantitatively evaluate the proposed model using perplexity, which is computed as follows:

$$P(\{x_i, y_i\}, W) = 10^{\left\{\frac{-1}{n_V}\sum_{i=1}^{n}\mathbb{I}(y_i \in V)\log p(y_i|x_{1:i};W)\right\}},$$

where $n_V = \sum_i \mathbb{I}(y_i \in V)$. Performance is measured for varying depth of the suffix trie with different penalties. Interpolated Kneser-Ney results were computed using the openly available SRILM toolkit (Stolcke, 2002).

Figure 2(a) shows perplexity values averaged over four data subsets as a function of the language model order. It can be observed that performance of unstructured ℓ_1 and squared ℓ_2 penalties improve until a relatively low order and then degrade, while ℓ_2^T penalty does not show such degradation, indicating



(a) Iteration time of random-pivoting on the collapsed and uncollapsed trees.

(b) Iteration time of random-pivoting and k-best heap on the collapsed tree.

Figure 3: Comparison of different methods for performing ℓ_∞^T proximal projection. The `rand-pivot` is the random pivoting method of (Bruckner, 1984) and `rand-pivot-col` is the same applied with the nodes collapsed. The `k-best heap` is the method described in Algorithm 4.

that taking the tree-structure into account is beneficial. Moreover, the log-linear language model with ℓ_2^T penalty performs similar to interpolated Kneser-Ney. The ℓ_∞^T-norm outperforms all other models at order 5, but taking the structure into account does not prevent a degradation of the performance at higher orders, unlike ℓ_2^T. This means that a single regularization for all model orders is still inappropriate.

To investigate this further, we adjust the penalties by choosing an exponential decrease of weights varying as α^m for a feature at depth m in the suffix tree. Parameter α was tuned on a smaller validation set. The best performing values for these weighted models $w\ell_2^2$, $w\ell_1$, $w\ell_2^T$ and $w\ell_\infty^T$ are 0.5, 0.7, 1.1 and 0.85 respectively. The weighting scheme further appropriates the regularization at various levels to suit the problem's structure. Perplexity plots for weighted models are shown in Figure 2(b). While $w\ell_1$ improves at larger depths, it fails to compare to others showing that the problem does not admit sparse solutions. Weighted ℓ_2^2 improves considerably and performs comparably to the unweighted tree-structured norms. However, the introduction of weighted features prevents us from using the suffix tree representation, making these models inefficient in terms of memory. Weighted ℓ_∞^T is corrected for overfitting at larger depths and $w\ell_2^T$ gains more than others. Optimal values for α are fractional for all norms except $w\ell_2^T$-norm showing that the unweighted model ℓ_2^T-norm was over-penalizing features at larger depths, while that of others were under-penalizing them. Interestingly, perplexity improves up to about 9-grams with $w\ell_2^T$ penalty for the data set we considered, indicating that there is more to gain from longer dependencies in natural language sentences than what is currently believed.

Figure 2(c) compares model complexity measured by the number of parameters for weighted models using structured penalties. The ℓ_2^T penalty is applied on trie-structured vectors, which grows roughly at a linear rate with increasing model order. This is similar to Kneser-Ney. However, the number of parameters for the $w\ell_\infty^T$ penalty grows logarithmically with the model order. This is due to the fact that it operates on the suffix tree-structured vectors instead of the suffix trie-structured vectors. These results are valid for, both, weighted and unweighted penalties.

Next, we compare the average time taken per iteration for different implementations of the ℓ_∞^T proximal step. Figure 3(a) shows this time against increasing depth of the language model order for random pivoting method with and without the collapsing of parameters at different constant value non-branching paths. The trend in this plot resembles that of the number of parameters in Figure 2(c). This shows that the complexity of the full proximal step is sublinear when accounting for the suffix tree data structure. Figure 3(b) plots time per iteration random pivoting and k-best heap against the varying size of training sequence. The two algorithms are operating directly on the suffix tree. It can be observed that the heap-based method are superior with

increasing size of training data.

7 Conclusion

In this paper, we proposed several log-linear language models. We showed that with an efficient data structure and structurally appropriate convex regularization schemes, they were able to outperform standard Kneser-Ney smoothing. We also developed a proximal projection algorithm for the tree-structured ℓ_∞^T-norm suitable for large trees.

Further, we showed that these models can be trained online, that they accurately learn the m-gram weights and that they are able to better take advantage of long contexts. The time required to run the optimization is still a concern. It takes 7583 minutes on a standard desktop computer for one pass of the of the complete AP-news dataset with 13 million words which is little more than time reported for (Mnih and Hinton, 2007). The most time consuming part is computing the normalization factor for the log-loss. A hierarchical model in the flavour of (Mnih and Hinton, 2008) should lead to significant improvements to this end. Currently, the computational bottleneck is due to the normalization factor in (1) as it appears in every gradient step computation. Significant savings would be obtained by computing it as described in (Wu and Khundanpur, 2000).

Abstract

Current automatic machine translation systems are not able to generate error-free translations and human intervention is often required to correct their output. Alternatively, an interactive framework that integrates the human knowledge into the translation process has been presented in previous works. Here, we describe a new interactive machine translation approach that is able to work with phrase-based and hierarchical translation models, and integrates error-correction all in a unified statistical framework. In our experiments, our approach outperforms previous interactive translation systems, and achieves estimated effort reductions of as much as 48% relative over a traditional post-edition system.

1 Introduction

Research in the field of *machine translation* (MT) aims to develop computer systems which are able to translate between languages automatically, without human intervention. However, the quality of the translations produced by any automatic MT system still remain below than that of human translation. Typical solutions to reach human-level quality require a subsequent manual *post-editing* process. Such decoupled post-edition solution is rather inefficient and tedious for the human translator. Moreover, it prevents the MT system from taking advantage of the knowledge of the human translator and, reciprocal, the human translator cannot take advantage of the adapting ability of MT technology.

An alternative way to take advantage of the existing MT technology is to use them in *collaboration* with human translators within a *computer-assisted translation* (CAT) or *interactive* framework (Isabelle and Church, 1998). The *TransType* and *TransType2* projects (Foster et al., 1998; Langlais and Lapalme, 2002; Barrachina et al., 2009) entailed an interesting focus shift in CAT technology by aiming interaction directly at the production of the target text. These research projects proposed to embed an MT system within an interactive translation environment. This way, the human translator can ensure a high-quality output while the MT system ensures a significant gain of productivity. Particularly interesting is the *interactive machine translation* (IMT) approach proposed in (Barrachina et al., 2009). In this scenario, a statistical MT (SMT) system uses the source sentence and a previously validated part (prefix[1]) of its translation to propose a suitable continuation. Then the user finds and corrects the next system error, thereby providing a longer prefix which the system uses to suggests a new, hopefully better continuation. The reported results showed that IMT can save a significant amount of human effort.

Barrachina et al,. (2009) provide a thorough description of the IMT approach and describe algorithms for its practical implementation. Nevertheless, we identify two basic problems for which we think there is room for improvement. The first problem arises when the system cannot generate the prefix validated by the user. To solve this problem, the authors simply provide an ad-hoc heuristic error-correction technique. The second problem is how the system deals with word reordering. Particularly, the models used by the system were either mono-

[1]We use the terms prefix and suffix to denote any sub-string at the beginning and end respectively of a string of characters (including spaces and punctuation). These terms do not imply any morphological significance as they usually do in linguistics.

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 244–254,
Seattle, Washington, USA, 18-21 October 2013.

tonic by nature or non-monotonic but heuristically defined (not estimated from training data).

We work on the foundations of Barrachina et al., (2009) and provide formal solutions to these two challenges. On the one hand, we adopt the statistical formalization of the IMT framework described in (Ortiz-Martínez, 2011), which includes a stochastic error-correction model in its formalization to address prefix coverage problems. Moreover, we refine this formalization proposing an alternative error-correction formalization for the IMT framework (Section 2). Additionally, we also propose a specific error-correction model based on a statistical interpretation of the Levenshtein distance (Levenshtein, 1966). These formalizations provide a unified statistical framework for the IMT model in comparison to the ad-hoc heuristic error-correction methods previously used.

In order to address the problem of properly deal with reordering in IMT, we introduce the use of hierarchical MT models (Chiang, 2005; Zollmann and Venugopal, 2006). These methods provide a natural approach to handle long range dependencies and allow the incorporation of reordering information into a consistent statistical framework. Here, we also describe how state-of-the-art hierarchical MT models can be extended to handle IMT (Sections 3 and 4).

We evaluate the proposed IMT approach on two different translation task. The comparative results against the IMT approach described by Barrachina et al., (2009) and a conventional post-edition approach show that our IMT formalization for hierarchical SMT models indeed outperform other approaches (Sections 5 and 6). Moreover, it leads to large reductions in the human effort required to generate error-free translations.

2 Statistical Framework

2.1 Statistical Machine Translation

Assuming that we are given a sentence $\mathbf{s}$ in a source language, the *translation* problem can be stated as finding its translation $\mathbf{t}$ in a target language of maximum probability (Brown et al., 1993):

$$\hat{\mathbf{t}} = \arg\max_{\mathbf{t}} \Pr(\mathbf{t} \mid \mathbf{s}) \quad (1)$$

$$= \arg\max_{\mathbf{t}} \Pr(\mathbf{t}) \cdot \Pr(\mathbf{s} \mid \mathbf{t}) \quad (2)$$

source ($\mathbf{s}$): Para ver la lista de recursos
desired translation ($\hat{\mathbf{t}}$): To view a listing of resources

IT-0	$\mathbf{p}$	
	$\mathbf{t}_s$	*To view the resources list*
IT-1	$\mathbf{p}$	To view
	k	a
	$\mathbf{t}_s$	*list of resources*
IT-2	$\mathbf{p}$	To view a list
	k	i
	$\mathbf{t}_s$	*ng resources*
IT-3	$\mathbf{p}$	To view a listing
	k	o
	$\mathbf{t}_s$	*f resources*
END	$\mathbf{p}$	To view a listing of resources

Figure 1: IMT session to translate a Spanish sentence into English. The desired translation is the translation the human user wants to obtain. At IT-0, the system suggests a translation ($\mathbf{t}_s$). At IT-1, the user moves the mouse to accept the first eight characters "To view " and presses the a key (k), then the system suggests completing the sentence with "*list of resources*" (a new $\mathbf{t}_s$). Iterations 2 and 3 are similar. In the final iteration, the user accepts the current translation.

The terms in the latter equation are the *language model* probability $\Pr(\mathbf{t})$ that represents the well-formedness of $\mathbf{t}$ (*n-gram* models are usually adopted), and the *(inverted) translation model* $\Pr(\mathbf{s} \mid \mathbf{t})$ that represents the relationship between the source sentence and its translation.

In practice all of these models (and possibly others) are often combined into a *log-linear model* for $\Pr(\mathbf{t} \mid \mathbf{s})$ (Och and Ney, 2002):

$$\hat{\mathbf{t}} = \arg\max_{\mathbf{t}} \left\{ \sum_{n=1}^{N} \lambda_n \cdot \log(f_n(\mathbf{t}, \mathbf{s})) \right\} \quad (3)$$

where $f_n(\mathbf{t}, \mathbf{s})$ can be any model that represents an important feature for the translation, N is the number of models (or features), and λ_n are the weights of the log-linear combination.

2.2 Statistical Interactive Machine Translation

Unfortunately, current MT technology is still far from perfect. This implies that, in order to achieve good translations, manual post-editing is needed. An alternative to this decoupled approach (first MT, then manual correction) is given by the IMT

paradigm (Barrachina et al., 2009). Under this paradigm, translation is considered as an iterative left-to-right process where the human and the computer collaborate to generate the final translation.

Figure 1 shows an example of the IMT approach. There, a source Spanish sentence $\mathbf{s}$ ="Para ver la lista de recursos" is to be translated into a target English sentence $\hat{\mathbf{t}}$. Initially, with no user feedback, the system suggests a complete translation $\mathbf{t}_s$ ="To view the resources list". From this translation, the user marks a prefix $\mathbf{p}$ ="To view" as correct and begins to type the rest of the target sentence. Depending on the system or the user's preferences, the user might type the full next word, or only some letters of it (in our example, the user types the single next character "a"). Then, the MT system suggests a new suffix $\mathbf{t}_s$ ="list of resources" that completes the validated prefix and the input the user has just typed ($\mathbf{p}$ ="To view a"). The interaction continues with a new prefix validation followed, if necessary, by new input from the user, and so on, until the user considers the translation to be complete and satisfactory.

The crucial step of the process is the production of the suffix. Again decision theory tells us to maximize the probability of the suffix given the available information. Formally, the best suffix of a given length will be:

$$\hat{\mathbf{t}}_s = \arg\max_{\mathbf{t}_s} \Pr(\mathbf{t}_s \mid \mathbf{s}, \mathbf{p}) \tag{4}$$

which can be straightforwardly rewritten as:

$$\hat{\mathbf{t}}_s = \arg\max_{\mathbf{t}_s} \Pr(\mathbf{p}, \mathbf{t}_s \mid \mathbf{s}) \tag{5}$$

$$= \arg\max_{\mathbf{t}_s} \Pr(\mathbf{p}, \mathbf{t}_s) \cdot \Pr(\mathbf{s} \mid \mathbf{p}, \mathbf{t}_s) \tag{6}$$

Note that, since $\mathbf{p}\,\mathbf{t}_s = \mathbf{t}$, this equation is very similar to Equation (2). The main difference is that now the search process is restricted to those target sentences $\mathbf{t}$ that contains $\mathbf{p}$ as prefix. This implies that we can use the same MT models (including the log-linear approach) if the search procedures are adequately modified (Och et al., 2003). Finally, it should be noted that the statistical models are usually defined at word level, while the IMT process described in this section works at character level. To deal with this problem, during the search process it is necessary to verify the compatibility between $\mathbf{t}$ and $\mathbf{p}$ at character level.

2.3 IMT with Stochastic Error-Correction

A common problem in IMT arises when the user sets a prefix which cannot be explained by the statistical models. To solve this problem, IMT systems typically include ad-hoc error-correction techniques to guarantee that the suffixes can be generated (Barrachina et al., 2009). As an alternative to this heuristic approach, Ortiz-Martínez (2011) proposed a formalization of the IMT framework that does include stochastic error-correction models in its statistical formalization. The starting point of this alternative IMT formalization accounts for the problem of finding the translation $\mathbf{t}$ that, at the same time, better explains the source sentence $\mathbf{s}$ and the prefix given by the user $\mathbf{p}$:

$$\hat{\mathbf{t}} = \arg\max_{\mathbf{t}} \Pr(\mathbf{t} \mid \mathbf{s}, \mathbf{p}) \tag{7}$$

$$= \arg\max_{\mathbf{t}} \Pr(\mathbf{t}) \cdot \Pr(\mathbf{s}, \mathbf{p} \mid \mathbf{t}) \tag{8}$$

The following naïve Bayes' assumption is now made: the source sentence $\mathbf{s}$ and the user prefix $\mathbf{p}$ are statistically independent variables given the translation $\mathbf{t}$, obtaining:

$$\hat{\mathbf{t}} = \arg\max_{\mathbf{t}} \Pr(\mathbf{t}) \cdot \Pr(\mathbf{s} \mid \mathbf{t}) \cdot \Pr(\mathbf{p} \mid \mathbf{t}) \tag{9}$$

where $\Pr(\mathbf{t})$ can be approximated with a language model, $\Pr(\mathbf{s} \mid \mathbf{t})$ can be approximated with a translation model, and $\Pr(\mathbf{p} \mid \mathbf{t})$ can be approximated by an error correction model that measures the compatibility between the user-defined prefix $\mathbf{p}$ and the hypothesized translation $\mathbf{t}$.

Note that the translation result, $\hat{\mathbf{t}}$, given by Equation (9) may not contain $\mathbf{p}$ as prefix because every translation is compatible with $\mathbf{p}$ with a certain probability. Thus, despite being close, Equation (9) is not equivalent to the IMT formalization in Equation (6).

To solve this problem, we define an alignment, $\mathbf{a}$, between the user-defined prefix $\mathbf{p}$ and the hypothesized translation $\mathbf{t}$, so that the unaligned words of $\mathbf{t}$, in an appropriate order, constitute the suffix searched in IMT. This allows us to rewrite the error correction probability as follows:

$$\Pr(\mathbf{p} \mid \mathbf{t}) = \sum_{\mathbf{a}} \Pr(\mathbf{p}, \mathbf{a} \mid \mathbf{t}) \tag{10}$$

To simplify things, we assume that $\mathbf{p}$ is monotonically aligned to $\mathbf{t}$, leaving the potential word-reordering to the language and translation models.

Under this assumption, $\mathbf{a}$ determines an alignment for $\mathbf{t}$, such that $\mathbf{t} = \mathbf{t}_p\mathbf{t}_s$, where $\mathbf{t}_p$ is fully-aligned to $\mathbf{p}$ and $\mathbf{t}_s$ remains unaligned. Taking all these things into consideration, and following a maximum approximation, we finally arrive to the expression:

$$(\hat{\mathbf{t}}, \hat{\mathbf{a}}) = \arg\max_{\mathbf{t},\mathbf{a}} \Pr(\mathbf{t}) \cdot \Pr(\mathbf{s} \mid \mathbf{t}) \cdot \Pr(\mathbf{p}, \mathbf{a} \mid \mathbf{t}) \quad (11)$$

where the suffix required in IMT is obtained as the portion of $\hat{\mathbf{t}}$ that is not aligned with the user prefix.

In practice, we combine the models in Equation (11) in a log-linear fashion as it is typically done in SMT (see Equation (3)).

2.4 Alternative Formalization for IMT with Stochastic Error-Correction

Alternatively to Equation (11), we can operate from Equation (9) and reach a different formalization for IMT with error-correction. We can re-write the first and last terms of Equation (9) as:

$$\Pr(\mathbf{t}) \cdot \Pr(\mathbf{p} \mid \mathbf{t}) = \Pr(\mathbf{p}) \cdot \Pr(\mathbf{t} \mid \mathbf{p}) \quad (12)$$

As in the previous section, we introduce an alignment variable, $\mathbf{a}$, between $\mathbf{t}$ and $\mathbf{p}$, giving:

$$\Pr(\mathbf{t} \mid \mathbf{p}) = \sum_{\mathbf{a}} \Pr(\mathbf{t}, \mathbf{a} \mid \mathbf{p}) \quad (13)$$

$$= \sum_{\mathbf{a}} \Pr(\mathbf{a} \mid \mathbf{p}) \cdot \Pr(\mathbf{t} \mid \mathbf{p}, \mathbf{a}) \quad (14)$$

If we consider monotonic alignments, $\mathbf{a}$ defines again an alignment between a prefix of the system translation ($\mathbf{t}_p$) and the user prefix, producing the suffix required in IMT ($\mathbf{t}_s$) as the unaligned part. Thus, we can re-write $\Pr(\mathbf{t} \mid \mathbf{p}, \mathbf{a})$ as:

$$\Pr(\mathbf{t} \mid \mathbf{p}, \mathbf{a}) = \Pr(\mathbf{t}_p, \mathbf{t}_s \mid \mathbf{p}, \mathbf{a}) \quad (15)$$

$$\approx \Pr(\mathbf{t}_p \mid \mathbf{p}, \mathbf{a}) \cdot \Pr(\mathbf{t}_s \mid \mathbf{p}, \mathbf{a}) \quad (16)$$

where Equation (16) has been obtained following a naïve Bayes' decomposition.

Combining equations (12), (14), and (16) into Equation (9), and following a maximum approximation for the summation of the alignment variable $\mathbf{a}$, we arrive to the following expression:

$$(\hat{\mathbf{t}}, \hat{\mathbf{a}}) = \arg\max_{\mathbf{t},\mathbf{a}} \Pr(\mathbf{s}|\mathbf{t}) \cdot \Pr(\mathbf{t}_p|\mathbf{p}, \mathbf{a}) \cdot \Pr(\mathbf{t}_s|\mathbf{p}, \mathbf{a}) \quad (17)$$

where $\Pr(\mathbf{p})$ and $\Pr(\mathbf{a}|\mathbf{p})$ have been dropped down because the former does not participate in the maximization and the latter is assumed uniform.

The terms in this equation can be interpreted similarly as those in Equation (9): $\Pr(\mathbf{s} \mid \mathbf{t})$ is the translation model, $\Pr(\mathbf{t}_p \mid \mathbf{p}, \mathbf{a})$ is the error-correction probability that measures the compatibility between the prefix $\mathbf{t}_p$ of the hypothesized translation and the user-defined prefix $\mathbf{p}$, and $\Pr(\mathbf{t}_s \mid \mathbf{p}, \mathbf{a})$ is the language model for the corresponding suffix $\mathbf{t}_s$ conditioned by the user-defined prefix. Again, in the experiments we combine the different models in a log-linear fashion.

The main difference between the two alternative IMT formalization (Equations (11) and (17)) is that in the latter the suffix to be returned is conditioned by the user-validated prefix $\mathbf{p}$. Thus, in the following we will refer to Equation (11) as *independent suffix formalization* while we will denote Equation (17) by *conditioned suffix formalization*.

3 Statistical Models

We now present the statistical models used to estimate the probability distributions described in the previous section. Section 3.1 describes the error-correction model, while Section 3.2 describes the models for the conditional translation probability.

3.1 Statistical Error-Correction Model

Following the vast majority of IMT systems described in the literature, we implement an error-correction model based on the concept of edit distance (Levenshtein, 1966). Typically, IMT systems use non-probabilistic error correction models. The first stochastic error correction model for IMT was proposed in (Ortiz-Martínez, 2011) and it is based on probabilistic finite state machines. Here, we propose a simpler approach which can be seen as a particular case of the previous one. Specifically, the proposed approach models the edit distance as a Bernoulli process where each character of the candidate string has a probability p_e of being erroneous. Under this interpretation, the number of characters that need to be edited E in a sentence of length n is a random variable that follows a binomial distribution, $E \sim \mathrm{B}(n, p_e)$, with parameters n and p_e. The probability of performing exactly k edits in a

sentence of n characters is given by the following probability mass function:

$$f(k; n, p_e) = \frac{n!}{k!(n-k)!} p_e^k (1-p_e)^{n-k} \quad (18)$$

Note that this error-correction model penalizes equally all edit operations. Alternatively, we can model the distance with a multinomial distribution and assign different probabilities to different types of edit operations. Nevertheless, we adhere to the binomial approximation due to its simplicity.

Finally, we compute the error-correction probability between two strings from the total number of edits required to transform the candidate translation into the reference translation. Specifically, we define the error-correction distribution in Equation (11) as:

$$\Pr(\mathbf{p}, \mathbf{a} \mid \mathbf{t}) \approx \frac{|\mathbf{p}|!}{k!(|\mathbf{p}|-k)!} p_e^k (1-p_e)^{|\mathbf{p}|-k} \quad (19)$$

where $k = \mathrm{Lev}(\mathbf{p}, \mathbf{t_a})$ is the character-level Levenshtein distance between the user defined prefix $\mathbf{p}$ and the prefix $\mathbf{t_a}$ of the hypothesized translation $\mathbf{t}$ defined by alignment $\mathbf{a}$. The error-correction probability $\Pr(\mathbf{t}_p \mid \mathbf{p}, \mathbf{a})$ in Equation (17) is computed analogously.

The probability of edition p_e is the single free parameter of this formulation. We will use a separate development corpus to find an adequate value for it.

3.2 Statistical Machine Translation Models

Next sections briefly describe the statistical translation models used to estimate the conditional probability distribution $\Pr(\mathbf{s} \mid \mathbf{t})$. A detailed description of each model can be found in the provided citations.

3.2.1 Phrase-Based Translation Models

Phrase-based translation models (Koehn et al., 2003) are an instance of the noisy-channel approach in Equation (2). The translation of a source sentence $\mathbf{s}$ is obtained through a generative process composed of three steps: first, the $\mathbf{s}$ is divided into K segments (phrases), next, each source phrase, $\tilde{\mathbf{s}}$, is translated into a target phrase $\tilde{\mathbf{t}}$, and finally the target phrases are reordered to compose the final translation.

The usual phrase-based implementation of the translation probability takes a log-linear form:

$$\Pr(\mathbf{s} \mid \mathbf{t}) \approx \lambda_1 \cdot |\mathbf{t}| + \lambda_2 \cdot K + \sum_{k=1}^{K} \left[\lambda_3 \cdot \log(P(\tilde{\mathbf{s}}_k \mid \tilde{\mathbf{t}}_k)) + \lambda_4 \cdot \mathrm{d}(j)\right] \quad (20)$$

where $P(\tilde{\mathbf{s}} \mid \tilde{\mathbf{t}})$ is the translation probability between source phrase $\tilde{\mathbf{s}}$ and target phrase $\tilde{\mathbf{t}}$, and $\mathrm{d}(j)$ is a function (distortion model) that returns the score of translating the k-th source phrase given that it is separated j words from the $(k{-}1)$-th phrase. Weights λ_1 and λ_2 play a special role since they are used to control the number of words and the number of phrases of the target sentence to be generated, respectively.

3.2.2 Hierarchical Translation Models

Phrase-based models have shown a very strong performance when translating between languages that have similar word orders. However, they are not able to adequately capture the complex relationships that exist between the word orders of languages of different families such as English and Chinese. Hierarchical translation models provide a solution to this challenge by allowing gaps in the phrases (Chiang, 2005):

$$\textsf{yu } X_1 \textsf{ you } X_2 \rightarrow \textsf{have } X_2 \textsf{ with } X_1$$

where subscripts denote placeholders for subphrases. Since these rules generalize over possible phrases, they act as discontinuous phrase pairs and may also act as phrase-reordering rules. Hence, they are not only considerably more powerful than conventional phrase pairs, but they also integrate reordering information into a consistent framework.

These hierarchical phrase pairs are formalized as rewrite rules of a synchronous context-free grammar (CFG) (Aho and Ullman, 1969):

$$X \rightarrow < \boldsymbol{\gamma}, \boldsymbol{\alpha}, \sim > \quad (21)$$

where X is a non-terminal, $\boldsymbol{\gamma}$ and $\boldsymbol{\alpha}$ are both strings of terminals (words) and non-terminals , and $\sim$ is a one-to-one correspondence between non-terminal occurrences in $\boldsymbol{\gamma}$ and $\boldsymbol{\alpha}$. Given the example above, $\boldsymbol{\gamma} \equiv$"yu X_1 you X_2", $\boldsymbol{\alpha} \equiv$"have X_2 with X_1", and $\sim$ is indicated by the subscript numbers.

Additionally, two *glue rules* are also defined:

$$S \rightarrow < S_1 X_2 \, , \, S_1 X_2 > \qquad S \rightarrow < X_1 \, , \, X_1 >$$

These give the model the option to build only partial translations using hierarchical phrases, and then combine them serially as in a phrase-based model.

The typical implementation of the hierarchical translation model also takes the form of a log-linear model. Let $\mathbf{s}_{\boldsymbol{\delta}}$ and $\mathbf{t}_{\boldsymbol{\delta}}$ be the source and target strings generated by a derivation $\boldsymbol{\delta}$ of the grammar. Then, the conditional translation probability is given by:

$$\Pr(\mathbf{s}_{\boldsymbol{\delta}} \mid \mathbf{t}_{\boldsymbol{\delta}}) \approx \lambda_1 \cdot |\mathbf{t}_{\boldsymbol{\delta}}| + \lambda_2 \cdot |\boldsymbol{\delta}| + \lambda_3 \cdot \#_{\mathrm{g}}(\boldsymbol{\delta}) + \sum_{r \in \boldsymbol{\delta}} [\lambda_4 \cdot w(r)] \quad (22)$$

where $|\boldsymbol{\delta}|$ denotes the total number of rules used in $\boldsymbol{\delta}$, $\#_{\mathrm{g}}(\boldsymbol{\delta})$ returns the number of applications of the glue rules, $r \in \boldsymbol{\delta}$ are the rules in $\boldsymbol{\delta}$, and $w(r)$ is the weight of rule r. Weights λ_1 and λ_2 have a similar interpretation as for phrase-based models, they respectively give some control over the total number of words and rules that conform the translation. Additionally, λ_3 controls the model's preference for hierarchical phrases over serial combination of phrases. Note that no distortion model is included in the previous equation. Here, reordering is defined at rule level by the one-to-one non-terminal correspondence. In other words, reordering is a property inherent to each rule and it is the individual score of each rule what defines, at each step of the derivation, the importance of reordering.

It should be noted that the IMT formalizations presented in Section 2 can be applied to other hierarchical or syntax-based SMT models such as those described in (Zollmann and Venugopal, 2006; Shen et al., 2010).

4 Search

In offline MT, the generation of the best translation for a given source sentence is carried out by incrementally generating the target sentence[2]. This process fits nicely into a *dynamic programming* (DP) (Bellman, 1957) framework, as hypotheses which are indistinguishable by the models can be recombined. Since the DP search space grows exponentially with the size of the input, standard DP search is prohibitive, and search algorithms usually resort to a beam-search heuristic (Jelinek, 1997).

[2]Phrase-based systems follow a left-to-right generation order while hierarchical systems rely on a CYK-like order.

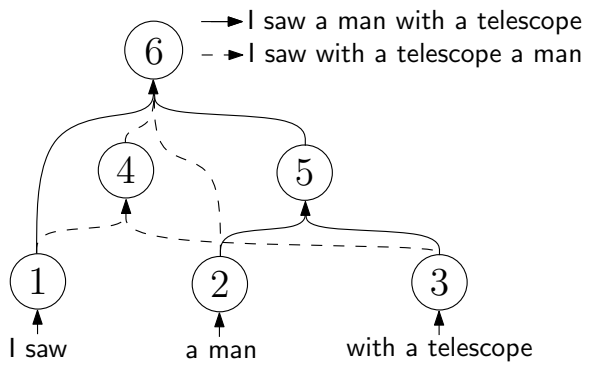

Figure 2: Example of a hypergraph encoding two different translations (one solid and one dotted) for the Spanish sentence "Vi a un hombre con un telescopio".

Due to the demanding temporal constraints inherent to any interactive environment, performing a full search each time the user validates a new prefix is unfeasible. The usual approach is to rely on a certain representation of the search space that includes the most probable translations of the source sentence. The computational cost of this approach is much lower, as the whole search for the translation must be carried out only once, and the generated representation can be reused for further completion requests.

Next, we introduce *hypergraphs*, the formalism chosen to represent the search space of both phrase-based and hierarchical systems (Section 4.1). Then, we describe the algorithms implemented to search for suffix completions in them (Section 4.2).

4.1 Hypergraphs

A hypergraph is a generalization of the concept of graph where the edges (now called hyperedges) may connect several nodes (hypernodes) at the same time. Formally, a hypergraph is a weighted acyclic graph represented by a pair $< \mathcal{V}, \mathcal{E} >$, where $\mathcal{V}$ is a set of hypernodes and $\mathcal{E}$ is a set of hyperedges. Each hyperedge $e \in \mathcal{E}$ connects a head hypernode and a set of tail hypernodes. The number of tail nodes is called the *arity* of the hyperedge and the arity of a hypergraph is the maximum arity of its hyperedges.

We can use hypergraphs to represent the derivations for a given CFG. Each hypernode represents a partial translation generated during the decoding process. Each ingoing hyperedge represents the rule with which the corresponding non-terminal was substituted. Moreover, hypergraphs can represent a whole set of possible translations. An example is

shown in Figure 2. Two alternative translations are constructed from the leave nodes (1, 2 and 3) up to the root node (6) of the hypergraph. Additionally, hypernodes and hyperedges may be shared among different derivations if they represent the same information. Thus, we can achieve a compact representation of the translation space that allows us to derive efficient search algorithms.

Note that *word-graphs* (Ueffing et al., 2002), which are used to represent the search space for phrase-based models, are a special case of hypergraphs in which the maximum arity is one. Thus, hypergraphs allow us to represent both phrase-based and hierarchical systems in a unified framework.

4.2 Suffix Search on Hypergraphs

Now, we describe a unified search process to obtain the suffix $\mathbf{t}_s$ that completes a prefix $\mathbf{p}$ given by the user according to the two IMT formulations (Equation (11) and Equation (17)) described in Section 2.

Given an hypergraph, certain hypernodes define a possible solution to the maximization defined in the two IMT formulations. Specifically, only those hypernodes that generate a prefix of a potential translation are to be taken into account[3]. The probability of the solution defined by each hypernode has two components, namely the probability of the SMT model (given by the language and translation models) and the probability of the error-correction model. On the one hand, the SMT model probability is given by the translation of maximum probability through the hypernode. On the other hand, the error-correction probability is computed between $\mathbf{p}$ and the partial translation of maximum probability actually covered by the hypernode. Among all the solutions defined by the hypernodes, we finally select that of maximum probability.

Once the best-scoring hypernode is identified, the rest of the translation not covered by it is returned as the suffix completion required in IMT.

5 Experimental Framework

The models and search procedure introduced in the previous sections were assessed through a series of IMT experiments with different corpora. These corpora, the experimental methodology, and the evaluation measures are presented in this section.

[3]For example, in Figure 2 the hypernodes that generate prefixes are those labeled with numbers 1 ("I saw"), 4 ("I saw with a telescope) and 6 ("I saw a man with a telescope" and "I saw with a telescope a man").

Vocabulary	42K / 52K	4K / 3K	4K / 4K

Table 1: Main figures of the processed EU and TED corpora. K and M stand for thousands and millions of elements respectively.

5.1 EU and TED corpora

We tested the proposed methods in two different translation tasks each one involving a different language pair: Spanish-to-English (Es–En) for the *EU* (Bulletin of the European Union) task, and Chinese-to-English (Zh–En) for the *TED* (TED[4] talks) task.

The EU corpora were extracted from the Bulletin of the European Union, which exists in all official languages of the European Union and is publicly available on the Internet. Particularly, the chosen Es–En corpus was part of the evaluation of the TransType2 project (Barrachina et al., 2009). The TED talks is a collection of recordings of public speeches covering a variety of topics, and for which high quality transcriptions and translations into several languages are available. The Zh–En corpus used in the experiments was part of the MT track in the 2011 evaluation campaign of the workshop on spoken language translation (Federico et al., 2011). Specifically, we used the `dev2010` partition for development and the `test2010` partition for test.

We process the Spanish and English parts of the EU corpus to separate words and punctuation marks keeping sentences truecase. Regarding the TED corpus, we tokenized and lowercased the English part (Chinese has no case information), and split Chinese sentences into words with the Stanford word

[4]`www.ted.com`

segmenter (Tseng et al., 2005). Table 1 shows the main figures of the processed EU and TED corpora.

5.2 Model Estimation and User Simulation

We used the standard configuration of the `Moses` toolkit (Koehn et al., 2007) to estimate one phrase-based and one hierarchical model for each corpus; log-linear weights were optimized by minimum error-rate training (Och, 2003) with the development partitions. Then, the optimized models were used to generate the word-graphs and hypergraphs with the translations of the development and test partitions.

A direct evaluation of the proposed IMT procedures involving human users would have been slow and expensive. Thus, following previous works in the literature (Barrachina et al., 2009; González-Rubio et al., 2010), we used the references in the corpora to simulate the translations that a human user would want to obtain. Each time the system suggested a new translation, it was compared to the reference and the *longest common prefix* (LCP) was obtained. Then, the first non-matching character was replaced by the corresponding character in the reference and a new system suggestion was produced. This process is iterated until a full match with the reference was obtained.

Finally, we used this user simulation to optimize the value for the probability of edition p_e in the error-correction model (Section 3.1), and for the log-linear weights in the proposed IMT formulations. In this case, these values were chosen so that they minimize the estimated user effort required to interactively translate the development partitions.

5.3 Evaluation Measures

Different measures have been adopted to evaluate the proposed IMT approach. On the one hand, different IMT systems can be compared according to the effort needed by a human user to generate the desired translations. This effort is usually estimated as the number of actions performed by the user while interacting with the system. In the user simulation described above these actions are: looking for the next error and *moving the mouse pointer* to that position (LCP computation), and correcting errors with some *key strokes*. Hence, we implement the following IMT effort measure (Barrachina et al., 2009):

Key-stroke and mouse-action ratio (KSMR): number of key strokes plus mouse movements performed by the user, divided by the total number of characters in the reference.

On the other hand, we also want to compare the proposed IMT approach against a conventional CAT approach without interactivity, such as a decoupled post-edition system. For such systems, character-level user effort is usually measured by the *Character Error Rate* (CER). However, it is clear that CER is at a disadvantage due to the auto-completion approach of IMT. To perform a fairer comparison between post-edition and IMT, we implement a post-editing system with autocompletion. Here, when the user enters a character to correct some incorrect word, the system automatically completes the word with the most probable word in the task vocabulary. To evaluate the effort of a user using such a system, we implement the following measure proposed in (Romero et al., 2010):

Post-editing key stroke ratio (PKSR): using a post-edition system with word-autocompleting, number of user key strokes divided by the total number of reference characters.

The counterpart of PKSR in an IMT scenario is (Barrachina et al., 2009):

Key-stroke ratio (KSR): number of key strokes, divided by the number of reference characters.

PKSR and KSR are fairly comparable and the relative difference between them gives us a good estimate of the reduction in human effort that can be achieved by using IMT instead of a conventional post-edition system.

We also evaluate the quality of the automatic translations generated by the MT models with the widespread BLEU score (Papineni et al., 2002).

Finally, we provide both confidence intervals for the results and statistical significance of the observed differences in performance. Confidence intervals were computed by pair-wise re-sampling as in (Zhang and Vogel, 2004) while statistical significance was computed using the Tukey's HSD (honest significance difference) test (Hsu, 1996).

	EU		TED	
	WG	HG	WG	HG
1-best BLEU [%]	45.0	45.1	11.0	11.2
1000-best Avg. BLEU [%]	43.6	44.2	10.2	11.0

Table 2: BLEU score of the word-graphs (WG) and hypergraphs (HG) used to implement the IMT procedures.

IMT	EU		TED	
Setup	PB	HT	PB	HT
ISF	27.4±.5	26.5±.5*	53.0±.4	52.3±.4*
CSF	26.6±.5*	**25.1±.5**★	52.2±.4*	**50.8±.4**★

Table 3: IMT results (KSMR [%]) for the EU and TED tasks using the independent suffix formalization (ISF) and the conditioned suffix formalization (CSF). PB stands for phrase-based model and HT stands for hierarchical translation model. For each task, the best result is displayed boldface, an asterisk * denotes a statistically significant better result (99% confidence) with respect to ISF with PB, and a star ★ denotes a statistically significant difference with respect to all the other systems.

6 Results

We start by reporting conventional MT quality results to test if the generated word-graphs and hypergraphs encode translations of similar quality. Table 2 displays the quality (BLEU (Papineni et al., 2002)) of the automatic translations generated for the test partitions. The lower 1-best BLEU results obtained for TED show that this is a much more difficult task than EU. Additionally, the similar average BLEU results obtained for the 1000-best translations indicate that word-graphs and hypergraphs encode translations of similar quality. Thus, the IMT systems that use these word-graphs and hypergraphs can be compared in a fair way.

Then, we evaluated different setups of the proposed IMT approach. Table 3 displays the IMT results obtained for the EU and TED tasks. We report KSMR (as a percentage) for the independent suffix formalization (ISF) and the conditioned suffix formalization (CSF) using both phase-based (PB) and hierarchical (HT) translation models. The KSMR result of ISF using a phrase-based model can be considered our baseline since this setup is comparable to that used in (Barrachina et al., 2009). Results for HT consistently outperformed the corresponding results for PB. Similarly, results for CSF were consistently better than those for ISF. More specifically, no statistically significant difference were found between ISF with HT and CSF with PB but both statistically outperformed the baseline (ISF with PB). Finally, CSF with HT statistically outperformed the other three configurations reducing KSMR by ~ 2.2 points with respect to the baseline. We hypothesize that the better results of HT can be explained by its more efficient representation of word reordering. Regarding the CSF, its better results are due to the better suffixes that can be obtained by taking into account the actual prefix validated by the user.

EU		TED	
PE	**IMT**	**PE**	**IMT**
PKSR [%]	KSR [%]	PKSR [%]	KSR [%]
27.1	**14.1 (48%)**	40.8	**29.7 (27.2%)**

Table 4: Estimation of the effort required to translate the test partition of the EU and TED tasks using post-editing with word-completion (PE) and IMT under the independent suffix formalization (IMT). We used hierarchical MT in both approaches. In parenthesis we display the estimated effort reduction of IMT with respect to PE.

Finally, we compared the estimated human effort required to translate the test partitions of the EU and TED corpora with the best IMT configuration (independent suffix formalization with hierarchical translation model) and a conventional post-editing (PE) CAT system with word-completion. That is, when the user corrects a character, the PE system automatically proposes a different word that begins with the given word prefix but, obviously, the rest of the sentence is not changed. According to the results, the estimated human effort to generate the error-free translations was significantly reduced with respect to using the conventional PE approach. IMT can save about 48% of the overall eastimated effort for the EU task and about 27% for the TED task.

7 Summary and Future Work

We have proposed a new IMT approach that uses hierarchical SMT models as its underlying translation technology. This approach is based on a statistical formalization previously described in the literature that includes stochastic error correction. Additionally, we have proposed a refined formalization that improves the quality of the IMT suffixes by taking

into account the prefix validated by the user. Moreover, since word-graphs constitute a particular case of hypergraphs, we are able to manage both phrase-based and hierarchical translation models in a unified IMT framework.

Simulated results on two different translation tasks showed that hierarchical translation models outperform phrase-based models in our IMT framework. Additionally, the proposed alternative IMT formalization also allows to improve the results of the IMT formalization previously described in the literature. Finally, the proposed IMT system with hierarchical SMT models largely reduces the estimated user effort required to generate correct translations in comparison to that of a conventional post-edition system. We look forward to corroborating these result in test with human translators.

There are many ways to build on the work described here. In the near future, we plan to explore the following research directions:

- Alternative IMT scenarios where the user is not bounded to correct translation errors in a left-to-right fashion. In such scenarios, the user will be allowed to correct errors at any position in the translation while the IMT system will be required to derive translations compatible with these isolated corrections.

- Adaptive translation engines that take advantage of the user's corrections to improve its statistical models. As the translator works and corrects the proposed translations, the translation engine will be able to make better predictions. One of the first works on this topic was proposed in (Nepveu et al., 2004). More recently, Ortiz-Martínez et al. (2010) described a set of techniques to obtain an incrementally updateable IMT system, solving technical problems encountered in previous works.

- More sophisticated measures to estimate the human effort. Specifically, measures that estimate the cognitive load involve in reading, understanding and detecting an error in a translation (Foster et al., 2002), in contrast KSMR simply considers a constant cost. This will lead to a more accurate estimation of the improvements that may be expected by a human user.

Max-Margin Synchronous Grammar Induction for Machine Translation

Xinyan Xiao and **Deyi Xiong***

Abstract

Traditional synchronous grammar induction estimates parameters by maximizing likelihood, which only has a loose relation to translation quality. Alternatively, we propose a max-margin estimation approach to discriminatively inducing synchronous grammars for machine translation, which directly optimizes translation quality measured by BLEU. In the max-margin estimation of parameters, we only need to calculate Viterbi translations. This further facilitates the incorporation of various non-local features that are defined on the target side. We test the effectiveness of our max-margin estimation framework on a competitive hierarchical phrase-based system. Experiments show that our max-margin method significantly outperforms the traditional two-step pipeline for synchronous rule extraction by 1.3 BLEU points and is also better than previous max-likelihood estimation method.

1 Introduction

Synchronous grammar induction, which refers to the process of learning translation rules from bilingual corpus, still remains an open problem in statistical machine translation (SMT). Although state-of-the-art SMT systems model the translation process based on synchronous grammars (including bilingual phrases), most of them still learn translation rules via a pipeline with word-based heuristics (Koehn et al., 2003). This pipeline first builds word alignments using heuristic combination strategies, then heuristically extracts rules that are consistent with word alignments. Such heuristic pipeline is not elegant theoretically. It brings an undesirable gap that separates modeling and learning in an SMT system.

Therefore, researchers have proposed alternative approaches to learning synchronous grammars directly from sentence pairs without word alignments, via generative models (Marcu and Wong, 2002; Cherry and Lin, 2007; Zhang et al., 2008; DeNero et al., 2008; Blunsom et al., 2009; Cohn and Blunsom, 2009; Neubig et al., 2011; Levenberg et al., 2012) or discriminative models (Xiao et al., 2012). Theoretically, these approaches describe how sentence pairs are generated by applying sequences of synchronous rules in an elegant way. However, they learn synchronous grammars by maximizing likelihood,[1] which only has a loose relation to translation quality (He and Deng, 2012). Moreover, generative models are normally hard to be extended to incorporate useful features, and the discriminative synchronous grammar induction model proposed by Xiao et al. (2012) only incorporates *local* features defined on parse trees of the source language. *Non-local* features, which encode information from parse trees of the target language, have never been exploited before due to the computational complexity of normalization in max-likelihood estimation.

Consequently, we would like to learn synchronous grammars in a discriminative way that can directly maximize the end-to-end translation quality measured by BLEU (Papineni et al., 2002), and is also able to incorporate non-local features from target parse trees.

We thus propose a max-margin estimation method

*Corresponding author

[1] More precisely, the discriminative model by Xiao et al. (2012) maximizes conditional likelihood.

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 255–264,
Seattle, Washington, USA, 18-21 October 2013.

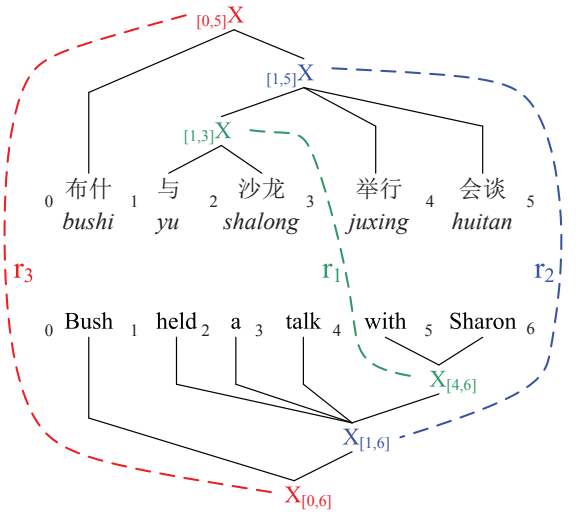
to discriminatively induce synchronous grammar directly from sentence pairs without word alignments. We try to maximize the margin between a reference translation and a candidate translation with translation errors that are measured by BLEU. The more serious the translation errors, the larger the margin. In this way, our max-margin method is able to learn synchronous grammars according to their translation performance. We further incorporate various *non-local* features defined on target parse trees. We efficiently calculate the non-local feature values of a translation over its exponential derivation space using the inside-outside algorithm. Because our max-margin estimation optimizes feature weights only by the feature values of Viterbi and reference translations, we are able to efficiently perform optimization even with non-local features.

We apply the proposed max-margin estimation method to learn synchronous grammars for a hierarchical phrase-based translation system (Chiang, 2007) which typically produces state-of-the-art performance. With non-local features defined on target parse trees, our max-margin method significantly outperforms the baseline that uses synchronous rules learned from the traditional pipeline by 1.3 BLEU points on large-scale Chinese-English bilingual training data.

The remainder of this paper is organized as follows. Section 2 presents the discriminative synchronous grammar induction model with the non-local features. In Section 3, we elaborate our max-margin estimation method which is able to directly optimize BLEU, and discuss how we induce grammar rules. Local and non-local features are described in Section 4. Finally, in Section 5, we verify the effectiveness of our method through experiments by comparing it against both the traditional pipeline and max-likelihood estimation method.

2 Discriminative Model with Non-local Features

Let $\mathcal{S}$ denotes the set of all strings in a source language. Given a source sentence $\mathbf{s} \in \mathcal{S}$, $\mathcal{T}(s)$ denotes all candidate translations in the target language that can be generated by a synchronous grammar $\mathbf{G}$. A translation $t \in \mathcal{T}(s)$ is generated by a sequence of translation steps $(r_1, ..., r_n)$, where we apply a synchronous rule $r \in \mathbf{G}$ in one step. We refer to such a sequence of translation steps as a **derivation** (See Figure 1) and denote it as $\mathbf{d} \in \mathcal{D}(\mathbf{s})$, where $\mathcal{D}(\mathbf{s})$ represents the derivation space of a source sentence. Given an input source sentence $\mathbf{s}$, we output a pair $\langle \mathbf{t}, \mathbf{d} \rangle$ in SMT. Thus, we study the triple $\langle \mathbf{s}, \mathbf{t}, \mathbf{d} \rangle$ in SMT.



r_1: $\langle$ *yu shalong* $\Rightarrow$ with Sharon $\rangle$
r_2: $\langle$ X *juxing huitan* $\Rightarrow$ *held a talk* X $\rangle$
r_3: $\langle$ *bushi* X $\Rightarrow$ Bush X $\rangle$

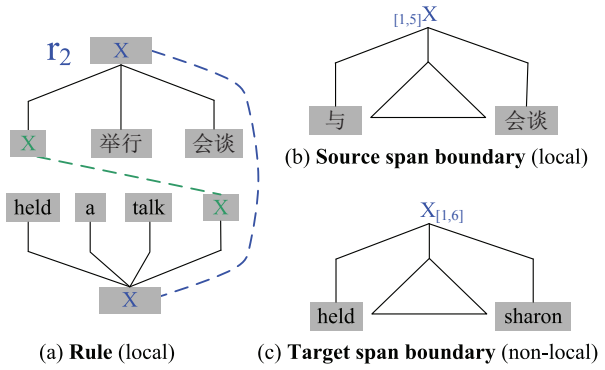
Figure 1: A derivation of a sentence pair represented by a synchronous tree. The above and below part are the parses in the source language side and the target language side respectively. Left subscript of a node X denotes the source span, while right subscript denotes the target span. A dashed line denotes an alignment from a source span to a target span. The annotation for a dashed line corresponds to the rewriting rule used in the corresponding step of the derivation.

In our discriminative model, we calculate the value of a triple $\langle \mathbf{s}, \mathbf{t}, \mathbf{d} \rangle$ according to the following **scoring function**:

$$f(\mathbf{s}, \mathbf{t}, \mathbf{d}) = \theta^T \Phi(\mathbf{s}, \mathbf{t}, \mathbf{d}) \quad (1)$$

where $\theta \in \mathbf{\Theta}$ is a feature weight vector, and Φ is the **feature function**.

There are exponential outputs in SMT. Therefore it is necessary to factorize the feature function in order to perform efficient calculation over the SMT output space using dynamic programming. We decompose the feature function of a triple $\langle \mathbf{s}, \mathbf{t}, \mathbf{d} \rangle$ into



(a) **Rule** (local) (b) **Source span boundary** (local) (c) **Target span boundary** (non-local)

Figure 2: Example features for the derivation in Figure 1. Shaded nodes denote information encoded in the feature.

$\mathbf{s}, \mathbf{S}, \mathcal{S}$	$\mathbf{s}$ is a sentence in a source language; $\mathbf{S}$ means source training sentences; $\mathcal{S}$ denotes all the possible sentences;
$\mathbf{t}, \mathbf{T}, \mathcal{T}$	symbols for the target language that similar to $\mathbf{s}$, $\mathbf{S}$, $\mathcal{S}$;
$\mathbf{d}, \mathcal{D}$	derivation and derivation space;
$\mathcal{D}(\mathbf{s})$	space of derivations for a source sentence;
$\mathcal{D}(\mathbf{s}, \mathbf{t})$	space of derivations for a source sentence with its translation;
$\mathcal{H}(\mathbf{s})$	hypergraph that represents $\mathcal{D}(\mathbf{s})$;
$\mathcal{H}(\mathbf{s}, \mathbf{t})$	hypergraph that represents $\mathcal{D}(\mathbf{s}, \mathbf{t})$;

Table 1: Notations in this paper. We give an abstract of related notations for clarity.

a sum of values of each synchronous rule in the derivation $\mathbf{d}$.

$$\Phi(\mathbf{s}, \mathbf{t}, \mathbf{d}) = \sum_{r \in \mathbf{d}} \underbrace{\phi(r, \mathbf{s})}_{\textbf{local}} + \sum_{r \in \mathbf{d}} \underbrace{\phi(r, \mathbf{s}, \mathbf{t})}_{\textbf{non-local}} \quad (2)$$

Our feature functions include both local and non-local features. A feature is a **local** feature if and only if it can be factored among the translation steps in a derivation. In other words, the value of a local feature for $\langle \mathbf{s}, \mathbf{t}, \mathbf{d} \rangle$ can be calculated as a sum of local scores in each translation step, and the calculation of each local score only requires to look at the rule used in corresponding step and the input sentence. Otherwise, the feature is a **non-local** feature. Our discriminative model allows to incorporate non-local features that are defined on target translations.

For example, a rule feature in Figure 2(a), which indicates the application of a specific rule in a derivation, is a local feature. A source span boundary feature in Figure 2(b) that is defined on the source parse tree is also a local feature. However, a target span boundary feature in Figure 2(c), which assesses the target parse structure, is a non-local feature. According to Figure 1, the span is parsed in step r_2, but it also depends on the translation boundary word "held" generated in previous step r_1. We will describe the details of both local and non-local features that we use in Section 4.

Non-local features enable us to model the target parse structure in a derivation. However, it is computationally expensive to calculate the expected values of non-local features over $\mathcal{D}(\mathbf{s})$, as non-local features require to record states of target boundary words and result in an extremely large number of states during dynamic programming. Fortunately, when integrating out derivations over the derivation space $\mathcal{D}(\mathbf{s}, \mathbf{t})$ of a source sentence and its translation, we can efficiently calculate the non-local features. Because all derivations in $\mathcal{D}(\mathbf{s}, \mathbf{t})$ share the same translation, there is no need to maintain states for target boundary words. We will discuss this computational problem in details in Section 3.3. In the proposed max-margin estimation described in next section, we only need to integrate out derivation for a Viterbi translation and a reference translation when updating feature weights. Therefore, the defined non-local features allow us to not only explore useful knowledge on the target parse trees, but also compute them efficiently over $\mathcal{D}(\mathbf{s}, \mathbf{t})$ during max-margin estimation.

3 Max-Margin Estimation

In this section, we describe how we use a parallel training corpus $\{\mathbf{S}, \mathbf{T}\} = \{(\mathbf{s}^{(i)}, \mathbf{t}^{(i)})\}_{i=1}^{N}$ to estimate feature weights θ, which contain parameters of the induced synchronous grammars and the defined non-local features.

We choose the parameters that maximize the translation quality measured by BLEU using the *max-margin estimation* (Taskar et al., 2004). Margin refers to the difference of the model score between a reference translation $\mathbf{t}^{(i)}$ and a candidate translation $\mathbf{t}$. We hope that the worse the translation quality of $\mathbf{t}$, the larger the margin between $\mathbf{t}$ and $\mathbf{t}^{(i)}$. In this way, we penalize larger translation

errors more severely than smaller ones. This intuition is expressed by the following equation.

$$\begin{aligned} &\min \ \frac{1}{2}\|\theta\|^2 \\ &s.t. \ f(\mathbf{s}^{(i)}, \mathbf{t}^{(i)}) - f(\mathbf{s}^{(i)}, \mathbf{t}) \geq cost(\mathbf{t}^{(i)}, \mathbf{t}) \\ &\quad \forall \mathbf{t} \in \mathcal{T}(\mathbf{s}^{(i)}) \end{aligned} \tag{3}$$

Here, $f(\mathbf{s}, \mathbf{t})$ is the feature function of a translation, and **cost function** $cost(\mathbf{t}^{(i)}, \mathbf{t})$ measures the translation errors of a candidate translation $\mathbf{t}$ comparing with a reference translation $\mathbf{t}^{(i)}$. We define the cost function via the widely-used translation evaluation metric BLEU. We use the smoothed sentence level BLEU-4 (Lin and Och, 2004) here:

$$cost(\mathbf{t}^{(i)}, \mathbf{t}) = 1 - \text{BLEU-4}(\mathbf{t}^{(i)}, \mathbf{t}) \tag{4}$$

In Section 3.1, we will discuss how we use the scoring function $f(\mathbf{s}, \mathbf{t}, \mathbf{d})$ to calculate $f(\mathbf{s}, \mathbf{t})$. Then in Section 3.2, we recast the equation (3) as an unconstrained empirical loss minimization problem, and describe the learning algorithm for optimizing θ and inducing $\mathbf{G}$. Finally, we give the details of inference for the learning algorithm in Section 3.3.

3.1 Integrate Out Derivation by Averaging

Although we only model the triple $\langle \mathbf{s}, \mathbf{t}, \mathbf{d} \rangle$ in the equation (1), it's necessary to calculate the scoring function $f(\mathbf{s}, \mathbf{t})$ of a translation by integrating out the variable of derivation as derivation is not observed in the training data.

We use an averaging computation over all possible derivations of a translation $\mathcal{D}(\mathbf{s}, \mathbf{t})$. We call this an average derivation based estimation:

$$f(\mathbf{s}, \mathbf{t}) = \frac{1}{|\mathcal{D}(\mathbf{s}, \mathbf{t})|} \sum_{\mathbf{d} \in \mathcal{D}(\mathbf{s}, \mathbf{t})} f(\mathbf{s}, \mathbf{t}, \mathbf{d}) \tag{5}$$

The "average derivation" can be considered as the geometric central point in the space $\mathcal{D}(\mathbf{s}, \mathbf{t})$.

Another possible way to deal with the latent derivation is max-derivation, which uses the max-operator over $\mathcal{D}(\mathbf{s}, \mathbf{t})$. The max derivation method sets $f(\mathbf{s}, \mathbf{t})$ as $\max_{\mathbf{d} \in \mathcal{D}(\mathbf{s}, \mathbf{t})} f(\mathbf{s}, \mathbf{t}, \mathbf{d})$. It is often adopted in traditional SMT systems. Nevertheless, we instead use average-derivation for two reasons.[2] First, as a translation has an exponential number of derivations, finding the max derivation of a reference translation for learning is nontrivial (Chiang et al., 2009). Second, the max derivation estimation will result in a low rule coverage, as rules in a max derivation only covers a small fraction of rules in the $\mathcal{D}(\mathbf{s}, \mathbf{t})$. Because rule coverage is important in synchronous grammar induction, we would like to explore the entire derivation space using the average operator.

[2] Imagine that $\mathcal{H}(\mathbf{s}, \mathbf{t})$ in the Algorithm 1 is replaced by a maximum derivation in $\mathcal{H}(\mathbf{s}, \mathbf{t})$.

3.2 Learning Algorithm

We reformulate the equation (3) as an unconstrained empirical loss minimization problem as follows:

$$\min \frac{\lambda}{2}\|\theta\|^2 + \frac{1}{N}\sum_{n=1}^{N} L(\mathbf{s}^{(i)}, \mathbf{t}^{(i)}, \theta) \tag{6}$$

Where λ denotes the regularization strength for L2-norm. The loss function of a sentence pair $L(\mathbf{s}^{(i)}, \mathbf{t}^{(i)}, \theta)$ is a convex hinge loss function denoted by:

$$\begin{aligned} &\max\{0, -f(\mathbf{s}^{(i)}, \mathbf{t}^{(i)}) \\ &\quad + \max_{\mathbf{t} \in \mathcal{T}(\mathbf{s}^{(i)})} \Big(f(\mathbf{s}^{(i)}, \mathbf{t}) + cost(\mathbf{t}^{(i)}, \mathbf{t}) \Big) \} \end{aligned} \tag{7}$$

According to the second max-operator in the hinge loss function, the optimization towards BLEU is expressed by **cost-augmented** inference. Cost-augmented inference finds a translation that has a maximum model score augmented with cost.

$$\hat{\mathbf{t}} = \max_{\mathbf{t} \in \mathcal{T}(\mathbf{s}^{(i)})} \Big(f(\mathbf{s}^{(i)}, \mathbf{t}) + cost(\mathbf{t}^{(i)}, \mathbf{t}) \Big) \tag{8}$$

We applied the Pegasos algorithm for the optimization of equation (6) (Shalev-Shwartz et al., 2007). This is an online algorithm, which alternates between stochastic gradient descent steps and projection steps. When the loss function is non-zero, it updates weights according to the sub-gradient of the hinge loss function. Using the average scoring function in the equation (5), the sub-gradient of hinge loss function for a sentence pair is the difference of average feature values between a Viterbi translation

Algorithm 1 UPDATE($\mathbf{s}, \mathbf{t}, \theta, \mathbf{G}$) ▷ One step in online algorithm. $\mathbf{s}$, $\mathbf{t}$ are short for $\mathbf{s}^{(i)}$, $\mathbf{t}^{(i)}$ here

1: $\mathcal{H}(\mathbf{s}, \mathbf{t}) \leftarrow$ BIPARSE($\mathbf{s}, \mathbf{t}, \theta$) ▷ Build hypergraph of reference translation
2: $\mathbf{G} \leftarrow \mathbf{G} + \mathcal{H}(\mathbf{s}, \mathbf{t})$ ▷ Discover rules from $\mathcal{H}(\mathbf{s}, \mathbf{t})$
3: $\hat{\mathbf{t}}, \hat{\mathbf{d}} \leftarrow \arg\max_{\langle \mathbf{t}', \mathbf{d}' \rangle \in \mathcal{D}(\mathbf{s})} f(\mathbf{s}, \mathbf{t}', \mathbf{d}') + cost(\mathbf{t}, \mathbf{t}')$ ▷ Find Viterbi translation
4: $\mathcal{H}(\mathbf{s}, \hat{\mathbf{t}}) \leftarrow$ BIPARSE($\mathbf{s}, \hat{\mathbf{t}}, \theta$) ▷ Build hypergraph of Viterbi translation
5: **if** $f(\mathbf{s}, \mathbf{t}) < f(\mathbf{s}, \hat{\mathbf{t}}) + cost(\mathbf{t}, \hat{\mathbf{t}})$ **then**
6: $\quad \theta \leftarrow (1 - \eta\lambda)\theta + \eta \times \frac{\partial \mathbf{L}}{\partial \theta}(\mathcal{H}(\mathbf{s}, \mathbf{t}), \mathcal{H}(\mathbf{s}, \hat{\mathbf{t}}))$ ▷ Update θ by gradient $\frac{\partial \mathbf{L}}{\partial \theta}$ and learning rate η
7: $\quad \theta \leftarrow \min\{1, \frac{1/\sqrt{\lambda}}{\|\theta\|}\} \times \theta$ ▷ Projection by scaling
8: **return** $\mathbf{G}$, θ

and a reference translation.

$$\frac{\partial \mathbf{L}}{\partial \theta} = \frac{1}{|\mathcal{D}(\mathbf{s}^{(i)}, \mathbf{t}^{(i)})|} \sum_{\mathbf{d} \in \mathcal{D}(\mathbf{s}^{(i)}, \mathbf{t}^{(i)})} \Phi(\mathbf{s}^{(i)}, \mathbf{t}^{(i)}, \mathbf{d}) - \frac{1}{|\mathcal{D}(\mathbf{s}^{(i)}, \hat{\mathbf{t}})|} \sum_{\mathbf{d} \in \mathcal{D}(\mathbf{s}^{(i)}, \hat{\mathbf{t}})} \Phi(\mathbf{s}^{(i)}, \hat{\mathbf{t}}, \mathbf{d}) \quad (9)$$

Algorithm 1 shows the procedure of one step in the online optimization algorithm. The procedure discovers rules and updates weights in an online fashion. In the procedure, we first biparse the sentence pair to construct a synchronous hypergraph of a reference translation (line 1). In the biparsing algorithm, synchronous rules for constructing hyperedges are not required to be in $\mathbf{G}$, but can be any rules that follow the form defined in Chiang (2007). Thus, the biparsing algorithm can discover new rules that are not in $\mathbf{G}$. Then we collect the translation rules discovered in the hypergraph of the reference translation (line 2), which are rules indicated by hyperedges in the hypergraph. We then calculate the Viterbi translation according to the scoring function and cost function (see Section 3.3) (line 3), and build the synchronous hypergraph for the Viterbi translation (line 4). Finally, we update weights according to the Pegasos algorithm (line 5). The sub-gradient is calculated based on the hypergraph of Viterbi translation and reference translation.

In practice, in order to process the data in a parallel manner, we use a larger step size of 1000 for the learning algorithm. In each step of our online optimization algorithm, we first biparse 1000 reference sentence pairs in parallel. Then, we collect grammar rules from the generated reference hypergraphs. After that, we compute the gradients of 1000 sentence pairs in parallel, by calculating feature weights over reference hypergraphs and Viterbi hypergraphs. Finally, we update the feature weights using the sum of these gradients.

3.3 Inference

There are two parts that need to be calculated in the learning algorithm: finding a cost-augmented Viterbi translation according to the scoring function and cost function (Equation 8), and constructing synchronous hypergraphs for the Viterbi and reference translation so as to discover rules and calculate average feature values in Equation (9). Following the traditional decoding procedure, we resort to the cube-pruning based algorithm for approximation.

To find the Viterbi translation, we run the traditional translation decoding algorithm (Chiang, 2007) to get the best derivation. Then we use the translation yielded by the best derivation as the Viterbi translation. In order to obtain the BLEU score in the cost function, we need to calculate the ngram precision. It is calculated in a way similar to the calculation of the ngram language model. The computation of BLEU-4 requires to record 3 boundary words in both the left and right side during dynamic programming. Therefore, even when we use a language model whose order is less than 4, we still expands the states to record 3 boundary words so as to calculate the cost measured by BLEU.

We build synchronous hypergraphs using the cube-pruning based biparsing algorithm (Xiao et al., 2012). Algorithm 2 shows the procedure. Using a chart, the biparsing algorithm constructs k-best alignments for every source word (lines 1-5) and k-best hyperedges for every source span (lines 6-13) from the bottom up. Thus, a synchronous hypergraph is generated during the construction of the chart. More specifically, for a source span, it first creates cubes $\mathcal{L}$ for all source parses γ that are in-

Algorithm 2 BIPARSE($\mathbf{s}, \mathbf{t}, \theta$) ▷ (Xiao et al., 2012)

▷ Create k-best alignments for each source word
1: **for** $i \leftarrow 1, .., |\mathbf{s}|$ **do**
2: **for** $j \leftarrow 1, .., |\mathbf{t}|$ **do**
3: $L_j \leftarrow \{\varepsilon, t_j\}$ ▷ s_i aligns to t_j or not
4: $\mathcal{L} \leftarrow \langle L_1, ..., L_{|t|} \rangle$
5: $chart[s, i] \leftarrow$ KBEST($\mathcal{L}$,$\otimes$,θ)
▷ Create k-best hyperedges for each source span
6: $\mathcal{H} \leftarrow \emptyset$
7: **for** $h \leftarrow 1, .., |\mathbf{s}|$ **do** ▷ h is the size of span
8: **for all** i, j s.t. $j - i = h$ **do**
9: $\mathcal{L} \leftarrow \emptyset$
10: **for** γ inferable from $chart$ **do**
11: $\mathcal{L} \leftarrow \mathcal{L}$ + $\langle chart[\gamma_1], ..., chart[\gamma_{|\gamma|}] \rangle$
12: $chart[X, i, j] \leftarrow$ KBEST($\mathcal{L}$,$\otimes$,θ)
13: $\mathcal{H} \leftarrow \mathcal{H}$ + $chart[X, i, j]$ ▷ save hyperedges
14: **return** $\mathcal{H}$

ferable from the chart (lines 9-11). Here γ_i is a partial source parse that covers either a single source word or a span of source words. Then it uses the cube pruning algorithm to keep the top k derivations among all partial derivations that share the same source span $[i, j]$ (line 12). Notably, this biparsing algorithm does not require specific translation rules as input. Instead, it is able to discover new synchronous grammar rules when constructing a synchronous hypergraph: extracting each hyperedge in the hypergraph as a synchronous rule.

Based on the biparsing algorithm, we are able to construct the reference hypergraph $\mathcal{H}(\mathbf{s}^{(i)}, \mathbf{t}^{(i)})$ and Viterbi hypergraph $\mathcal{H}(\mathbf{s}^{(i)}, \hat{\mathbf{t}})$. By the reference hypergraph, we collect new synchronous translation rules and record them in the grammar $\mathbf{G}$. We also calculate the average feature values of hypergraphs using the inside-outside algorithm (Li et al., 2009), so as to compute the gradients.

4 Features

One advantage of the discriminative method is that it enables us to incorporate arbitrary features. As shown in Section 2, our model incorporates both local and non-local features.

4.1 Local Features

Rule features We associate each rule with an indicator feature. Each indicator feature counts the number of times that a rule appears in a derivation. In this way, we are able to learn a weight for every rule according to the entire structure of sentence.

Word association features Lexicalized features are widely used in traditional SMT systems. Here we adopt two lexical weights called noisy-or features (Zens and Ney, 2004). The noisy-or feature is estimated by word translation probabilities output by GIZA++. We set the initial weight of these two lexical scores with equivalent positive values. The lexical weights enable our system to score and rank the hyperedges at the beginning. Although word alignment features are used, we do not constrain the derivation space of a sentence pair by prefixed word alignment, and do not require any heuristic alignment combination strategy.

Length feature We integrate the length of target translation that is used in traditional SMT system as our feature.

Source span boundary features We use this kind of feature to assess the source parse tree in a derivation. Previous work (Xiong et al., 2010) has shown the importance of phrase boundary features for translation. Actually, this kind of feature is a good cue for deciding the boundary where a rule is to be learnt. Following Taskar et al. (2004), for a bispan $[i, j, k, l]$ in a derivation, we define the feature templates that indicates the boundaries of a span by its beginning and end words: $\{B : s_{i+1}; E : s_j; BE : s_{i+1}, s_j\}$.

Source span orientation features Orientation features are only used for those spans that are swapping. In Figure 1, the translation of source span $[1, 3]$ is swapping with that of span $[4, 5]$ by r_2, thus orientation feature for span $[1, 3]$ is activated. We also define three feature templates for a swapping span similar to the boundary features: $\{B : s_{i+1}; E : s_j; BE : s_{i+1}, s_j\}$. In practice, we add a prefix to the orientation features so as to distinguish these features from the boundary features.

4.2 Non-local Features

Target span boundary features We also want to assess the target tree structure in a derivation. We define these features in a way similar to source span boundary features. For a bispan $[i, j, k, l]$ in a derivation, we define the feature templates that indicates

System	Grammar Size	MT03	MT04	MT05	Avg.
Moses	302.5M	34.26	36.56	32.69	34.50
Baseline	77.8M	33.83	35.81	33.23	34.29
Max-margin	59.4M	34.62	37.14	34.00	35.25
+Sparse feature		35.48	37.31	34.07	35.62

Table 2: Experiment results. Baseline is an in-house implementation of hierarchical phrase based system. *Moses* denotes the implementation of hierarchical phrased-model in Moses (Koehn et al., 2007). $+Sparsefeature$ means that those sparse features used in the grammar induction are also used during decoding. The improvement of max-margin over Baseline is statistically significant ($p < 0.01$).

target span boundary as: $\{B : t_{k+1}; E : t_l; BE : t_{k+1}, t_l\}$.

Target span orientation features Similar target orientation features are used for a swapping span $[i, j, k, l]$ with feature templates $\{B : t_{k+1}; E : t_l; BE : t_{k+1}, t_l\}$.

Relative position features Following Blunsom and Cohn (Blunsom and Cohn, 2006), we integrate features indicating the closeness to the alignment matrix diagonal. For an aligned word pair with source position i and target position j, the value of this feature is $|\frac{i}{|\mathbf{s}|} - \frac{j}{|\mathbf{t}|}|$. As this feature depends on the length of the target sentence, it is a non-local feature.

Language model We also incorporate an ngram language model which is an important component in SMT. For efficiency, we use a 3-gram language model trained on the target side of our training data during the induction of synchronous grammars.

5 Experiment

In this section, we present our experiments on the NIST Chinese-to-English translation tasks. We first compare our max-margin based method with the traditional pipeline on a large bitext which contains 1.1 million sentences. We then present a detailed comparison on a smaller dataset, in order to analyze the effectiveness of max-margin estimation comparing with the max likelihood estimation (Xiao et al., 2012), and also the effectiveness of the non-local features that are defined on the target side.

5.1 Setup

The baseline system is the hierarchical phrase based system (Chiang, 2007). We used a bilingual corpus that contains 1.1M sentences (44.6 million words) of up to length 40 from the LDC data.[3] Our 5-gram language model was trained by SRILM toolkit (Stolcke, 2002). The monolingual training data includes the Xinhua section of the English Gigaword corpus and the English side of the entire LDC data (432 million words).

We used the NIST 2002 (MT02) as our development set, and the NIST 2003-2005 (MT03-05) as the test set. Case-insensitive NIST BLEU-4 (Papineni et al., 2002) is used to measure translation performance, and also the cost function in the max-margin estimation. Statistical significance in BLEU differences was tested by paired bootstrap re-sampling (Koehn, 2004). We used minimum error rate training (MERT) (Och, 2003) to optimize feature weights for the traditional log-linear model.

We used the same decoder as the baseline system in all estimation methods. Without special explanation, we used the same features as those in the traditional pipeline: forward and backward translation probabilities, forward and backward lexical weights, count of extracted rules, count of glue rules, length of translation, and language model. For the lexical weights we used the noisy-or in all configurations including the baseline system. For the discriminative grammar induction, rule translation probabilities were calculated using the expectations of rules in the synchronous hypergraphs of sentence pairs.

As our max-margin synchronous grammar induction is trained on the entire bitext, it is necessary to load all the rules into the memory during training. To control the size of rule table, we used Viterbi-

[3]Including LDC2002E18, LDC2003E07, LDC2003E14, LDC2004T07, LDC2005T06 and Hansards portion of LDC2004T08.

System	Feature Function	MT03	MT04	MT05	Avg.
Baseline	—	31.76	33.08	31.06	31.96
Max-likelihood	local	32.84	34.54	31.61	33.00
Max-margin	local	32.97	34.92	31.99	33.29
	local,non-local	33.27	34.83	32.32	33.47

Table 3: Comparison of Max-margin and Max-likelihood estimation on a smaller corpus. For max-margin method, we present two results according to the usages of non-local features. The max-margin with non-local features significantly outperforms the Baseline ($p < 0.01$) and also the max-likelihood estimation ($p < 0.05$).

pruning (Huang, 2008) when collecting rules as shown in line 2 of optimization procedure in Section 3.2. Furthermore, we aggressively discarded those large rules (The number of source symbols or the number of target symbols are more than two) that occur only in one sentence. Whenever the learning algorithm processes 50K sentences, we performed this discarding operation for large rules.

5.2 Result on Large Dataset

Table 2 shows the translation results. Our method induces 59.4 million synchronous rules, which are 76.3% of the grammar size of baseline. Note that Moses allows the boundary words of a phrase to be unaligned, while our baseline constraints the initial phrase to be tightly consistent with word alignment. Therefore, Moses extract a much larger rule table than that of our baseline.

With fewer translation rules, our method obtains an average improvement of +0.96 BLEU points on the three test sets over the Baseline. As the difference between the baseline and our max-margin synchronous grammar induction model only lies in the grammar, this result clearly denotes that our learnt grammar does outperform the grammar extracted by the traditional two-step pipeline.

We also incorporate the sparse features during decoding in a way similar to Xiao et al. (2012) and Dyer et al. (2011). In order to optimize these sparse features with the dense features by MERT, we group features of the same type into one coarse "summary feature", and get three such features including: rule, phrase-boundary and phrase orientation features. In this way, we rescale the weights of the three "summary features" with the 8 dense features by MERT. We achieve a further improvement of +0.37 BLEU points. Therefore, our training algorithm is able to learn the useful information encoded by the sparse features for translation.

5.3 Comparison of Estimation Objective and Non-Local Feature

We want to investigate whether the max-margin estimation is able to outperform the max-likelihood estimation method (Xiao et al., 2012). Therefore we carried out experiments to compare them directly. As the max-margin method is able to use non-local features, we compare two settings of features for the max-margin method. One uses only local features, the other uses both local and non-local features. Because the training procedure need to run on the entire corpus, which is time consuming, we therefore use a smaller corpus containing 50K sentences from the entire bitext for comparison.

Table 3 shows the results. When using only local features, the max-margin method consistently outperforms the max-likelihood method in all three test sets. This clearly shows the advantage of learning grammars by optimizing BLEU over likelihood.

When incorporating the non-local features into the max-margin method, we achieve further improvement against the max-margin method without non-local features. With non-local features, our max-margin estimation method outperforms the baseline by 1.5 BLEU points, and is better than the max-likelihood estimation by 0.5 BLEU points. Based on these results, we believe that non-local features, which encode information from target parse structures, are helpful for grammar induction. This further confirms the advance of the max-margin estimation, as it provides us a convenient way to use non-local features.

6 Related Work

As the synchronous grammar is the key component in SMT systems, researchers have proposed various methods to improve the quality of grammars. In addition to the generative and discriminative models introduced in Section 1, researchers also have made efforts on word alignment and grammar weight rescoring.

The first line is to modify word alignment by exploring information of syntactic structures (May and Knight, 2007; DeNero and Klein, 2010; Pauls et al., 2010; Burkett et al., 2010; Riesa et al., 2011). Such syntactic information is combined with word alignment via a discriminative framework. These methods prefer word alignments that are consistent with syntactic structure alignments. However, labeled word alignment data are required in order to learn the discriminative model.

Yet another line is to rescore the weights of translation rules. This line of work tries to improve the relative frequency estimation used in the traditional pipeline. They rescore the weights or probabilities of extracted rules. The rescoring is done by using the similar latent log-linear model as ours (Blunsom et al., 2008; Kääriäinen, 2009; He and Deng, 2012), or incorporating various features using labeled word aligned bilingual data (Huang and Xiang, 2010). However, in rescoring, translation rules are still extracted by the heuristic two-step pipeline. Therefore these previous work still suffers from the inelegance problem of the traditional pipeline.

Our work also relates to the discriminative training (Och, 2003; Watanabe et al., 2007; Chiang et al., 2009; Xiao et al., 2011; Gimpel and Smith, 2012) that has been widely used in SMT systems. Notably, these discriminative training methods are not used to learn grammar. Instead, they assume that grammar are extracted by the traditional two-step pipeline.

7 Conclusion

In this paper we have presented a max-margin estimation for discriminative synchronous grammar induction. By associating the margin with the translation quality, we directly learn translation rules that optimize the translation performance measured by BLEU. Max-margin estimation also provides us a convenient way to incorporate non-local features. Experiment results validate the effectiveness of optimizing parameters by BLEU, and the importance of incorporating non-local features defined on the target language. These results confirm the advantage of our max-margin estimation framework as it can both optimize BLEU and incorporate non-local features.

Feature engineering is very important for discriminative models. Researchers have proposed various types of features for machine translation, which are often estimated from word alignments. We would like to investigate whether further improvement can be achieved by incorporating such features, especially the context model (Shen et al., 2009) in the future. Because our proposed model is quite general, we are also interested in applying this method to induce linguistically motivated synchronous grammars for syntax-based SMT.

Error-Driven Analysis of Challenges in Coreference Resolution

Jonathan K. Kummerfeld and **Dan Klein**

Abstract

Coreference resolution metrics quantify errors but do not analyze them. Here, we consider an automated method of categorizing errors in the output of a coreference system into intuitive underlying error types. Using this tool, we first compare the error distributions across a large set of systems, then analyze common errors across the top ten systems, empirically characterizing the major unsolved challenges of the coreference resolution task.

1 Introduction

Metrics produce measurements that concisely summarize performance on the full range of error types, and for coreference resolution there has been extensive work on developing effective metrics (Luo, 2005; Recasens and Hovy, 2011). However, it is also valuable to tease apart the errors to understand their relative importance.

Previous investigations of coreference errors have focused on quantifying the importance of subtasks such as named entity recognition and anaphoricity detection, typically by measuring accuracy improvements when partial gold annotations are provided (Stoyanov et al., 2009; Pradhan et al., 2011; Pradhan et al., 2012). For coreference resolution the drawback of this approach is that decisions are often interdependent, and so even partial gold information is extremely informative. Also, previous work only considered errors by counting links, which does not capture certain errors in a natural way, e.g. when a system incorrectly divides a large entity into two parts, each with multiple mentions. Recent work has considered some of these issues, but only with small scale manual analysis (Holen, 2013).

We present a new tool that automatically classifies errors in the standard output of any coreference resolution system. Our approach is to identify changes that convert the system output into the gold annotations, and map the steps in the conversion onto linguistically intuitive error types. Since our tool uses only system output, we are able to classify errors made by systems of any architecture, including both systems that use link-based inference and systems that use global inference methods.

Using our tool we perform two studies to understand similarities and differences between systems. First, we compare the error distributions on coreference resolution of all of the systems from the CoNLL 2011 shared task plus several publicly available systems. This comparison adds to the analysis from the shared task by illustrating the substantial variation in the types of errors different systems make. Second, we investigate the aggregate behavior of ten state-of-the-art systems, providing a detailed characterization of each error type. This investigation identifies key outstanding challenges and presents the impact that solving each of them would have in terms of changes in the standard coreference resolution metrics.

We find that the best systems are not best across all error types, that a large proportion of span errors are due to superficial parse differences, and that the biggest performance loss is on missed entities that contain a small number of mentions.

This work presents a comprehensive investigation of common errors in coreference resolution, identifying particular issues worth focusing on in future research. Our analysis tool is available at code.google.com/p/berkeley-coreference-analyser/.

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 265–277,
Seattle, Washington, USA, 18-21 October 2013.

2 Background

Most coreference work focuses on accuracy improvements, as measured by metrics such as MUC (Vilain et al., 1995), B^3 (Bagga and Baldwin, 1998), CEAF (Luo, 2005), and BLANC (Recasens and Hovy, 2011). The only common forms of further analysis are results for anaphoricity detection and scores for each mention type (nominal, pronoun, proper). Two exceptions are: the detailed analysis of the Reconcile system by Stoyanov et al. (2009), and the multi-system comparisons in the CoNLL shared task reports (Pradhan et al., 2011, 2012).

A common approach to performance analysis is to calculate scores for nominals, pronouns and proper names separately, but this is a very coarse division (Ng and Cardie, 2002; Haghighi and Klein, 2009). More fine consideration of some subtasks does occur, for example, anaphoricity detection, which has been recognized as a key challenge in coreference resolution for decades and regularly has separate results reported (Paice and Husk, 1987; Sobha et al., 2011; Yuan et al., 2012; Björkelund and Farkas, 2012; Zhekova et al., 2012). Some work has also included anecdotal discussion of specific error types or manual classification of a small set of errors, but these approaches do not effectively quantify the relative impact of different errors (Chen and Ng, 2012; Martschat et al., 2012; Haghighi and Klein, 2009). In a recent paper, Holen (2013) presented a detailed manual analysis that considered a more comprehensive set of error types, but their focus was on exploring the shortcomings of current metrics, rather than understanding the behavior of current systems.

The detailed investigation presented by Stoyanov et al. (2009) is the closest to the work we present here. First, they measured accuracy improvements when their system was given gold annotations for three subtasks of coreference resolution: mention detection, named entity recognition, and anaphoricity detection. To isolate other types of errors they defined resolution classes, based on both the type of a mention, and properties of possible antecedents (for example, nominals that have a possible antecedent that is an exact string match). For each resolution class they measured performance while giving the system gold annotations for all other classes. While this approach is effective at characterizing variations between the nine classes they defined, it misses the cascade effect of errors that only occur when all mentions are being resolved at once.

President Clinton$_1$ is questioning the legitimacy of George W. Bush's election victory. Speaking last night to Democratic supporters in Chicago, **he** said Bush won the election only because Republicans stopped the vote-counting in Florida, and Mr. Clinton$_1$ praised Al Gore's campaign manager, Bill Daley, for the way he handled the election. "I$_2$ want to thank Bill Daley for his exemplary service as Secretary of Commerce. He was brilliant. I$_2$ think he did a brilliant job in leading Vice President Gore to victory myself$_2$."

Figure 1: Two coreference errors. Mentions are underlined and subscripts indicate entities. One error is a mention missing from the system output, *he*. The other is the division of references to Bill Clinton into two entities.

The only multi-system comparisons are the CoNLL task reports (Pradhan et al., 2011, 2012), which explored the impact of mention detection and anaphoricity detection through subtasks with different types of gold annotation. With a large set of systems, and well controlled experimental conditions, the tasks provided a great snapshot of progress in the field, which we aim to supplement by characterizing the major outstanding sources of error.

This work adds to previous investigations by providing a comprehensive and detailed analysis of errors. Our tool can automatically analyze any system's output, giving a reliable estimate of the relative importance of different error types.

3 Error Classification

When inspecting the output of coreference resolution systems, several types of errors become immediately apparent: entities that have been divided into pieces, spurious entities, non-referential pronouns that have been assigned antecedents, and so on. Our goal in this work is to automatically assign intuitive labels like these to errors in system output.

A simple approach, refining results by measuring the accuracy of subsets of the mentions, can be misleading. For example, in Figure 1, we can intuitively see two pronoun related mistakes: a missing mention (*he*), and a divided entity where the two pieces are the blue pronouns (I_2, I_2, *myself*$_2$) and the red proper names (*President Clinton*$_1$, *Mr. Clinton*$_1$).

Simply counting the number of incorrect pronoun links would miss the distinction between the two types of mistakes present.

One question in designing an error analysis tool like ours is whether to operate on just system output, or to also consider intermediate system decisions. We focused on using system output because other methods cannot uniformly apply to the full range of coreference resolution decoding methods, from link based methods to global inference methods.

Our overall approach is to transform the system output into the gold annotations, then map the changes made in the conversion process to errors. The transformation process is presented in Section 3.1 and Figure 2, and the mapping process is described in Section 3.2 and Figure 3.

3.1 Transformations

The first part of our error classification process determines the changes needed to transform the system output into the gold annotations. This five stage process is described below, and an abstract example is presented in Figure 2.

1. **Alter Span** transforms an incorrect system mention into a gold mention that has the same head token. In Figure 2 this stage is demonstrated by a mention in the leftmost entity, which has its span altered, indicated by the change from an X to a light blue circle.
2. **Split** breaks the system entities into pieces, each containing mentions from a single gold entity. In Figure 2 there are three changes in this stage: the leftmost entity is split into a red piece and a light blue piece, the middle entity is split into a dark red piece and an X, and the rightmost entity is split into singletons.
3. **Remove** deletes every mention that is not present in the gold annotations. In Figure 2 this means the four singleton X's are removed.
4. **Introduce** creates a singleton entity for each mention that is missing from the system output. In Figure 2 this stage involves the introduction of a light blue mention and two white mentions.
5. **Merge** combines entities to form the final, completely correct, set of entities. In Figure 2 the two red entities are merged, the singleton blue entity is merged with the rest of the blue entity, and the two white mentions are merged.

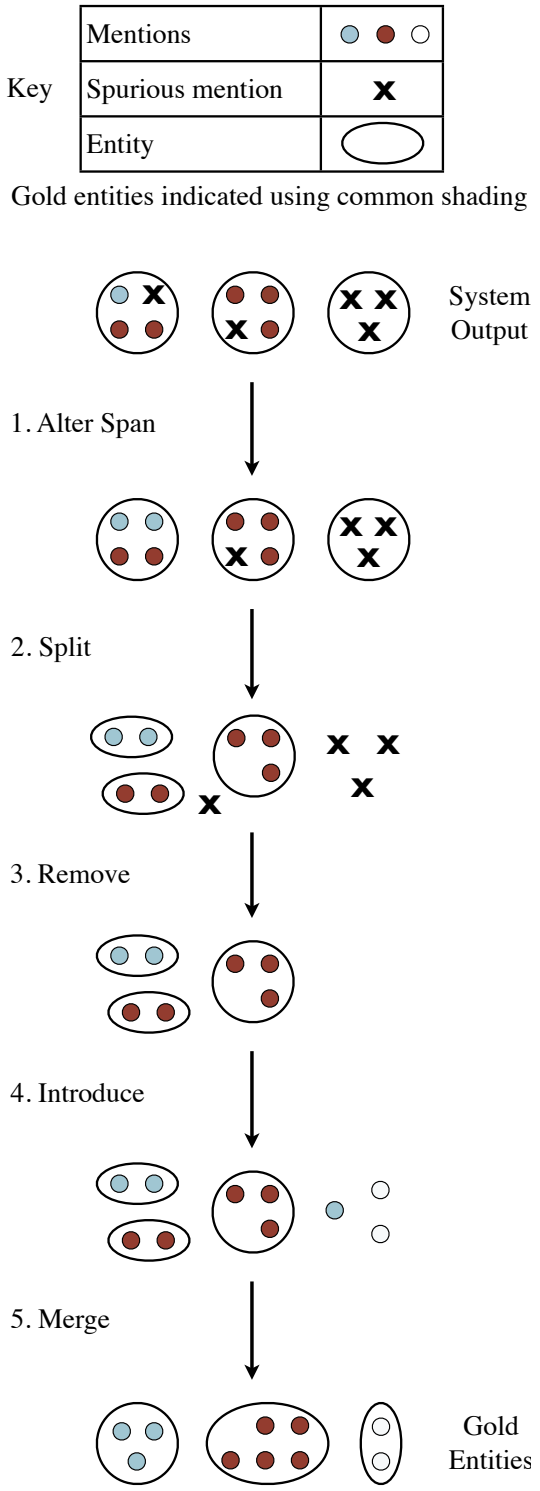

Figure 2: Abstract example of the transformation process that converts system output (at the top) to gold annotations (at the bottom).

	Operation(s)	Error	System	Gold
i)	Alter Span	Span error	*Gorbachev*	*Soviet leader Gorbachev*
ii)	Multiple Introduces and Merges	Missing Entity	- -	*the pills* *the tranquilizing pills*
iii)	Multiple Splits and Removes	Extra Entity	*human rights* *Human Rights*	- -
iv)	Introduce and Merge	Missing Mention	*the Arab region* *the region* -	*the Arab region* *the region* *it*
v)	Split and Remove	Extra Mention	*her story* *this* *it*	*her story* *this* -
vi)	Merge	Divided Entity	$Iraq_1$ *this* $nation_2$ *the* $nation_2$ its_1	$Iraq_1$ *this* $nation_1$ *the* $nation_1$ its_1
vii)	Split	Conflated Entities	*Mohammed* $Rashid_1$ *the Rashid* $case_1$ $Rashid_1$ *the* $case_1$	*Mohammed* $Rashid_1$ *the Rashid* $case_2$ $Rashid_1$ *the* $case_2$

Figure 3: Examples of the error types. In examples (i) - (iv) and (vi) the system output contains a single entity. When multiple entities are involved, they are marked with subscripts. Mentions are in the order in which they appear in the text. All examples are from system output on the dev set of the CoNLL task.

One subtle point in the split stage is how to record an entity being split into several pieces. This could either be a single operation, one entity being split into N pieces, or $N-1$ operations, each involving a single piece being split off from the rest of the entity. We use the second approach, as it fits more naturally with the error mapping we describe in the following section. Similarly, for the merge operation, we record N entities being merged as $N-1$ operations.

3.2 Mapping

The operations in Section 3.1 are mapped onto seven error types. In some cases, a single change maps onto a single error, while in others a single error represents several closely related operations from adjacent stages in the error correction process. The mapping is described below and in Figure 3.

1. **Span Error**. Each Alter Span operation is mapped to a Span Error, e.g. in Figure 3(i), the system mention *Gorbachev* is replaced by the annotated mention *Soviet leader Gorbachev*.
2. **Missing Entity**. A set of Introduce and Merge operations that forms an entirely new entity, e.g. the white entity in Figure 2, and *the pills* in Figure 3(ii). This error is still assigned if the new entity includes pronouns that were already present in the system output. The reasoning for this is that most pronouns in the corpus are coreferent, so including just the pronouns from an entity is not meaningfully different from missing the entity entirely.
3. **Extra Entity**. A set of Split and Remove operations that completely remove an entity, e.g. the rightmost entity in Figure 2, and Figure 3(iii). As for the Missing Entity error type, this error is still assigned if the original entity contained pronouns that were valid.
4. **Missing Mention**. An Introduce and a Merge that apply to the same mention, e.g. *it* in Figure 3(iv), and the blue mention in Figure 2.
5. **Extra Mention**. A Split and a Remove that apply to the same mention, e.g. *it* in Figure 3(v), and the X in the red entity in Figure 2.
6. **Divided Entity**. Each remaining Merge operation is mapped to a Divided Entity error, e.g. Figure 3(vi), and the red entity in Figure 2.
7. **Conflated Entities**. Each remaining Split operation is mapped to a Conflated Entity error, e.g. Figure 3(vii), and the blue and red entities in Figure 2.

4 Methodology

Our tool processes the CoNLL task output, with no other information required. During development, and when choosing examples for this paper, we used the development set of the CoNLL shared task (Hovy et al., 2006; Pradhan et al., 2007; Pradhan et al., 2011). The results we present in the rest of the paper are all for the test set. Using the development set would have been misleading, as the entrants in the shared task used it to tune their systems.

4.1 Systems

We analyzed all of the 2011 CoNLL task systems, as well as several publicly available systems. For the shared task systems we used the output data from the task itself, provided by the organizers. For the publicly available systems we used the default configurations. Finally, we included another run of the Stanford system, with their OntoNotes-tuned parameters (STANFORD-T).

The publicly available systems we used are: BERKELEY (Durrett and Klein, 2013), IMS (Björkelund and Farkas, 2012), STANFORD (Lee et al., 2013), RECONCILE (Stoyanov et al., 2010), BART (Versley et al., 2008), UIUC (Bengtson and Roth, 2008), and CHERRYPICKER (Rahman and Ng, 2009). The systems from the shared task are listed in Table 1 and in the references.

5 Broad System Comparison

Table 1 presents the frequency of errors for each system and F-Scores for standard metrics[1] on the test set of the 2011 CoNLL shared task. Each bar is filled in proportion to the number of errors the system made, with a full bar corresponding to the number of errors listed in the bottom row.

The metrics provide an effective overall ranking, as the systems with high scores generally make fewer errors. However, the metrics do not convey the significant variation in the types of errors systems make. For example, YANG and CHARTON are assigned almost the same scores, but YANG makes more than twice as many Extra Mention errors.

The most frequent error across all systems is Divided Entity. Unlike parsing errors (Kummerfeld et al., 2012), improvements are not monotonic, with better systems often making more errors of one type when decreasing the frequency of another type.

One outlier is the Irwin et al. (2011) system, which makes very few mistakes in five categories, but many in the last two. This reflects a high precision, low recall approach, where clusters are only formed when there is high confidence.

The third section of Table 1 shows results for systems that were run with gold noun phrase span information. This reduces all errors slightly, though most noticeably Extra Mention, Missing Mention, and Span Error. On inspection of the remaining Span Errors we found that many are due to inconsistencies regarding the inclusion of the possessive.

The final section of the table shows results for systems that were provided with the set of mentions that are coreferent. In this setting, three of the error types are not present, but there are still Missing Mentions and Missing Entities because systems do not always choose an antecedent, leaving a mention as a singleton, which is then ignored.

While this broad comparison gives a complete view of the range of errors present, it is still a coarse representation. In the next section, we characterize the common errors on a finer level by breaking down each error type by a range of properties.

6 Common Errors

To investigate the aggregate state of the art, in this section we consider results averaged over the top ten systems: CAI, CHANG, IMS, NUGUES, SANTOS, SAPENA, SONG, STANFORD-T, STOYANOV, URYUPINA-OPEN.[2] These systems represent a broad range of approaches, all of which are effective.

In each section below, we focus on one or two error types, characterizing the mistakes by a range of properties. We then consider a few questions that apply across multiple error types.

6.1 Span Errors

To characterize the Span Errors, we considered the text that is in the gold mention, but not the system

[1] CEAF and BLANC are not included as the most recent version of the CoNLL scorer (v5) is incorrect, and there are no standard implementations available.

[2] For systems that occur multiple times in Table 1, we only use the best instance. The BERKELEY system was not included as it had not been published at submission time.

System	Metric F-Scores Mention	MUC	B^3	Span Error	Conflated Entities	Extra Mention	Extra Entity	Divided Entity	Missing Mention	Missing Entity

Type	Missing	Extra
NP	65.8	45.0
POS	12.4	96.9
,	71.2	22.4
SBAR	55.9	1.9
PP	46.2	10.3
DT	17.0	35.9
Total	271.1	224.6

Table 2: Counts of Span Errors grouped by the label over the extra/missing part of the mention.

mention (missing text), and vice versa (extra text). We then found nodes in the gold parse that covered just this extra/missing text, e.g. in Figure 3(i) we would consider the node over *Soviet leader*. In Table 2 we show the most frequent parse nodes.

Some of these differences are superficial, such as the possessive and the punctuation. Others, such as the missing PP and SBAR cases, may be due to parse errors. Of the system mentions involved in span errors, 27.0% do not correspond to a node in the gold parse. The frequency of punctuation errors could also be parse related, because punctuation is not considered in the standard parser evaluation.

Overall it seems that span errors can best be dealt with by improving parsing, though it is not possible to completely eliminate these errors because of inconsistent annotations.

6.2 Extra Mention and Missing Mention

We consider Extra and Missing Mentions together as they mirror each other, forming a precision-recall tradeoff, where a high precision system will have fewer Extra Mentions and more Missing Mentions, and a high recall system will have the opposite.

Table 3 divides these errors by the type of mention involved and presents some of the most frequent Extra Mentions and Missing Mentions. For the corpus statistics we count as mentions all NP spans in the gold parse plus any word tagged with PRP, WP, WDT, or WRB (following the definition of gold mention boundaries for the CoNLL tasks).

The mentions *it* and *you* are the most common errors, matching observations from several of the papers cited in Section 2. However, there is a surprising imbalance between Extra and Missing cases, e.g. *it* accounts for a third of the extra errors, but only 12% of the Missing errors. This imbalance may

	Av. Errors		Corpus Stats

Total	281.6	297.7	484.2	516.5

Table 4: Counts of Extra and Missing Mentions, grouped by properties of the mention and the entity it is in.

be the result of systems being tuned to the metrics, which seem to penalize Missing Mentions more than Extra Mentions (shown in Section 6.7).

In Table 4 we consider the Extra Mention errors and Missing Mention errors involving proper names and nominals. The top section counts errors in which the mention involved in the error has an exact string match with a mention in the cluster, or whether it has just a head match. The second section of the table considers the named entity annotations in OntoNotes, counting how often the mention's type matches the type of the cluster.

In all cases shown in the table it appears that systems are striking a balance between these two types of errors. One exception may be the use of exact string matching for nominals, which seems to be biased towards Extra Mentions.

For these two error types, our observations agree with previous work: the most common specific error is the identification of pleonastic pronouns, named entity types are of limited use, and head matching is already being used about as effectively as it can be.

Composition			Av. Errors	
Name	Nom	Pro	Extra	Missing
0	1	1	70.7	271.6
1	0	1	13.2	28.1
1	1	0	26.6	86.2

	Nominal	92.8	235.3
	Pronoun	60.0	21.4

Table 6: Counts of Extra and Missing Entity errors grouped by properties of the mentions in the entity.

6.3 Extra Entities and Missing Entities

In this section, we consider the errors that involve an entire entity that was either missing from the system output or does not exist in the annotations.

Table 5 counts these errors based on the composition of the entity. There are several noticeable differences between the two error types, e.g. for entities containing one nominal and one pronoun (row 0 1 1) there are far more Missing errors than Extra errors, while entities containing two pronouns (row 0 0 2) have the opposite trend.

It is clear that entities consisting of a single type of mention are the primary source of these errors, accounting for 85.3% of the Extra Entity errors, and 47.7% of Missing Entity errors. Table 6 shows counts for these cases divided into three groups: when all mentions are identical, when all mentions have the same head, and the rest.

Nominals are the most frequent type in Table 6, and have the greatest variation across the three sections of the table. For the Extra column, Exact match cases are a major challenge, accounting for over half of the nominal errors. These errors include cases like the example below, where two mentions are not considered coreferent because they are generic:

everybody tends to mistake the part for the whole.
Here, mistaking the part for the whole is ...

For missing entities we see the opposite trend, with Exact match cases accounting for less than 12% of nominal errors. Instead, cases with no match are the greatest challenge, such as this example, which requires semantic knowledge to correctly resolve:

The charges related to her sale of ImClone stock.
She sold the share a day before ...

The other common case in Table 5 is an entity containing a pronoun and a nominal. In Table 7 we present the most frequent pronouns for this case and the similar case involving a pronoun and a name.

Mention	Extra	Missing
that	6.9	99.7
it	47.7	47.8
this	0.9	36.2
they	3.8	29.1
their	2.1	23.5
them	0.9	13.8
Any pronoun	83.9	299.7

Table 7: Counts of common Missing and Extra Entity errors where the entity has just two mentions: a pronoun and either a nominal or a proper name.

One way of interpreting these errors is from the perspective of the pronoun, which is either incorrectly coreferent (Extra), or incorrectly non-coreferent (Missing). From this perspective, these errors are similar in nature to those described by Table 3. However, the distribution of errors is quite different, with *it* being balanced here where previously it skewed heavily towards extra mentions, while *that* was balanced in Table 3 but is skewed towards being part of Missing Entities here.

Extra Entity errors and Missing Entity errors are particularly challenging because they are dominated by entities that are either just nominals, or a nominal and a pronoun, and for these cases the string matching features are often misleading. This implies that reducing Extra Entity and Missing Entity errors will require the use of discourse, context, and semantics.

Incorrect Part			Rest of Entity			Av. Errors	
Na	No	Pr	Na	No	Pr	Conflated	Divided
-	-	1+	-	-	1+	312.7	69.9
-	-	1+	-	1+	1+	238.5	179.8

Table 8: Counts of Conflated and Divided entities errors grouped by the Name / Nominal / Pronoun composition of the parts involved.

6.4 Conflated Entities and Divided Entities

Table 8 breaks down the Conflated Entities errors and Divided Entity errors by the composition of the part being split/merged and the rest of the entity involved. Each 1+ indicates that at least one mention of that type is present (Name / Nominal / Pronoun).

Clearly pronouns being placed incorrectly is the biggest issue here, with almost all of the common errors involving a part with just pronouns. It is also clear that not having proper names in the rest of the entity presents a challenge. One particularly noticeable issue involves entities composed entirely of pronouns, which are often created by systems conflating the pronouns of two entities together.

Table 8 aggregates errors by the presence of different types of mentions. Aggregating instead by the exact composition of the incorrect part being conflated or divided we found that instances with a part containing a single pronoun account for 38.9% of conflated cases and 35.8% of divided cases.

Finally, it is worth noting that in many cases a part is both conflated with the wrong entity, and divided from its true entity. Only 12.6% of Conflated Entity errors led to a complete gold entity with no other errors, and only 21.3% of Divided Entity errors came from parts that were not involved in another error.

Conflated Entities and Divided Entities are dominated by pronoun link errors: cases where a pronoun was placed in the wrong entity. Finding finer characterizations of these errors is difficult, as almost any division produces sparse counts, reflecting the long tail of mistakes that make up these two error types.

Gold	System Decision	Count
Cataphoric	Same referent	10.6
	Different referent	13.4
	Not cataphoric	208.2
	Not present	42.8
Not cataphoric	Cataphoric	46.2
Not present	Cataphoric	186.8

Table 9: Occurrence of mistakes involving cataphora.

6.5 Cataphora

Cataphora (when an anaphor precedes its antecedent) is a pronoun-specific problem that does not fit easily in the common left-to-right coreference resolution approach. In the CoNLL test set, 2.8% of the pronouns are cataphoric. In Table 9 we show how well systems handle this challenge by counting mentions based on whether they are cataphoric in the annotations, are cataphoric in the system output, and whether the antecedents match.

Systems handle cataphora poorly, missing almost all of the true instances, and introducing a large number of extra cases. However, this issue is a fairly small part of the task, with limited metric impact.

6.6 Entity Properties

Gender, number, person, and named entity type are properties commonly used in coreference resolution systems. In some cases, two mentions with different properties are placed in the same entity. Some of these cases are correct, such as variation in person between mentions inside and outside of quotes. However, many of these cases are errors. In Table 11 we present the percentage of entities that contain mentions with properties of more than one type. For named entity types we considered the annotations in OntoNotes; for the other properties we derive them from the pronouns in each cluster.

For all of the properties, there are many entities that we could not assign a value to, either because no named entity information was available, or because no pronouns with an unambiguous value for the property were present. For named entity information, OntoNotes only has annotations for 68% of gold entities, suggesting that named entity taggers are of limited usefulness, matching observations on the MUC and ACE corpora (Stoyanov et al., 2009).

The results in the 'Gold' column of Table 11 in-

	Mentions			MUC			B^3		
Error type	P	R	F	P	R	F	P	R	F
Span Error	2.8	2.8	2.7	2.8	2.8	2.8	1.0	2.0	1.6
Conflated Entities	1.7	0.0	0.8	9.9	0.0	4.5	**15.9**	0.0	6.2
Extra Mention	5.5	0.0	2.6	6.4	0.0	3.0	5.3	0.0	2.2
Extra Entity	**15.3**	0.0	7.0	**11.4**	0.0	5.2	6.1	0.0	2.4
Divided Entity	1.8	6.8	4.3	5.7	**16.8**	**10.9**	-10.0	**21.6**	4.5
Missing Mention	1.8	7.0	4.4	3.2	9.2	6.1	-1.3	7.3	3.4
Missing Entity	3.8	**16.2**	**9.8**	5.3	13.7	9.3	1.7	11.4	**7.0**

Table 10: Average accuracy improvement if all errors of a particular type are corrected. Each row in the lower section is calculated independently, relative to the change after the span errors have been corrected. Some values are negative because the merge operations involved in fixing the errors are applying to clusters that contain mentions from more than one gold entity.

Property	System	Gold
Named Entity	1.7%	0.7%
Gender	0.8%	0.1%
Number	2.1%	0.8%
Person	6.4%	5.1%

Table 11: Percentage of entities that contain mentions with properties that disagree.

dicate possible errors in the annotations, e.g. in the 0.7% of entities with a mixture of named entity types there may be mistakes in the coreference annotations, or mistakes in the named entity annotations.[3] However, even after taking into consideration cases where the mixture is valid and cases of annotation errors, current systems are placing mentions with different properties in the same clusters.

6.7 Impact of Errors on Metric Scores

Table 10 shows the performance impact of correcting errors of each type. The Span Error row gives improvements over the original scores, while all other rows are relative to the scores after Span Errors are corrected.[4] By fixing each of the other error types in isolation, we can get a sense of the gain if just that error type is addressed. However, it also means some mentions are incorrectly placed in the same cluster, causing some negative scores.

Interaction between the error types and the way the metrics are defined means that the deltas do not add up to the overall average gap in performance, but it is still clear that every error type has a noticeable impact. Missing Entity errors have the most substantial impact, which reflects the precision oriented nature of many coreference resolution systems.

7 Conclusion

While the improvement of metrics and the organization of shared tasks have been crucial for progress in coreference resolution, there is much insight to be gained by performing a close analysis of errors.

We have presented a new means of automatically classifying coreference errors that provides an exhaustive view of error types. Using our tool we have analyzed the output of a large set of coreference resolution systems and investigated the common challenges across state-of-the-art systems.

We find that there is considerable variability in the distribution of errors, and the best systems are not best across all error types. No single source of errors stands out as the most substantial challenge today. However, it is worth noting that while confidence measures can be used to reduce precision-related errors, no system has been able to effectively address the recall-related errors, such as Missed Entities. Our analysis tool is available at code.google.com/p/berkeley-coreference-analyser/.

Acknowledgments

We would like to thank the CoNLL task organizers for providing us with system outputs. This work was supported by a General Sir John Monash fellowship to the first author and by BBN under DARPA contract HR0011-12-C-0014.

[3] This kind of cross-annotation analysis may be a useful way of detecting annotation errors.

[4] This difference was necessary as the later errors make changes relative to the state of the entities after the Span Errors are corrected, e.g. in Figure 2 a blue and red entity is split that previously contained an X instead of one of the blue mentions.

Abstract

Coreference resolution plays a critical role in discourse analysis. This paper focuses on exploiting zero pronouns to improve Chinese coreference resolution. In particular, a simplified semantic role labeling framework is proposed to identify clauses and to detect zero pronouns effectively, and two effective methods (refining syntactic parser and refining learning example generation) are employed to exploit zero pronouns for Chinese coreference resolution. Evaluation on the CoNLL-2012 shared task data set shows that zero pronouns can significantly improve Chinese coreference resolution.

1 Introduction

As one of the most important tasks in discourse analysis, coreference resolution aims to link a given mention (i.e., entity or event) to its co-referring expression in a text and has been a focus of research in natural language processing (NLP) for decades.

Over the last decade, various machine learning techniques have been applied to coreference resolution and have performed reasonably well (Soon et al., 2001; Ng and Cardie, 2002; Fernandes et al., 2012). Current techniques rely primarily on surface level features such as string match, syntactic features such as apposition, and shallow semantic features such as number, gender, semantic class, etc.

Despite similarities between Chinese and English, there are differences that have a significant impact on coreference resolution. In this paper, we focus on exploiting one of the key characteristics of Chinese text, zero pronouns (ZPs), to improve Chinese coreference resolution. In particular, a simplified semantic role labeling (SRL) framework is proposed to identify Chinese clauses and to detect zero pronouns effectively, and two effective methods are employed to exploit zero pronouns for Chinese coreference resolution. Experimental results show the effectiveness of our approach in improving the performance of Chinese coreference resolution. Our work is novel in that it is the first work that incorporates the use of zero pronouns to significantly improve Chinese coreference resolution

The rest of this paper is organized as follows. Section 2 describes our baseline Chinese coreference resolution system. Section 3 motivates how the detection of zero pronouns can improve Chinese coreference resolution, using an illustrating example. Section 4 presents our approach to detect zero pronouns. Section 5 proposes two methods to exploit zero pronouns to improve Chinese coreference resolution, based on a corpus study and preliminary experiments. Section 6 briefly outlines the related work. Finally, we conclude our work in Section 7.

2 Chinese Coreference Resolution

According to Webber (1978), coreference resolution can be decomposed into two complementary subtasks: (1) anaphoricity determination: deciding whether a given noun phrase (NP) is anaphoric or not; and (2) anaphora resolution: linking together multiple mentions of a given entity in the world. Our Chinese coreference resolution system also contains these two components. Using the training data set of CoNLL-2012 shared task, we first train an anaphoricity classifier to determine whether

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 278–288,
Seattle, Washington, USA, 18-21 October 2013.

a mention is anaphoric or not, and then employ an independently-trained coreference resolution system to resolve those mentions which are classified as anaphoric. The lack of gender and number makes both anaphoricity determination and coreference resolution in Chinese more difficult.

2.1 Anaphoricity Determination

Since only the mentions that take part in coreference chains are annotated in the CoNLL-2012 shared task data set, we first generate a high-recall, low-precision mention extraction module to extract as many mentions as possible. The mention extraction module relies mainly on syntactic parse trees. We extract all NP nodes, QP (quantifier phrase, i.e., complex amount/measure phrase) nodes, and all terminals with part-of-speech tags PN (pronoun) and NR (proper noun) in parse trees to form a mention candidate set. Then, we employ some rules to remove unlikely mentions, e.g., those which contain (1) measure words such as '一年/one year' and '一顿/one time'; (2) named entities whose categories are PERCENT, MONEY, QUANTITY, and CARDINAL; (3) interrogative pronouns such as '什么/what' and '哪儿/where'.

After pruning, we employ a learning-based method to train an independent classifier to determine whether the remaining mentions are anaphoric. Table 1 lists all the features employed in our anaphoricity determination system.

2.2 Coreference Resolution

Our Chinese coreference resolution system adopts the same learning-based model and the same set of 12 features as Soon et al. (2001). Considering the special characteristics of conversation and web texts (i.e., a large proportion of personal pronouns and the organization of a text into several parts[1]) and preparing for dealing with zero pronouns, we add some features shown in Table 2.[2]

[1]A text in the CoNLL-2012 data set is broken down into different "parts".

[2]AN denotes anaphor, CA denotes antecedent candidate, IP denotes a simple clause, and CP denotes a clause headed by a complementizer. For the feature ANPronounRanking, the relative ranking of a given pronoun is based on its semantic role and surface position, and we assign the highest rank to zero pronouns, similar to Kong et al. (2009).

Table 4: Performance of our Chinese coreference resolution system on the CoNLL-2012 test set

2.3 Results and Analysis

All experiments in this section are conducted on the CoNLL-2012 shared task data set. The SVM-light toolkit (Joachims, 1999) with radial basis kernel and default learning parameters is employed in both anaphoricity determination and coreference resolution.

Table 3 reports the performance of anaphoricity determination on the CoNLL-2012 test set using gold-standard parse trees (GS) and automatic parse trees (Auto). All performance figures in this paper are given in percentages. The results show that using both gold parse trees and automatic parse trees, our anaphoricity determination system achieves higher precision than recall. In comparison with using gold parse trees, precision decreases by about 9% and recall 11% on automatic parse trees.

Table 4 reports the performance of our Chinese coreference resolution system on the CoNLL-2012 test set under three different experimental settings: with automatic mentions (AM), with gold mention

Feature	Description
NPType	Type of the current mention (pronoun, demonstrative, proper NP).
NPNumber	Number of the current mention (singular, plural).
NPGender	Gender of the current mention (male, female).
IsHeadWord	Whether the current mention is the same as its headword.
StrMatch	Whether there is a string match between the current mention and another phrase in the previous context.
AliasMatch	Whether the current mention is a name alias or abbreviation of another phrase in the previous context.
Appositive	Whether the current mention and another phrase in the previous context are in an appositive relation.
NestIn	Whether another NP is nested in the current mention.
NestOut	Whether the current mention is nested in another NP.
FirstNP	Whether the current mention is the first NP of the sentence.
FrontDistance	The number of words between the current mention and the nearest previous clause.
BackDistance	The number of words between the current mention and the nearest following clause.
WordSense	Whether the current mention and another phrase in the previous context have the same word sense. Word sense annotation is provided in the CoNLL-2012 data set, based on the IMS software (Zhong and Ng, 2010).

Table 1: Features employed in our anaphoricity determination system

Feature	Description
AN/CAPronounType	Whether the anaphor or the antecedent candidate is a zero pronoun, first person, second person, third person, neutral pronoun, or others. In our coreference resolution system, a zero pronoun is viewed as a kind of special pronoun.
AN/CAGrammaticalRole	Whether the anaphor or the antecedent candidate is a subject, object, or others.
AN/CAOwnerClauseType	Whether the anaphor or the antecedent candidate is in a matrix clause, an independent clause, a subordinate clause, or none of the above.
AN/CARootPath	Whether the path of nodes from the anaphor (or the antecedent candidate) to the root of the parse tree contains NP, IP, CP, or VP.
ANPronounRanking	Whether the anaphor is a pronoun and is ranked highest among the pronouns (including zero pronouns) of the sentence.
AN/CAClosestNP	Whether the antecedent candidate is the closest preceding NP of the anaphor.
AN/CAPartDistance	This feature captures the distance (in parts) between the antecedent candidate and the anaphor. If they are in the same part, the value is 0; if they are one part apart, the value is 1; and so on.
AN/CASameSpeaker	Whether the antecedent candidate and the anaphor appear in sentences spoken by the same person.

Table 2: Additional features employed in our Chinese coreference resolution system

boundaries (GMB), and with gold mentions (GM). From the results, we find that:

- Using automatic mentions, our system achieves 56.27, 76.73, and 49.13 in F-measure on MUC, BCUBED, and CEAF evaluation metrics, respectively.
- Using gold mention boundaries improves the performance of our system by 14.57, 4.31, and 5.62 in F-measure, due to large gains in both recall and precision. We also find that using gold mention boundaries can boost the recall of mention detection. As described above, our anaphoricity determination model relies mainly on the parser. Using gold mention boundaries can improve the parser performance. Thus our coreference resolution system can benefit much from using gold mention boundaries (especially the recall).
- Employing gold mentions further boosts our system significantly. In comparison with using gold mention boundaries, the performance improvement is attributed more to an increase in precision.

In comparison with the three best systems of CoNLL-2012 in the Chinese closed track (shown in Table 5), considering average F-measure, we find that using automatic mentions, our system is only inferior to that of Chen and Ng (2012); using gold mention boundaries, our system achieves the best performance; and using gold mentions, our system is only a little worse than that of Chen and Ng (2012).

3 Motivation

In order to analyze the impact of zero pronouns on Chinese coreference resolution, we first use the released OntoNotes v5.0 data (i.e., the training and development portions of the CoNLL-2012 shared task) in a corpus study.

Statistics show that anaphoric zero pronouns account for 10.7% of the mentions in coreference chains in the training data, while in the development data, the proportion is 11.3%. The experimental results of our Chinese coreference resolution system (i.e., the baseline) show that using both gold mention boundaries and gold mentions significantly improves system performance, especially for recall, largely due to improved parser performance. We then analyze the impact of zero pronouns on Chinese syntactic parsing. As a preliminary exploration, we integrate Chinese zero pronouns into the Berkeley parser (Petrov et al., 2006), experimenting with gold-standard or automatically determined zero pronouns kept or stripped off (using gold-standard word segmentation provided in the CoNLL-2012 data). The results indicate that given gold-standard zero pronouns, parsing performance improves by 1.8% in F-measure. Using automatically determined zero pronouns by our zero pronoun detector to be introduced in Section 4, parsing performance also improves by 1.4% in F-measure.

In order to illustrate the impact of zero pronouns on parsing performance, consider the following example:[3]

> Example (1):
>
> 将来我们有**一个重建计划**。
>
> **#**分公园成七个区域，**#**带来多一些的景点。
>
> ...
>
> **这个计划**我们现在是等到政府的批准我们就可以再进行，预算是**#**明年可以动工了。
>
> (In future, we have **a reconstruction plan**.
>
> Divide the park into seven regions, and bring some more attractions.
>
> ...
>
> Now we wait for approval of the government before implementing **this plan** again. It is expected that work can start next year.)

Without considering zero pronouns, the parse tree of the second sentence output by the Berkeley parser is shown in Figure 1.

Prior to parsing, using our zero pronoun detector to be introduced in Section 4, the presence of zero pronouns (denoted by #) can be detected. Figure 2

[3] In this paper, zero pronouns are denoted by "#" and mentions in the same coreference chain are shown in bold for all examples.

Table 5: Performance (F-measure) of the three best Chinese coreference resolution systems on the CoNLL-2012 test set

shows the new parse tree, which includes the detected zero pronouns, output by the Berkeley parser on the same sentence. Comparing these two parse trees, we can see that the detected zero pronouns contribute to better division of clauses and improved parsing performance, which in turn leads to improved Chinese coreference resolution.

Detecting the presence of zero pronouns also helps to improve local salience modeling, leading to improved Chinese coreference resolution. Long sentences containing multiple clauses occur more frequently in Chinese compared to English. Furthermore, a coreference chain can span many sentences. Zero pronouns can occur not only within one sentence (e.g., the first and second zero pronouns of Example (1)), but can also be scattered across multiple sentences (e.g., the first and third zero pronouns of Example (1)). The subjects in the second sentence of Example (1) are omitted.[4] Detection of zero pronouns improves local salience modeling, and leads to the correct identification of all the noun phrases of the coreference chain in Example (1).

4 Zero Pronoun Detection

Empty elements are those nodes in a parse tree that do not have corresponding surface words or phrases. Although empty elements exist in many languages and serve different purposes, they are particularly important for some languages, such as Chinese, where subjects and objects are frequently dropped to keep a discourse concise. Among empty elements, type *pro*, namely zero pronoun, is either used for dropped subjects or objects, which can be recovered from the context (anaphoric), or it is of little interest for the reader or listener to know (non-anaphoric). In the Chinese Treebank, type *pro* constitutes about 20% (Yang and Xue, 2010), and more than 85% of them are anaphoric (Kong and Zhou, 2010). Thus, zero pronouns are very important in bridging the information gap in a Chinese text. In this section, we will introduce our zero pronoun detector.

In Chinese, a zero pronoun always occurs just before a predicate phrase node (e.g., VP). In particular, if the predicate phrase node occurs in a coordinate structure or is modified by an adverbial node, we only need to consider its parent. A simplified semantic role labeling (SRL) framework (only including predicate recognition, argument pruning, and argument identification) is adopted to identify the predicate phrase subtree (Xue, 2008), i.e., the minimal subtree governed by a predicate and all its arguments.

We carry out zero pronoun detection for every predicate phrase subtree in an iterative manner from a parse tree, i.e., determining whether there is a zero pronoun before the given predicate phrase sub-

[4] In Chinese, pro-dropped subjects account for more than 36% of subjects in sentences (Kim, 2000).

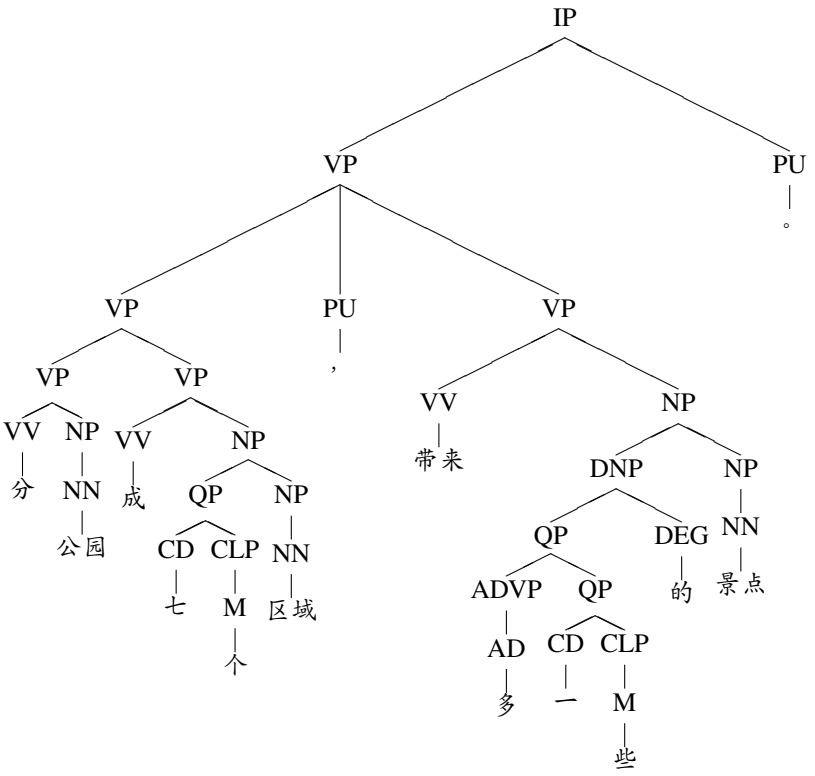

Figure 1: The parse tree without considering zero pronouns

tree. Viewing the position before the given predicate phrase subtree as a zero pronoun candidate, we can perform zero pronoun detection using a machine learning approach.

During training, if a zero pronoun candidate has a counterpart in the same position in the annotated training corpus (either anaphoric or non-anaphoric), a positive example is generated. Otherwise, a negative example is generated. During testing, each zero pronoun candidate is presented to the zero pronoun detector to determine whether it is a zero pronoun.

The features that are employed to detect zero pronouns mainly model the context of the clause itself, the left and right siblings, and the path of the clause to the root node. Table 6 lists the features in detail.

4.1 Results and Analysis

We evaluate our zero pronoun detector using gold parse trees and automatic parse trees produced by the Berkeley parser. The SVM-light toolkit with radial basis kernel and default learning parameters is employed as our learning algorithm.

Table 7 lists the results. From the results, we find that the performance of our zero pronoun detector drops about 12% in F-measure when using automatic parse trees, compared to using gold parse trees. That is, the performance of zero pronoun detection also depends on the performance of the syntactic parser.

5 Exploiting Zero Pronouns to Improve Chinese Coreference Resolution

In this section, we will propose two methods, refining the syntactic parser and refining learning example generation, to exploit zero pronouns to improve Chinese coreference resolution.

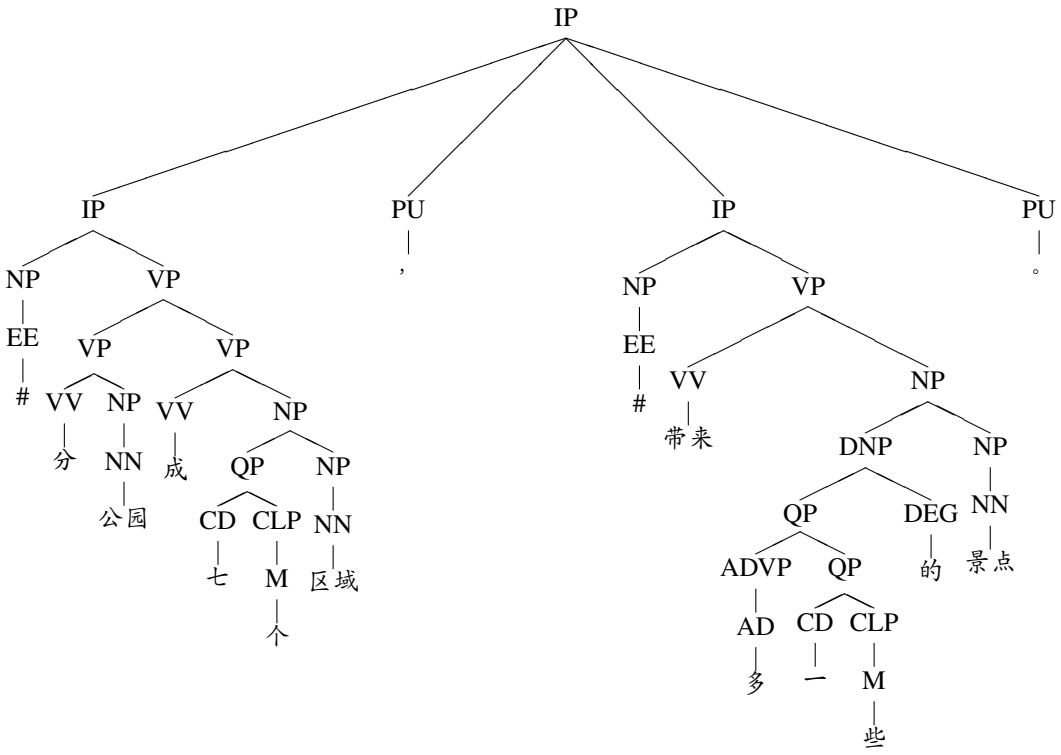

Figure 2: The parse tree with the detected zero pronouns

5.1 Refining the Syntactic Parser

Similar to our preliminary experiments, we retrain the Berkeley parser with explicit, automatically detected zero pronouns in the training set and parse the test set with explicit, automatically detected zero pronouns using the retrained model. In both anaphoricity determination and coreference resolution, the output results of the retrained parser are employed to generate all features.

5.2 Refining Learning Example Generation

In order to model the salience of all entities, we regard all zero pronouns as a special kind of NPs when generating the learning examples. Considering the modest performance of our anaphoricity determination module, we do not determine the anaphoricity of zero pronouns. Instead, in the coreference resolution stage, all zero pronouns will be considered during learning example generation (including both training and test example generation).

For example, consider a coreference chain A1-A2-Z0-A3-A4 containing one zero pronoun found in an annotated training document. A1, A2, A3, and A4 are traditional entity mentions, and Z0 is a zero pronoun. During training, pairs of mentions in the chain that are immediately adjacent (i.e., A1-A2, A2-Z0, Z0-A3, and A3-A4) are used to generate the positive training examples. Among them, two examples (i.e., A2-Z0 and Z0-A3) are associated with a zero pronoun, which can act as both an anaphor and an antecedent. For each positive pair, e.g., Z0-A3, we find any noun phrase and zero pronoun occurring between the anaphor A3 and the antecedent Z0, and pair each of them with A3 to form a negative example. Similarly, test examples can be generated except that only the preceding mentions and zero pronouns in the current and previous two sentences will be paired with an anaphor.

Incorporating zero pronouns models salience of all entities more accurately. The ratio of positive to negative examples is also less skewed as a result of considering zero pronouns – the ratio changes from 1:7.9 to 1:6.8 after considering zero pronouns.

5.3 Reprocessing

Although in the OntoNotes corpus, dropped subjects and objects (i.e., zero pronouns) are considered during coreference resolution for Chinese, they are not

Feature	Description
ClauseClass	Whether the given clause is a terminal clause or non-terminal clause.
LeftSibling	Whether the given clause has a sibling immediately to its left.
LeftSiblingNP	Whether the left siblings of the given clause contain an NP.
RightSibling	Whether the given clause has a sibling immediately to its right.
RightSiblingVP	Whether the right siblings of the given clause contain a VP.
ParentIP/VP	Whether the syntactic category of the immediate parent of the given clause is an IP or VP.
RootPath	Whether the path from the given clause to the root of the parse tree contains an NP or VP or CP. This feature models how the given clause is syntactically connected to the sentence as a whole, reflecting its function within the sentence.
ClauseType	The given clause is an independent clause, a subordinate clause, or others.
Has-Arg0/Arg1	Whether the given clause has an agent or patient argument.

Table 6: Features employed to detect zero pronouns

used in the CoNLL-2012 shared task (i.e., in the gold evaluation keys, all the links formed by zero pronouns are removed).

As described in Subsection 5.2, during training and testing, all links associated with zero pronouns will be considered in our coreference resolution system. That is, we do not distinguish zero pronoun resolution from traditional coreference resolution, and only view zero pronouns as special pronouns. After generating all the links, zero pronouns are included in coreference chains. For every coreference chain, all zero pronouns will be removed before evaluation.

5.4 Experimental Results and Analysis

For fair comparison, all our experiments in this subsection have been conducted using the same experimental settings as our baseline system. When compared to our baseline system, all improvements are statistically significant ($p < 0.005$).

Table 8 lists the coreference resolution performance incorporating automatically detected zero pronouns. The results show that:

- Using automatically detected zero pronouns achieves better performance under all experimental settings. In particular, using automatic mentions, performance improves by 3.31%, 1.42%, and 2.34% in F-measure on the MUC, BCUBED, and CEAF evaluation metric, respectively. Using gold mention boundaries, automatic zero pronouns contribute 1.82% in average F-measure. Using gold mentions, the

		R	P	F
AM	Mention Detection	71.09	69.58	70.33
	MUC	55.06	64.91	59.58
	BCUBED	76.04	80.38	78.15
	CEAF	53.98	49.19	51.47
	Average			63.07
GMB	Mention Detection	82.44	70.10	75.77
	MUC	75.58	69.89	72.62
	BCUBED	76.35	87.27	81.45
	CEAF	65.17	52.31	58.04
	Average			70.70
GM	Mention Detection	84.31	100.00	91.49
	MUC	80.83	86.27	83.46
	BCUBED	74.18	92.74	82.43
	CEAF	69.91	62.29	65.88
	Average			77.26

Table 8: Performance of our Chinese coreference resolution system incorporating zero pronouns

contribution of zero pronouns is only 0.24% in average F-measure. This is because employing either gold mention boundaries or gold mentions improves parsing performance.

- Our system incorporating zero pronouns outperforms the three best systems in the CoNLL-2012 shared task when using automatic mentions or gold mention boundaries. Using gold mentions, our average F-measure is slightly lower than that of Chen and Ng (2012).[5]

Table 9 presents the contribution of our two methods of exploiting zero pronouns and the impact of gold-standard zero pronouns. We conclude that:

- Both the refined parser and refined example generation improve performance. While the refined parser improves the recall of mention detection and coreference resolution, refined example generation contributes more to precision. Combining these two methods further improves coreference resolution.

- There is a performance gap of 6.01%, 4.08%, and 3.19% in F-measure on the MUC, BCUBED, and CEAF evaluation metric, respectively, between the coreference resolution system with gold-standard zero pronouns and without zero pronouns. This suggests the usefulness of zero pronoun detection in Chinese coreference resolution.

- Our proposed methods incorporating automatic zero pronouns reduce the performance gap by about half. This shows the effectiveness of our proposed methods.

5.5 Discussion

Although the evaluation of the CoNLL-2012 shared task does not consider zero pronouns, we also evaluate the performance of zero pronoun resolution on the development data set (i.e., extracting all the resolved coreference links containing zero pronouns, acting as anaphor or antecedent, to conduct the evaluation independently). The results show that, for the correct anaphoric zero pronouns, the precision of our system is 94.76%. So viewing zero pronouns as a special kind of NP, zero pronouns can bridge salience and contribute to coreference resolution. In Example (1), the zero pronouns occurring in the second sentence help to bridge the coreferential relation between the mention "这个计划/this plan" in the last sentence and the mention "一个重建计划/a reconstruction plan" in the first sentence.

[5]Statistical significance testing cannot be conducted since their output files are not released.

6 Related Work

In the last decade, both manual rule-based approaches (Lee et al., 2011) and statistical approaches (Soon et al., 2001; Ng and Cardie, 2002; Fernandes et al., 2012) have been proposed for coreference resolution. Besides frequently used syntactic and semantic features, more linguistic features are exploited in recent work (Ponzetto and Strube, 2006; Ng, 2007; Versley, 2007). There is less research on Chinese coreference resolution compared to English.

Although zero pronouns are prevalent in Chinese, there is relatively little work on this topic. For Chinese zero pronoun resolution, representative work includes Converse (2006), Zhao and Ng (2007), and Kong and Zhou (2010).

For the use of zero pronouns, Chung and Gildea (2010) applied some extracted patterns to recover two types of empty elements (*PRO* and *pro*). Although the performance is still not satisfactory (e.g., 63.0 and 44.0 in F-measure for *PRO* and *pro* respectively), it nevertheless improves machine translation performance by 0.96 in BLEU score.

7 Conclusion

In this paper, we focus on exploiting one of the key characteristics of Chinese text, zero pronouns, to improve Chinese coreference resolution. In particular, a simplified semantic role labeling framework is proposed to detect zero pronouns effectively, and two effective methods are employed to incorporate zero pronouns into Chinese coreference resolution. Experiments on the CoNLL-2012 shared task show the effectiveness of our proposed approach. To the best of our knowledge, this is the first attempt at incorporating zero pronouns into Chinese coreference resolution.

Joint Coreference Resolution and Named-Entity Linking with Multi-pass Sieves

Abstract

Many errors in coreference resolution come from semantic mismatches due to inadequate world knowledge. Errors in named-entity linking (NEL), on the other hand, are often caused by superficial modeling of entity context. This paper demonstrates that these two tasks are complementary. We introduce NECo, a new model for named entity linking and coreference resolution, which solves both problems jointly, reducing the errors made on each. NECo extends the Stanford deterministic coreference system by automatically linking mentions to Wikipedia and introducing new NEL-informed mention-merging sieves. Linking improves mention-detection and enables new semantic attributes to be incorporated from Freebase, while coreference provides better context modeling by propagating named-entity links within mention clusters. Experiments show consistent improvements across a number of datasets and experimental conditions, including over 11% reduction in MUC coreference error and nearly 21% reduction in F1 NEL error on ACE 2004 newswire data.

1 Introduction

Coreference resolution and named-entity linking are closely related problems, but have been largely studied in isolation. This paper demonstrates that they are complementary by introducing a simple joint model that improves performance on both tasks.

Coreference resolution is the task of determining when two textual mentions name the same individual. The biggest challenge in coreference resolution — accounting for 42% of errors in the state-of-the-art Stanford system — is the inability to reason effectively about background semantic knowledge (Lee et al., 2013). For example, consider the sentence in Figure 1. "President" refers to "Donald Tsang" and "the park" refers to "Hong Kong Disneyland," but automated algorithms typically lack the background knowledge to draw such inferences. Incorporating knowledge is challenging, and many efforts to do so have actually hurt performance, e.g. (Lee et al., 2011; Durrett and Klein, 2013).

[Michael Eisner]$_1$ and [Donald Tsang]$_2$ announced the grand opening of [[Hong Kong]$_3$ Disneyland]$_4$ yesterday. [Eisner]$_1$ thanked [the President]$_2$ and welcomed [fans]$_5$ to [the park]$_4$.

Figure 1: A text passage illustrating interactions between coreference resolution and NEL.

Named-entity linking (NEL) is the task of matching textual mentions to corresponding entities in a knowledge base, such as Wikipedia or Freebase. Such links provide rich sources of semantic knowledge about entity attributes — Freebase includes *president* as Tsang's title and `Disneyland` as having the attribute *park*. But NEL is itself a challenging problem, and finding the correct link requires disambiguating based on the mention string and often non-local contextual features. For example, "Michael Eisner" is relatively unambiguous but the isolated mention "Eisner" is more challenging. However, these mentions could be clustered with a coreference model, allowing for improved NEL through link propagation from the easier mentions.

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 289–299,
Seattle, Washington, USA, 18-21 October 2013.

We present NECO, a new algorithm for jointly solving named entity linking and coreference resolution. Our work is related to that of Ratinov and Roth (2012), which also uses knowledge derived from an NEL system to improve coreference. However, NECO is the first joint model we know of, is purely deterministic with no learning phase, does automatic mention detection, and improves performance on both tasks.

NECO extends the Stanford's sieve-based model, in which a high recall mention detection phase is followed by a sequence of cluster merging operations ordered by decreasing precision (Raghunathan et al., 2010; Lee et al., 2013). At each step, it merges two clusters only if all available information about their respective entities is consistent. We use NEL to increase recall during the mention detection phase and introduce two new cluster-merging sieves, which compare the Freebase attributes of entities. NECO also improves NEL by initially favoring high precision linking results and then propagating links and attributes as clusters are formed.

In summary we make the following contributions:

- We introduce NECO, a novel, joint approach to solving coreference and NEL, demonstrating that these tasks are complementary by achieving joint error reduction.
- We present experiments showing improved performance at coreference resolution, given both gold and automatic mention detection: e.g., 6.2 point improvement in MUC recall on ACE 2004 newswire text and 3.1 point improvement in MUC precision the CoNLL 2011 test set.
- NECO also leads to better performance at named-entity linking, given both gold and automatic linking, improving F1 from 61.7% to 69.2% on a newly labeled test set.[1]

2 Background

We make use of existing models for coreference resolution and named entity linking.

[1]Our corpus and the source code for NECO can be downloaded from `https://www.cs.washington.edu/research-projects/nlp/neco`.

2.1 Coreference Resolution

Coreference resolution is the the task of identifying all text spans (called *mentions*) that refer to the same entity, forming mention clusters.

Stanford's Sieve Model is a state-of-the-art coreference resolver comprising a pipeline of "sieves" that merge coreferent mentions according to deterministic rules. Mentions are automatically predicted by selecting all noun phrases (NP), pronouns, and named entities. Each sieve either merges a cluster to its single best antecedent from a list of previous clusters, or declines to merge.

Higher precision sieves are applied earlier in the pipeline according to the following order, looking at different aspects of the text, including: (1) speaker identification, (2-3) exact and relaxed string matches between mentions, (4) precise constructs, including appositives, acronyms and demonyms, (5-9) different notions of strict and relaxed head matches between mentions, and finally (10) a number of syntactic and distance cues for pronoun resolution.

2.2 Named Entity Linking

Named-entity linking (NEL) is the task of identifying mentions in a text and linking them to the entity they name in a knowledge base, usually Wikipedia. NECO uses two existing NEL systems: GLOW (Ratinov et al., 2011) and WikipediaMiner (Milne and Witten, 2008).

WikipediaMiner links mentions based on a notion of semantic similarity to Wikipedia pages, considering all substrings up to a fixed length. Since there are often many possible links, it disambiguates by choosing the entity whose Wikipedia page is most semantically related to the nearby context of the mention. The semantic scoring function includes n-gram statistics and also counts shared links to other unambiguous mentions in the text.

GLOW finds mentions by selecting all the NPs and named entities in the text. Linking is framed as an integer linear programming optimization problem that takes into account using similar local constraints but also includes global constraints such as entity link co-occurrence.

Both systems return confidence values. To maintain high precision, NECO uses an ensemble of

- Let $Exemplar(c)$ be a representative mention of the cluster c, computed as defined below
- Let c_j be an antecedent cluster of c_i if c_j has a mention which is before the first mention of c_i
- Let $l(m)$ be a Wikipedia page linked to mention m or $\varnothing$ if there is no link
- Let $l(c)$ be a Wikipedia page linked to mention $Exemplar(c)$ or $\varnothing$ if there is no link

1. **Initialize Linked Mentions:**
   (a) Let $M_{NEL} = \{m_i \mid i = 1 \dots p\}$ be the NEL output mentions, m_i, each with a link $l(m_i)$
   (b) Let $M_{CR} = \{m_i \mid i = 1 \dots q\}$ be the mentions m_i from coreference mention detection
   (c) Let $M \leftarrow M_{CR} \cup M_{NEL}$ (Sec. 3.1)
   (d) Update entity links for all $m \in M$ and prune M (Sec. 3.2)
   (e) Extract attributes from Wikipedia and Freebase for all $m \in M$ (Sec. 3.3)
   (f) Let $C \leftarrow M$ be singleton mention clusters where $Exemplar(c_i) = m_i$, $l(c_i) = l(m_i)$
2. **Merge Clusters:** For every sieve S (including NEL sieves, Sec. 3.6) and cluster $c_i \in C$
   (a) For every cluster $c_j, j = [i-1 \dots 1]$ (traverse the preceding clusters in reverse order)
      i. **NEL constraints**: Prevent merge if $l(c_i) \neq l(c_j)$ (Sec. 3.4)
      ii. If all rules of sieve S are satisfied for clusters c_i and c_j
         A. $c_k \leftarrow Merge(c_i, c_j)$, including entity link and attribute updates (Sec. 3.5)
         B. $C \leftarrow C \cup \{c_k\} \setminus \{c_i, c_j\}$
3. **Output:** Coreference clusters C and linked Wikipedia pages $l(c_i) \forall c_i \in C$

Figure 2: NECO: A joint algorithm for named-entity linking and coreference resolution.

GLOW and WikipediaMiner, selecting only high confidence links.

3 Joint Coreference and Linking

We introduce a joint model for coreference resolution and NEL. Building on the Stanford sieve architecture, our algorithm incrementally constructs clusters of mentions using deterministic coreference rules under NEL constraints.

Figure 2 presents the complete algorithm. The input to NECO is a document and the output is a set C of coreference clusters, with links $l(c)$ to Wikipedia pages for a subset of the clusters $c \in C$. Step 1 detects mentions, merging the outputs of the base systems (Sec. 3.1). Step 2 repeatedly merges coreference clusters, while ensuring that NEL constraints (Sec. 3.4) are satisfied. It uses the original Stanford sieves and also two new NEL-informed sieves (Sec. 3.6). NEL links are propagated to new clusters as they are formed (Sec. 3.5).

3.1 Mention Detection

In Steps 1(a-c) in Fig. 2, NECO combines mentions from the base coreference and NEL systems.

Let M_{CR} be the set of mentions returned by using Stanford's rule-based mention detection algorithm (Lee et al., 2013). Let M_{NEL} be the set of mentions output by the two NEL systems. NECO creates an initial set of mentions, M, by taking the union of all the mentions in M_{NEL} and M_{CR}. In practice, taking the union increases diversity in the mention pool. For example, it is often the case that M_{NEL} will include sub-phrases such as "Suharto" when they are part of a larger mention "ex-dictator Suharto" that is detected in M_{CR}.

3.2 Mention Entity Links and Pruning

Step 1(d) in Fig. 2 assigns Wikipedia links to a subset of the detected mentions.

For mentions m output by the base NEL systems, we assign an *exact* link $l(m)$ if the entire mention span is linked. Mentions m' that differ from an exact linked mention m by only a pre- or post-fix stop word are similarly assigned exact links $l(m') = l(m)$. For example, the mention "the president" will be assigned the same link as "president" but "The governor of Alaska Sarah Palin" would not be assigned an exact link to `Sarah Palin`.

For mentions m' that do not receive an exact link, we assign a *head* link $h(m')$ if the head word[2] m has been linked, by setting $h(m') = l(m)$. For instance, the head link for the mention "President Clinton" (with "Clinton" as head word) will be the Wikipedia title of `Bill Clinton`. We use head links for the Relaxed NEL sieve (Sec. 3.6).

Next, we define $L(m)$ to be the set con-

[2] A head word is assigned to every mention with the Stanford parser head finding rules (Klein and Manning, 2003).

country	*president*	*city*	*area*
company	*state*	*region*	*location*
place	*agency*	*power*	*unit*
body	*market*	*park*	*province*
manager	*organization*	*owner*	*trial*
site	*prosecutor*	*attorney*	*county*
senator	*stadium*	*network*	*building*
attraction	*government*	*department*	*person*
origin	*plant*	*airport*	*kingdom*
capital	*operation*	*author*	*period*
nominee	*candidate*	*film*	*venue*

Figure 3: The most commonly used fine-grained attributes from Freebase and Wikipedia (out of over 500 total attributes).

taining $l(m)$ and $l(m')$ for all sub-phrases m' of m. We add the sub-phrase links only if their confidence is higher than the confidence for $l(m)$. For instance, assuming appropriate confidence values, $L(m)$ would include the pages for {`List of governors of Alaska`, `Alaska`, `Sarah Palin`} given the mention "The governor of Alaska Sarah Palin." We will use $L(m)$ for NEL constraints and filtering (Sec. 3.4).

After updating the entity links for all mentions, NECo prunes spurious mentions that begin or end with a stop word where the remaining subexpression of the mention exists in M. It also removes time expressions and numbers from M if they are not included in M_{NEL}.

3.3 Mention Attributes

Step 1(e) in Fig. 2 also assigns attributes for a mention m linked to Wikipedia page $l(m)$, at both *coarse* and *fine-grained* levels, based on information from the Freebase entry corresponding to exact link $l(m)$ or head link $h(m)$.

The coarse attributes include gender, type, and NER classes such as PERSON, LOCATION, and ORGANIZATION. These attributes are part of the original Stanford coreference system and are used to avoid merging conflicting clusters. We use the Freebase values for these attributes when available. For instance, if the linked entity contains the Freebase type *location* or *organization*, we include the coarse type to LOCATION or ORGANIZATION respectively. In order to account for both links to specific people (Barack Obama) and generic links to positions held by people (President), we include the type PERSON if the linked entity has any of the Freebase types *person*, *job_title*, or *government_office_or_title*. If no coarse Freebase types are available for an attribute, we default to predicted NER classes.

We add fine-grained attributes from Freebase and Wikipedia by importing additional type information. We use all of the Freebase *notable types*, a set of hundreds of commonly used Freebase types, ranging from *us_president* to *tropical_cyclone* and *synthpop_album*. We also include all of the Wikipedia categories, on average six per entity. For example, the mention "Indonesia" is assigned fine-grained attributes such as *book_subject*, *military_power*, and *olympic_participating_country*. Since many of these fine-grained attributes are extremely specific, we use the last word of each attribute to define an additional fine-grained attribute (see Fig. 3). These fine-grained attributes are used in the Relaxed NEL sieve (Sec. 3.6).

3.4 NEL Constraints

While applying sieves to merge clusters in Figure 2 Step 2(a), NECo uses NEL constraints to eliminate some otherwise acceptable merges.

We avoid merging inconsistent clusters that link to different entities. Clusters c_i and c_j are inconsistent if both are linked (i.e., both clusters have non-null entity assignments) and $l(c_i) \neq l(c_j)$ or $h(c_i) \neq h(c_j)$. Also, in order to consider an antecedent cluster c as a merge candidate, we require a pair of entities in the set of linked entities $L(c)$ to be related to one another in Freebase. Two entities are related in Freebase if they both appear in a relation; for example, `Bill Clinton` and `Arkansas` are related because Bill Clinton has a "governor-of" relation with Arkansas.

3.5 Merging Clusters and Update Entity Links

When two clusters c_i and c_j are merged to form a new cluster c_k, the entity link information $L(c_k)$, $l(c_k)$, and $h(c_k)$ must be updated (Step 2 of Fig. 2). We set $L(c_k)$ to the union of the linked entities found in $l(c_i)$ and $l(c_j)$ and merge coarse attributes at this point.

In order to set the exact and head entity links $l(c_k)$ and $h(c_k)$, we use the exemplar mention

$Exemplar(c_k)$ that denotes the most representative mention of the cluster. $Exemplar(c)$ is selected according to a set of rules in the Stanford system, based on textual position and mention type (proper noun vs. common). We augment this function by considering information from exact and head entity links as well. Mentions appearing earlier in text, proper mentions, and mentions that have exact or head named-entity links are preferred to those which do not. Given exemplars, we set $l(c_k) = l(Exemplar(c_k))$ and $h(c_k) = h(Exemplar(c_k))$.

3.6 NEL Sieves

Finally, we introduce two new sieves that use NEL information at the beginning and end of the Stanford sieves pipeline in the merging stage (Step 2 of Fig. 2).

Exact NEL sieve The Exact NEL sieve merges two clusters c_i and c_j if both are linked and their links match, $l(c_i) = l(c_j)$. For example, all mentions that have been linked to `Barack Obama` will become members of the same coreference cluster. Because the Exact NEL sieve has high precision, we place it at the very beginning of the pipeline.

Relaxed NEL sieve The Relaxed NEL sieve uses fine-grained attributes of the linked mentions to merge proper nouns with common nouns when they share attributes. For example, this sieve is able to merge the proper mention "Disneyland" with the "the mysterious park", because *park* is one of the fine-grained attributes assigned to `Disneyland`.

More formally, let $m_i = Exemplar(c_i)$ and $m_j = Exemplar(c_j)$. For every common noun mention m_i, we merge c_i with an antecedent cluster c_j if (1) m_j is a linked proper noun, (2) if m_i or the title of its linked Wikipedia page is in the list of fine-grained attributes of m_j, or (3) if $h(m_j)$ is related to the head link $h(m_i)$ according to Freebase as defined above.

Because this sieve has low precision, we only allow merges between mentions that have a maximum distance of three sentences between one another. We add the Relaxed NEL sieve near the end of the pipeline, just before pronoun resolution.

4 Experimental Setup

Core Components and Baselines The Stanford sieve-based coreference system (Lee et al., 2013), the GLOW NEL system (Ratinov et al., 2011), and WikipediaMiner (Milne and Witten, 2008) provide core functionality for our joint model, and are also the state-of-the-art baselines against which we measure performance.

Parameter Settings Based on performance on the development set, we set the GLOW's confidence parameter to 1.0 and WikipediaMiner's to 0.4 to assure high-precision NEL. We also optimized for the set of fine-grained attributes to import from Wikipedia and Freebase, and the best way to incorporate the NEL constraints into the sieve architecture.

Datasets We report results on the following three datasets: ACE2004-NWIRE, CONLL2011, and ACE2004-NWIRE-NEL. ACE2004-NWIRE, the newswire subset of the ACE 2004 corpus (NIST, 2004), includes 128 documents. The CONLL2011 coreference dataset includes text from five different domains: broadcast conversation (BC), broadcast news (BN), magazine (MZ), newswire (NW), and web data (WB) (Pradhan et al., 2011). The broadcast conversation and broadcast news domains consist of transcripts, whereas magazine and newswire contain more standard written text. The development data includes 303 documents and the test data includes 322 documents.

We created ACE2004-NWIRE-NEL by taking a subset of ACE2004-NWIRE and annotating with gold-standard entity links. We segment and link all the expressions in text that refer to Wikipedia pages, allowing for nested linking. For instance, both the phrase "Hong Kong Disneyland," and the sub-phrase "Hong Kong" are linked. This dataset includes 12 documents and 350 linked entities.

Metrics We evaluate our system using MUC (Vilain et al., 1995), B^3 (Bagga and Baldwin, 1998), and pairwise scores. MUC is a link-based metric which measures how many clusters need to be merged to cover the gold clusters and favors larger clusters; B^3 computes the proportion of intersection between predicted and gold clusters for every mention and favors singletons (Recasens and Hovy, 2010). We computed the scores using the Stanford

Method	MUC			B^3			Pairwise		
	P	R	F1	P	R	F1	P	R	F1
Stanford Sieves	39.9	46.2	42.8	67.9	71.8	69.8	44.2	29.7	35.6
NECo	**46.8**	**52.5**	**49.5**	70.4	**72.6**	**71.5**	**51.5**	**34.6**	**41.4**

5 Experimental Results

We first look at NECo's performance at coreference resolution and then evaluate its ability at NEL.

5.1 Coref. Results with Predicted Mentions

Overall System Performance on ACE Data Table 1 shows NECo's performance at coreference resolution on ACE-2004 compared to the Stanford sieve implementation (Lee et al., 2013). The table shows that NECo has both significantly improved precision and recall compared to the Stanford baseline, across all metrics. We generally observe larger gains in MUC due to better mention detection and the Relaxed NEL Sieve.

Contribution of System Components Table 1 also details the performance of four variants of our system that ablate various components and features. Specifically, we consider the following cases:

- **No NEL Mentions:** We discard additional mentions, M_{NEL}, provided by NEL (Sec. 3.1). This increases B^3 precision at the expense of recall. Inspection shows that some of the errors introduced by M_{NEL} are actually due to correctly linked entities that were not annotated as mentions in the dataset, but also some improperly linked mentions.
- **No Mention Pruning:** We disable the initial step of updating mention boundaries and removing spurious mentions (Sec. 3.2). As expected, removing this step drops precision and recall significantly, even compared to the No NEL Mentions variant.
- **No Attributes:** Ablating coarse and fine-grained attributes (Sec. 3.3) drops F1 and recall measures across all metrics. To understand this effect, note that NECo uses attributes in two different settings. Updating coarse attributes tends to increase precision because it prevents dangerous merges, such as merging "Staples" with the mention "it" in a situation when "Staples" refers to the person entity `Todd Staples`. Fine-grained attributes also help with recall, when merging a specific name of an entity with a mention that uses a more general term; for instance, "Hong Kong Disneyland" can be merged with "the mysterious park" because "park" is a fine-grained attribute for `Disneyland`. However, when fine-grained attributes are used, precision sometimes drops (e.g., when "president" might merge with "Bush" when it should really merge with "Clinton").
- **No NEL Constraints:** Removing these constraints (Sec. 3.4) drops precision dramatically leading to drop in F1. In the case of incorrect linking, however, NEL constraints can affect recall. For instance, NEL constraints might prevent merging "Staples" with "Todd Staples" if the former were linked to the company and the latter to the politician.

Overall System Performance on CoNLL Data We also compare our full system (with added NEL sieves, constraints, and mention pruning[3]) with the Stanford sieve coreference system on CoNLL data

[3]Due to CoNLL annotation guidelines, a named entity is added to the mention list if it is *not* inside a larger mention with an exact named entity link.

Table 2: Coreference results on CoNLL 2011 development and test data, using predicted mentions. Rows denoted with * indicate runs using the fully automated Stanford CoreNLP pipeline rather than the predicted annotations provided with the CoNLL data. Given the relatively close results, we ran the Mann-Whitney U test for this table; values with the $^+$ superscript are significant with $p < 0.05$.

(Table 2). We ran NECo and the baseline in two settings: in the first, we use the standard predicted annotations (for POS, parses, NER, and speaker tags) provided with the CoNLL data, and in the second, we use the automated Stanford CoreNLP pipeline to predict this information. On both the development and test sets, we gain about 1 point in MUC F1 as well as a smaller improvement in B^3. Closer inspection indicates that our system increases precision primarily due to mention pruning and NEL constraints. Due to the differences in mention annotation guidelines between ACE and CoNLL, performance on ACE benefits more from improved mention detection from NEL. Moreover, the ACE corpus is all newswire text, which contains more entities that can benefit from linking. CoNLL, on the other hand, contains a wider variety of texts, some of which do not mention many named entities in Wikipedia.

To examine the performance of our system on the different domains covered by the CoNLL data, we also test our system on each domain separately (Table 3). We found NEL provided the biggest improvement for the news domains, broadcast news (BN) and newswire (NW). These domains especially benefit from the improved mention detection and pruning provided by NEL, and strong linking benefitted both precision and recall in these domains. We found that the magazine (MZ) section of the corpus benefited the least from NEL, as there were relatively few entities that our NEL systems were able to connect to Wikipedia.

5.2 Coreference Results with Gold Linking

Some of the errors introduced in our system are due to incorrect or incomplete links discovered by the automatic linking system. To assess the effect of NEL performance on NECo, we tested on a portion of ACE2004-NWIRE dataset for which we hand-labeled correct links for the gold and predicted mentions. "NECo + Gold NEL" denotes a version of our system which uses gold links instead of those predicted by NEL. As shown in Table 4, gold linking significantly improves the performance of our system across all measures. This suggests that further work to improve automatic NEL may have substantial reward.

Gold linking improves precision for two main rea-

Finkel and Manning (2008)	78.7	58.5	67.1	86.8	65.2	74.5	76.1	44.2	55.9

Table 5: Coreference results on ACE2004-NWIRE with gold mentions and automatic linking.

sons. First, it reduces the coreference errors caused by incorrect NEL links. For instance, gold linking replaces the erroneous link generated by our NEL systems for "Nasser al-Kidwa" to the correct Wikipedia entity. As another example, two mentions of "Rutgers" will not be merged if one links to the university and the other links to their football team. Second, gold linking leads to better mention detection and better linked mentions. For instance, under gold linking, the whole mention, "The governor of Alaska, Sarah Palin," is linked to the politician, while automatic linking systems only link the substring containing her name, "Sarah Palin." Still, gold NEL cannot compensate for all coreference errors in cases of generic or unlinked entities.

5.3 Coreference Results with Gold Mentions

Many of the previous papers evaluate coreference resolution assuming gold mentions so we also run under that condition (Table 5) using ACE2004-NWIRE data. As the table shows, with gold mentions our system outperforms Haghighi and Klein (2009), Poon and Domingos (2008), Finkel and Manning (2008) and the Stanford sieve algorithm across all metrics. Our method shows a relatively smaller gain in precision, because this condition adds no benefit to our technique of using NEL information for pruning mentions.

5.4 Improving Named Entity Linking

While our previous experiments show that named-entity linking can improve coreference resolution, we now address the question of whether coreference techniques can help NEL. We compare NECo with a baseline ensemble[4] composed of GLOW (Ratinov et al., 2011) and WikipediaMiner (Milne and Witten, 2008) on our ACE2004-NWIRE-NEL dataset (Table 6). Our system gains about 8% in absolute recall and 5% in absolute precision. For instance, our system correctly adds links from "Bullock" to the entity `Sandra Bullock` because coreference resolution merges two mentions. In another example, it correctly links "company" to `Nokia`. Overall, there is a 21% relative reduction in F1 error.

[4]We take the union of all the links returned by GLOW and WikipediaMiner, but if they link a mention to two different entities, we use only the output of WikipediaMiner.

Method	F1	Precision	Recall
NECo	**70.6**	**72.0**	**69.2**
Baseline NEL	64.4	67.4	61.7

Table 6: NEL performance of our system and the ensemble baseline linker on ACE2004-NWIRE-NEL.

5.5 Error Analysis

We analyzed 90 precision and recall errors and present our findings in Table 7. Spurious mentions accounted for the majority of non-semantic errors. Despite the improvements that come from NEL, a large portion of coreference errors can still be attributed to incomplete semantic information, including precision errors caused by incorrect linking. For instance, the mention "Disney" sometimes refers to the company, and other times refers to the amusement park; however, the NEL systems we used had difficulty disambiguating these cases, and NECo often incorrectly merges such mentions. Overly general fine-grained attributes caused precision errors in cases where many proper noun mentions were potential antecedents for a common noun. Although attributes such as *country* are useful for resolving a generic "country" mention, this information is insufficient when two distinct mentions such as "China" and "Russia" both have the *country* attribute.

However, many recall errors are also caused by the lack of fine-grained attributes. Finding the ideal set of fine-grained attributes remains an open problem.

6 Related Work

Coreference resolution has a fifty year history which defies brief summarization; see Ng (2010) for a recent survey. Section 2.1 described the Stanford multi-pass sieve algorithm, which is the foundation for NECo.

Earlier coreference resolution systems used shallow semantics and pioneered knowledge extraction from online encyclopedias (Ponzetto and Strube, 2006; Daumé III and Marcu, 2005; Ng, 2007). Some recent work shows improvement in coreference resolution by incorporating semantic information from Web-scale structured knowledge bases. Haghighi and Klein (2009) use a rule-based system to extract fine-grained attributes for mentions by analyzing precise constructs (e.g., appositives) in Wikipedia articles. Subsequently, Haghighi and Klein (2010) used a generative approach to learn entity types from an initial list of unambiguous mention types. Bansal and Klein (2012) use statistical analysis of Web n-gram features including lexical relations.

Rahman and Ng (2011) use YAGO to extract type relations for all mentions. These methods incorporate knowledge about all possible meanings of a mention. If a mention has multiple meanings, extraneous information might be associated with it. Zheng et al. (2013) use a ranked list of candidate entities for each mention and maintain the ranked list when mentions are merged. Unlike previous work, our method relies on NEL systems to disambiguate possible meanings of a mention and capture high-precision semantic knowledge from Wikipedia categories and Freebase notable types.

Ratinov and Roth (2012) investigated using NEL to improve coreference resolution, but did not consider a joint approach. They extracted attributes from Wikipedia categories and used them as features in a learned mention-pair model, but did not do mention detection. Unfortunately, it is difficult to compare directly to the results of both systems, since they reported results on portions of ACE and CoNLL datasets using gold mentions. However, our approach provides independent evidence for the benefit of NEL, and joint modeling in particular, since it outperforms the state-of-the-art Stanford sieve system (winner of the CoNLL 2011 shared task (Pradhan et al., 2011)) and other recent comparable approaches on benchmark datasets.

Our work also builds on a long trajectory of work in named entity resolution stemming from SemTag (Dill et al., 2003). Section 2.2 discussed GLOW and WikipediaMiner (Ratinov et al., 2011; Milne and Witten, 2008). Kulkarni et al. (2009) present an elegant collective disambiguation model, but do not exploit the syntactic nuances gleaned by within-document coreference resolution. Hachey et al. (2013) provide an insightful summary and evaluation of different approaches to NEL.

7 Conclusions

Observing that existing coreference resolution and named-entity linking have complementary strengths

Error Type	Percentage	Example
Extra mentions	31.1	**The other thing Paula really important** is that they talk a lot about the fact ...
Pronoun	27.7	However , [*all 3 women gymnasts , taking part in the internationals for the first time*], performed well , because they had strong events and their movements had difficulty .
Contextual semantic	16.6	[*The Chinese side*] hopes that each party concerned continues to make constructive efforts to ...Considering the requirements of the Korean side , ... the Chinese government decided to ...
NEL semantic	13.3	The most important thing about **Disney** is that it is a global brand. ... The subway to Disney has already been constructed.
Attributes	11.1	The **Hong Kong** government turned over to Disney Corporation [*200 hectares of land ...*]. ... this area has become a prohibited zone in Hong Kong.

Table 7: Examples of different error categories and the relative frequency of each. For every example, the mention to be resolved is underlined, and the correct antecedent is *italicized*. For precision errors, the wrongly merged mention is **bolded**. For recall errors, the missed mention is surrounded by [brackets].

and weaknesses, we present a joint approach. We introduce NECO, a novel algorithm which solves the problems *jointly*, demonstrating improved performance on both tasks.

We envision several ways to improve the joint model. While the current implementation of NECO only introduces NEL once, we could also integrate predictions with different levels of confidence into different sieves. It would be interesting to more tightly integrate the NEL system so it operates on clusters rather than individual mentions — after each sieve merges an unlinked cluster, the algorithm would retry NEL with the new context information. NECO uses a relatively modest number of Freebase attributes. While using more semantic knowledge holds the promise of increased recall, the challenge is maintaining precision. Finally, we would also like to explore the extent to which a joint probabilistic model (e.g., (Durrett and Klein, 2013)) might be used to learn how to best make this tradeoff.

Abstract

Interpreting *anaphoric shell nouns* (ASNs) such as *this issue* and *this fact* is essential to understanding virtually any substantial natural language text. One obstacle in developing methods for automatically interpreting ASNs is the lack of annotated data. We tackle this challenge by exploiting *cataphoric shell nouns* (CSNs) whose construction makes them particularly easy to interpret (e.g., *the fact that X*). We propose an approach that uses automatically extracted antecedents of CSNs as training data to interpret ASNs. We achieve precisions in the range of 0.35 (baseline = 0.21) to 0.72 (baseline = 0.44), depending upon the shell noun.

1 Introduction

Anaphors such as *this fact* and *this issue* encapsulate complex abstract entities such as propositions, facts, and events. An example is shown below.

(1) Here is another bit of advice: Environmental Defense, a national advocacy group, notes **that "Mowing the lawn with a gas mower produces as much pollution in half an hour as driving a car 172 miles."** **This fact** may help to explain the recent surge in the sales of the good old-fashioned push mowers or the battery-powered mowers.

Here, the anaphor *this fact* is interpreted with the help of the clausal antecedent marked in bold. The antecedent here is complex because it involves a number of entities and events (e.g., mowing the lawn, a gas mower) and relationships between them, and is abstract because the antecedent itself is not a purely physical entity.

The distinguishing property of these anaphors is that they contain semantically rich abstract nouns (e.g., *fact* in (1)) which *characterize* and *label* their corresponding antecedents. Linguists and philosophers have studied such abstract nouns for decades (Vendler, 1968; Halliday and Hasan, 1976; Francis, 1986; Ivanic, 1991; Asher, 1993). Our work is inspired by one such study, namely that of Schmid (2000). Following Schmid, we refer to these abstract nouns as *shell nouns*, as they serve as conceptual *shells* for complex chunks of information. Accordingly, we refer to the anaphoric occurrences of shell nouns (e.g., *this fact* in (1)) as *anaphoric shell nouns* (ASNs).

An important reason for studying ASNs is their ubiquity in all kinds of text. Schmid (2000) observed that shell nouns such as *fact*, *idea*, *point*, and *problem* were among the 100 most frequently occurring nouns in a corpus of 225 million words of British English. Moreover, ASNs can play several roles in organizing a discourse such as encapsulation of complex information, cohesion, and topic boundary marking. So correct interpretation of ASNs can be an important step for correct interpretation of a discourse, and in a number of NLP applications such as text summarization, information extraction, and non-factoid question answering.

Despite their importance, ASNs have not received much attention in Computational Linguistics, and research in this field remains in its earliest stages. At

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 300–310,
Seattle, Washington, USA, 18-21 October 2013.

present, the major obstacle is that there is very little annotated data available that could be used to train a supervised machine learning system for robustly interpreting these anaphors, and manual annotation is an expensive and time-consuming task.

We tackle this challenge by exploiting a category of examples, as shown in (2), whose construction is particularly easy to interpret.

(2) Congress has focused almost solely on **the fact that special education is expensive – and that it takes away money from regular education**.

Here, in contrast with (1), *the fact* is not anaphoric in the traditional sense, but is an easy case of a forward-looking anaphor — a cataphor. While the resolution process of *this fact* in (1) is quite challenging as it requires the use of semantics and world knowledge, it is fairly easy to interpret *the fact* in (2) based on the syntactic structure alone. We refer to these easy-to-interpret cataphoric occurrences of shell nouns as *cataphoric shell nouns* (CSNs). The interpretation of both ASNs and CSNs will be referred to as *antecedent*.[1] The antecedent of *the fact* in (2) is given in the post-nominal *that* clause. We use the term *shell concept* to refer to the general *notion* of a shell noun, i.e., the semantic type of the antecedent. For example, the notion of an *issue* is an important problem which requires a solution.

In this work, we propose an approach to interpret ASNs that exploits *unlabelled* but easy-to-interpret CSN examples to extract characteristic features associated with the antecedent of different shell concepts. We evaluate our approach using crowdsourcing. Our results show that these unlabelled CSN examples provide useful linguistic properties that help in interpreting ASNs.

2 Related work

The resolution of anaphors to non-nominal antecedents has been well analyzed taking discourse structure and semantic types into account (Webber, 1991; Passonneau, 1989; Asher, 1993). Most work in machine anaphora resolution, however, is restricted to anaphora that involve nominal antecedents only (Poesio et al., 2011).

[1]Sadly, the more-logical term for the interpretation of a CSN, *succedent*, does not actually exist.

There are some notable exceptions which have tackled the challenge of interpreting non-nominal antecedents (Eckert and Strube, 2000; Strube and Müller, 2003; Byron, 2004; Müller, 2008). These approaches are limited as they either rely heavily on domain-specific syntactic and semantic annotation or prepossessing, or mark only verbal proxies for non-nominal antecedents.

Recently, Kolhatkar and Hirst (2012) presented a machine-learning based resolution system for *this issue* anaphora, identifying full syntactic phrases as antecedents. Although they achieved promising results, their approach was limited in two respects. First, it focused on only one type of shell noun anaphora (*issue* anaphora). Second, their training data was restricted to MEDLINE abstracts in which *this issue* is used in a rather systematic way. Furthermore, their work is based on manually labelled ASN antecedents, whereas we use automatically identified CSN antecedents, which we interpret as explicitly expressed antecedents in comparison to the more implicitly expressed ASN antecedents.

Using explicitly expressed structure in the text to identify implicit structure is not new. The same idea has been applied before in computational linguistics. Marcu and Echihabi (2002) identified implicit discourse relations using explicit ones. Markert and Nissim (2005) used Hearst's (1992) explicit patterns to learn lexical semantic relations for NP-coreference and *other*-anaphora resolution from the web. Although our work focuses on a different topic, the methodology is in the same vein.

3 Hypothesis of this work

The hypothesis of this work is that CSN antecedents and ASN antecedents share some linguistic properties and hence linguistic knowledge encoded in CSN antecedents will help in interpreting ASNs. Accordingly, we examine which features present in CSN antecedents are relevant in interpreting ASNs.

The motivation and intuition behind this hypothesis is as follows. The antecedents of both ASNs and CSNs represent the corresponding shell concept. So are there any characteristic features associated with this shell concept? Do speakers of English follow certain patterns of syntactic shape or words, for instance, when they state facts, decisions,

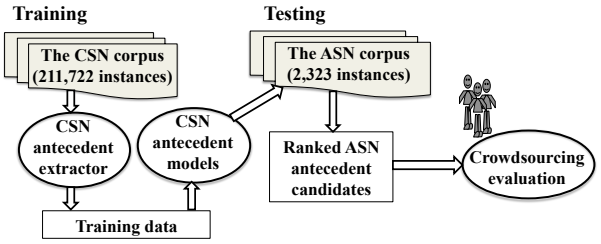

Figure 1: Overview of our approach

or issues? There is an abundance of data for CSN antecedents and if we are able to capture particular linguistic characteristic features associated with a shell concept using this data, we can use this information to interpret ASNs. For instance, example (2) demonstrates characteristic properties of antecedents of the shell noun *fact* including that (a) they are propositions and are generally expressed with clauses or sentences rather than noun phrases, and (b) they are generally expressed in the present tense. Observe that these properties also hold for the antecedent of *this fact* in example (1).

We test our hypothesis by building machine learning models that are trained on automatically extracted CSN antecedents and then applying these models to recover ASN antecedents. Figure 1 shows an overview of our methodology.

4 Background

Formal definition *Shell-nounhood* is a functional notion; it is defined by the *use* of an abstract noun rather than the inherent properties of the noun itself (Schmid, 2000). An abstract noun is a shell noun when the speaker decides to *use* it as a shell noun.

Shell noun categorization Schmid (2000) gives a list of 670 English nouns which are frequently used as shell nouns. He divides them into six broad semantic classes: *factual*, *linguistic*, *mental*, *modal*, *eventive*, and *circumstantial*. Table 1 shows this classification, along with example shell nouns for each category. For this work, we selected six frequently occurring shell nouns covering four of Schmid's six classes: *fact* and *reason* from factual, *issue* and *decision* from mental, *question* from linguistic, and *possibility* from modal. These shell nouns tend to have antecedents that lie within a single sentence. We excluded *eventive* and *circumstantial* classes because the shell nouns in these classes tend to have rather unclear and long antecedents.[2]

Class	Description	Examples
factual	states of affairs	***fact***, ***reason***
linguistic	linguistic acts	***question***
mental	ideas	***issue***, ***decision***
modal	judgements	***possibility***
eventive	events	*act*, *reaction*
circumstantial	situations	*situation*, *way*

Table 1: Schmid's classification of shell nouns. The nouns given in the *Example* column tend to occur frequently with the respective class. The shell nouns used in this work are shown in boldface.

Pattern	Example
N-to	Several people at the group said the **decision *to*** *write the letters* was not controversial internally.
N-be-to	The principal **reason is *to*** *create a representative government* rather than to select the most talented person.
N-that	Mr. Shoval left open the **possibility *that*** *Israel would move into other West Bank cities*.
N-be-that	The simple and reassuring **fact is *that*** *a future generation of leaders is seeking new challenges during challenging times*.
N-wh	There is now some **question *whether*** *the country was ever really in a recession*.
N-be-wh	Of course, the central, and probably insoluble, **issue is *whether*** *animal testing is cruel*.

Table 2: Easy-to-interpret CSN patterns given by Schmid (2000). In the *Example* column, the patterns are marked in boldface and the antecedents are marked in italics.

Shell noun patterns Schmid (2000) also provides a number of lexico-grammatical patterns for shell nouns. In Section 1, we noted two such patterns: *this-N* (*this fact* in example (1)) and *N-that* (*fact that* in example (2)). We also noted that CSNs with pattern *N-that* are fairly easy to interpret compared to the ASN pattern *this-N*. Table 2 shows some other easy-to-interpret CSN patterns given by Schmid. Generally, for all these patterns, the antecedent is

[2]These observations are based on an exploratory pilot annotation we carried out on sample data of 150 ASN instances.

quite easy to extract with a few predefined rules.

Shell antecedent properties Antecedents of CSNs and ASNs share some properties while they are distinguished by others. The distinguishing property is that CSNs, by their construction, have their antecedents in the same sentence, as shown in example (2). On the other hand, ASNs can have long-distance as well as short-distance antecedents.[3] The common properties are as follows. First, antecedents of both ASNs and CSNs represent the corresponding shell concept, e.g., the notion of a *fact* or an *issue*. Second, in both cases, the antecedents are complex abstract entities, which involve a number of entities and relationships between them. Finally, in both cases, there is no one-to-one correspondence between the syntactic type of an antecedent and semantic type of its referent (Webber, 1991). For instance, a semantic type such as *fact* can be expressed with different syntactic shapes such as a clause, a verb phrase, or a complex sentence. Conversely, a syntactic shape, such as a clause, can function as several semantic types, including *fact*, *proposition*, and *event*.

5 Training phase

As shown in Figure 1, the goal of the training phase is to build training data from CSNs and their antecedents and train models which can be used for resolving ASNs.

5.1 The CSN corpus

We automatically constructed a corpus, a subset of the New York times (NYT) corpus[4], which contains 211,722 sentences following CSN patterns from Table 2. We considered part-of-speech information[5] while looking for the patterns. For instance, instead of the pattern *N-that*, we actually looked for {shell_noun_*NN that_IN*}.

[3] In our annotated sample data, we observed ASN antecedents as close as the same sentence and as far as 7 sentences away from the anaphor.

[5] http://nlp.stanford.edu/software/tagger.shtml

5.2 Antecedent extractor for CSNs

The goal of the antecedent extractor is to create automatically labelled CSN antecedent data. Recall that antecedents of CSNs can be extracted using simple predefined rules that are based on the syntactic structure alone. For instance, the antecedent extraction rule for example (2) would be: if the example follows the pattern *fact-that*, extract the post-nominal *that* clause as the antecedent. To come up with a list of such extraction rules, we systematically analyzed a sample of examples (about 20 examples) of each pattern for each shell noun. Table 3 summarizes the resulting antecedent extraction rules.

The actual antecedent extraction works as follows. First, we parsed the examples from the CSN corpus using the Stanford parser.[6] Then for each example, we applied rules from Table 3 depending on the shell noun and the pattern it follows to extract an appropriate syntactic constituent as the CSN antecedent. For instance, for the noun *fact* following the *N-that* pattern, as in example (2), we first looked for the NP constituent containing the shell noun *fact*, and then extracted the sentential constituent following the NP constituent as the CSN antecedent. Although, in most of the cases, the antecedent is given in the post-nominal *wh*, *that*, or infinitive clauses, sometimes it is not present in the immediately following clause but is given only as a predicate, as shown in (3).

(3) The primary **reason that** the archdiocese cannot pay teachers more is **that its students cannot afford higher tuition**.

In such cases, we looked for the pattern *(VP (VB be_verb) X)* in the right sibling of the NP containing the pattern *shell_noun-that* and extracted *X* as the CSN antecedent.

Two contradictory goals need to be achieved while extracting antecedents of CSNs. The first requires only considering CSNs with high-confidence patterns, whereas the second requires considering as many patterns as possible to allow a wide variety of antecedent examples with different linguistic properties (e.g., syntactic shape). Our antecedent extractor tries to find a balance between the two goals.

[6] http://nlp.stanford.edu/software/lex-parser.shtml

	fact	***reason***	***issue***	***decision***	***question***	***possibility***
N-to	–	–	–	***inf* clause**	predicate	*inf* clause
N-be-to	–	*inf* clause	*inf* clause	*inf* clause	*inf*/*wh* clause	*inf* clause
N-that	***that* clause**	**predicate**	**predicate**	–	**predicate**	***that* clause**
N-be-that	*that* clause	*that* clause	*that* clause	*that* clause	*that* clause	*that* clause
N-wh	–	predicate	*wh* clause	*wh* clause	*wh* clause	–
N-be-wh	*wh* clause	*wh* clause	*wh* clause	*wh* clause	*wh* clause	*wh* clause

Table 3: Content extraction patterns for CSNs. Patterns in boldface are the prominent patterns for the respective shell noun. *inf* clause = infinitive clause. Discarded patterns are denoted by –.

To address the first goal, we filter examples following noisy patterns, i.e., the patterns that do not unambiguously encode antecedents of that CSN. For instance, the pattern *N-to* is a highly preferred pattern for *decision*, as shown in (4). The antecedent extraction rule here is relatively simple: if the example follows the pattern *decision-to*, extract the postnominal infinitive clause as the correct antecedent.

(4) President Jacques Chirac's arrogant **decision to defy the world and go ahead with two nuclear bomb tests in Polynesia** deserves contempt.

But the same pattern is noisy for *reason*. In (5), for example, the actual reason is not given anywhere in the sentence. So we discard the examples following the pattern *N-to* for *reason*.

(5) Investors have had **reason to** worry about stocks.

We also discard examples with negative determiners, as in (6), because in such cases, the extraction rules do not precisely give the antecedent of the given CSN.

(6) He was careful to repeat anew that he had made **no decision to** go to war.

For the *N-wh* pattern, we exclude certain *wh* words for certain nouns. For example, we exclude the *wh* word *which* for *question* as the Penn Treebank tagset[7] does not distinguish between *which* as a relative pronoun and as a question. We are interested in the latter but not the former. Other discarded *wh* words include *which* and *when* for *fact*; all *wh* words except *when* and *why* for *reason*, all *wh* words except *how* and *whether* for *issue*; *which*, *whom*, *when*, and *why* for *decision*; *which* and *when* for *question*; and all *wh* words for *possibility*.

[7]The Stanford tagger we employ uses the Penn Treebank tagset (Marcus et al., 1993).

To address the second goal of allowing a wide variety of antecedent examples, we try to include as many patterns as possible for each shell noun, as shown in Table 3. For instance, the patterns *question-to* and *question-be-to* will have infinitive clauses as antecedents (marked as VP or S+VP by the parser), whereas for the examples following patterns *question-wh* and *question-be-wh* the antecedent will be in the *wh* clauses (marked as SBAR). For the pattern *question-that*, the antecedent will be in the predicate (similar to example (3)), which can be a prepositional phrase, a noun phrase or a clause.

5.3 Models for CSN antecedents

The antecedent extractor gives labels for each instance in the CSN corpus. Using this labelled data, we train machine learning ranking models for different shell concepts that capture the characteristic features associated with that shell concept. The following sections describe each step of our ranking models in detail.

5.3.1 Candidate extraction

The first step is to extract the set of eligible antecedent candidates $C = \{C_1, C_2, ..., C_k\}$ for the CSN instance a_i. To train a machine learning model we need positive and negative examples. We already have positive examples for antecedent candidates — the *true* antecedents given by the antecedent extractor. But we also need negative examples of antecedent candidates. By their construction, CSNs have their antecedents in the same sentence. So we extract all syntactic constituents of this sentence, given by the Stanford parser. All the syntactic constituents, except the *true* antecedent, are considered as negative examples. With this candidate extraction method, we end up with many more negative exam-

ples than positive examples, but that is exactly what we expect with ASN antecedent candidates, i.e., the test data on which we will be applying our models.

5.3.2 Features

Although our problem is similar to anaphora resolution, we cannot make use of the usual anaphora or coreference resolution features such as agreement or string matching (Soon et al., 2001) because of the nature of ASN and CSN antecedents. We came up with a set of features based on the properties that were common in both ASN and CSN antecedents, according to our judgement.

Syntactic type of the candidate (S) We observed that each shell noun prefers specific CSN patterns and each pattern involves a particular syntactic type. For instance, *decision* prefers the pattern *N-to* and consequently realizes as its antecedents more verb phrases than, for example, noun phrases. We employ two versions of syntactic type: fine-grained syntactic type given by the Stanford parser (e.g., NP-TMP, RRC) and coarse-grained syntactic type (e.g., NP, VP, S, PP) in which we consider ten basic syntactic categories and map all fine-grained syntactic types to these categories.

Context features (C) Context features allow our models to learn about the contextual clues that signal the antecedent. This class contains two features: (a) coarse-grained syntactic type of left and right siblings of the candidate, and (b) part-of-speech tag of the preceding and following words of the candidate.

Embedding level features (E) These features (Müller, 2008) encode the embedding level of the candidate within its sentence. We consider two embedding level features: top embedding level and immediate embedding level. Top embedding level is the level of embedding of the given candidate with respect to its top clause (the root node), and immediate embedding level is the level of embedding with respect to its immediate clause (the closest ancestor of type S or SBAR). The intuition behind this feature is that if the candidate is deep in the parse tree, it is possibly not salient enough to be an antecedent. As we consider all syntactic constituents as potential candidates, there are many that clearly cannot be antecedents. This feature will allow us to get rid of this noise.

Subordinating conjunctions (SC) As we can see in Table 2, subordinating conjunctions are common with CSN and ASN antecedents. Vendler (1968) points out that the shell noun *fact* prefers a *that*-clause, and *question* and *issue* prefer a *wh*-question clause. We observed that the pattern *because X* is common with *reason*. The subordinating conjunction feature encodes these preferences for different shell nouns. The feature checks whether the candidate follows the pattern *SBAR* $\rightarrow$ *(IN sconj) (S ...)*, where *sconj* is a subordinating conjunction.

Verb features (V) A prominent property of CSN and ASN antecedents is that they tend to contain verbs. All examples from Table 2, for example, contain verbs. Moreover, certain shell nouns have tense and aspect preferences. For instance, for shell noun *fact*, lexical verbs in past and present tenses predominate (Schmid, 2000), whereas modal forms are extremely common for *possibility*. We use three verb features that capture this idea: (a) presence of verbs in general, (b) whether the main verb is finite or non-finite, and (c) presence of modals.

Length features (L) The intuition behind these features is that CSN and ASN antecedents tend to be long, especially for nouns such as *fact*. We consider two length features: (a) length of the candidate in words, and (b) relative length of the candidate with respect to the sentence containing the antecedent.

Lexical features (LX) Our extractor gives us a large number of antecedent examples for each shell noun. A natural question is whether certain words tend to occur more frequently in the antecedent than non-antecedent parts of the sentence. To deal with this question, we extracted all antecedent unigrams (i.e., unigrams occurring in antecedent part of the sentence) and non-antecedent unigrams (i.e., unigrams occurring in non-antecedent parts of the sentence) for each shell noun. Then for all antecedent unigrams for a particular shell noun, we computed *term goodness* in terms of information gain (Yang and Pedersen, 1997) and considered the first 50 highly ranked unigrams as the lexical features for that noun. Note that, in contrast with the other features, these lexical features are tailored for each shell noun and are extracted *a priori*.

5.3.3 Candidate ranking models

Now that we have the set of candidate antecedents and a set of features, we are ready to train CSN antecedent models. We follow the *candidate-ranking* models proposed by Denis and Baldridge (2008) because they allow us to evaluate how good an antecedent candidate is relative to *all* other candidates.

For every shell noun, we gather automatically extracted antecedent data given by the extractor for all instances of that shell noun. Then for each instance in this data, we extract the set C as explained in Section 5.3.1. For each candidate $C_i \in C$, we extract a feature vector to create a corresponding set of feature vectors, $C_f = \{C_{f1}, C_{f2}, ..., C_{fk}\}$. For every CSN a_i and a set of feature vectors corresponding to its eligible candidates $C_f = \{C_{f1}, C_{f2}, ..., C_{fk}\}$, we create training examples $(a_i, C_{fi}, rank), \forall C_{fi} \in C_f$. The rank is 1 if C_i is same as the *true* antecedent, i.e., the automatically extracted antecedent for that CSN, otherwise the rank is 2. We use the `svm_rank_learn` call of SVM^{rank} (Joachims, 2002) for training the candidate-ranking models.

6 Testing phase

In this phase, we use the learned candidate ranking models to identify the antecedents of ASNs.

6.1 The ASN corpus

We started with about 450 instances for each of the six selected shell nouns (2,700 total instances), containing the pattern {*this* shell_noun}. The instances were extracted from the NYT. Each instance contains three paragraphs from the corresponding NYT article: the paragraph containing the ASN and two preceding paragraphs as context. After automatically removing duplicates and ASNs with a non-abstract sense (e.g., *this issue* with a publication-related sense), we were left with 2,323 instances.

6.2 Antecedent identification

Candidate extraction The search space of ASN antecedents is quite large for two reasons: ASNs tend to have long-distance as well as short-distance antecedents, and there is no clear restriction on the syntactic type of the antecedents. In the ASN corpus, each sentence on average had 49.5 distinct syntactic constituents given by the Stanford parser. If we consider n preceding sentences, the sentence containing the anaphor, and one following sentence[8] as sources for antecedents, then the average number of antecedent candidates will be $49.5 \times (n+2)$. This is large compared to the search space of ordinary nominal anaphora. In our previous work (Kolhatkar et al., 2013), we have developed methods that identify the sentence containing the antecedent of the ASN before identifying the precise antecedent. In brief, given a set of a fixed number of sentences around the sentence containing an ASN, these methods reliably identify the sentence containing the antecedent. In this paper, we treat these methods as a black box.

Given the sentence containing the antecedent, we extract all syntactic constituents given by the Stanford parser from that sentence as potential antecedent candidates as for the training phase. In the training phase, the antecedent is always contained in the set of syntactic constituents given by the Stanford parser because the extractor obtains the appropriate antecedent using the syntactic information. But in the testing phase, we cannot guarantee that the true antecedent occurs in the extracted syntactic constituents due to the parser's errors. So for robust candidate extraction, we extract all distinct constituents from the 30-best parses instead of only considering the best parse, which increases the average number of candidates from 49.5 to 55.2.

Feature extraction and candidate ranking Given the antecedent candidates, feature extraction and candidate ranking are essentially the same as for the training phase, except of course we do not know the *true* antecedent. Once we have the feature vectors for each antecedent candidate, the appropriate trained model, i.e., the model trained for the corresponding shell noun, is invoked and the candidates are ranked using the `svm_rank_classify` call of SVM^{rank}.

7 Evaluation

We evaluate the ranked candidates of ASN instances using crowdsourcing.

[8] The ASN corpus contains a few cataphoric examples that do not follow the standard patterns of the CSNs shown in Table 2, but actually refer to an antecedent in the following sentence (e.g., *Mr. Dukakis put **this question** to him: **X***).

Interface We chose to use CrowdFlower[9] as our crowdsourcing interface because of its integrated quality-control mechanism. For instance, it throws gold questions randomly at the workers and the workers who do not answer them correctly are not allowed to continue.

We presented to the crowd evaluators the ASN instances from the ASN corpus. Recall that each ASN instance is made up of the paragraph containing the ASN and two preceding paragraphs as context. We displayed the first 10 highly-ranked candidates (ordered randomly) given by our testing phase and asked the evaluators to choose the best answer that represents the ASN antecedent. We encouraged the evaluators to select *None* when they did not agree with any of the displayed answers. We also asked them how satisfied they were with the displayed answers. We provided them with three options: *unsatisfied*, *satisfied*, and *partially satisfied*.

Our job contained 2,323 evaluation units. We asked for 8 judgements per instance and paid 6 cents per evaluation unit. As we were interested in the verdict of native speakers of English, we limited the allowed demographic region to English-speaking countries.

Results Among the 2,323 ASN instances, 96% of them were labelled as *satisfied*, 3% as *partially satisfied* and 1% as *unsatisfied*. Only 2% of the instances were labelled as *None*. As expected, evaluators were *unsatisfied* or *partially satisfied* with the options of these instances. These results suggest that our resolution models trained on automatically extracted antecedents of CSNs bring the relevant candidates of ASN antecedents to the top, i.e., within first 10 highly-ranked candidates. This itself is a positive result given the large search space of ASN antecedent candidates (more than 55 candidates on average).

Among the evaluation units, more than half of the evaluators agreed on an answer for 1,810 units. We used these instances for further analysis.

To examine which CSN antecedent features are relevant in identifying ASN antecedents, we carried out ablation experiments with all feature class combinations. We compared the rankings given by our ranker to the crowd's answer using *precision at n* (P@n).[10] More specifically, we count the number of instances where the crowd's answers occur within our ranker's first n choices. P@n then is this count divided by the total number of instances. Note that P@1 is equivalent to the standard precision.

We compared our results against two baselines: *preceding sentence* and *chance*. The preceding sentence baseline chooses the previous sentence as the correct antecedent. The chance baseline chooses a candidate from a uniform random distribution over the set of 10 top-ranked candidates.

The results are shown in Table 4. Although different feature combinations gave the best results for different shell nouns, the features that occur frequently in many best-performing combinations were embedding level (E), lexical (LX), and subordinating conjunction (SC) features. The SC features were particularly effective for *issue* and *question*, where we expected patterns such as *whether X*.

Surprisingly, the syntactic type features (S) did not show up very often in the best-performing feature combinations, suggesting that the ASN antecedents had a greater variety of syntactic types than what was available in our CSN training data.

The context features (C) did not appear in any of the best-performing feature combinations. In fact, they resulted in a sharp decline in the precision. For instance, for *question*, adding the context features to the best-performing combination {E,SC,V,L,LX} resulted in a drop of 16 percentage points. This result was not surprising because although the antecedents of ASNs and CSNs share similar properties such as common words, we know that their context is generally different.

We did not observe specific features associated with Schmid's semantic categories. An exception was the E features which were particularly effective for the factual nouns *fact* and *reason*: the results with them alone gave high precision (0.68 for *fact* and 0.72 for *reason*). That said, the E features were present in most of the best-performing combinations even for the shell nouns in other semantic categories.

[9] `http://crowdflower.com/`

[10] CrowdFlower gives us a unique answer for each instance, which we take to be the crowd's answer. During annotation, every annotator is presented with a few gold questions randomly and each annotator is assigned a trust score based on her performance on these gold questions. The unique answer for an instance is the answer with the highest sum of trusts.

PSbaseline	.34	–	–	–

Table 4: Evaluation of our ranker for antecedents of six ASNs. For each noun we show the three best-performing feature combinations. P@n is the precision at rank n (P@1 = standard precision). Boldface indicates the best in the column. PSbaseline = preceding sentence baseline. The P@1 results significantly higher than PSbaseline are marked with *(two-sample χ^2 test: $p < 0.05$). The chance baseline results were 0.1, 0.2, 0.3, and 0.4 for P@1, P@2, P@3, and P@4, respectively.

The only previous work with which our results could be compared is that of Kolhatkar and Hirst (2012). The work reports precision in the range of 0.41 to 0.61 in resolving *this issue* anaphora in the Medline domain. In our case, for *this issue* instances from the NYT corpus, we achieved precision in the range of 0.40 to 0.47. Furthermore, we applied our models to resolve *this issue* instances from Kolhatkar and Hirst's (2012) work.[11] Even with models trained on automatically labelled CSN antecedents, we achieved similar results to Kolhatkar and Hirst's results: P@1 of 0.45, P@2 of 0.59, P@3 of 0.65, and P@4 of 0.67. These results show the domain robustness of our methods with respect to the shell noun *issue*. Recall that Kolhatkar and Hirst (2012) looked at only very specific cases of *this issue* and used manually annotated data (Section 2), as opposed to the automatically extracted CSN antecedent data we use.

[11] We thank an anonymous reviewer for suggesting this to us.

8 Discussion and conclusion

The goal of this paper was to examine to what extent CSNs help in interpreting ASNs. Based on the evaluators' satisfaction level and very few *None* responses, we conclude that our models trained on CSN antecedents were able to bring the relevant ASN antecedent candidates into the top 10 candidates.

When we applied the models trained on CSN antecedents to interpret ASNs, we achieved precision in the range of 0.35 to 0.72. The precision results as high as 0.72 for *reason* and 0.70 for *fact* and *question* support our hypothesis that the linguistic knowledge provided by CSN antecedents helps in identifying the antecedents of ASNs. We observed different behaviour for different nouns. The mental nouns *issue* and *decision* in general were harder to interpret than other shell nouns. The models trained on CSNs achieved precisions of 0.35 for *decision* and 0.47 for *issue*. So there is still much room for improvement. That said, for the same nouns, the antecedents were in the first four ranks about 76% to 81% of the times,

suggesting that in future research, our models can be used as base models to reduce the large search space of ASN antecedent candidates.

We observed a wide range of performance for different shell nouns. One reason is that the size of the training data was different for different shell nouns. After excluding the noisy examples (Section 5.2), there were about 43,000 training examples for *fact*, but only about 3,000 for *issue*. In addition, a particular shell concept itself can be difficult, e.g., the very idea of what counts as an *issue* is more fuzzy than what counts as a *fact*.

One limitation of our approach is that it only learns the properties that are present in CSN antecedents. However, ASN antecedents have additional properties which are not always captured by CSN antecedents. For instance, for the shell noun *decision*, most of the training examples were infinitive phrases of the form *to X*. But antecedents of the ASN *decision* were mostly court decisions and were expressed with full sentences.

Moreover, although the models trained on CSN antecedents are able to encode characteristic features associated with the general shell concept, they are unable to distinguish between two competing candidates both containing the characteristic features of that shell concept. For instance, our approach will not be able to handle the constructed examples in (7).

(7) The teacher erased the solutions before John had time to copy them out, as he had momentarily been distracted by a band playing outside.

a) **This fact** infuriated him, as the teacher always erased the board quickly and John suspected it was just to punish anyone who was lost in thought, even for a moment.

b) **This fact** infuriated the teacher, who had already told John several times to focus on class work.

Here, both propositions possess properties of the shell concept *fact*. Understanding the context of the anaphor itself is crucial in correctly identifying the fact in each case, which cannot be learnt from CSN antecedents due to their specific context patterns.

A number of extensions are planned for this work. First, we plan to use both kinds of data, CSN and ASN antecedent data, which will give us a basis for developing a better performing ASN resolver. We also plan to incorporate contextual features (e.g., right-frontier rule (Webber, 1991) and context ranking (Eckert and Strube, 2000)). Finally, we will examine whether a model trained for one shell noun can be generalized to other shell nouns from the same semantic category.

Exploring Representations from Unlabeled Data with Co-training for Chinese Word Segmentation

Longkai Zhang Houfeng Wang* Xu Sun Mairgup Mansur

Abstract

Nowadays supervised sequence labeling models can reach competitive performance on the task of Chinese word segmentation. However, the ability of these models is restricted by the availability of annotated data and the design of features. We propose a scalable semi-supervised feature engineering approach. In contrast to previous works using pre-defined task-specific features with fixed values, we dynamically extract representations of label distributions from both an in-domain corpus and an out-of-domain corpus. We update the representation values with a semi-supervised approach. Experiments on the benchmark datasets show that our approach achieve good results and reach an f-score of 0.961. The feature engineering approach proposed here is a general iterative semi-supervised method and not limited to the word segmentation task.

1 Introduction

Chinese is a language without natural word delimiters. Therefore, Chinese Word Segmentation (CWS) is an essential task required by further language processing. Previous research shows that sequence labeling models trained on labeled data can reach competitive accuracy on the CWS task, and supervised models are more accurate than unsupervised models (Xue, 2003; Low et al., 2005). However, the resource of manually labeled training corpora is limited. Therefore, semi-supervised learning has become one of the most natural forms of training for CWS. Traditional semi-supervised methods focus on adding new unlabeled instances to the training set by a given criterion. The possible mislabeled instances, which are introduced from the automatically labeled raw data, can hurt the performance and not easy to exclude by setting a sound selecting criterion.

In this paper, we propose a simple and scalable semi-supervised strategy that works by providing semi-supervision at the level of representation. Previous works mainly assume that context features are helpful to decide the potential label of a character. However, when some of the context features do not appear in the training corpus, this assumption may fail. An example is shown in table 1. Although the context of "水" and "篮" is totally different, they share a homogeneous structure as "verb-noun". Therefore. A much better way is to map the context information to a kind of representation. More precisely, the mapping should let the similar contexts map to similar representations, while let the distinct contexts map to distinct representations.

	吃水果	打篮球
Label	B	B
Character	吃 水 果	打 篮 球
Context Features	C-1= 吃 C0= 水 C1= 果	C-1= 打 C0= 篮 C1= 球

Table 1: Example of the context of "水" in "吃水果 (Eat fruits)" and the context of "篮" in "打篮球 (Play basketball)"

We use the label distribution information that

*Corresponding author

Seattle, Washington, USA, 18-21 October 2013.

is extracted from the unlabeled corpus as this representation to enhance the supervised model. We add "pseudo-labels" by tagging the unlabeled data with the trained model on the training corpus. These "pseudo-labels" are not accurate enough. Therefore, we use the label distribution, which is much more accurate.

To accurately calculate the precise label distribution, we use a framework similar to the co-training algorithm to adjust the feature values iteratively. Generally speaking, unlabeled data can be classified as in-domain data and out-of-domain data. In previous works these two kinds of unlabeled data are used separately for different purposes. In-domain data is mainly used to solve the problem of data sparseness (Sun and Xu, 2011). On the other hand, out-of domain data is used for domain adaptation (Chang and Han, 2010). In our work, we use in-domain and out-of-domain data together to adjust the labels of the unlabeled corpus.

We evaluate the performance of CWS on the benchmark dataset of Peking University in the second International Chinese Word Segmentation Bakeoff. Experiment results show that our approach yields improvements compared with the state-of-art systems. Even when the labeled data is insufficient, our methods can still work better than traditional methods. Compared to the baseline CWS model, which has already achieved an f-score above 0.95, we further reduce the error rate by 15%.

Our method is not limited to word segmentation. It is also applicable to other problems which can be solved by sequence labeling models. We also applied our method to the Chinese Named Entity Recognition task, and also achieved better results compared to traditional methods.

The main contributions of our work are as follows:

- We proposed a general method to utilize the label distribution given text contexts as representations in a semi-supervised framework. We let the co-training process adjust the representation values from label distribution instead of using manually predefined feature templates.
- Compared with previous work, our method achieved a new state-of-art accuracy on the CWS task as well as on the NER task.

The remaining part of this paper is organized as follows. Section 2 describes the details of the problem and our algorithm. Section 3 describes the experiment and presents the results. Section 4 reviews the related work. Section 5 concludes this paper.

2 System Architecture

2.1 Sequence Labeling

Nowadays the character-based sequence labeling approach is widely used for the Chinese word segmentation problem. It was first proposed in Xue (2003), which assigns each character a label to indicate its position in the word. The most prevalent tag set is the BMES tag set, which uses 4 tags to carry word boundary information. This tag set uses B, M, E and S to represent the Beginning, the Middle, the End of a word and a Single character forming a word respectively. We use this tag set in our method. An example of the "BMES" representation is shown in table 2.

Character:	我	爱	北	京	天	安	门
Tag:	S	S	B	E	B	M	E

Table 2: An example for the "BMES" representation. The sentence is "我爱北京天安门" (I love Beijing Tian-an-men square), which consists of 4 Chinese words: "我" (I), "爱" (love), "北京" (Beijing), and "天安门" (Tian-an-men square).

2.2 Unlabeled Data

Unlabeled data can be divided into in-domain data and out-of-domain data. In previous works, these two kinds of unlabeled data are used separately for different purposes. In-domain data only solves the problem of data sparseness (Sun and Xu, 2011). Out-of domain data is used only for domain adaptation (Chang and Han, 2010). These two functionalities are not contradictory but complementary. Our study shows

that by correctly designing features and algorithms, both in-domain unlabeled data and out-of-domain unlabeled data can work together to help enhancing the segmentation model. In our algorithm, the dynamic features learned from one corpus can be adjusted incrementally with the dynamic features learned from the other corpus.

As for the out-of-domain data, it will be even better if the corpus is not limited to a specific domain. We choose a Chinese encyclopedia corpus which meets exactly this requirement. We use the corpus to learn a large set of informative features. In our experiment, two different views of features on unlabeled data are considered:

Static Statistical Features (SSFs): These features capture statistical information of characters and character n-grams from the unlabeled corpus. The values of these features are fixed during the training process once the unlabeled corpus is given.

Dynamic Statistical Features (DSFs): These features capture label distribution information from the unlabeled corpus given fixed text contexts. As the training process proceeds, the value of these features will change, since the trained tagger at each training iteration may assign different labels to the unlabeled data.

2.3 Framework

Suppose we have labeled data L, two unlabeled corpora U_a and U_b (one is an in-domain corpus and the other is an out-of-domain corpus). Our algorithm is shown in Table 3.

During each iteration, we tag the unlabeled corpus U_a using T_b to get pseudo-labels. Then we extract features from the pseudo-labels. We use the label distribution information as dynamic features. We add these features to the training data to train a new tagger T_a. To adjust the feature values, we extract features from one corpus and then apply the statistics to the other corpus. This is similar to the principle of co-training (Yarowsky, 1995; Blum and Mitchell, 1998; Dasgupta et al., 2002). The difference is that there are not different views of features, but different kinds of unlabeled data. Detailed description of features is given in the next section.

Algorithm
Init:
Using baseline features only:
Train an initial tagger T_0 based on L ()
Label U_a and U_b individually using T_0
BEGIN LOOP:
Generate DSFs from tagged U_a
Augment L with DSFs to get L_a
Generate DSFs from tagged U_b
Augment L with DSFs to get L_b
Using baseline features, SSFs and DSFs:
Train new tagger T_a using L_a
Train new tagger T_b using L_b
Label U_a using T_b
Label U_b using T_a
LOOP until performance does not improve
RETURN the tagger which is trained with in-domain features.

Table 3: Algorithm description

2.4 Features

2.4.1 Baseline Features

Our baseline feature templates include the features described in previous works (Sun and Xu, 2011; Sun et al., 2012). These features are widely used in the CWS task. To be convenient, for a character c_i with context $\ldots c_{i-1}c_ic_{i+1}\ldots$, its baseline features are listed below:

- Character uni-grams: c_k $(i-3<k<i+3)$
- Character bi-grams: c_kc_{k+1} $(i-3<k<i+2)$
- Whether c_k and c_{k+1} are identical $(i-2<k<i+2)$
- Whether c_k and c_{k+2} are identical $(i-4<k<i+2)$

The last two feature templates are designed to detect character reduplication, which is a morphological phenomenon in Chinese language. An example is "十全十美" (Perfect), which is a Chinese idiom with structure "ABAC".

2.4.2 Static statistical features

Statistical features are statistics that distilled from the large unlabeled corpus. They are proved useful in the Chinese word segmentation task. We define Static Statistical Features (SSFs) as features whose value do not change during the training process. The SSFs in our approach includes Mutual information, Punctuation information and Accessor variety. Previous works have already explored the functions of the three static statistics in the Chinese word segmentation task, e.g. Feng et al. (2004); Sun and Xu (2011). We mainly follow their definitions while considering more details and giving some modification.

Mutual information

Mutual information (MI) is a quantity that measures the mutual dependence of two random variables. Previous works showed that larger MI of two strings claims higher probability that the two strings should be combined. Therefore, MI can show the tendency of two strings forming one word. However, previous works mainly focused on the balanced case, i.e., the MI of strings with the same length. In our study we find that, in Chinese, there remains large amount of imbalanced cases, like a string with length 1 followed by a string with length 2, and vice versa. We further considered the MI of these string pairs to capture more information.

Punctuation information

Punctuations can provide implicit labels for the characters before and after them. The character after punctuations must be the first character of a word. The character before punctuations must be the last character of a word. When a string appears frequently after punctuations, it tends to be the beginning of a word. The situation is similar when a string appears frequently preceding punctuations. Besides, the probability of a string appears in the corpus also affects this tendency. Considering all these factors, we propose "punctuation rate" (PR) to capture this information. For a string with length len and probability p in the corpus, we define the left punctuation rate LPR_{len} as the number of times the string appears after punctuations, divided by p. Similarly, the right punctuation rate RPR_{len} is defines as the number of times it appears preceding punctuations divided by its probability p. The length of string we consider is from 1 to 4.

Accessor variety

Accessor variety (AV) is also known as letter successor variety (LSV) (Harris, 1955; Hafer and Weiss, 1974). If a string appears after or preceding many different characters, this may provide some information of the string itself. Previous work of Feng et al. (2004), Sun and Xu (2011) used AV to represent this statistic. Similar to punctuation rate, we also consider both left AV and right AV. For a string s with length l, we define the left accessor variety (LAV) as the types of distinct characters preceding s in the corpus, and the right accessor variety (RAV) as the types of distinct characters after s in the corpus. The length of string we consider is also from 1 to 4.

2.4.3 Dynamic statistical features

The unlabeled corpus lacks precise labels. We can use the trained tagger to give the unlabeled data "pseudo-labels". These labels cannot guarantee an acceptable precision. However, the label distribution will not be largely affected by small mistakes. Using the label distribution information is more accurate than using the pseudo-labels directly.

Based on this assumption, we propose "dynamic statistical features" (DSFs). The DSFs are intended to capture label distribution information given a text context. The word "Dynamic" is in accordance with the fact that these feature values will change during the training process.

We give a formal description of DSFs. Suppose there are K labels in our task. For example, $K = 4$ if we take BMES labeling method. We define the whole character sequence with length n as $X = (x_1, x_2 \cdots x_j \cdots x_n)$. Given a text context C_i, where i is current character position, the DSFs can be represented as a list,

$$DSF(C_i) = (DSF(C_i)_1, \cdots, DSF(C_i)_K)$$

Each element in the list represents the probability of the corresponding label in the distribution.

For convenience, we further define function 'count(condition)' as the total number of times a 'condition' is true in the unlabeled corpus. For example, count (current='a') represents the times the current character equals 'a', which is exactly the number of times character 'a' appears in the unlabeled corpus.

According to different types of text context C_i, we can divide DSFs into 3 types:

1.Basic DSF

For Basic DSF of C_i, we define $D(C_i)$:

$$D(C_i) = (D(C_i)_1, \ldots, D(C_i)_K)$$

We define Basic DSF with current character position i, text context C_i and label l (the lth dimension in the list) as:

$$\begin{aligned} D(C_i)_l &= P(y = l | C_i = x_i) \\ &= \frac{count(C_i = x_i \wedge y = l)}{count(C_i = x_i)} \end{aligned}$$

In this equation, the numerator counts the number of times current character is x_i with label l. The denominator counts the number of times current character is x_i.

We use the term "Basic" because this kind of DSFs only considers the character of position i as its context. The text context refers to the current character itself. This feature captures the label distribution information given the character itself.

2.BigramDSF

Basic DSF is simple and very easy to implement. The weakness is that it is less powerful to describe word-building features. Although characters convey context information, characters themselves in Chinese is sometimes meaningless. Character bi-grams can carry more context information than uni-grams. We modify Basic DSFs to bi-gram level and propose Bigram DSFs.

For Bigram DSF of C_i, we define $B(C_i)$:

$$B(C_i) = (B(C_i)_1, \ldots, B(C_i)_K)$$

We define Bigram DSF with current character position i, text context C_i and label l (the lth dimension in the list) as:

$$\begin{aligned} B(C_i)_l &= P(y = l | C_i = x_{i-j}x_{i-j+1}) \\ &= \frac{count(C_i = x_{i-j}x_{i-j+1} \wedge y = l)}{count(C_i = x_{i-j}x_{i-j+1})} \end{aligned}$$

j can take value 0 and 1.

In this equation, the numerator counts the number of times current context is $x_{i-j}x_{i-j+1}$ with label l. The denominator counts the number of times current context is $x_{i-j}x_{i-j+1}$.

3.WindowDSF

Considering Basic DSF and Bigram DSF only might cause the over-fitting problem, therefore we introduce another kind of DSF. We call it Window DSF, which considers the surrounding context of a character and omits the character itself.

For Window DSF, we define $W(C_i)$:

$$W(C_i) = (W(C_i)_1, \ldots, W(C_i)_K)$$

We define Window DSF with current character position i, text context C_i and label l (the lth dimension in the list) as:

$$\begin{aligned} W(C_i)_l &= P(y = l | C_i = x_{i-1}x_{i+1}) \\ &= \frac{count(C_i = x_{i-1}x_{i+1} \wedge y = l)}{count(C_i = x_{i-1}x_{i+1})} \end{aligned}$$

In this equation, the numerator counts the number of times current context is $x_{i-1}x_{i+1}$ with label l. The denominator counts the number of times current context is $x_{i-1}x_{i+1}$.

2.4.4 Discrete features VS. Continuous features

The statistical features may be expressed as real values. A more natural way is to use discrete values to incorporate them into the sequence labeling models . Previous works like Sun and Xu (2011) solve this problem by setting thresholds and converting the real value into boolean values. We use a different method to solve this, which does not need to consider tuning thresholds. In our method, we process static and dynamic statistical features using different strategies.

For static statistical value:

For mutual information, we round the real value to their nearest integer. For punctuation rate and accessor variety, as the values tend to be large, we first get the log value of the feature and then use the nearest integer as the corresponding discrete value.

For dynamic statistical value:

Dynamic statistical features are distributions of a label. The values of DSFs are all percentage values. We can solve this by multiply the probability by an integer N and then take the integer part as the final feature value. We set the value of N by cross-validation..

2.5 Conditional Random Fields

Our algorithm is not necessarily limited to a specific baseline tagger. For simplicity and reliability, we use a simple Conditional Random Field (CRF) tagger, although other sequence labeling models like Semi-Markov CRF Gao et al. (2007) and Latent-variable CRF Sun et al. (2009) may provide better results than a single CRF. Detailed definition of CRF can be found in Lafferty et al. (2001); McCallum (2002); Pinto et al. (2003).

3 Experiment

3.1 Data and metrics

We used the benchmark datasets provided by the second International Chinese Word Segmentation Bakeoff[1] to test our approach. We chose the Peking University (PKU) data in our experiment. Although the benchmark provides another three data sets, two of them are data of traditional Chinese, which is quite different from simplified Chinese. Another is the data from Microsoft Research (MSR). We experimented on this data and got 97.45% in f-score compared to the state-of-art 97.4% reported in Sun et al. (2012). However, this corpus is much larger than the PKU corpus. Using the labeled data alone can get a relatively good tagger and the unlabeled data contributes little to the performance. For simplicity and efficiency, our further experiments are all conducted on the PKU data. Details of the PKU data are listed in table 4.

We also used two un-segmented corpora as unlabeled data. The first one is Chinese Gigaword[2] corpus. It is a comprehensive archive of newswire data. The second one is articles from Baike[3] of baidu.com. It is a Chinese encyclopedia similar to Wikipedia but contains more Chinese items and their descriptions. In the experiment we used about 5 million characters from each corpus for efficiency. Details of unlabeled data can be found in table 5.

In our experiment, we did not use any extra resources such as common surnames, part-of-speech or other dictionaries.

F-score is used as the accuracy measure. We define precision P as the percentage of words in the output that are segmented correctly. We define recall R as the percentage of the words in reference that are correctly segmented. Then F-score is as follows:

$$F = \frac{2 \times P \times R}{P + R}$$

The recall of out-of-vocabulary is also taken into consideration, which measures the ability of the model to correctly segment out of vocabulary words.

3.2 Main Results

Table 6 summarizes the segmentation results on test data with different feature combinations. We performed incremental evaluation. In this table, we first present the results of the tagger only using baseline features. Then we show the results of adding SSF and DSF individually. In the end we compare the results of combining SSF and DSF with baseline features.

Because the baseline features is strong to reach a relative good result, it is not easy to largely enhance the performance. Nevertheless, there are significant increases in f-score and OOV-Recall when adding these features. From table 6 we can see that by adding SSF and DSF individually, the F-score is improved by +1.1%

Identical words	Total word	Identical Character	Total character
5.5×10^4	1.1×10^6	5×10^3	1.8×10^6

Table 4: Details of the PKU data

Corpus	**Character used**
Gigaword	5000193
Baike	5000147

Table 5: Details of the unlabeled data.

	P	R	F	OOV
Baseline	0.950	0.943	0.946	0.676
+SSF	0.961	0.953	0.957	0.728
+DSF	0.958	0.953	0.955	0.678
+SSF+DSF	0.965	0.958	0.961	0.731

Table 6: Segmentation results on test data with different feature combinations. The symbol "+" means this feature configuration contains features set containing the baseline features and all features after '+' . The size of unlabeled data is fixed as 5 million characters.

and +0.9%. The OOV-Recall is also improved, especially after adding SSFs. When considering SSF and DSF together, the f-score is improved by +1.5% while the OOV-Recall is improved by +5.5%.

To compare the contribution of unlabeled data, we conduct experiments of using different sizes of unlabeled data. Note that the SSFs are still calculated using all the unlabeled data. However, each iteration in the algorithm uses unlabeled data with different sizes.

Table 7 shows the results when changing the size of unlabeled data. We experimented on three different sizes: 0.5 million, 1 million and 5 million characters.

	P	R	F	OOV
DSF(0.5M)	0.962	0.954	0.958	0.727
DSF(1M)	0.963	0.955	0.959	0.728
DSF(5M)	0.965	0.958	0.961	0.731

Table 7: Comparison of results when changing the size of unlabeled data. (0.5 million, 1 million and 5 million characters).

We further experimented on unlabeled corpus with larger size (up to 100 million characters). However the performance did not change significantly. Besides, because the number of features in our method is very large, using too large unlabeled corpus is intractable in real applications due to the limitation of memory.

Our method can keep working well even when the labeled data are insufficient. Table 8 shows the comparison of f-scores when changing the size of labeled data. We compared the results of using all labeled data with 3 different situations: using 1/10, 1/2 and 1/4 of all the labeled data. In fact, the best system on the Second International Chinese Word Segmentation bakeoff reached 0.95 in f-score by using all labeled data. From table 8 we can see that our algorithm only needs 1/4 of all labeled data to achieve the same f-score.

	Baseline	+SSF+DSF	Improve
1/10	0.934	0.943	+0.96%
1/4	0.946	0.951	+0.53%
1/2	0.952	0.956	+0.42%
All	0.957	0.961	+0.42%

Table 8: Comparison of f-scores when changing the size of labeled data. (1/10, 1/4, 1/2 and all labeled data. The size of unlabeled data is fixed as 5 million characters.)

We also explored how the performance changes as iteration increases. Figure 1 shows the change of F-score during the first 10 iterations. From figure 1 we find that f-score has a fast improvement in the first few iterations, and then stables at a fixed point. Besides, as the size of labeled data increases, it converges faster.

Using an in-domain corpus and an out-of-domain corpus is better than use one corpus alone. We compared our approach with the method which uses only one unlabeled corpus. To use only one corpus, we modify our algorithm to extract DSFs from the Chinese Giga word corpus and apply the learned features to itself.

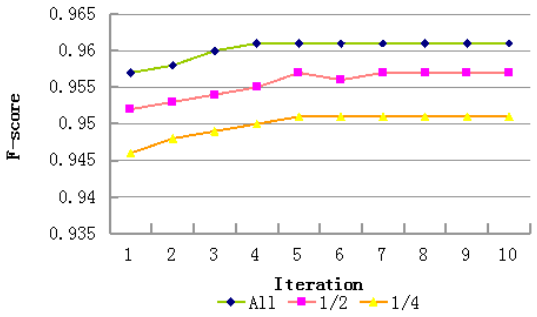

Figure 1: Learning curve of using different size of labeled data

Table 9 shows the result. We can see that our method outperforms by +0.2% in f-score and +0.7% in OOV-Recall.

Finally, we compared our method with the state-of-art systems reported in the previous papers. Table 10 listed the results. Best05 represents the best system reported on the Second International Chinese Word Segmentation Bakeoff. CRF + Rule system represents a combination of CRF model and rule based model presented in Zhang et al. (2006). Other three systems all represent the methods using their corresponding model in the corresponding papers. Note that these state-of-art systems are either using complicated models with semi-Markov relaxations or latent variables, or modifying models to fit special conditions. Our system uses a single CRF model. As we can see in table 10, our method achieved higher F-scores than the previous best systems.

3.3 Results on NER task

Our method is not limited to the CWS problem. It is applicable to all sequence labeling problems. We applied our method on the Chinese NER task. We used the MSR corpus of the sixth SIGHAN Workshop on Chinese Language Processing. It is the only NER corpus using simplified Chinese in that workshop. We compared our method with the pure sequence labeling approach in He and Wang (2008). We reimplemented their method to eliminate the difference of various CRFs implementations. Experiment results are shown in table 11. We can see that our methods works better, especially when handling the out-of-vocabulary named entities;

4 Related work

Recent studies show that character sequence labeling is an effective method of Chinese word segmentation for machine learning (Xue, 2003; Low et al., 2005; Zhao et al., 2006a,b). These supervised methods show good results. Unsupervised word segmentation (Maosong et al., 1998; Peng and Schuurmans, 2001; Feng et al., 2004; Goldwater et al., 2006; Jin and Tanaka-Ishii, 2006) takes advantage of the huge amount of raw text to solve Chinese word segmentation problems. These methods need no annotated corpus, and most of them use statistics to help model the problem. However, they usually are less accurate than supervised ones.

Currently "feature-engineering" methods have been successfully applied into NLP applications. Miller et al. (2004) applied this method to named entity recognition. Koo et al. (2008) applied this method to dependency parsing. Turian et al. (2010) applied this method to both named entity recognition and text chunking. These papers shared the same concept of word clustering. However, we cannot simply equal Chinese character to English word because characters in Chinese carry much less information than words in English and the clustering results is less meaningful.

Features extracted from large unlabeled corpus in previous works mainly focus on statistical information of characters. Feng et al. (2004) used the accessor variety criterion to extract word types. Li and Sun (2009) used punctuation information in Chinese word segmentation by introducing extra labels 'L' and 'R'. Chang and Han (2010), Sun and Xu (2011) used rich statistical information as discrete features in a sequence labeling framework. All these approaches can be viewed as using static statistics features in a supervised approach. Our method is different from theirs. For the static statistics features in our approach, we not only consider richer string pairs with the different lengths, but also consider term frequency when processing

punctuation features.

There are previous works using features extracted from label distribution of unlabeled corpus in NLP tasks. Schapire et al. (2002) use a set of features annotated with majority labels to boost a logistic regression model. We are different from their approach because there is no pseudo-example labeling process in our approach. Qi et al. (2009) investigated on large set of distribution features and used these features in a self-training way. They applied the method on three tasks: named entity recognition, POS tagging and gene name recognition and got relatively good results. Our approach is different from theirs. Although we all consider label distribution, the way we use features are different. Besides, our approach uses two unlabeled corpora which can mutually enhancing to get better result.

5 Conclusion and Perspectives

In this paper, we presented a semi-supervised method for Chinese word segmentation. Two kinds of new features are used for the iterative modeling: static statistical features and dynamic statistical features. The dynamic statistical features use label distribution information for text contexts, and can be adjusted automatically during the co-training process. Experimental results show that the new features can improve the performance on the Chinese word segmentation task. We further conducted experiments to show that the performance is largely improved, especially when the labeled data is insufficient.

The proposed iterative semi-supervised method is not limited to the Chinese word segmentation task. It can be easily extended to any sequence labeling task. For example, it works well on the NER task as well. As our future work, we plan to apply our method to other natural language processing tasks, such as text chunking.

Efficient Higher-Order CRFs for Morphological Tagging

Thomas Müller[†‡], Helmut Schmid[†‡], and Hinrich Schütze[†]

[†]Center for Information and Language Processing, University of Munich, Germany
[‡]Institute for Natural Language Processing , University of Stuttgart, Germany
muellets@cis.lmu.de

Abstract

Training higher-order conditional random fields is prohibitive for huge tag sets. We present an approximated conditional random field using coarse-to-fine decoding and early updating. We show that our implementation yields fast and accurate morphological taggers across six languages with different morphological properties and that across languages higher-order models give significant improvements over 1^{st}-order models.

1 Introduction

Conditional Random Fields (CRFs) (Lafferty et al., 2001) are arguably one of the best performing sequence prediction models for many Natural Language Processing (NLP) tasks. During CRF training forward-backward computations, a form of dynamic programming, dominate the asymptotic runtime. The training and also decoding times thus depend polynomially on the size of the tagset and exponentially on the order of the CRF. This probably explains why CRFs, despite their outstanding accuracy, normally only are applied to tasks with small tagsets such as Named Entity Recognition and Chunking; if they are applied to tasks with bigger tagsets – e.g., to part-of-speech (POS) tagging for English – then they generally are used as 1^{st}-order models.

In this paper, we demonstrate that fast and accurate CRF training and tagging is possible for large tagsets of even thousands of tags by approximating the CRF objective function using coarse-to-fine decoding (Charniak and Johnson, 2005; Rush and Petrov, 2012). Our pruned CRF (PCRF) model has much smaller runtime than higher-order CRF models and may thus lead to an even broader application of CRFs across NLP tagging tasks.

We use POS tagging and combined POS and morphological (POS+MORPH) tagging to demonstrate the properties and benefits of our approach. POS+MORPH disambiguation is an important preprocessing step for syntactic parsing. It is usually tackled by applying sequence prediction. POS+MORPH tagging is also a good example of a task where CRFs are rarely applied as the tagsets are often so big that even 1^{st}-order dynamic programming is too expensive. A workaround is to restrict the possible tag candidates per position by using either morphological analyzers (MAs), dictionaries or heuristics (Hajič, 2000). In this paper, however we show that when using pruning (i.e., PCRFs), CRFs can be trained in reasonable time, which makes hard constraints unnecessary.

In this paper, we run successful experiments on six languages with different morphological properties; we interpret this as evidence that our approach is a general solution to the problem of POS+MORPH tagging. The tagsets in our experiments range from small sizes of 12 to large sizes of up to 1811. We will see that even for the smallest tagset, PCRFs need only 40% of the training time of standard CRFs. For the bigger tagset sizes we can reduce training times from several days to several hours. We will also show that training higher-order PCRF models takes only several minutes longer than training 1^{st}-order models and – depending on the language – may lead to substantial accuracy im-

Table 1: Training set statistics. Out-Of-Vocabulary (OOV) rate is regarding the development sets.

provements. For example in German POS+MORPH tagging, a 1^{st}-order model (trained in 32 minutes) achieves an accuracy of 88.96 while a 3^{rd}-order model (trained in 35 minutes) achieves an accuracy of 90.60.

The remainder of the paper is structured as follows: Section 2 describes our CRF implementation[1] and the feature set used. Section 3 summarizes related work on tagging with CRFs, efficient CRF tagging and coarse-to-fine decoding. Section 4 describes experiments on POS tagging and POS+MORPH tagging and Section 5 summarizes the main contributions of the paper.

2 Methodology

2.1 Standard CRF Training

In a standard CRF we model our sentences using a globally normalized log-linear model. The probability of a tag sequence $\vec{y}$ given a sentence $\vec{x}$ is then given as:

$$p(\vec{y}|\vec{x}) = \frac{\exp \sum_{t,i} \lambda_i \cdot \phi_i(\vec{y}, \vec{x}, t)}{Z(\vec{\lambda}, \vec{x})}$$
$$Z(\vec{\lambda}, \vec{x}) = \sum_{\vec{y}} \exp \sum_{t,i} \lambda_i \cdot \phi_i(\vec{y}, \vec{x}, t)$$

Where t and i are token and feature indexes, ϕ_i is a feature function, λ_i is a feature weight and Z is a normalization constant. During training the feature weights λ are set to maximize the conditional log-likelihood of the training data D:

$$ll_D(\vec{\lambda}) = \sum_{(\vec{x},\vec{y}) \in D} \log\, p(\vec{y}|\vec{x}, \vec{\lambda})$$

In order to use numerical optimization we have to calculate the gradient of the log-likelihood, which is a vector of partial derivatives $\partial ll_D(\vec{\lambda})/\partial \lambda_i$. For a training sentence $\vec{x}, \vec{y}$ and a token index t the derivative wrt feature i is given by:

$$\phi_i(\vec{y}, \vec{x}, t) - \sum_{\vec{y}'} \phi_i(\vec{y}', \vec{x}, t)\, p(\vec{y}'|\vec{x}, \vec{\lambda})$$

This is the difference between the empirical feature count in the training data and the estimated count in the current model $\vec{\lambda}$. For a 1^{st}-order model, we can replace the expensive sum over all possible tag sequences $\vec{y}'$ by a sum over all pairs of tags:

$$\phi_i(y_t, y_{t+1}, \vec{x}, t) - \sum_{y,y'} \phi_i(y, y', \vec{x}, t)\, p(y, y'|\vec{x}, \vec{\lambda})$$

The probability of a tag pair $p(y, y'|\vec{x}, \vec{\lambda})$ can then be calculated efficiently using the forward-backward algorithm. If we further reduce the complexity of the model to a 0-order model, we obtain simple maximum entropy model updates:

$$\phi_i(y_t, \vec{x}, t) - \sum_{y} \phi_i(y, \vec{x}, t)\, p(y|\vec{x}, \vec{\lambda})$$

2.2 Pruned CRF Training

As we discussed in the introduction, we want to decode sentences by applying a variant of coarse-to-fine tagging. Naively, to later tag with n^{th}-order

[1] Our java implementation MarMoT is available at https://code.google.com/p/cistern/

accuracy we would train a series of n CRFs of increasing order. We would then use the CRF of order $n-1$ to restrict the input of the CRF of order n. In this paper we approximate this approach, but do so while training only one integrated model. This way we can save both memory (by sharing feature weights between different models) and training time (by saving lower-order updates).

The main idea of our approach is to create increasingly complex lattices and to filter candidate states at every step to prevent a polynomial increase in lattice size. The first step is to create a 0-order lattice, which as discussed above, is identical to a series of independent local maximum entropy models $p(y|\vec{x},t)$. The models base their prediction on the current word x_t and the immediate lexical context. We then calculate the posterior probabilities and remove states y with $p(y|\vec{x},t) < \tau_0$ from the lattice, where τ_0 is a parameter. The resulting reduced lattice is similar to what we would obtain using candidate selection based on an MA.

We can now create a first order lattice by adding transitions to the pruned lattice and pruning with threshold τ_1. The only difference to 0-order pruning is that we now have to run forward-backward to calculate the probabilities $p(y|\vec{x},t)$. Note that in theory we could also apply the pruning to transition probabilities of the form $p(y,y'|\vec{x},t)$; however, this does not seem to yield more accurate models and is less efficient than state pruning.

For higher-order lattices we merge pairs of states into new states, add transitions and prune with threshold τ_i.

We train the model using l_1-regularized Stochastic Gradient Descent (SGD) (Tsuruoka et al., 2009). We would like to create a cascade of increasingly complex lattices and update the weight vector with the gradient of the last lattice. The updates, however, are undefined if the gold sequence is pruned from the lattice. A solution would be to simply reinsert the gold sequence, but this yields poor results as the model never learns to keep the gold sequence in the lower-order lattices. As an alternative we perform the gradient update with the highest lattice still containing the gold sequence. This approach is similar to "early updating" (Collins and Roark, 2004) in perceptron learning, where during beam search an update with the highest scoring partial hypothesis is performed whenever the gold candidate falls out of the beam. Intuitively, we are trying to optimize an n^{th}-order CRF objective function, but apply small lower-order corrections to the weight vector when necessary to keep the gold candidate in the lattice. Figure 1 illustrates the lattice generation process. The lattice generation during decoding is identical, except that we always return a lattice of the highest order n.

```
1: function GetSumLattice(sentence, τ⃗)
2:     gold-tags ← getTags(sentence)
3:     candidates ← getAllCandidates(sentence)
4:     lattice ← ZeroOrderLattice(candidates)
5:     for i = 1 → n do
6:         candidates ← lattice.prune(τ_{i−1})
7:         if gold-tags ∉ candidates then
8:             return lattice
9:         end if
10:        if i > 1 then
11:            candidates ← mergeStates(candidates)
12:        end if
13:        candidates ← addTransitions(candidates)
14:        lattice ← SequenceLattice(candidates, i)
15:    end for
16:    return lattice
17: end function
```

Figure 1: Lattice generation during training

The savings in training time of this integrated approach are large; e.g., training a maximum entropy model over a tagset of roughly 1800 tags and more than half a million instances is slow as we have to apply 1800 weight vector updates for every token in the training set and every SGD iteration. In the integrated model we only have to apply 1800 updates when we lose the gold sequence during filtering. Thus, in our implementation training a 0-order model for Czech takes roughly twice as long as training a 1^{st}-order model.

2.3 Threshold Estimation

Our approach would not work if we were to set the parameters τ_i to fixed predetermined values; e.g., the τ_i depend on the size of the tagset and should be adapted during training as we start the training with a uniform model that becomes more specific. We therefore set the τ_i by *specifying μ_i, the average number of tags per position that should remain in the lattice after pruning*. This also guarantees stable lattice sizes and thus stable training times. We

achieve stable average number of tags per position by setting the τ_i dynamically during training: we measure the real average number of candidates per position $\hat{\mu}_i$ and apply corrections after processing a certain fraction of the sentences of the training set. The updates are of the form:

$$\tau_i = \begin{cases} +0.1 \cdot \tau_i & \text{if } \hat{\mu}_i < \mu_i \\ -0.1 \cdot \tau_i & \text{if } \hat{\mu}_i > \mu_i \end{cases}$$

Figure 2 shows an example training run for German with $\mu_0 = 4$. Here the 0-order lattice reduces the number of tags per position from 681 to 4 losing roughly 15% of the gold sequences of the development set, which means that for 85% of the sentences the correct candidate is still in the lattice. This corresponds to more than 99% of the tokens. We can also see that after two iterations only a very small number of 0-order updates have to be performed.

2.4 Tag Decomposition

As we discussed before for the very large POS+MORPH tagsets, most of the decoding time is spent on the 0-order level. To decrease the number of tag candidates in the 0-order model, we decode in two steps by separating the fully specified tag into a coarse-grained part-of-speech (POS) tag and a fine-grained MORPH tag containing the morphological features. We then first build a lattice over POS candidates and apply our pruning strategy. In a second step we expand the remaining POS tags into all the combinations with MORPH tags that were seen in the training set. We thus build a sequence of lattices of both increasing order and increasing tag complexity.

2.5 Feature Set

We use the features of Ratnaparkhi (1996) and Manning (2011): the current, preceding and succeeding words as unigrams and bigrams and for rare words prefixes and suffixes up to length 10, and the occurrence of capital characters, digits and special characters. We define a rare word as a word with training set frequency ≤ 10. We concatenate every feature with the POS and MORPH tag and every morphological feature. E.g., for the word "der", the POS tag `art` (article) and the MORPH tag `gen|sg|fem` (genitive, singular, feminine) we get the following features for the current word template: `der+art`, `der+gen|sg|fem`, `der+gen`, `der+sg` and `der+fem`.

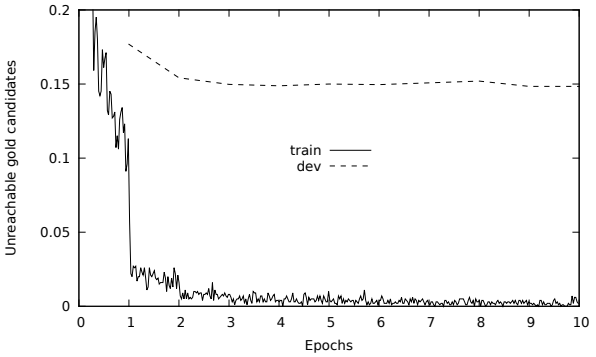

Figure 2: Example training run of a pruned 1^{st}-order model on German showing the fraction of pruned gold sequences (= sentences) during training for training (train) and development sets (dev).

We also use an additional binary feature, which indicates whether the current word has been seen with the current tag or – if the word is rare – whether the tag is in a set of open tag classes. The open tag classes are estimated by 10-fold cross validation on the training set: We first use the folds to estimate how often a tag is seen with an unknown word. We then consider tags with a relative frequency $\geq 10^{-4}$ as open tag classes. While this is a heuristic, it is safer to use a "soft" heuristic as a feature in the lattice than a hard constraint.

For some experiments we also use the output of a morphological analyzer (MA). In that case we simply use every analysis of the MA as a simple nominal feature. This approach is attractive because it does not require the output of the MA and the annotation of the treebank to be identical; in fact, it can even be used if treebank annotation and MA use completely different features.

Because the weight vector dimensionality is high for large tagsets and productive languages, we use a hash kernel (Shi et al., 2009) to keep the dimensionality constant.

3 Related Work

Smith et al. (2005) use CRFs for POS+MORPH tagging, but use a morphological analyzer for candidate selection. They report training times of several days

and that they had to use simplified models for Czech.

Several methods have been proposed to reduce CRF training times. Stochastic gradient descent can be applied to reduce the training time by a factor of 5 (Tsuruoka et al., 2009) and without drastic losses in accuracy. Lavergne et al. (2010) make use of feature sparsity to significantly speed up training for moderate tagset sizes (< 100) and huge feature spaces. It is unclear if their approach would also work for huge tag sets (> 1000).

Coarse-to-fine decoding has been successfully applied to CYK parsing where full dynamic programming is often intractable when big grammars are used (Charniak and Johnson, 2005). Weiss and Taskar (2010) develop cascades of models of increasing complexity in a framework based on perceptron learning and an explicit trade-off between accuracy and efficiency.

Kaji et al. (2010) propose a modified Viterbi algorithm that is still optimal but depending on task and especially for big tag sets might be several orders of magnitude faster. While their algorithm can be used to produce fast decoders, there is no such modification for the forward-backward algorithm used during CRF training.

4 Experiments

We run POS+MORPH tagging experiments on Arabic (ar), Czech (cs), Spanish (es), German (de) and Hungarian (hu). The following table shows the type-token (T/T) ratio, the average number of tags of every word form that occurs more than once in the training set ($\overline{A}$) and the number of tags of the most ambiguous word form ($\hat{A}$):

	T/T	$\overline{A}$	$\hat{A}$
ar	0.06	2.06	17
cs	0.13	1.64	23
es	0.09	1.14	9
de	0.11	2.15	44
hu	0.11	1.11	10

Arabic is a Semitic language with nonconcatenative morphology. An additional difficulty is that vowels are often not written in Arabic script. This introduces a high number of ambiguities; on the other hand it reduces the type-token ratio, which generally makes learning easier. In this paper, we work with the transliteration of Arabic provided in the Penn Arabic Treebank. Czech is a highly inflecting Slavic language with a large number of morphological features. Spanish is a Romance language. Based on the statistics above we can see that it has few POS+MORPH ambiguities. It is also the language with the smallest tagset and the only language in our setup that – with a few exceptions – does not mark case. German is a Germanic language and – based on the statistics above – the language with the most ambiguous morphology. The reason is that it only has a small number of inflectional suffixes. The total number of nominal inflectional suffixes for example is five. A good example for a highly ambiguous suffix is "en", which is a marker for infinitive verb forms, for the 1^{st} and 3^{rd} person plural and for the polite 2^{nd} person singular. Additionally, it marks plural nouns of all cases and singular nouns in genitive, dative and accusative case.

Hungarian is a Finno-Ugric language with an agglutinative morphology; this results in a high type-token ratio, but also the lowest level of word form ambiguity among the selected languages.

POS tagging experiments are run on all the languages above and also on English.

4.1 Resources

For Arabic we use the Penn Arabic Treebank (Maamouri et al., 2004), parts 1–3 in their latest versions (LDC2010T08, LDC2010T13, LDC2011T09). As training set we use parts 1 and 2 and part 3 up to section `ANN20020815.0083`. All consecutive sections up to `ANN20021015.0096` are used as development set and the remainder as test set. We use the unvocalized and pretokenized transliterations as input. For Czech and Spanish, we use the CoNLL 2009 data sets (Hajič et al., 2009); for German, the TIGER treebank (Brants et al., 2002) with the split from Fraser et al. (2013); for Hungarian, the Szeged treebank (Csendes et al., 2005) with the split from Farkas et al. (2012). For English we use the Penn Treebank (Marcus et al., 1993) with the split from Toutanova et al. (2003).

We also compute the possible POS+MORPH tags for every word using MAs. For Arabic we use the AraMorph reimplementation of Buckwalter (2002), for Czech the "free" morphology (Hajič, 2001), for Spanish Freeling (Padró and Stanilovsky, 2012), for German DMOR (Schiller, 1995) and for Hungarian

Magyarlanc 2.0 (Zsibrita et al., 2013).

4.2 Setup

To compare the training and decoding times we run all experiments on the same test machine, which features two Hexa-Core Intel Xeon X5680 CPUs with 3,33 GHz and 6 cores each and 144 GB of memory. The baseline tagger and our PCRF implementation are run single threaded.[2] The taggers are implemented in different programming languages and with different degrees of optimization; still, the run times are indicative of comparative performance to be expected in practice.

Our Java implementation is always run with 10 SGD iterations and a regularization parameter of 0.1, which for German was the optimal value out of $\{0, 0.01, 0.1, 1.0\}$. We follow Tsuruoka et al. (2009) in our implementation of SGD and shuffle the training set between epochs. All numbers shown are averages over 5 independent runs. Where not noted otherwise, we use $\mu_0 = 4$, $\mu_1 = 2$ and $\mu_2 = 1.5$. We found that higher values do not consistently increase performance on the development set, but result in much higher training times.

4.3 POS Experiments

In a first experiment we evaluate the speed and accuracy of CRFs and PCRFs on the POS tagsets. As shown in Table 1 the tagset sizes range from 12 for Czech and Spanish to 54 and 57 for German and Hungarian, with Arabic (38) and English (45) in between. The results of our experiments are given in Table 2. For the 1^{st}-order models, we observe speed-ups in training time from 2.3 to 31 at no loss in accuracy. For all languages, training pruned higher-order models is faster than training unpruned 1^{st}-order models and yields more accurate models. Accuracy improvements range from 0.08 for Hungarian to 0.25 for German. We can conclude that for small and medium tagset sizes PCRFs give substantial improvements in both training and decoding speed[3] and thus allow for higher-order tagging, which for all languages leads to significant[4] accuracy improvements.

4.4 POS+MORPH Oracle Experiments

Ideally, for the full POS+MORPH tagset we would also compare our results to an unpruned CRF, but our implementation turned out to be too slow to do the required number of experiments. For German, the model processed ≈ 0.1 sentences per second during training; so running 10 SGD iterations on the 40,472 sentences would take more than a month. We therefore compare our model against models that perform oracle pruning, which means we perform standard pruning, but always keep the gold candidate in the lattice. The oracle pruning is applied during training and testing on the development set. The oracle model performance is thus an upper bound for the performance of an unpruned CRF.

The most interesting pruning step happens at the 0-order level when we reduce from hundreds of candidates to just a couple. Table 3 shows the results for 1^{st}-order CRFs.

We can roughly group the five languages into three groups: for Spanish and Hungarian the damage is negligible, for Arabic we see a small decrease of 0.07 and only for Czech and German we observe considerable differences of 0.14 and 0.37. Surprisingly, doubling the number of candidates per position does not lead to significant improvements.

We can conclude that except for Czech and German losses due to pruning are insignificant.

4.5 POS+MORPH Higher-Order Experiments

One argument for PCRFs is that while they might be less accurate than standard CRFs they allow to train higher-order models, which in turn might be more accurate than their standard lower-order counterparts. In this section, we investigate how big the improvements of higher-order models are. The results are given in the following table:

n	ar	cs	es	de	hu
1	90.90	92.45	97.95	88.96	96.47
2	91.86*	93.06*	98.01	90.27*	96.57*
3	91.88*	92.97*	97.87	90.60*	96.50

[2]Our tagger might actually use more than one core because the Java garbage collection is run in parallel.

[3]Decoding speeds are provided in an appendix submitted separately.

[4]Throughout the paper we establish significance by running approximate randomization tests on sentences (Yeh, 2000).

Table 2: POS tagging experiments with pruned and unpruned CRFs with different orders n. For every language the training time in minutes (TT) and the POS accuracy (ACC) are given. * indicates models significantly better than CRF (first line).

		ar	cs	es	de	hu
1	Oracle $\mu_0 = 4$	90.97	92.59	97.91	89.33	96.48
2	Model $\mu_0 = 4$	90.90	92.45*	97.95	88.96*	96.47
3	Model $\mu_0 = 8$	90.89	92.48*	97.94	88.94*	96.47

Table 3: Accuracies for models with and without oracle pruning. * indicates models significantly worse than the oracle model.

We see that 2^{nd}-order models give improvements for all languages. For Spanish and Hungarian we see minor improvements ≤ 0.1.

For Czech we see a moderate improvement of 0.61 and for Arabic and German we observe substantial improvements of 0.96 and 1.31. An analysis on the development set revealed that for all three languages, case is the morphological feature that benefits most from higher-order models. A possible explanation is that case has a high correlation with syntactic relations and is thus affected by long-distance dependencies.

German is the only language where fourgram models give an additional improvement over trigram models. The reason seem to be sentences with long-range dependencies, e.g., "Die Rebellen haben kein Lösegeld verlangt" (The rebels have not demanded any ransom); "verlangt" (demanded) is a past particple that is separated from the auxilary verb "haben" (have). The 2^{nd}-order model does not consider enough context and misclassifies "verlangt" as a finite verb form, while the 3^{rd}-order model tags it correctly.

We can also conclude that the improvements for higher-order models are always higher than the loss we estimated in the oracle experiments. More precisely we see that if a language has a low number of word form ambiguities (e.g., Hungarian) we observe a small loss during 0-order pruning but we also have to expect less of an improvement when increasing the order of the model. For languages with a high number of word form ambiguities (e.g., German) we must anticipate some loss during 0-order pruning, but we also see substantial benefits for higher-order models.

Surprisingly, we found that higher-order PCRF models can also avoid the pruning errors of lower-order models. Here is an example from the German data. The word "Januar" (January) is ambiguous: in the training set, it occurs 108 times as dative, 9 times as accusative and only 5 times as nominative. The development set contains 48 nominative instances of "Januar" in datelines at the end of news articles, e.g., "TEL AVIV, 3. Januar". For these 48 occurrences, (i) the oracle model in Table 3 selects the *correct* case nominative, (ii) the 1^{st}-order PCRF model selects the *incorrect* case accusative, and (iii) the 2^{nd}- and 3^{rd}-order models select – unlike the 1^{st}-order model – the *correct* case nominative. Our interpretation is that the correct nominative reading is pruned from the 0-order lattice. However, the higher-order models can put less weight on 0-order features as they have access to more context to disambiguate the sequence. The lower weights of order-0 result in a more uniform posterior distribution and the nominative reading is not pruned from the lattice.

4.6 Experiments with Morph. Analyzers

In this section we compare the improvements of higher-order models when used with MAs. The re-

CRFSuite	89.05	90.97	97.60	85.68	95.82
PCRF 1	90.32*	92.31*	97.82*	86.92*	96.22*
PCRF 2	**91.29***	92.94*	**97.93***	88.48*	**96.34***
PCRF 3	91.22*	**92.99***	97.82*	**88.58***	96.29*

Table 7: Test results for POS+MORPH tagging. Best baseline results are underlined and the overall best results bold. * indicates a significant difference between the best baseline and a PCRF model.

sults are given in the following table:

	n	ar	cs	es	de	hu
	1	90.90^-	92.45^-	97.95^-	88.96^-	96.47^-
	2	91.86^+	93.06	98.01^-	90.27^+	96.57^-
	3	91.88^+	92.97^-	97.87^-	90.60^+	96.50^-
MA	1	91.22	93.21	98.27	89.82	97.28
MA	2	92.16^+	93.87^+	98.37^+	91.31^+	97.51^+
MA	3	92.14^+	93.88^+	98.28	91.65^+	97.48^+

Plus and minus indicate models that are significantly better or worse than MA1. We can see that the improvements due to higher-order models are orthogonal to the improvements due to MAs for all languages. This was to be expected as MAs provide additional lexical knowledge while higher-order models provide additional information about the context. For Arabic and German the improvements of higher-order models are bigger than the improvements due to MAs.

4.7 Comparison with Baselines

We use the following baselines: SVMTool (Giménez and Màrquez, 2004), an SVM-based discriminative tagger; RFTagger (Schmid and Laws, 2008), an n-gram Hidden Markov Model (HMM) tagger developed for POS+MORPH tagging; Morfette (Chrupała et al., 2008), an averaged perceptron with beam search decoder; CRFSuite (Okazaki, 2007), a fast CRF implementation; and the Stanford Tagger (Toutanova et al., 2003), a bidirectional Maximum Entropy Markov Model. For POS+MORPH tagging, all baselines are trained on the concatenation of POS tag and MORPH tag. We run SVMTool with the standard feature set and the optimal c-values $\in \{0.1, 1, 10\}$. Morfette is run with the default options. For CRFSuite we use l_2-regularized SGD training. We use the optimal regularization parameter $\in \{0.01, 0.1, 1.0\}$ and stop after 30 iterations where we reach a relative improvement in regularized likelihood of at most 0.01 for all languages. The feature set is identical to our model except for some restrictions: we only use concatenations with the full tag and we do not use the binary feature that indicates whether a word-tag combination has been observed. We also had to restrict the combinations of tag and features to those observed in the training set[5]. Otherwise the memory requirements would exceed the memory of our test machine (144 GB) for Czech and Hungarian. The Stanford Tagger is used as a bidirectional 2^{nd}-order model and trained using OWL-BFGS. For Arabic, German and English we use the language specific feature sets and for the other languages the English feature set.

Development set results for POS tagging are shown in Table 4. We can observe that Morfette, CRFSuite and the PCRF models for different orders have training times in the same order of magnitude. For Arabic, Czech and English, the PCRF accuracy is comparable to the best baseline models. For the other languages we see improvements of 0.13 for Spanish, 0.18 for Hungarian and 0.24 for German. Evaluation on the test set confirms these results, see Table 5.[6]

The POS+MORPH tagging development set results are presented in Table 6. Morfette is the fastest discriminative baseline tagger. In comparison with Morfette the speed up for 3^{rd}-order PCRFs lies between 1.7 for Czech and 5 for Arabic. Morfette gives the best baseline results for Arabic, Spanish and Hungarian and CRFSuite for Czech and German. The accuracy improvements of the best PCRF models over the best baseline models range from 0.27 for Spanish over 0.58 for Hungarian, 1.91 for Arabic, 1.96 for Czech to 2.82 for German. The test set experiments in Table 7 confirm these results.

5 Conclusion

We presented the pruned CRF (PCRF) model for very large tagsets. The model is based on coarse-to-fine decoding and stochastic gradient descent training with early updating. We showed that for moderate tagset sizes of $\approx$ 50, the model gives significant speed-ups over a standard CRF with negligible losses in accuracy. Furthermore, we showed that training and tagging for approximated trigram and fourgram models is still faster than standard 1^{st}-order tagging, but yields significant improvements in accuracy.

In oracle experiments with POS+MORPH tagsets we demonstrated that the losses due to our approximation depend on the word level ambiguity of the respective language and are moderate (≤ 0.14) except for German where we observed a loss of 0.37.

[5] We set the CRFSuite option $\mathrm{possible\_states} = 0$

[6] Giménez and Màrquez (2004) report an accuracy of 97.16 instead of 97.12 for SVMTool for English and Manning (2011) an accuracy of 97.29 instead of 97.28 for the Stanford tagger.

We also showed that higher order tagging – which is prohibitive for standard CRF implementations – yields significant improvements over unpruned 1^{st}-order models. Analogous to the oracle experiments we observed big improvements for languages with a high level of POS+MORPH ambiguity such as German and smaller improvements for languages with less ambiguity such as Hungarian and Spanish.

The Effects of Syntactic Features in Automatic Prediction of Morphology

Wolfgang Seeker and **Jonas Kuhn**
Institute for Natural Language Processing
University of Stuttgart
{seeker,jonas}@ims.uni-stuttgart.de

Abstract

Morphology and syntax interact considerably in many languages and language processing should pay attention to these interdependencies. We analyze the effect of syntactic features when used in automatic morphology prediction on four typologically different languages. We show that predicting morphology for languages with highly ambiguous word forms profits from taking the syntactic context of words into account and results in state-of-the-art models.

1 Introduction

In this paper, we investigate the interplay between syntax and morphology with respect to the task of assigning morphological descriptions (or tags) to each token of a sentence. Specifically, we examine the effect of syntactic information when it is integrated into the feature model of a morphological tagger. We test the effect of syntactic features on four languages – Czech, German, Hungarian, and Spanish – and find that syntactic features improve our tagger considerably for Czech and German, but not for Hungarian and Spanish. Our analysis of constructions that show morpho-syntactic agreement suggests that syntactic features are important if the language shows frequent word form syncretisms[1] that can be disambiguated by the syntactic context.

The meaning of a sentence is structurally encoded by morphological and syntactic means.[2] Different languages, however, use them to a different extent. Languages like English encode grammatical information (like the subject vs object status of an argument) via word order, whereas languages like Czech or Hungarian use different word forms. Automatic analysis of languages with rich morphology needs to pay attention to the interaction between morphology and syntax in order to arrive at suitable computational models. Linguistic theory (e. g., Bresnan (2001), Melčuk (2009)) suggests many interactions between morphology and syntax. For example, languages with a case system use different forms of the same word to mark different syntactic (or semantic) relations (Blake, 2001). In many languages, two words that participate in a syntactic relation show covariance in some or all of their morphological features (so-called agreement, Corbett (2006)).[3]

Automatic annotation of morphology assigns morphological descriptions (e. g., *nominative-singular-masculine*) to word forms. It is usually modeled as a sequence model, often in combination with part-of-speech tagging and lemmatization (Collins, 2002; Hajič, 2004; Smith et al., 2005; Chrupała et al., 2008, and others). Sequence models achieve high accuracy and coverage but since they only use linear context they only approximate some of the underlying hierarchical relationships. As an example for these hierarchical relationships,

[1] Syncretism describes the situation where a word form is ambiguous between several different morphological descriptions within its inflection paradigm.

[2] And also by prosodic means, which we will not discuss since text-based tools rarely have access to this information.

[3] For example, in English, the subject of a sentence and the finite verb agree with respect to their number and person feature.

'the regions that are economically most developed, modern, and partly catholic'

Figure 1: Example of a German noun phrase. First and last word agree in number, gender, and case value.

Figure 1 shows a German noun phrase taken from the German TiGer corpus (Brants et al., 2002). The two bold-faced words are the determiner and the head noun of the phrase, and they agree in their gender, number, and case values. The word *Regionen* (regions) is four-way ambiguous for its case value, which is reduced to a two-way ambiguity between *nominative* and *accusative* by the determiner. Further disambiguation would require information about the syntactic role of the noun phrase in a sentence. There are 11 tokens between these two words, which would require a context window of at least 13 to capture the agreement relation within a sequence model. Syntactically, however, as indicated by the dependency tree, the determiner and the head are linked directly. The interdependency between morphology and syntax in the example thus manifests itself in the morphological disambiguation of a highly syncretic word form because of its government or agreement relation to its respective syntactic head/dependents.

Of course, the sequence model is most of the time a reasonable approximation, because the majority of noun phrases in the TiGer corpus are not as long as the example in Figure 1.[4] Furthermore, not all languages show this kind of relationship between morphological forms and syntactic relation as demonstrated for German. But taking advantage of the morphosyntactic dependencies in a language can give us better models that may even be capable of handling the more difficult or rare cases. We therefore advocate that models for predicting morphology should be designed with the typological characteristics of a language and its morphosyntactic properties in mind, and should, where appropriate, integrate syntactic information in order to better model the morphosyntactic interdependencies of the language.

In the remainder of the paper, we show empirically that taking syntactic information into account produces state-of-the-art models for languages with a high interdependency between morphology and syntax. We use a simple setup, where we combine a morphological tagger and a dependency parser in a bootstrapping architecture in order to analyze the effect of syntactic information on the performance of the morphological tagger (Section 2). Using syntactic features in morphology prediction requires a syntactically annotated corpus for training a statistical parser, which may not be available for languages with few resources. We show in Section 3 that only very little syntactically annotated data is required to achieve the improvements. We furthermore expect that the improved morphological information also improves parsing performance and present a preliminary experiment in Section 4.

2 Experiments

In this section, we present a series of experiments that investigate the effect of syntactic information on the prediction of morphological features. We start by describing our data sets and the system that we used for the experiments.

2.1 Languages and Data Sets

We test our hypotheses on four different languages: Czech, German, Hungarian, and Spanish.

Spanish, a Romance language, and German, a Germanic language, constitute inflecting languages that show verbal and nominal morphology, but not as sophisticated as Czech and Hungarian. As we will see in the experiments, it is relatively easy to

[4] We find 57,551 noun phrases with less than three tokens between determiner and noun and 4,670 with three or more.

predict the morphological information annotated in the Spanish data set.

Czech and Hungarian represent languages with very rich morphological systems both in verbal and nominal morphological paradigms. They differ significantly in the way in which morphological information is encoded in word forms. Czech, a Slavic language, is an inflecting language, where one suffix may signal several different morphological categories simultaneously (e. g., number, gender, case). In contrast, Hungarian, a Finno-Ugric language, is of the agglutinating type, where each morphological category is marked by its own morpheme.

Both German and Czech show various form syncretisms in their inflection paradigms. Form syncretisms emerge when the same word form is ambiguous between several different morphological descriptions, and they are a major challenge to automatic morphological analysis. Spanish shows syncretism in the verbal inflection paradigms. In Hungarian, form syncretisms are much less frequent. The case paradigm of Hungarian only shows one form syncretism between dative and genitive case (out of about 18 case suffixes).

All languages show agreement between subject and verb, and within the noun phrase. The word order in Czech and Hungarian is very variable whereas it is more restrictive in Spanish and German.

As our data, we use the CoNLL 2009 Shared Task data sets (Hajič et al., 2009) for Czech and Spanish. For German, we use the dependency conversion of the TiGer treebank by Seeker and Kuhn (2012), splitting it into 40k/5k/5k sentences for training/development/test. For Hungarian, we use the Szeged Dependency Treebank (Vincze et al., 2010), with the split of Farkas et al. (2012).

2.2 System Description

To test our hypotheses, we implemented a tagger that assigns full morphological descriptions to each token in a sentence. The system was inspired by the morphological tagger included in mate-tools.[5] Like the tagger provided with mate-tools, it is a classifier that tags each token using the surrounding tokens in its feature model. Models are trained using passive-aggressive online training (Crammer et al., 2003). The system makes two passes over each sentence: The first pass provides predicted tags that are used as features during the second pass. We also adopted the idea of a tag filter, which deterministically assigns tags for words that always occur with the same tag in the training data.

For all matters of syntactic annotation in this paper, we use the graph-based dependency parser by Bohnet (2010), also included in mate-tools. All data sets are annotated with gold syntactic information, which is used to train the parsing models.

For our experiments, we use a bootstrapping approach: the parser uses the output of the morphology in its feature set, and the morphological tagger we want to analyze uses the output of the parser as syntactic features. Since it is best to keep the training setting as similar as possible to the test setting, we use 10-fold jackknifing to annotate our training data with predicted morphology or syntax respectively.

Jackknifing differs from cross-validation only in its purpose. Cross-validation is used for evaluating data, jackknifing is used to annotate data. The data set is split into n parts, and n-1 parts are used to train a model for annotating the n^{th} part. This is then rotated n times such that each part is annotated by the automatic tool without training it on its own test data. Jackknifing is important for creating a realistic training scenario that provides automatic preprocessing. For annotating development and test sets, models are trained on the jackknifed training set.

2.3 The Effects of Syntactic Features

In the first experiment, we use the system described in Section 2.2 to predict morphological information on all four languages. We start with describing the general setup and the feature set, and continue with a discussion of the results.

The experimental setup is as follows: the German and Spanish data sets are annotated with lemma and part-of-speech information using 10-fold jackknifing. The annotation is done with mate-tools' lemmatizer and pos-tagger. For Czech and Hungarian, we keep the annotation provided with the data sets.

Note that our experimental setup does not include lemmas or part-of-speech tags as part of the prediction of the morphology but annotates them in a pre-

[5] A collection of language independent, data-driven analysis tools for lemmatization, pos-tagging, morphological analysis, and dependency parsing: http://code.google.com/p/mate-tools

processing step. It is not necessary to separate part-of-speech and lemma from the prediction of morphology and, in fact, many systems perform these steps simultaneously (e. g. Spoustová et al. (2009)). Doing morphology prediction as a separate step allows us to use lemma and part-of-speech information in the feature set.[6]

static features

Spanish only features		
s5	p1	p4
p5	s2_1a	s3_1a
s4_1a		

Table 1: Baseline feature set. *form* means word form, *lemma* is lemma, *pos* is part-of-speech, *s1*/*p1* stand for suffix and prefix of length 1 (characters), *tag* is the morphological tag predicted by the system, *1b*/*1a* means 1 token before/after the current token, and + marks feature conjunctions. *number* marks if the form contains a digit.

After preprocessing the data, our baseline system is trained using the feature set shown in Table 1. The baseline system does not make use of any syntactic information but predicts morphological information based solely on tokens and their linear context. The features are divided into static features, which can be computed on the input, and dynamic features, which are computed also on previous output of the system (cf. two passes in Section 2.2).

[6]Lemma and part-of-speech prediction may also profit from syntactic information, see e.g. Prins (2004) or Bohnet and Nivre (2012).

The feature sets in Table 1 were developed specifically for our experiments and are the result of an automatic forward/backward feature selection process. The purpose of the feature selection was to arrive at a baseline system that performs well without any syntactic information. With such an optimized baseline system, we can measure the contribution of syntactic features more reliably.

The *last-verb*/*next-verb* and *pos+case* features are variants of the features proposed in Votrubec (2006). They extract information about the first verb within the last 10/the next 30 tokens in the sentence. The *case* feature extracts the case value from previously assigned morphological tags. Note that the *verb* features are approximating syntactic information by making the assumption that the closest verbs are likely to be syntactic heads for many words.

static features

ld_s1	ld_s2	ld_p1	ld_p4	
dynamic features				
h_tag	ld_tag			

Table 2: Syntactic features. *h_* and *ld_* mark features from the head and the left-most daughter, *dir* is a binary feature marking the direction of the head with respect to the current token.

After training the baseline models, we use them to annotate the whole data set with morphological information (using 10-fold jackknifing for the training portions). We then use 10-fold jackknifing again to annotate the data sets with the dependency parser.

At this point, all our data sets are annotated with predicted morphology from our baseline system and with syntactic information from the parser, which uses the morphological information from our baseline system in its feature set. We can now retrain our morphological tagger using features that are derived from the dependency trees provided by the parser. Note that this is not a stacking architecture, since the second system does not use the predicted morphology output from the baseline system. The loop simply ensures that we get the best possible syntactic features.

We extract two kinds of syntactic features: features of the syntactic head of the current token, and

features of the left-most daughter of the current token. We also experimented with other types, e. g. the right-most daughter, but these features did not improve the model. This is likely due to the way these languages encode morphological information and may be different for other languages. From the head and the left-most daughter, we construct features about form, lemma, affixes, and tags. Table 2 lists the syntactic features that we use in the model.

With the syntactic features available due to the parsing step, we train new models with the full system. For each language, we run four experiments. The first two are baseline experiments, where we use the off-the-shelf morphological tagger morfette (Chrupała et al., 2008) and our own baseline system, both of which do not use any syntactic features. In the third experiment, we evaluate our full system using the syntactic features provided by the dependency parser. As an oracle experiment, we also report results on the full system when using the gold standard syntax from the treebank. Table 3 presents all results in terms of accuracy on all tokens (all) and out-of-vocabulary tokens only (oov). Out-of-vocabulary tokens do not occur in the training data.

We find trends along several axes: Generally, the syntactic features work well for Czech and German, whereas for Hungarian and Spanish, they do not yield any significant improvement. The improvements for German and Czech are between 0.5 (Czech) and 1.0 (German) percentage points absolute in token accuracy, and between 0.2 (Czech test set) and 2.5 (German dev set) percentage points absolute in accuracy of unknown words. There are no obvious differences between the development and the test set in any of the languages.

Compared to the morfette baseline, we find our systems to be either superior or equal to morfette in terms of token accuracy. Regarding accuracy on unknown words, morfette outperforms our systems for Hungarian, but is outperformed on Czech and German. For Spanish, all systems yield similar results.

Looking at the oracle experiment, we see that for all languages, the system can learn something from syntax. For Czech and German, this is clearly the

case, for Hungarian and Spanish, the differences are small but visible. There are pronounced differences between the predicted and the gold syntax experiments in Czech and German. Clearly, the parser makes mistakes that propagate through to the prediction of the morphology.

2.4 Syntax vs Lexicon

The current state-of-the-art in predicting morphological features makes use of morphological lexicons (e.g. Hajič (2000), Hakkani-Tür et al. (2002), Hajič (2004)). Lexicons define the possible morphological descriptions of a word and a statistical model selects the most probable one among them. In the following experiment, we test whether the contribution of syntactic features is similar or different to the contribution of morphological lexicons.

Lexicons encode important knowledge that is difficult to pick up in a purely statistical system, e. g. the gender of nouns, which often cannot be deduced from the word form (Corbett, 1991).[7]

We extend our system from the previous experiment to include information from a morphological dictionaries. For Czech, we use the morphological analyzer distributed with the Prague Dependency Treebank 2 (Hajič et al., 2006). For German, we use DMor (Schiller, 1994). For Hungarian, we use (Trón et al., 2006), and for Spanish, we use the morphological analyzer included in Freeling (Carreras et al., 2004). The output of the analyzers is given to the system as features that simply record the presence of a particular morphological analysis for the current word. The system can thus use the output of any tool regardless of its annotation scheme, especially if the annotation scheme of the treebank is different from the one of the morphological analyzer.

Table 4 presents the results of experiments where we add the output of the morphological analyzers to our system. Again, we run experiments with and without syntactic features. For Czech, we also show results from featurama[8] with the feature set developed by Votrubec (2006). For German, we show results for RFTagger (Schmid and Laws, 2008).

As expected, the information from the morphological lexicon improves the overall performance considerably compared to the results in Table 3, especially on unknown tokens. This shows that even with the considerable amounts of training data available nowadays, rule-based morphological analyzers are important resources for morphological description (cf. Hajič (2000)). The contribution of syntactic features in German and Czech is almost the same as in the previous experiment, indicating that the syntactic features contribute information that is orthogonal to that of the morphological lexicon. The lexicon provides lexical knowledge about a word form, while the syntactic features provide the syntactic context that is needed in German and Czech to decide on the right morphological tag.

2.5 Language Differences

From the previous experiments, we conclude that syntactic features help in the prediction of morphology for Czech and German, but not for Hungarian and Spanish. To further investigate the difference between Czech and German on the one hand, and Hungarian and Spanish on the other, we take a closer look at the output of the tagger.

We find an interesting difference between the two pairs of languages, namely the performance with respect to agreement. Agreement is a phenomenon where morphology and syntax strongly interact. Morphological features co-vary between two items in the sentence, but the relation between these items can occur at various linguistic levels (Corbett, 2006). If the syntactic information helps with predicting morphological information, we expect this to be particularly helpful with getting agreement right. All languages show agreement to some extent. Specifically, all languages show agreement in number (and person) between the subject and the verb of a clause. Czech, German, and Spanish show agreement in number, gender, and case (not Spanish) within a noun phrase. Hungarian shows case agreement within the noun phrase only rarely, e.g. for attributively used demonstrative pronouns.

In order to test the effect on agreement, we measure the accuracy on tokens that are in an agreement relation with their syntactic head. We counted subject verb agreement as well as agreement with respect to number, gender, and case (where applicable) between a noun and its dependent adjective and determiner. Table 5 displays the counts from the devel-

[7] Lexicons are also often used to speed up processing considerably by restricting the search space of the statistical model.

[8] http://sourceforge.net/projects/featurama/

opment sets of each language. We compare the baseline system that does not use any syntactic information with the output of the morphological tagger that uses the gold syntax. We use the gold syntax rather than the predicted one in order to eliminate any influence from parsing errors. As can be seen from the results, the level of agreement relations in Czech and German improves when using syntactic information, whereas in Spanish and Hungarian, only very tiny changes occur.

agreement	baseline	gold syntax
	Czech	
sbj-verb	3199/4044 = 79.10	3264/4044 = 80.71
NP case	8719/9132 = 95.48	8821/9132 = 96.59
NP num	8933/9132 = 97.82	9016/9132 = 98.73
NP gen	8493/9132 = 93.00	8768/9132 = 96.01
	German	
sbj-verb	4412/4696 = 93.95	4562/4696 = 97.15

	Spanish	
sbj-verb	1930/2004 = 96.31	1932/2004 = 96.41
NP num	8810/8849 = 99.56	8816/8849 = 99.63
NP gen	8810/8849 = 99.56	8821/8849 = 99.68

Table 5: Agreement counts in morphological annotation compared between the baseline system and the oracle system using gold syntax.

For Czech and German, these results sugguest that syntactic information helps with agreement. We believe that the reasons why it does not help for Hungarian and Spanish are the following: for Spanish, we see that also the baseline model achieves very high accuracies (cf. Table 3) and also high rates of correct agreement. It seems that for Spanish, syntactic context is simply not necessary to make the correct prediction. For Hungarian, the reason lies within the inflectional paradigms of the language, which do not show any form syncretism, meaning that word forms in Hungarian are usually not ambiguous within one morphological category (e.g. case). Making a morphological tag prediction, however, is difficult only if the word form itself is ambiguous between several morphological tags. In this case, using the agreement relation between the word and its syntactic head can help the system making the proper prediction. This is the situation that we find in Czech and German, where form syncretism is pervasive in the inflectional paradigms.

2.6 Syntactic Features in Czech

In Section 2.4 we compared the performance of our system on Czech to another system, featurama (see Table 4). Featurama outperforms our baseline system by a percentage point in token accuracy (and even more for unknown tokens). Syntactic information closes that gap to a large extent but only using gold syntax gets our system on a par with featurama.

The question then arises whether the syntactic features actually contribute something new to the task, or whether the same effect could also be achieved with linear context features alone as in featurama. In order to test this we run an additional experiment, where we add some of the syntax features to the feature set of featurama. Specifically, we add the static features from Table 2 that do not use lemma or part-of-speech information. Due to the way featurama works, we cannot use features from the morphological tags (the dynamic features).

The results in Table 6 show that also featurama profits from syntactic features, which corroborates the findings from the previous experiments. We also note again that better syntax would improve results even more.

	dev set		test set	
	all	oov	all	oov
featurama	94.75	84.12	94.78	84.23
pred syntax	95.18	84.65	95.09	84.52
gold syntax	*95.39	84.62	*95.34	85.03

Table 6: Syntactic features for featurama (Czech). * mark statistically significantly better models compared to featurama (sentence-based t-test with $\alpha = 0.05$).

3 How Much Syntax is Needed?

Syntactic features require syntactically annotated corpora. Without a treebank to train the parser, the morphology cannot profit from syntactic features.[9] This may be problematic for languages for which there is no treebank, because creating a treebank is expensive. Fortunately, it turns out that very small amounts of syntactically annotated data are enough

[9] Which is of course only a problem for statistical parsers.

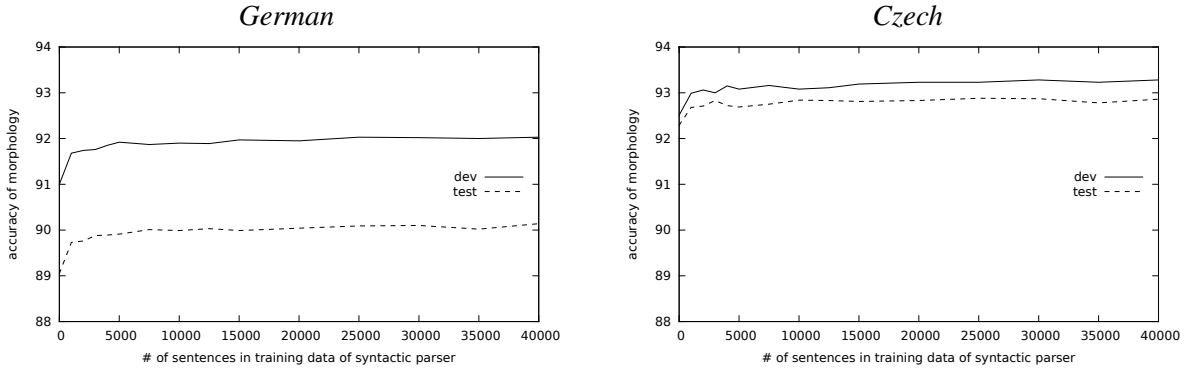

Figure 2: Dependency between amount of training data for syntactic parser and quality of morphological prediction.

to provide a parsing quality that is sufficient for the morphological tagger.

In order to test what amount of training data is needed, we train several parsing models on increasing amounts of syntactically annotated data. For example, the first experiment uses the first 1,000 sentences of the treebank. We perform 5-fold jackknifing with the parser on these sentences to annotate them with syntax. Then we train one parsing model on these 1,000 sentences and use it to annotate the rest of the training data as well as the development and the test set. This gives us the full data set annotated with syntax that was learned from the first 1,000 sentences of the treebank. The morphological tagger is then trained on the full training set and applied to development and test set.

Figure 2 shows the dependency between the amount of training data given to the parser and the quality of the morphological tagger using syntactic features provided by this parser. The left-most point corresponds to a model that does not use syntactic information. For both languages, German and Czech, we find that already 1,000 sentences are enough training data for the parser to provide useful syntactic information to the morphological tagger. After 5,000 sentences, both curves flatten out and stay on the same level. We conclude that using syntactic features for morphological prediction is viable even if there is only small amounts of syntactic data available to train the parser.

As a related experiment, we also test if we can get the same effect with a very simple and thus much faster parser. We use the brute-force algorithm described in Covington (2001), which selects for each token in the sentence another token as the head. It does not have any tree requirements, so it is not even guaranteed to yield a cycle-free tree structure. In Table 7, we compare the simple parser with the mate-parser, both trained on the first 5,000 sentences of the treebank. Evaluation is done in terms of labeled (LAS) and unlabeled attachment score (UAS).[10]

	dev set		test set	
	LAS	UAS	LAS	UAS
Czech				
simple parser (5k)	71.57	78.96	69.09	77.23
full parser (5k)	76.77	84.38	74.70	83.00
German				
simple parser (5k)	83.06	85.23	78.56	81.18
full parser (5k)	87.56	90.08	83.69	86.58

Table 7: Simple parser vs full parser – syntactic quality. Trained on first 5,000 sentences of the training set.

As expected, the simple parser performs much worse in terms of syntactic quality. Table 8 shows the performance of the morphological tagger when using the output of both parsers as syntactic features. For Czech, both parsers seem to supply similar information to the morphological tagger, while for German, using the full parser is clearly better. In both cases, the morphological tagger outperforms the models that do not use syntactic information (cf. Table 3). The performance on unknown words is however much worse for both languages. We conclude that even with a simple parser and little training data, the morphology can make use of syntactic information to some extent.

[10] LAS: $\frac{\text{correct edges with correct labels}}{\text{all edges}}$, UAS: $\frac{\text{correct edges}}{\text{all edges}}$

	dev set		test set	
	all	oov	all	oov
Czech				
no syntax	92.51	73.12	92.29	72.58
simple syntax	92.96	73.45	92.53	72.66
full syntax	93.08	73.64	92.69	73.39
German				
no syntax	90.92	72.52	89.11	69.67
simple syntax	91.52	73.34	89.66	70.52
full syntax	91.92	83.46	89.91	80.50

Table 8: Simple parser vs full parser – morphological quality. The parsing models were trained on the first 5,000 sentences of the training data, the morphological tagger was trained on the full training set.

4 Does Better Morphology lead to Better Parses?

In the previous sections, we show that syntactic information improves a model for predicting morphology for Czech and German, where syntax and morphology interact considerably. A natural question then is whether the improvement also occurs in the other direction, namely whether the improved morphology also leads to better parsing models.

In the previous experiments, we run a 10-fold jackknifing process to annotate the training data with morphological information using no syntactic features and afterwards use jackknifing with the parser to annotate syntax. The syntax is subsequently used as features for our predicted-syntax experiments. We can apply the same process once more with the morphology prediction in order to annotate the training data with morphological information that is predicted using the syntactic features. A parser trained on this data will then use the improved morphology as features. If the improved morphology has an impact on the parser, the quality of the second parsing model should then be superior to the first parsing model, which uses the morphology predicted without syntactic information. Note that for the following experiments, neither morphology model uses the morphological lexicon.

Table 9 presents the evaluation of the two parsing models (one using morphology without syntactic features, the other one using the improved morphology). The results show no improvement in parsing performance when using the improved morphology. Looking closer at the output, we find differences between the two parsing models with respect to grammatical functions that are morphologically marked. For example, in German, performance on subjects and accusative objects improves while performance for dative objects and genitives decreases. This suggests different strengths in the two parsing models. However, the question how to make use of the improved morphology in parsing clearly needs more research in the future. A promising avenue may be the approach by Hohensee and Bender (2012).

5 Related Work

Morphological taggers have been developed for many languages. The most common approach is the combination of a morphological lexicon with a statistical disambiguation model (Hakkani-Tür et al., 2002; Hajič, 2004; Smith et al., 2005; Spoustová et al., 2009; Zsibrita et al., 2013).

Our work has been inspired by Versley et al. (2010), who annotate a treebank with morphological information after the syntax had been annotated already. The system used a finite-state morphology to propose a set of candidate tags for each word, which is then further restricted using hand-crafted rules over the already available syntax tree.

Lee et al. (2011) pursue the idea of jointly predicting syntax and morphology, out of the motivation that joint models should model the problem more faithfully. They demonstrate that both sides can use information from each other. However, their model is computationally quite demanding and its overall performance falls far behind the standard pipeline approach where both tasks are done in sequence.

The problem of modeling the interaction between morphology and syntax has recently attracted some attention in the SPMRL workshops (Tsarfaty et al.,

2010). Modeling morphosyntactic relations explicitly has been shown to improve statistical parsing models (Tsarfaty and Sima'an, 2010; Goldberg and Elhadad, 2010; Seeker and Kuhn, 2013), but the co-dependency between morphology and syntax makes it a difficult problem, and linguistic intuition is often contradicted by the empirical findings. For example, Marton et al. (2013) show that case information is the most helpful morphological feature for parsing Arabic, but only if it is given as gold information, whereas using case information from an automatic system may even harm the performance.

Morphologically rich languages pose different challenges for automatic systems. In this paper, we work with European languages, where the problem of predicting morphology can be reduced to a tagging problem. In languages like Arabic, Hebrew, or Turkish, widespread ambiguity in segmentation of single words into meaningful morphemes adds an additional complexity. Given a good segmentation tool that takes care of this, our approach is applicable to these languages as well. For Hebrew, this problem has also been addressed by jointly modeling segmentation, morphological prediction, and syntax (Cohen and Smith, 2007; Goldberg and Tsarfaty, 2008; Goldberg and Elhadad, 2013).

6 Conclusion

In this paper, we have demonstrated that using syntactic information for predicting morphological information is helpful if the language shows form syncretism in combination with morphosyntactic phenomena like agreement. A model that uses syntactic information is superior to a sequence model because it leverages the syntactic dependencies that may hold between morphologically dependent words as suggested by linguistic theory. We also showed that only small amounts of training data for a statistical parser would be needed to improve the morphological tagger. Making use of the improved morphology in the dependency parser is not straight-forward and requires more investigation in the future.

Modeling the interaction between morphology and syntax is important for building successful parsing pipelines for languages with free word order and rich morphology. Moreover, our experiments show that paying attention to the individual properties of a language can help us explain and predict the behavior of automatic tools. Thus, the term "morphologically rich language" should be viewed as a broad term that covers many different languages, whose differences among each other may be as important as the difference with languages with a less rich morphology.

Acknowledgments

We would like to thank Jan Hajič and Jan Štěpánek for their kind help with the Czech morphology and featurama. We would also like to thank Thomas Müller for sharing resources and thoughts with us, and Anders Björkelund for commenting on earlier versions of this paper. Adaptor Grammars for Learning Non-Concatenative Morphology

Jan A. Botha and **Phil Blunsom**
Department of Computer Science
University of Oxford
Oxford, OX1 3QD, UK
{jan.botha,phil.blunsom}@cs.ox.ac.uk

Abstract

This paper contributes an approach for expressing non-concatenative morphological phenomena, such as stem derivation in Semitic languages, in terms of a mildly context-sensitive grammar formalism. This offers a convenient level of modelling abstraction while remaining computationally tractable. The nonparametric Bayesian framework of adaptor grammars is extended to this richer grammar formalism to propose a probabilistic model that can learn word segmentation and morpheme lexicons, including ones with discontiguous strings as elements, from unannotated data. Our experiments on Hebrew and three variants of Arabic data find that the additional expressiveness to capture roots and templates as atomic units improves the quality of concatenative segmentation and stem identification. We obtain 74% accuracy in identifying triliteral Hebrew roots, while performing morphological segmentation with an F1-score of 78.1.

1 Introduction

Unsupervised learning of morphology is the task of acquiring, from unannotated data, the intra-word building blocks of a language and the rules by which they combine to form words. This task is of interest both as a gateway for studying language acquisition in humans and as a way of producing morphological analyses that are of practical use in a variety of natural language processing tasks, including machine translation, parsing and information retrieval.

A particularly interesting version of the morphology learning problem comes from languages that use *templatic* morphology, such as Arabic, Hebrew and Amharic. These Semitic languages derive verb and noun stems by interspersing abstract *root* morphemes into *templatic* structures in a non-concatenative way. For example, the Arabic root k·t·b can combine with the template (i-a) to derive the noun stem *kitab* (book). Established morphological analysers typically ignore this process and simply view the derived stems as elementary units (Buckwalter, 2002), or their account of it coincides with a requirement for extensive linguistic knowledge and hand-crafting of rules (Finkel and Stump, 2002; Schneider, 2010; Altantawy et al., 2010). The former approach is bound to suffer from vocabulary coverage issues, while the latter clearly does not transfer easily across languages. The practical appeal of unsupervised learning of templatic morphology is that it can overcome these shortcomings.

Unsupervised learning of *concatenative* morphology has received extensive attention, partly driven by the MorphoChallenge (Kurimo et al., 2010) in recent years, but that is not the case for root-templatic morphology (Hammarström and Borin, 2011).

In this paper we present a model-based method that learns concatenative and root-templatic morphology in a unified framework. We build on two disparate strands of work from the literature: Firstly, we apply *simple Range Concatenating Grammars* (SRCGs) (Boullier, 2000) to parse contiguous and discontiguous morphemes from an input string. These grammars are *mildly-context sensitive* (Joshi, 1985), a superset of context-free grammars that retains polynomial parsing time-complexity. Secondly, we generalise the nonparametric Bayesian learning framework of *adaptor grammars* (Johnson et al., 2007) to SRCGs.[1] This should also be rel-

[1]Our formulation is in terms of SRCGs, which are equivalent in power to linear context-free rewrite systems (Vijay-Shanker et al., 1987) and multiple context-free grammars (Seki et al., 1991), all of which are weaker than (non-simple) range concatenating grammars (Boullier, 2000).

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 345–356,
Seattle, Washington, USA, 18-21 October 2013.

evant to other applications of probabilistic SRCGs, e.g. in parsing (Maier, 2010), translation (Kaeshammer, 2013) and genetics (Kato et al., 2006).

In addition to unannotated data, our method requires as input a minimal set of high-level grammar rules that encode basic intuitions of the morphology. This is where there would be room to become very language specific. Our aim, however, is not to obtain a best-published result in a particular language, but rather to create a method that is applicable across a variety of morphological processes. The specific rules used in our empirical evaluation on Arabic and Hebrew therefore contain hardly any explicit linguistic knowledge about the languages and are applicable across the family of Semitic languages.

2 A powerful grammar for morphology

Concatenative morphology lends itself well to an analysis in terms of finite-state transducers (FSTs) (Koskenniemi, 1984). With some additional effort, FSTs can also encode non-concatenative morphology (Kiraz, 2000; Beesley and Karttunen, 2003; Cohen-Sygal and Wintner, 2006; Gasser, 2009). Despite this seeming adequacy of regular languages to describe morphology, we see two main shortcomings that motivate moving further up the Chomsky hierarchy of formal languages: first is the issue of learning. We are not aware of successful attempts at inducing FST-based morphological analysers in an unsupervised way, and believe the challenge lies in the fact that FSTs do not offer a *convenient* way of expressing prior linguistic intuitions to guide the learning process. Secondly, an FST composed of multiple machines might capture morphological processes well and excel at analysis, but interpretability of its internal operations are limited.

These shortcomings are overcome for concatenative morphology by context-free adaptor grammars, which allowed diverse segmentation models to be formulated and investigated within a single framework (Johnson et al., 2007; Johnson, 2008; Sirts and Goldwater, 2013). In principle, that covers a wide range of phenomena (typical example language in parentheses): affixal inflection (Czech) and derivation (English), agglutinative derivation (Turkish, Finnish), compounding (German). Our agenda here is to extend that approach to include non-concatenative processes such as root-templatic derivation (Arabic), infixation (Tagalog) and circumfixation (Indonesian). In this pursuit, an abstraction that permits discontiguous constituents is a highly useful modelling tool, but requires looking beyond context-free grammars.

An idealised generative grammar that would capture all the aforementioned phenomena could look like this:

$$\text{Word} \rightarrow (\text{Pre}^* \ \text{Stem} \ \text{Suf}^*)^+ \quad (1)$$

e.g. English *un+accept+able*

$$\text{Stem} \mid \text{Pre} \mid \text{Suf} \rightarrow \text{Morph} \quad (2)$$

$$\text{Stem} \rightarrow \mathbf{intercal}(\text{Root}, \text{Template}) \quad (3)$$

e.g. Arabic derivation $k{\cdot}t{\cdot}b + i{\cdot}a \Rightarrow$ *kitab* (book)

$$\text{Stem} \rightarrow \mathbf{infix}(\text{Stem}, \text{Infix}) \quad (4)$$

e.g. Tagalog *sulat* (write) $\Rightarrow$ ***sum****ulat* (wrote)

$$\text{Stem} \rightarrow \mathbf{circfix}(\text{Stem}, \text{Circumfix}) \quad (5)$$

e.g. Indonesian *percaya* (to trust)

$\Rightarrow$ ***ke****percaya****an*** (belief)

where the symbols (excluding Word and Stem) implicitly expand to the relevant terminal strings. The bold-faced "functions" combine the potentially discontiguous yields of the argument symbols into single contiguous strings, e.g. $\mathbf{infix}$(s·ulat, um) produces stem *sumulat*.

Taken by themselves, the first two rules are simply a CFG that describes word formation as the concatenation of stems and affixes, a formulation that matches the underlying grammar of Morfessor (Creutz and Lagus, 2007), a well-studied unsupervised model.

The key aim of our extension is that we want the grammar to capture a discontiguous string like k·t·b as a single constituent in a parse tree. This leads to well-understood problems in probabilistic grammars (e.g. what is this rule's probability?), but also corresponds to the linguistic consideration that k·t·b is a proper morpheme of the language (Prunet, 2006).

3 Simple range concatenating grammars

In this section we define SRCGs formally and illustrate how they can be used to model non-concatenative morphology. SRCGs define languages that are recognisable in polynomial time, yet can capture discontiguous elements of a string under a single category (Boullier, 2000). An SRCG-

rule operates on vectors of ranges in contrast to the way a CFG-rule operates on single ranges (spans). In other words, a non-terminal symbol in an SRCG (CFG) derivation can dominate a subset (substring) of terminals in an input string.

3.1 Formalism

An SRCG $\mathcal{G}$ is a tuple (N, T, V, P, S), with finite sets of non-terminals (N), terminals (T) and variables (V), with a start symbol $S \in N$. A rewrite rule $p \in P$ of rank $r = \rho(p) \geq 0$ has the form $A(\alpha_1, \ldots, \alpha_{\psi(A)}) \rightarrow B_1(\beta_{1,1}, \ldots, \beta_{1,\psi(B_1)}) \ldots B_r(\beta_{r,1}, \ldots, \beta_{r,\psi(B_r)})$, where each $\alpha, \beta \in (T \cup V)^*$, and $\psi(A)$ is the number of arguments a non-terminal A has, called its *arity*. By definition, the start symbol has arity 1. Any variable $v \in V$ appearing in a given rule must be used exactly once on each side of the rule. Terminating rules are written with ϵ as the right-hand side and thus have rank 0.

A *range* is a pair of integers (i, j) denoting the substring $w_{i+1} \ldots w_j$ of a string $w = w_1 \ldots w_n$. A non-terminal becomes *instantiated* when its variables are bound to ranges through substitution. Variables within an argument imply concatenation and therefore have to bind to adjacent ranges.

An instantiated non-terminal A' is said to derive ϵ if the consecutive application of a sequence of instantiated rules rewrite it as ϵ. A string w is within the language defined by a particular SRCG iff the start symbol S, instantiated with the exhaustive range $(0, w_n)$, derives ϵ.

An important distinction with regard to CFGs is that, due to the instantiation mechanism, the ordering of non-terminals on the right-hand side of an SRCG rule is irrelevant, i.e. $A(ab) \rightarrow B(a)C(b)$ and $A(ab) \rightarrow C(b)B(a)$ are the same rule.[2] Consequently, the isomorphisms of any given SRCG derivation tree all encode the same string, which is uniquely defined through the instantiation process.

3.2 Application to morphological analysis

A fragment of the idealised grammar schema from the previous section (§2) can be rephrased as an SRCG by writing the rules in the newly introduced notation, and supplying a definition of the **intercal** function as simply another rule of the grammar, with instantiation for $w =$ kitab shown below:

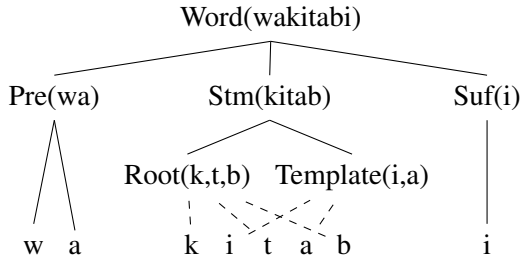

Figure 1: Example derivation for *wakitabi* (and my book) using the SRCG fragment from §3.2. CFGs cannot capture such crossing branches.

$$\text{Word}(abc) \rightarrow \text{Pre}(a)\ \text{Stem}(b)\ \text{Suf}(c)$$
$$\text{Stem}(abcde) \rightarrow \text{Root}(a, c, e)\ \text{Template}(b, d),$$

$$\text{Stem}(\langle 0..1\rangle, \langle 1..2\rangle, \langle 2..3\rangle, \langle 3..4\rangle, \langle 4..5\rangle) \rightarrow \text{Root}(\langle 0..1\rangle, \langle 2..3\rangle, \langle 4..5\rangle)\ \text{Template}(\langle 1..2\rangle, \langle 3..4\rangle)$$

Given an appropriate set of grammar rules (as we present in §5), we can parse an input string to obtain a tree as shown in Figure 1. The overlapping branches of the tree demonstrate that this grammar captures something a CFG could not. From the parse tree one can read off the word's root morpheme and the template used.

Although SRCGs specify mildly context-sensitive grammars, each step in a derivation is context-free – a node's expansion does not depend on other parts of the tree. This property implies that a recognition/parsing algorithm can have a worst-case time complexity that is polynomial in the input length n, $O(n^{(\rho+1)\psi})$ for arity ψ and rank ρ, which reduces to $O(n^{3\psi})$ for a binarised grammar. To capture the maximal case of a root with $k-1$ characters and k discontiguous templatic characters forming a stem would require a grammar that has arity $\psi = k$. For Arabic, which has up to quadriliteral roots ($k = 5$), the time complexity would be $O(n^{15})$.[3] This is a daunting proposition for parsing, but we are careful

[2] Certain ordering restrictions over the variables *within* an argument need to hold for an SRCG to indeed be a *simple* RCG (Boullier, 2000).

[3] The trade-off between arity and rank with respect to parsing complexity has been characterised (Gildea, 2010), and the appropriate refactoring may bring down the complexity for our grammars too.

to set up our application of SRCGs in such a way that this is not too big an obstacle:

Firstly, our grammars are defined over the characters that make up a word, and not over words that make up a sentence. As such, the input length n would tend to be shorter than when parsing full sentences from a corpus.

Secondly, we do type-based morphological analysis, a view supported by evidence from Goldwater et al. (2006), so each unique word in a dataset is only ever parsed once with a given grammar. The set of word types attested in the data sources of interest here is fairly limited, typically in the tens of thousands. For these reasons, our parsing and inference tasks turn out to be tractable despite the high time complexity.

4 Learning

4.1 Probabilistic SRCG

The probabilistic extension of SRCGs is similar to the probabilistic extension of CFGs, and has been used in other guises (Kato et al., 2006; Maier, 2010). Each rule $r \in P$ has an associated probability θ_r such that $\sum_{r \in P_A} \theta_r = 1$. A random string in the language of the grammar can then be obtained through a generative procedure that begins with the start symbol S and iteratively expands it until deriving ϵ: At each step for some current symbol A, a rewrite rule r is sampled randomly from P_A in accordance with the distribution over rules and used to expand A. This procedure terminates when no further expansions are possible. Of course, expansions need to respect the range concatenating and ordering constraints imposed by the variables in rules. The expansions imply a chain of variable bindings going down the tree, and instantiation happens only when rewriting into ϵs but then propagates back up the tree.

The probability $P(w, t)$ of the resulting tree t and terminal string w is the product $\prod_r \theta_r$ over the sequence of rewrite rules used. This generative procedure is a conceptual device; in practice, one would care about parsing some input string under this probabilistic grammar.

4.2 PYSRCAG

A central property of the generative procedure underlying probabilistic SRCGs is the fact that each expansion happens independently, both of the other expansions in the tree under construction and of any other trees. To some extent, this flies in the face of the reality of estimating a grammar from text, where one would expect certain sub-trees to be used repeatedly across different input strings.

Adaptor grammars weaken this independence assumption by allowing whole subtrees to be reused during expansion. Informally, they act as a cache of tree fragments whose tendency to be reused during expansion is governed by the choice of adaptor function. Following earlier applications of adaptor grammars (Johnson et al., 2007; Huang et al., 2011), we employ the Pitman-Yor process (Pitman, 1995; Pitman and Yor, 1997) as adaptor function.

A Pitman-Yor Simple Range Concatenating Adaptor Grammar (PYSRCAG) is a tuple $\mathcal{G} = (\mathcal{G}_\mathcal{S}, M, \boldsymbol{a}, \boldsymbol{b}, \boldsymbol{\alpha})$, where $\mathcal{G}_\mathcal{S}$ is a probabilistic SRCG as defined before and $M \subseteq N$ is a set of *adapted non-terminals*. The vectors $\boldsymbol{a}$ and $\boldsymbol{b}$, indexed by the elements of M, are the discount and concentration parameters for each adapted non-terminal, with $a \in [0, 1], b \geq 0$. $\boldsymbol{\alpha}$ are parameters to Dirichlet priors on the rule probabilities θ.

PYSRCAG defines a generative process over a set of trees $\boldsymbol{T}$. Unadapted non-terminals $A' \in N \setminus M$ are expanded as before (§4.1). For each adapted non-terminal $A \in M$, a cache C_A is maintained for storing the terminating tree fragments expanded from A earlier in the process, and we denote the fragment corresponding to the i-th expansion of A as z_i. In other words, the sequence of indices z_i is the assignment of a sequence of expansions of A to particular tree fragments. Given a cache C_A that has n previously generated trees comprising m unique trees each used $n_1, \ldots, n_m$ times (where $n = \sum_k n_k$), the tree fragment for the next expansion of A, z_{n+1}, is sampled conditional on the previous assignments $\boldsymbol{z}_<$ according to

$$z_{n+1}|\boldsymbol{z}_< \sim \begin{cases} \frac{n_k - a}{n+b} & \text{if } z_{n+1} = k \in [1, m] \\ \frac{ma+b}{n+b} & \text{if } z_{n+1} = m+1, \end{cases}$$

where a and b are those elements of $\boldsymbol{a}$ and $\boldsymbol{b}$ corresponding to A. The first case denotes the situation where a previously cached tree is reused for this $n+1$-th expansion of A; to be clear, this expands A with a fully terminating tree fragment, meaning that none of the nodes descending from A in the

tree being generated are subject to further expansion. The second case by-passes the cache and expands A according to the rules P_A and rule probabilities θ_A of the underlying SRCG $\mathcal{G}_S$. Other caches $C_B(B \in M)$ may come into play during those expansions of the descendants of A; thus a PYSRCAG can define a hierarchical stochastic process. Both cases eventually result in a terminating tree-fragment for A, which is then added to the cache, updating the counts n, n_{z_n+1} and potentially m.

The adaptation does not affect the string language of $\mathcal{G}_S$, but it maps the distribution over trees to one that is distributed according to the PYP.

The invariance of SRCGs trees under isomorphism would make the probabilistic model deficient, but we side-step this issue by requiring that grammar rules are specified in a canonical way that ensures a one-to-one correspondence between the order of nodes in a tree and of terminals in the yield.

4.3 Inference under PYSRCAG

The inference procedure under our model is very similar to that of CFG PY-adaptor grammars, so we restate the central aspects here but refer the reader to the original article by Johnson et al. (2007) for further details. First, one may integrate out the adaptors to obtain a single distribution over the set of trees generated from a particular non-terminal. Thus, the joint probability of a particular sequence $\boldsymbol{z}$ for the adapted non-terminal A with cached counts $(n_1, \ldots, n_m)$ is

$$PY(\boldsymbol{z}|a,b) = \frac{\prod_{k=1}^{m}(a(k-1)+b)\ \prod_{j=1}^{n_k-1}(j-a)}{\prod_{i=0}^{n-1}(i+b)}. \tag{6}$$

Taking all the adapted non-terminals into account, the joint probability of a set of full trees $\boldsymbol{T}$ under the grammar $\mathcal{G}$ is

$$P(\boldsymbol{T}|\boldsymbol{a},\boldsymbol{b},\boldsymbol{\alpha}) = \prod_{A\in M} \frac{\mathrm{B}(\boldsymbol{\alpha}_A + \boldsymbol{f}_A)}{\mathrm{B}(\boldsymbol{\alpha}_A)} PY(\boldsymbol{z}(\boldsymbol{T})|\boldsymbol{a},\boldsymbol{b}), \tag{7}$$

where $\boldsymbol{f}_A$ is a vector of the usage counts of rules $r \in P_A$ across $\boldsymbol{T}$, and B is the Euler beta function.

The posterior distribution over a set of *strings* $\boldsymbol{w}$ is obtained by marginalising (7) over all trees that have $\boldsymbol{w}$ as their yields. This is intractable to compute directly, so instead we use MCMC techniques to obtain samples from that posterior using a component-wise Metropolis-Hastings sampler. The sampler works by visiting each string w in turn and drawing a new tree for it under a proposal grammar $\mathcal{G}_Q$ and randomly accepting that as the new analysis for w according to the Metropolis-Hastings accept-reject probability. As proposal grammar, we use the analogous approximation of our $\mathcal{G}$ as Johnson et al. used for PCFGs, namely by taking a static snapshot $\mathcal{G}_Q$ of the adaptor grammar where additional rules rewrite adapted non-terminals as the terminal strings of their cached trees. Drawing a sample from the proposal distribution is then a matter of drawing a random tree from the parse chart of w under G_Q.

Lastly, the adaptor hyperparameters $\boldsymbol{a}$ and $\boldsymbol{b}$ are modelled by placing flat $\mathrm{Beta}(1,1)$ and vague $\mathrm{Gamma}(10, 0.1)$ priors on them, respectively, and inferring their values using slice sampling (Johnson and Goldwater, 2009).

5 Modelling root-templatic morphology

We start with a CFG-based adaptor grammar[4] that models words as a stem and any number of prefixes and suffixes:

$$\text{Word} \rightarrow \underline{\text{Pre}}^* \ \underline{\text{Stem}} \ \underline{\text{Suf}}^* \tag{8}$$

$$\underline{\text{Pre}} \mid \underline{\text{Stem}} \mid \underline{\text{Suf}} \rightarrow \text{Char}^+ \tag{9}$$

This fragment can be seen as building on the stem-and-affix adaptor grammar presented in (Johnson et al., 2007) for morphological analysis of English, of which a later version also covers multiple affixes (Sirts and Goldwater, 2013). In the particular case of Arabic, multiple affixes are required to handle the attachment of particles and proclitics onto base words.

To extend this to *complex stems* consisting of a root with three radicals we have rules like the following:

$$\underline{\text{Stem}}(abcdefg) \rightarrow \underline{\text{R3}}(b,d,e)\ \text{T4}(a,c,e,g) \tag{10}$$

$$\underline{\text{Stem}}(abcdef) \rightarrow \underline{\text{R3}}(a,c,e)\ \text{T3}(b,d,f) \tag{11}$$

$$\underline{\text{Stem}}(abcde) \rightarrow \underline{\text{R3}}(a,c,e)\ \text{T2}(b,d) \tag{12}$$

$$\underline{\text{Stem}}(abcd) \rightarrow \underline{\text{R3}}(a,c,d)\ \text{T1}(b) \tag{13}$$

$$\underline{\text{Stem}}(abc) \rightarrow \underline{\text{R3}}(a,b,c) \tag{14}$$

[4] Adapted non-terminals are indicated by underlining and we use the following abbreviations: X $\rightarrow$ Y$^+$ means one or more instances of Y and encodes the rules X $\rightarrow$ Ys and Ys $\rightarrow$ Ys Y $\mid$ Y. Similarly, X $\rightarrow$ Y* Z allows zero or more instances of Y and encodes the rules X $\rightarrow$ Z and X $\rightarrow$ Y$^+$ Z. Further relabelling is added as necessary to avoid cycles among adapted non-terminals.

The actual rules include certain permutations of these, e.g. rule (13) has a variant $\underline{\text{R3}}(a, b, d)\text{T1}(c)$. In unvocalised text, the standard written form of Modern Standard Arabic (MSA), it may happen that the stem and the root of a word form are one and the same. So while rule (14) may look trivial, it ensures that in such cases the radicals are still captured as descendants of the non-terminal category $\underline{\text{R3}}$, thereby making their appearance in the cache.

A discontiguous non-terminal $\text{A}n$ is rewritten through recursion on its arity down to 1, i.e. $\text{A}n(v_1, \ldots, v_n) \rightarrow \text{A}l(v_1, \ldots, v_{n-1})\ \text{Char}(v_n)$ with base case $\text{A1}(v) \rightarrow \text{Char}(v)$, where Char rewrites all individual terminals as ϵ, v_i are variables and $l = n-1$.[5] Note that although we provide the model with two sets of discontiguous non-terminals R and T, we do not specify their mapping onto the actual terminal strings; no subdivision of the alphabet into vowels and consonants is hard-wired.

6 Experiments

We evaluate our model on standard Arabic, Quranic Arabic and Hebrew in terms of segmentation quality and lexicon induction ability. These languages share various properties, including morphology and lexical cognates, but are sufficiently different so as to require manual intervention when transferring rule-based morphological analysers across languages. A key question in this evaluation is therefore whether an appropriate instantiation of our model successfully generalises across related languages.

6.1 Data sets

Our models are unsupervised and therefore learn from raw text, but their evaluation requires annotated data as a gold-standard and these were derived[6] as follows:

Arabic (MSA) We created the dataset BW by synthesising 50k morphotactically correct word types from the morpheme lexicons and consistency rules supplied with the Buckwalter Arabic Morphological Analyser (BAMA).[7] This allowed control over the word shapes, which is important to focus the evaluation, while yielding reliable segmentation and root annotations. BW has no vocalisation; we denote the corresponding *vocalised* dataset as BW′.

	Types	Stems	Roots	m/w	c/w
BW	48428	24197	4717	2.3	6.4
BW′	48428	30891	4707	2.3	10.7
QU′	18808	12021	1270	1.9	9.9
HEB	5231	3164	492	2.1	6.7

Table 1: Corpus statistics, including average number of morphemes (m/w) and characters (c/w) per word, and total surface-realised roots of length 3 or 4.

Quranic Arabic We extracted the roughly 18k word types from a morphologically analysed version of the Quran (Dukes and Habash, 2010). As an additional challenge, we left all given diacritics intact for this dataset, QU′.

Hebrew We leveraged the Hebrew CHILDES database as an annotated resource (Albert et al., 2013) and were able to extract 5k word types that feature at least one affix to use as dataset HEB. The corrected versions of words marked as non-standard child language were used, diacritics were dropped, and we conflated stressed and unstressed vowels to overcome inconsistencies in the source data.

6.2 Models

We consider two classes of models. The first is the strictly context-free adaptor grammar for morphemes as sequences of characters using rules (8)-(9), which we denote as **Concat** and **MConcat**, where the latter allows multiple prefixes/suffixes in a word. These serve as baselines for the second class in which non-concatenative rules are added. **MTpl** and **Tpl** denote the canonical ver-

[5] Including the arity as part of the non-terminal symbol names forms part of our convention here to ensure that the grammar contains no cycles, a situation which would complicate inference under PYSRCAG.

[6] Our data preprocessing scripts are obtainable from `http://github.com/bothameister/pysrcag-data`.

[7] We used version 2.0, LDC2004L02, and sampled word types having a single stem and at most one prefix, suffix or both, according to the following random procedure: Sample a shape (stem: 0.1, pre+stem: 0.25 stem+suf: 0.25, pre+stem+suf: 0.4). Sample uniformly at random (with replacement) a stem from the BAMA stem lexicon, and affix(es) from the ones consistent with the chosen stem. The BAMA lexicons contain affixes and their legitimate concatenations, so some of the generated words would permit a linguistic segmentation into multiple prefixes/suffixes. Nonetheless, we take as gold-standard segmentation precisely the items used by our procedure.

sions with stems as shown in the set of rules above, and we experiment with a variant **Tpl3Ch** that allows the non-terminal T1 to be rewritten as up to three Char symbols, since the data indicate there are cases where multiple characters intervene between the radicals of a root.

These models exclude rule (10), which we include only in the variant **Tpl+T4**. Lastly, **TplR4** is the extension of **Tpl+T4** to include a stem-forming rule that uses $R4$.

As external baseline model we used **Morfessor** (Creutz and Lagus, 2007), which performs decently in morphological segmentation of a variety of languages, but only handles concatenation.

6.3 Method

The MCMC samplers converged within a few hundred iterations and we collected 100 posterior samples after 900 iterations of burn-in. Collected samples, each of which is a set of parse trees of the input word types, are used in two ways:

First, by averaging over the samples we can estimate the joint probability of a word type w and a parse tree t under the adaptor grammar, conditional on the data and the model's hyperparameters. We take the most probable parse of each word type and evaluate the implied segmentation against the gold standard segmentation. Likewise, we evaluate the implied lexicon of stems, affixes and roots against the corresponding reference sets. It should be emphasised that using this maximally probable analysis is aimed at simplifying the evaluation set-up; one could also extract multiple analyses of a word since the model defines a distribution over them.

The second method abstracts away from individual word-types and instead averages over the union of all samples to obtain an estimate of the probability of a string s being generated by a certain category (non-terminal) of the grammar. In this way we can obtain a lexicon of the morphemes in each category, ranked by their probability under the model.

6.4 Inducing Morpheme Lexicons

The quality of each induced lexicon is measured with standard set-based precision and recall with respect to the corresponding gold lexicon. The results are summarised by balanced F-scores in Table 2.

The main result is that all our models capable of forming complex stems obtain a marked improvement in F-scores over the baseline concatenative adaptor grammar, and the margin of improvement grows along with the expressivity of the complex-stem models tested. This applies across prefix, stem and suffix categories and across our datasets, with the exception of QU′, which we elaborate on in §6.5.

Stem lexicons of Arabic were learnt with relatively constant precision (∼70%), but modelling complex stems broadened the coverage by about 3000 stems over the concatenative model (against a reference set of 24k stems). On vocalised Arabic, the improvements for stems are along both dimensions. In contrast, affix lexicons for both BW and BW′ are noisy and the models all generate greedily to obtain near perfect recall but low precision.

On our Hebrew data, which comprises only 5k words, the gains in lexicon quality from modelling complex stems tend to be larger than on Arabic. This is consistent with our intuition that an appropriate, richer Bayesian prior helps overcome data sparsity.

Extracting a lexicon of roots is rendered challenging by the unsupervised nature of the model as the labelling of grammar symbols is ultimately arbitrary. Our simple approach was to regard a character tuple parsed under category R3 as a root. This had mixed success, as demonstrated by the outlier scores in Table 2. In the one case where it was obvious that T3 had been been co-opted for the role, we report the F-score obtained on the union of R3 and T3 strings.

Soft decisions The preceding set-based evaluation imposes hard decisions about category membership. But adaptor grammars are probabilistic by definition and should thus also be evaluated in terms of probabilistic ability. One method is to turn the model predictions into a binary classifier of strings using Receiver-Operator-Characteristic (ROC) theory. We plot the true positive rate versus the false positive rate for each prediction lexicon L_τ containing strings that have probability greater than τ under the model (for a grammar category of interest). A perfect classifier would rank all true positives (e.g. stem strings) above false positives (e.g. non-stem strings), corresponding to a curve in the upper left corner of the ROC plot. A random guesser would trace a diagonal line. The area under the curves (AUC) is the probability that the classifier would discriminate correctly.

	Vocalised Arabic (BW′)				**Unvocalised Arabic** (BW)				**Hebrew** (HEB)			
	Pre	Stem	Suf	R3	Pre	Stem	Suf	R3	Pre	Stem	Suf	R3

Table 3: Segmentation quality in SBF1. The QU′ results are for the corresponding **M*** models .

Our models with complex stem formation improve over the baseline on the AUC metric too. We include the ROC plots for Hebrew stem and root induction in Figure 2, along with the roots the model was most confident about (Table 4).

6.5 Morphological Analysis per Word Type

In this section we turn to the analyses our models assign to each word type. Two aspects of interest are the segmentation into sequential morphemes and the identification of the root.

Our intercalating adaptor grammars consistently obtain large gains in segmentation accuracy over the baseline concatenative model, across all our datasets (Table 3). We measure segmentation quality as *segment border F1-score* (SBF) (Sirts and Goldwater, 2013), which is the F-score over word-internal segmentation points of the predicted analysis with respect to the gold segmentation.

Of the two MSA datasets, the vocalised version BW′ presents a more difficult segmentation task as its words are on average longer and feature 31k unique contiguous morphemes, compared to the 24k in BW for the same number of words. It should thus benefit more from additional model expressivity, as is reflected in the increase of 10 SBF when adding the **TplR4** rule to the other triliteral ones.

The best triliteral root identification accuracy (on a per-word basis) was found for HEB (74%) and BW (67%).[8,9] Refer to Figure 3 for example analyses.

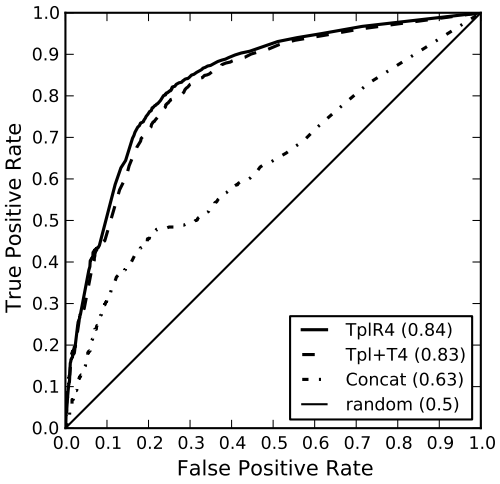
An interesting aspect of these results is that templatic rules may aid segmentation quality without necessarily giving perfect root identification. Modelling stem substructure allows any regularities that give rise to a higher data likelihood to be picked up.

The low performance on the Quran demands further explanation. All our adaptor grammars severely oversegmented this data, although the mistakes were not uniformly distributed. Most of the performance loss is on the 79% of words that have 1-2 morphemes. On the remaining words (having 3-5 morphemes), our models recover and approach the Morfessor baseline (**MConcat**: 32.7 , **MTpl3Ch**: 38.6).

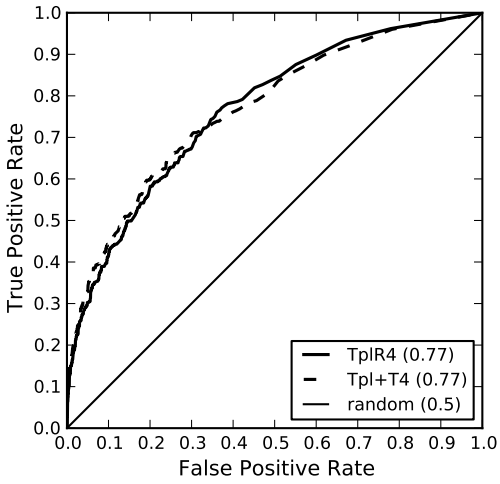
Preliminary experiments on BW had indicated that adaptation of (single) affix categories is crucial for good performance. Our multi-affixing models used on QU′ lacked a further level of adaptation for composite affixes, which we suspect as a contributing factor to the lower performance on that dataset. This remains to be confirmed in future experiments, but would be consistent with other observations on the role of hierarchical adaptation in adaptor grammars (Sirts and Goldwater, 2013). The trend that intercalated rules improve segmentation (compared to the concatenative grammar) remains consistent

[8]When excluding cases where root equals stem, root identification on BW is 55%. Those cases are still not trivial, since words without roots also exist.

[9]By way of comparison, Rodrigues and Ćavar (2007) presented an unsupervised statistics-based root identification method that obtained precision ranging between 50-75%, the higher requiring vocalised words.



(a) Stems



(b) Triliteral roots

Figure 2: ROC curves for predicting the stem and root lexicons for the HEB dataset. The area under each curve (AUC), as computed with the trapezium rule, is given in parentheses.

across datasets, despite the lower absolute performance on QU′.

The performance of the Morfessor baseline was quite mixed. Contrary to our expectations, it performs best on the "harder" BW′, worst on the arguably simpler HEB and struggled less than the adaptor grammars on QU′.

One factor here is that it learns according to a grammar with multiple consecutive affixes and stems, whereas all our experiments (except on QU′) presupposed single affixes. This biases the evaluation slightly in our favour, but works in Morfessor's favour on the QU′ data which is annotated with multiple affixes.

7 Related work

The distinctive feature of our morphological model is that it jointly addresses root identification and morpheme segmentation, and our results demonstrate the mutual benefit of this.

In contrast, earlier unsupervised approaches tend to focus on these tasks in isolation.

In unsupervised Arabic segmentation, the parametric Bayesian model of (Lee et al., 2011) achieves F1-scores in the high eighties by incorporating sentential context and inferred syntactic categories, both of which our model forgoes, although theirs has no account of discontiguous root morphemes.

Root		Example instances
1. spr ✓	G	**šaǒař**.ti te.**šaǒř** ye.**šaǒř**.u
	B	**sipur**.im hi$_x$**štaǒ**$_x$ař_t

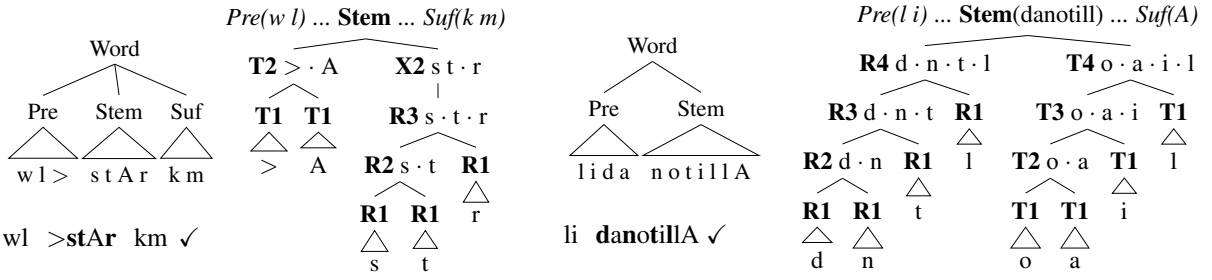
	B	le_ha$_x$**ǐǐb**i**Š** ti_t$_x$**ǐaǐbŠ**.i
3. ptx ✓	G	**ǒaťax**.ti ti.**ǒťex**.i
	B	li.**ǒťoax** ni$_x$**ǒťax**.at
5. !al ×	B	ya.**!al**.u ḿa$_x$**!aǐ**.a **!ač**ǐ$_x$an_it

Table 4: Top Hebrew roots hypothesised by **Tpl+T4**. Numbers indicate position when ranked by model probability. (G)ood and (B)ad instances from the corpus are given with morpheme boundaries marked: true positive (.), false negative (_) and false positive ($_x$). Hypothesised root characters are boldfaced, while accent (ˇ) marks gold root characters.

Previous approaches to Arabic root identification that sought to use little supervision typically constrain the search space of candidate characters within a word, leveraging pre-existing dictionaries (Darwish, 2002; Boudlal et al., 2009) or rule constraints (Elghamry, 2005; Rodrigues and Ćavar, 2007; Daya et al., 2008).

In contrast to these approaches, our model requires no dictionary, and while our grammar rules effect some constraints on what could be a root, they are specified in a convenient and flexible manner that



(a) **Concat** & **TplT4**, "wl>stArkm" (BW) (b) **Concat** & **TplR4**, "lidanotillA" (BW′)

Figure 3: Parse trees produced for words in the two standard Arabic datasets that were incorrectly segmented by the baseline grammar. The templatic grammars correctly identified the triliteral and quadriliteral roots, also fixing the segmentation of (a). In (b), the templatic grammar improved over the baseline by finding the correct prefix but falsely posited a suffix. Unimportant subtrees are elided for space, while the yields of discontiguous constituents are indicated next to their symbols, with dots marking gaps. Crossing branches are not drawn but should be inferrable. Root characters are bold-faced in the reference analysis ✓. The nonterminal X2 in (a) is part of a number of implementation-specific helper rules that ensure the appropriate handling of partly contiguous roots.

makes experimentation with other phenomena easy.

Recent work by Fullwood and O'Donnell (2013) goes some way toward jointly dealing with non-concatenative and concatenative morphology in the unsupervised setting, but their focus is limited to inflected stems and does not handle multiple consecutive affixes. They analyse the Arabic verb stem (e.g. kataba "he wrote") into a templatic bit-string denoting root and non-root characters (e.g. r-r-r-) along with a root morpheme (e.g. ktb) and a so-called residue morpheme (e.g. aaa). Their nonparametric Bayesian model induces lexicons of these entities and achieves very high performance on templates. The explicit formulation of templates alleviates the labelling ambiguity that hampered our evaluation (§6.4), but we believe their method of analysis can be simulated in our framework using the appropriate SRCG-rules.

Learning root-templatic morphology is loosely related to morphological paradigm induction (Clark, 2001; Dreyer and Eisner, 2011; Durrett and DeNero, 2013). Our models do not represent templatic paradigms explicitly, but it is interesting to note that preliminary experiments with German indicate that our adaptor grammars pick up on the past participle forming circumfix in ab+**ge**+spiel+**t** (*played back*).

8 Conclusion and Outlook

We presented a new approach to modelling non-concatenative phenomena in morphology using simple range concatenating grammars and extended adaptor grammars to this formalism. Our experiments show that this richer model improves morphological segmentation and morpheme lexicon induction on different languages in the Semitic family.

Various avenues for future work present themselves. Firstly, the lightly-supervised, meta-grammar approach to adaptor grammars (Sirts and Goldwater, 2013) can be extended to this more powerful formalism to lessen the burden of defining the "right" grammar rules by hand, and possibly boost performance. Secondly, the discontiguous constituents learnt with our framework can be used as features in other downstream applications. Especially in low-resource languages, the ability to model non-concatenative phenomena (e.g. circumfixing, ablaut, etc.) can play an important role in reducing data sparsity for tasks like word alignment and language modelling. Finally, the PYSRCAG presents another way of learning SRCGs in general, which can thus be employed in other applications of SRCGs, including syntactic parsing and translation.

Acknowledgements

We thank the anonymous reviewers for their valuable comments. Our PYSRCAG implementation leveraged the adaptor grammar code released by Mark Johnson, whom we thank, along with the individuals who contributed to the public data sources that enabled the empirical elements of this paper.

Abstract

This paper describes a method that predicts which trades players execute during a win-lose game. Our method uses data collected from chat negotiations of the game *The Settlers of Catan* and exploits the conversation to construct dynamically a partial model of each player's preferences. This in turn yields equilibrium trading moves via principles from game theory. We compare our method against four baselines and show that tracking how preferences evolve through the dialogue and reasoning about equilibrium moves are both crucial to success.

1 Introduction

Rational agents act so as to maximise their *expected utilities*—an optimal trade off between what they *prefer* and what they *believe* they can achieve (Savage, 1954). Solving a game problem involves finding *equilibrium strategies*: an optimal action for each player that maximises his expected utility, assuming that the other players perform their specified action (Shoham and Leyton-Brown, 2009). Calculating equilibria thus requires knowledge of the other players' preferences but almost all *bargaining* games occur under the handicap of imperfect information about this (Osborne and Rubinstein, 1994). Players therefore try to extract their opponents' preferences from what they say, likewise revealing their own preferences in their own utterances. These elicited preferences guide an agent's decisions, like choosing to make such and such a bargain with such and such a person. Tracking preferences through dialogue is thus crucial for analyzing the agents' strategic reasoning in real game scenarios.

In this paper, we design a model that maps what people say in a win-lose game into a prediction of exactly which players, if any, trade with each other, and exactly what resources they exchange. We use both statistics and logic: we use a corpus of negotiation dialogues to learn classifiers that map each utterance to its speech act and to other acts pertinent to bargaining; and we develop a symbolic algorithm that, from the classifiers' output, dynamically constructs a model of each player's preferences as the conversation proceeds (for instance, the preference to receive a certain resource, or to accept a certain trade). This preference model uses CP-nets (Boutilier et al., 2004), a representation of preferences for which algorithms for computing equilibrium strategies exist. We adapt those algorithms to predict the trades executed in the game.

The algorithm for construcing CP-nets uses *only* the output of our classifiers, which in turn rely entirely on shallow features in the raw text and robust parsers. Together they provide an end to end model, from raw text to a prediction of which trade, if any, occurred. We evaluate the various components of this (pipeline) algorithm separately, as well as the end to end model.

Our study exploits a corpus of negotiation dialogues from an online version of the win lose game *The Settlers of Catan*. Sections 2 and 3 describe the corpus and its annotation. Section 4 introduces our method for constructing the agents' preferences from the dialogues. We use this in Section 5 to predict whether a trade is executed as a result of the

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 357–368,
Seattle, Washington, USA, 18-21 October 2013.

players' negotiations, and if so we predict who took part in the trade, and what they exchanged. Our method shows promising results, beating baselines that don't adequately track or reason about preferences. We compare our model to related work in Section 6 and point to future work in Section 7.

2 The game

The Settlers of Catan (`www.catan.com`) is a win-lose game that involves negotiations over restricted resources. Each player (three or more) acquires resources (of 5 types: ore, wood, wheat, clay, sheep), which they use in different combinations to build roads, settlements and cities, which in turn earns them points towards winning. The first player to 10 points wins. Players acquire resources in several ways, in particular through agreed trades with other players. Some methods (e.g., robbing) are hidden from view, so players lack complete information about their opponents' resources.

Our corpus contains conversations of humans playing an online version of *Settlers* (Afantenos et al., 2012). Players must converse in a chat interface to carry out trades. Each game contains several dozen self-contained bargaining dialogues. Our experiments use 10 *Settlers* games, consisting of more than 2000 individual dialogue turns (see Section 3).

Table 1 is a sample dialogue from the corpus. The sentences in the corpus have a relatively simple syntax, though many also exhibit long distance dependencies. However, these conversations are pragmatically complex. They exhibit complex anaphoric dependences (e.g., utterance ID 4 in Table 1). Other pragmatic inferences, which are dependent on reasoning about intentions, speech acts and discourse structure, are also ubiquitous. For example, the question *Have you got any ore?* implies an offer for the speaker to receive ore in exchange for something from someone unspecified, and its response *I've got wheat* not only implies a willingness to exchange wheat for something, but as a response to the question it also implies a refusal to give any ore.

More generally, a dialogue turn in our corpus can express an offer, a counteroffer, an acceptance or rejection of an offer, or a commentary on the above or on moves in the game. All except the last provide clues about preferences: e.g., which players a speaker wants to execute a trade with; or what resources to exchange. For instance, the utterance *Anybody have any sheep for wheat?* conveys several preferences. First, it conveys the speaker's preference to trade with someone unspecified. Other informative but underspecified preferences include: the speaker's preference to acquire some sheep over alternatives; and in a context where she receives sheep, a preference to give away some of her wheat over the alternatives. Crucially, it does not convey a preference to give away wheat in a context where she receives nothing or something other than sheep.

In line with a non-cooperative bargaining game, the preferences and offers that a speaker reveals are less specific than an executable trade requires, where the trading partners and the type of resources offered and received must all be defined. Such general dialogue moves are essentially information seeking—evidence that humans playing *Settlers* have imperfect information about their opponents' preferences. In fact, many offers to trade result in no trade being agreed to and executed. While observed negotiation failure would be puzzling in a bargaining game with perfect information (Osborne and Rubinstein, 1994), it occurs relatively frequently in *Settlers*.

3 Annotation

We have a multi-layered dialogue annotation scheme that includes: (1) a pre-annotation that segments the dialogue into turns which are further segmented into Elementary Discourse Units (EDUs) with the author of each turn automatically given; (2) a characterization of each EDU in terms of basic speech acts (assertion, question, request) as well as dialogue acts that are specific to bargaining (offers, counteroffers, etc.); and (3) associated information about the givable and/or receivable resources that EDUs express.

Two annotators received training on 77 dialogues, totaling 699 EDUs. They then both annotated the remaining dialogues independently (2741 EDUs and 511 dialogues in total). Kappas for inter-annotator agreement are given below.

3.1 Dialogue act annotation (Kappa=0.79)

Each turn logs what a player enters in the chat window and also aspects of the game state at the time:

ID	Dialogue Act	Text	Speaker	Addressee	Resource
1	Offer	i need clay, any1 have?	Rainbow	All	Receivable (clay, ?)
2	Refusal	Nope, sorry	inca	Rainbow	
3	Refusal	Not at the moment, unfortunately.	ariachiba	Rainbow	
4	Refusal	need mine sorry	Kittles	Rainbow	Not givable (Anaphoric, ?) Anaphora Link:(mine , clay)
5	Offer	no one has ore to giv?	Rainbow	All	Receivable (ore, ?)
6	Accept	oh yeah me	Kittles	Rainbow	
7	Counteroffer	ore for wheat again?	Kittles	Rainbow	Givable (ore, ?) Receivable (wheat, ?)
8	Accept	ya	Rainbow	Kittles	
9	Accept	ok	Kittles	Rainbow	

Table 1: Example of an annotated negotiation dialogue.

his resources, the state of the game board and a time stamp. The pre-annotation divides each turn into EDUs. The annotators then have to specify the *dialogue act* of each EDU: *Offer*, *Counteroffer*, *Accept* or *Refusal* (of an offer addressed to the emitter), and *Other*. *Other* labels units that either comment on strategic moves in the game or are not directly pertinent to bargaining. Annotators also specify the *addressee* of the EDU and its *surface type*: *Question*, *Request* or *Assertion*.

3.2 Resource type annotation (Kappa=0.80)

Annotators also specify for each EDU and its dialogue act an associated *feature structure*, which captures (partial) information that the EDU expresses about the type and quantity of resources that are of the following four attributes: *Givable*, *Not Givable*, *Receivable* or *Not Receivable*. These attributes can take Boolean combinations of resources as values via two operators AND and OR, that respectively stand for conjunction (the agent expresses two preferences and he prefers to achieve one of them if he cannot have both, such as *I need clay and wood*) and disjunction (free choice) of preferences (e.g., *I can give you clay or wood*). We allow attributes to have unknown values: the annotation tool inserts a ? in these cases. We also insist that the annotators resolve anaphoric dependencies when specifying values to attributes, as shown in EDU (4) in Table 1.

4 Dialogue act and resource prediction

Predicting the executed trades from the dialogues starts with three sub-tasks: automatically identifying each EDU's dialogue act; detecting the EDU's resources; and specifying the attributes of those resources (i.e., *Givable*, *Receivable*, etc.).

4.1 Identifying dialogue acts

As is well established, one EDU's dialogue act depends on previous dialogue acts (Stolcke et al., 2000). In our corpus, *Accept* or *Reject* frequently follow *Offer* and *Counteroffer*. Since labeling is sequential, we use Conditional Random Fields (CRFs) to learn dialogue acts. CRFs have been shown to yield better results in dialogue act classification on online chat than HMM-SVN and Naive Bayes (Kim et al., 2012).

We use three types of features: lexical, syntactic and semantic. And we exploit them as unigrams and bigrams: unigrams associate the value of the feature with the current output class (level 0); bigrams take account of the value of the feature associated with a combination of the current output class and previous output class (level -1). 6 features were used exclusively as unigrams: the EDU's position in the dialogue, its first and last words, its subject lemma, a boolean feature to indicate if the current speaker is the one that initiates the dialogue and the position of the speaker's first turn in the dialogue.

We have 15 unigram and bigram features (at levels 0 and -1), as well as templates that combine feature values for the two levels. These include 14 boolean features that indicate if the EDU contains: bargaining verbs (e.g. *trade, offer*), references to another player (e.g. *you*), resource tokens as encoded in a task dedicated lexicon (e.g. *wheat, clay*), quantifiers (e.g. *one, none*), anaphoric pronouns, occurrences of "for" prepositional phrases (e.g. *wheat for clay*), acceptance words (e.g. *OK*), negation words, emoticons, opinion words (from (Benamara et al., 2011)), words of politeness, exclamation marks, questions, and finally whether the EDU's speaker has talked previously in the dialogue.

The last feature gives the EDU speaker lemma. In addition, 3 unigram and bigram booleans indicate whether the current EDU contains the most frequent tokens, couple of tokens and syntactic patterns in our corpus. Finally, we use 2 composed bigram features that encode whether the EDU contains an acceptance or refusal word, given that the previous EDU is a question.

To assign sequential tags of dialogue acts within a negotiation dialogue, we use the CRF++ tool (`crfpp.googlecode.com`). Our data consists of 2741 EDUs in 511 dialogues. Each EDU is associated with a dialogue act resulting in 410 *Offer*, 197 *Counteroffer*, 179 *Accept*, 398 *Refusal* and 1557 *Other*. We use 10-fold cross-validation to evaluate our model, computing precision, recall and F-score for each class and global accuracy from the total number of true positives, false positives, false negatives and true negatives obtained by summing over all fold decisions. The results (in percent) are given in Table 2 (MaF is the average of F-scores of all the classes). Our model significantly outperforms the frequency-based baseline (MaF=14.5; Accuracy=56.8), with the best F-score achieved for *Other*. The least good results are for the two least frequent classes in our data. In addition to the frequency problem, the lower score for *Counteroffer* is mainly due to the model confusing it with *Offer*. Errors in the *Accept* class were often due to misspelling or to chat style conversation; e.g., *kk*, *yup*.

Dialogue act	Precision	Recall	F-score
Other	87.4	93.1	90.1
Offer	80.0	81.0	80.5
Counterof.	64.8	53.3	58.5
Accept	65.1	53.1	58.5
Refusal	81.7	73.9	77.6
Macro-averaged F-score (MaF)			**73.0**
Accuracy			**83.0**

Table 2: Results for dialogue act classification.

4.2 Finding resource text spans

Since the resource vocabulary in *The Settlers of Catan* is a closed set composed of words denoting specific resources (e.g., *clay*, *wood*) and their synonyms (*brick*), we use a simple rule to detect them: a noun phrase (NP) is a resource text span if and only if it contains a lemma from our resource lexicon. A closed set resource vocabulary is common to many different types of negotiation dialogues. We used the Stanford parser (Klein and Manning, 2003) to obtain the NPs: there are 4361 NPs, where (by the gold standard annotations) 21% are resources and 79% are not. We obtain an F-score of 96.9% and accuracy of 97.9%, clearly beating both the frequency and random baselines for this task.

4.3 Recognizing the type of resources

Recall that each resource within an EDU can be the value of four types of attributes: *Givable, Receivable, Not Givable* or *Not Receivable* (cf. Section 3.2). We predict these attributes using CRFs with the following features. 8 features are used as unigram at the current and the previous EDU level: the speaker, the EDU's subject, the dialogue act, and (if present) the lemma of a bargaining verb, and 4 boolean features indicate if the EDU contains an opinion word, a reference to another speaker, if the resource comes after a "for" and if it contains a refusal word. These features also serve as bigrams at the current EDU level. Additionally, we have a set of unigram and bigram boolean features that indicate if the current EDU contains the most frequent verbs in the corpus. And finally, we use a feature that encodes the combination subject/bargaining verb in the current EDU.

We used CRF++ to implement our classifier. Our corpus data consists of 1077 Resources, split into 510 *Receivable*, 432 *Givable*, 116 *Not Givable* and 19 *Not Receivable*. We use again 10-fold cross-validation to evaluate our model and compute the results by summing over all fold decisions. We present them (in percent) in Table 3. They beat the frequency-based baseline (MaF=16.1; Accuracy=47.4), although performance on the *Not Receivable* class is poor probably due to its low frequency in the data.

Ambiguities make this task challenging. For instance, *anyone wheat for clay?* can mean that the speaker wants to receive wheat and give clay or the opposite, and resolving which meaning is intended involves reasoning not only with the previous and/or the following EDU, but also sometimes EDUs with long distance attachments, which are not supported by our classifier and require a full discourse parser.

Res. type	Precision	Recall	F-score
Receivable	66.8	71.4	69.0
Givable	62.6	59.7	61.1
Not Giv.	88.1	89.7	88.9
Not Rec.	0	0	0
Macro-averaged F-score (MaF)			**54.8**
Accuracy			**67.4**

Table 3: Results for resource type classification.

5 Predicting Players' Strategic Actions

We aim to capture the evolution of commitments to certain preferences as the dialogue proceeds so as to predict the agents' bargaining behavior. In other words, we wish to predict which of the 61 possible trade actions is executed at the end of each dialogue. The possible trades vary over which partner the player whose turn it is trades with (3 options in a 4 player game), the resources exchanged (assuming each partner gives one type of resource and receives another type yields $5 \times 4 = 20$ possibilities), or there is no trade; i.e., $(3 \times 20) + 1 = 61$ possible actions in the hypothesis space (we predict the types of resources that are exchanged, but not their quantity).

We predict the executed action by identifying the equilibrium trade entailed by the model of the players' preferences, which in turn we construct dynamically from the output of the classifiers in Section 4. We use the attributes of resources in the EDUs (*Givable*, etc.) to identify the preference that a speaker conveys in the EDU, and we use the dialogue acts (*Offer*, *Accept*, etc.) to update a model of the preferences expressed so far in the dialogue with this new preference (see Section 5.2). Our model of preferences consists of a set of partial CP-nets, one for each player (see Section 5.1 for details). The resulting CP-nets are then used to infer the executed trading action (if any) automatically, via well-understood principles from game theory for identifying rational behavior (Bonzon, 2007).

5.1 CP-Nets

Following Cadilhac et al. (2011), we use CP-nets (Boutilier et al., 2004) to model preferences and their dependencies. CP-nets are compatible with the kind of partial information about preferences that utterances reveal, and inference with CP-nets is computationally efficient.

Just as Bayesian nets are a graphical model that exploits probabilistic conditional independence to provide a compact representation of a joint probability distribution (Pearl, 1988), CP-nets are a graphical model that exploits *conditional preferential independence* to provide a compact representation of the preference order over all outcomes. The CP-net structures the decision maker's preferences under a *ceteris paribus* assumption: outcomes are compared, other things being equal.

More formally, let V be a finite set of variables whose combination of values determine all outcomes O. Then a *preference relation* $\succeq$ over O is a reflexive and transitive binary relation with strict preference $\succ$ defined as: $o \succeq o'$ and $o' \not\succeq o$. Indifference, written $o \sim o'$, means $o \succeq o'$ and $o' \succeq o$. Definition 1 defines *conditional preference independence* and Definition 2 defines *CP-nets*: the graphical component $\mathcal{G}$ of a CP-net specifies for each variable $X \in V$ its *parent variables* $Pa(X)$ that affect the agent's preferences over the values of X, such that X is conditionally preferentially independent of $V \setminus (\{X\} \cup Pa(X))$ given $Pa(X)$.

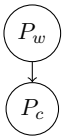
Definition 1 *Let V be a set of variables, each variable X_i with a domain $D(X_i)$. Let $\{X, Y, Z\}$ be a partition of V. X is* **conditionally preferentially independent** *of Y given Z if and only if $\forall z \in D(Z)$, $\forall x_1, x_2 \in D(X)$ and $\forall y_1, y_2 \in D(Y)$, $x_1 y_1 z \succeq x_2 y_1 z$ iff $x_1 y_2 z \succeq x_2 y_2 z$.*

Definition 2 *$\mathcal{N}_\mathcal{V} = \langle \mathcal{G}, \mathcal{T} \rangle$ is a* **CP-net** *on variables V, where $\mathcal{G}$ is a directed graph over V, and $\mathcal{T}$ is a set of Conditional Preference Tables (CPTs). That is, $\mathcal{T} = \{\text{CPT}(X_j)\text{: } X_j \in V\}$, where $\text{CPT}(X_j)$ specifies for each combination p of values of the parent variables $Pa(X_j)$ either $p : x_j \succ \overline{x_j}$, $p : \overline{x_j} \succ x_j$ or $p : x_j \sim \overline{x_j}$ where the $\overline{\ }$ symbol sets the variable to false.*

We discuss below how a CP-net predicts rational action, but first we describe how CP-nets are constructed from the dialogues. In the *Settlers* corpus, preferences involve a quadruplet *(o, a, <r,q>)* where: *o* is the preference owner, *a* is the addressee, *r* is the resource and *q* is its quantity. So each variable in the CP-nets we construct is such a quadruplet, and for each variable the possibles values are *Givable* (Giv), *Not Givable* ($\overline{Giv}$), *Receiv-*

able (Rcv) and *Not Receivable* ($\overline{Rcv}$).

For example, the utterance *Anyone want to give me a wheat for a clay?* expresses two preferences: one for receiving wheat, represented by the variable P_w = (A,All,<wheat,1>); and given this preference, another for giving clay, represented by P_c = (A,All,<clay,1>) (where A is the name of the speaker). The corresponding CP-Net is Figure 1.



CPT(P_w) = $Rcv \succ \overline{Rcv}$

CPT(P_c) = $Rcv\_P_w : Giv \succ \overline{Giv}$

Figure 1: An example CP-net

5.2 Modeling players' preferences

As stated above, we first automatically acquire a CP-net from each EDU by using the EDU's dialogue act and the attributes (*Givable*, etc.) of its resources. We then apply the rules presented in (Cadilhac et al., 2011) to dynamically construct a preference model of the dialogue overall: this uses an equivalence between their coherence relations and our dialogue acts. Our CP-nets reasoning model handles uncertain information and noise because it use as input only the outputs of the statistical models described in Section 4, and these prior models handle uncertain information and noise. The symbolic rules for constructing CP-nets have complete coverage over any possible combination of classes that are output by the statistical models, and so they are robust. We give our rules below where π_i stands for EDU ID i.

Offers. Because an *Offer* may specify or refine an existing preference or offer, we must model how the preferences expressed in an EDU that's an *Offer* updates the prior declared preferences. So, while our annotations treat *Offer* as a property of EDUs, we treat them here as *binary relations*: *Offer(π_1, π_2)*, where the second term, π_2, is the actual EDU whose dialogue act is *Offer* and π_1 is the set of EDUs occurring between π_2 and the last EDU uttered by the same speaker. *Offers* then have a similar effect on the CP-net as the coherence relation *Elaboration* presented in (Cadilhac et al., 2011). That is, to automatically update the CP-net constructed so far with a current EDU that's an *Offer*, the two step rule for *Offer(π_1, π_2)* is:

1. to update the speaker's CP-net according to the preferences expressed in π_1, and
2. if π_2 expresses preferences, to enrich the CP-net with these new preferences so that each variable in π_2 depends on each variable in π_1.

Counteroffers. They specify or modify the terms of a previous *Offer* or *Counteroffer*. Their purpose is to give new information to refine the negotiation. Like *Offers* they must also receive a contextually dependent interpretation. The rule is quite similar to that for *Offer*; however, *Counteroffer* can modify or *correct* elements in a previously introduced offer. So for *Counteroffer(π_1, π_2)*, the rule is :

1. to *partially* update the speaker's CP-net according to the preferences expressed in π_1 which do not have the same resource type (*Givable, Receivable*) than the ones in π_2.
2. same as step 2 *Offer* rule.

Accepts and Refusals. As they are answers to *Offers* and *Counteroffers*, they behave like question answer pairs (*QAPs*) presented in (Cadilhac et al., 2011). Because we are not doing full discourse parsing, we once again approximate its effects by making *Accepts* and *Refusals* respond to the set of EDUs between the current EDU and the speaker's last turn.

Accepts are positive responses to *Offers* or *Counteroffers* and are *de facto* similar to *QAP(π_1, π_2)* where π_2 is *Yes*. Thus, the rule is, as for *Offer*, to update and enrich the CP-net.

Refusals are instead negative responses and behave like *QAP(π_1, π_2)* where π_2 is *No*. For *Refusal(π_1, π_2)*, there is no update of the preferences expressed in π_1. Instead, we enrich the CP-net with the *Non Givable* and *Non Receivable* information obtained from the negation of the preferences expressed in the previous *Offer* or *Counteroffer*. We then enrich the CP-net based on any new preferences expressed in π_2. If there is a conflict between the value of a variable to be updated and the current value in the CP-net, we apply the *Correction* rule: all occurrences of the old value are replaced by the new value in π_2.

Other. This category pertains to content that does not directly relate to trading in the game, and so we choose to ignore resources expressed in the EDUs with this dialogue act.

At the end of the negotiation dialogue, to predict exactly what trade is executed (if any), the method

checks if there are complete and reciprocal preferences expressed in the CP-nets that respectively represent the declared preferences of two agents A and B. This is done in two steps. First, we use the logic of CP-nets to determine each agent's best outcome $bestO_A$ and $bestO_B$ from their respective CP-nets (we'll discuss how shortly). Secondly, we compare these best outcomes: if they correspond to the same trade, we predict that this trade was executed; if not, we predict no trade is executed. Specifically, $bestO_A$ (resp. $bestO_B$) corresponds to a preference for receiving a resource r_1 from an agent B (or from all the agents indifferently) and for giving a resource r_2 to this (or these) agent(s). We predict that A gives B r_2 and B gives A r_1 if and only if: $bestO_A = Rcv(A,\ B,\ r_1) \wedge Giv(A,\ B,\ r_2)$ and $bestO_B = Rcv(B,\ A,\ r_2) \wedge Giv(B,\ A,\ r_1)$.

The first step—computing each agent's best outcome from his CP-net—can be found in linear time using the *forward sweep algorithm* (Boutilier et al., 2004): sweep through the CP-net's graph from top to bottom, instantiating each variable with its preferred value, given the values that are (already) assigned to its parents. This algorithm is *sound* with respect to the semantics of CP-nets.

Example. We apply this method for constructing CP-nets and determining the executed trade to the negotiation dialogue presented in Table 1.

π_1 The EDU is an *Offer*, so Rainbow's CP-net is updated according to π_1's content.
CPT(R,All,<clay,?>) = $Rcv \succ \overline{Rcv}$

π_2 It's a *Refusal*, so we update inca's CP-net with the negation of the preferences expressed in Rainbow's offer.
CPT(I,R,<clay,?>) = $\overline{Giv} \succ Giv$

π_3 Idem for ariachiba.
CPT(A,R,<clay,?>) = $\overline{Giv} \succ Giv$

π_4 Idem for Kittles where the preferences expressed in this EDU are redundant with the negation of the preferences in Rainbow's offer.
CPT(K,R,<clay,?>) = $\overline{Giv} \succ Giv$

π_5 It's an *Offer*, so Rainbow's CP-net is first updated according to previous EDUs (π_2 to π_4 until his last speaking), then according to the content of π_5.
CPT(R,All,<clay,?>) = $Rcv \succ \overline{Rcv}$ ***(inactive)***
CPT(R,I,<clay,?>) = $\overline{Rcv} \succ Rcv$
CPT(R,A,<clay,?>) = $\overline{Rcv} \succ Rcv$
CPT(R,K,<clay,?>) = $\overline{Rcv} \succ Rcv$
CPT(R,All,<ore,?>) = $\overline{Rcv}$*(R,I,<clay,?>)* $\wedge$ $\overline{Rcv}$*(R,A,<clay,?>)* $\wedge$ $\overline{Rcv}$*(R,K,<clay,?>)*: $Rcv \succ \overline{Rcv}$
The introduction of the preference to receive ore conflicts with the prior one for receiving clay. So the method adds to the associated CPT the label "inactive" to indicate that this is older and should be ignored if the preference about ore is satisfied.

π_6 The EDU is an *Accept*, so Kittles's CP-net is updated according to previous EDUs (only π_5).[1]
CPT(K,R,<ore,?>) = $\overline{Giv}$*(K,R,<clay,?>)*: $Giv \succ \overline{Giv}$

π_7 The EDU is a *Counteroffer*. Since she is the last speaker, her CP-net gets updated only according to the content of the current EDU, to obtain:
CPT(K,R,<ore,?>) = $\overline{Giv}$*(K,R,<clay,?>)*: $Giv \succ \overline{Giv}$
CPT(K,R,<wheat,?>) = $\overline{Giv}$*(K,R,<clay,?>)* $\wedge$ *Giv(K,R, <ore,?>)* : $Rcv \succ \overline{Rcv}$

π_8 The EDU is an *Accept*, so Rainbow's CP-net is updated according to previous EDUs (π_6 and π_7):
CPT(R,K,<ore,?>) = $\overline{Rcv}$*(R,I,<clay,?>)* $\wedge$ $\overline{Rcv}$*(R,A,<clay,?>)* $\wedge$ $\overline{Rcv}$*(R,K,<clay,?>)* : $Rcv \succ \overline{Rcv}$
CPT(R,K,<wheat,?>) = $\overline{Rcv}$*(R,I,<clay,?>)* $\wedge$ $\overline{Rcv}$*(R,A,<clay,?>)* $\wedge$ $\overline{Rcv}$*(R,K,<clay,?>)* $\wedge$ *Rcv(R,K,<ore,?>)* : $Giv \succ \overline{Giv}$

π_9 It's an *Accept* with nothing new to update.

At the end of the dialogue, these agents' CP-nets (correctly) predict that Kittles gave ore to Rainbow in exchange for wheat.

5.3 Evaluation and results

We compare our model against four baselines. Since none of these baselines support reasoning about equilibrium moves, they all rely on the presence of an *Accept* act to predict there was a trade, and its absence to predict there wasn't. The baselines differ, however, in how they identify the trading partners and resources in an executed trade. The **first baseline** predicts a trade according to the first *Offer* and the last person to *Accept*, and if the *Offer* doesn't specify one of the resources then it is chosen randomly (similar random choices complete all partial predictions in all the models we consider here): e.g., for Table 1 this would predict that Kittles gave clay to Rainbow (which is incorrect) in exchange for

[1] Due to lack of space, in the following CP-nets, we do not copy the inactive CPTs and CPTs about *Not Givable* or *Not Receivable* resources.

something that's chosen randomly (which will probably be incorrect). The **second baseline** uses the last *Offer* and the last person to *Accept*: e.g., for Table 1 this predicts that Kittles gave ore to Rainbow (correct) for something random (probably incorrect). The **third baseline** uses the last *Offer* or *Counteroffer*, whichever is latest, and the last person to *Accept*: e.g., for Table 1 this correctly predicts that Kittles gave ore to Rainbow in exchange for wheat. And the **fourth baseline**, uses *default unification* between the prior *Offers* or *Counteroffers* and the current one to resolve any of the current offer's elided parts and to replace specific values in prior offers with conflicting specific values in the current offer (Ehlen and Johnston, 2013). One then takes the executed trade to be the result of this unification process at the point where the last *Accept* occurs. This makes the same predictions as the third baseline for Table 1, but outperforms it in the corpus example (1) by predicting the correct and *complete* trade (i.e., Rainbow gave Kittles sheep for wheat, rather than for something random):

(1) Rainbow: i need clay ore or wheat
Kittles: i got wheat
Rainbow: i cn giv sheep
Kittles: ok

We performed the evaluation on the data presented in Sections 3 and 4: 254 dialogues in total since we ignore dialogues that contain only *Other*s. 90 of these dialogues end with a trade being executed and 2 of them end with 2 trades. A random baseline would give 1.6% accuracy (given the 61 possible trading actions) and a frequency baseline (always choose no trade) gives 64.1% accuracy.

Table 4 presents the accuracy figures for all the models when calculated from the gold standard labels rather than the classifiers' predicted labels from Section 4, so that we can compare the models in isolation of the classifiers' errors. McNemar's test shows that our model significantly outperforms all the baselines ($p < 0.05$). A predicted trade counts as correct only if it specifies the right participants and the correct type of resources offered and received (we ignore their quantity). True Positives (TP) are thus examples where the model correctly predicts not only that a trade happened, but also the correct partners and resources; Wrong Positives (WP), on the other hand, constitute a correct prediction that there was a trade but errors on the partners and/or resources involved (so WPs undermine accuracy). True Negatives (TN) are examples where the model correctly predicts there was no trade (so TPs and TNs contribute to accuracy). False Positives (FP) and False Negatives (FN) are respectively incorrect predictions that there was a trade, or that there was no trade.

While Table 4 does not reflect this, the first three baselines tend to predict *incomplete* information about the trade even when what they do predict is correct: that is, they predict the correct addressee and the owner but resort to random choice for a resource that's missing from the *Offer* or *Counteroffer* that predicts which trade occurred. For the first baseline 34 examples are like this; for the second and third baselines it's 32. In contrast, this problem occurs only once with the fourth baseline, and all the trades predicted by our method are complete, making random choice unnecessary. Moreover, the first three baselines often make incorrect predictions about the addressee or resources exchanged because in contrast to our model and the fourth baseline, they don't track how potential trades *evolve* through a *sequence* of offers and counteroffers.

Even though the fourth baseline, which uses default unification to track the content of the current offer, is smart and gives good results, it has statistically significant lower accuracy than our model. One major problem with the fourth baseline is that, in contrast to our model, it does not track each player's *attitude* towards the current offer. Instead, like all our baselines, it relies on the presence of an *Accept* act to predict that there's a trade.[2] But several corpus examples are like (2), in which a trade is executed but there's no *Accept* act, thus yielding a False Negative (FN) for all four baselines:

(2) Joel: anyone have sheep or wheat
Cardlinger: neither :(
Joel: will give clay or ore
Euan: not just now
Jon: got a wheat for a clay
(*Joel gives clay to Jon and receives wheat*)

[2]We tried a baseline that doesn't rely on the presence of an *Accept* act, but rather predicts a trade whenever default unification yields a complete offer. It performed worse than the fourth baseline.

So overall, our analysis shows that using CP-nets significantly outperforms all baselines that don't model how preferences evolve in the dialogue, and error analysis yields evidence that our model outperforms the fourth baseline because our model supports *reasoning* about player preferences, rational behavior and equilibrium strategies.

1st baseline: first *Offer*/last *Accept*					
TP	FP	FN	TN	WP	Accuracy
24	14	30	150	38	**68.0**
2nd baseline: last *Offer*/last *Accept*					
TP	FP	FN	TN	WP	Accuracy
29	6	32	158	31	**73.0**
3rd baseline: last *(Counter)Offer*/last *Accept*					
TP	FP	FN	TN	WP	Accuracy
39	4	23	160	30	**77.7**
4th baseline: *default unification*					
TP	FP	FN	TN	WP	Accuracy
64	4	23	160	5	**87.5**
Our method					
TP	FP	FN	TN	WP	Accuracy
75	4	15	160	2	**91.8**

Table 4: Results for trade prediction. TP, FP, FN, TN and WP are the True and False Positives, False and True Negatives and Wrong Positives.

Table 5 presents the results for the end to end evaluation, where trade predictions are made from the classifiers' output from Section 4 rather than the gold standard labels. As expected, performance decreases due to the classifiers' errors, mainly on the type of resources (*Givable*, etc.). But our method still significantly outperforms all the baselines with an accuracy of 73.4% when the baselines obtain values between 60.9% and 68.4%.

4th baseline: *default unification*					
TP	FP	FN	TN	WP	Accuracy
23	12	37	152	32	**68.4**
Our method					
TP	FP	FN	TN	WP	Accuracy
34	10	43	154	15	**73.4**

Table 5: Results for the end to end trade prediction.

6 Related Work

6.1 Dialogue act modeling

Most work on dialogue act modeling focuses on spoken dialogue (Stolcke et al., 2000; Fernández et al., 2005; Keizer et al., 2002). But live chats introduce specific complications (Kim et al., 2012): ill-formed data, abbreviations and acronyms, emotional indicators and entanglement (especially for multi-party chat). Among related work in this emerging field, Joty et al. (2011) use unsupervised learning to model dialogue acts in Twitter, Ivanovic (2008) and Kim et al. (2010) analyze one-to-one online chat in a customer service domain, and Wu et al. (2002) and Kim et al. (2012) predict dialogue acts in a multi-party setting. We used a similar classifier to predict dialogue acts as the one reported in (Kim et al., 2012) and evaluation yields similar results.

This paper proposes an approach to dialogue act identification in online chat that aims to predict strategic actions like bargaining. Compared to (Sidner, 1994) and DAMSL (Core and Allen, 1997), our domain level annotation is much more detailed: we not only predict moves like *Accept* but also features like the *Givable* and *Receivable* resources. Our general speech act typology of EDUs lacks intentional descriptions of speech acts, however. This reflects a conscious choice to specify the semantics of each act purely by the public commitments made to offer or to receive goods.

6.2 Preference extraction

While preference extraction from non-linguistic actions is well studied (Chen and Pu, 2004; Fürnkranz and Hüllermeier, 2011), their extraction from spontaneous conversation has received little attention. To our knowledge, the only existing work is (Asher et al., 2010; Cadilhac et al., 2011; Cadilhac et al., 2012) which we build on. Cadilhac et al. (2011) compute CP-nets from *coherence relations*, found in the annotation of the Verbmobil corpus (Baldridge and Lascarides, 2005). Here we adapt their algorithm from coherence relations to *unary* dialogue acts. Further, while they assume that preferences are given, here we apply versions of the NLP techniques from Cadilhac et al (2012) to *estimate* the preferences of EDUs automatically. And we go further than any of these works by using the elicited pref-

erences to infer the domain-level actions that result from information exchanged in the conversation.

In this respect, our work relates to models for *grounding language*, where semantic parsing techniques are used to automatically map linguistic instructions to domain-level actions (Artzi and Zettlemoyer, 2013; Kim and Mooney, 2013). Our domain of application is more challenging, however: to our knowledge, this is the first attempt to map *non-cooperative* dialogues into predictions about domain-level actions. We can tackle these strategic scenarios because we exploit a logic of preferences as part of our model, yielding inferences about rational action even when agents' preferences conflict.

Compared to previous work, our task is new. Our aim is not to predict what dialogue act to perform next, but what non verbal action should be performed, mapping dialogue acts to non verbal actions. The difference between our work and other work on grounding is that we are grounding non-cooperative dialogue rather than instructions in a cooperative setting. There is no prior work of which we're aware that maps a non-cooperative dialogue into a prediction about which joint non-verbal action the agents will do as a result of what they've learned about their opponent through conversation. Furthermore, both the CP-net and the fourth baseline, whose accuracy is quite high (making it a hard baseline to beat), use the dialogue history as they incrementally build up the preference model.

6.3 Predicting strategic actions

Modeling player behavior in real-time strategy games is a growing research area in AI. These models can be used to identify common strategic states, discover new strategies as they emerge or predict an opponents future actions and so help players to optimize their choices. For example, Schadd et al. (2007) develop a hierarchical opponent model in the game *Spring*, Dereszynski et al. (2011) reason about strategic behavior in *StarCraft* using hidden Markov models and Amato and Shani (2010) use reinforcement learning to acquire a policy for switching among high-level strategies in *Civilization IV*.

In comparison, we propose a novel approach for predicting strategic action based on the *symbolically* formalized preferences that each agent commits to in spontaneous conversation. Our approach thus deals with imperfect information by exploiting the agents' declared preferences. By predicting what bargain (if any) will take place, we are able to verify the correctness of our preference descriptions. Our task is a subtask of learning a strategy over an entire game space, but our approach yields good predictive results on relatively little data—an advantage of exploiting CP-nets and the symbolic rules that guide their evolution from observable evidence.

7 Conclusion

We have proposed a linguistic approach to strategy prediction in spontaneous conversation, exploiting dialogue acts to build a partial model of the agents' declared preferences. Our method tracks how preferences evolve during the dialogue, which we use to infer their bargaining behavior, i.e. what resources, if any, are exchanged, and by whom.

We based our study on a corpus collected using an online version of *The Settlers of Catan*. Negotiations in this game mirror complex real life negotiations and provide a fruitful arena to study strategic conversation. Evaluation shows that our approach provides more accurate and complete information about trades than baselines that don't track how an offer evolves through the dialogue, and we also argued that game-theoretic reasoning about rational behavior has advantages over relying on the presence or absence of an *Accept* act to make predictions.

Our approach, however, does not exploit discourse structure, which is needed to properly handle long distance dependencies of offers on prior material. We will exploit this in future work to improve our results. We also plan to investigate other aspects of strategic reasoning on a larger dataset.

We have proposed a method that relies on a typology of dialogue acts that is domain sensitive. However, in other work we have shown how to adapt our algorithms to several domains (Cadilhac et al., 2012). In future work, we plan to link our preference extraction algorithms to an automatically acquired discourse structure for a given text. This will provide a domain independent means for extracting preferences from dialogue.

Abstract

Human engagement in narrative is partially driven by reasoning about discourse relations between narrative events, and the expectations about what is likely to happen next that results from such reasoning. Researchers in NLP have tackled modeling such expectations from a range of perspectives, including treating it as the inference of the CONTINGENT discourse relation, or as a type of common-sense causal reasoning. Our approach is to model likelihood between events by drawing on several of these lines of previous work. We implement and evaluate different unsupervised methods for learning event pairs that are likely to be CONTINGENT on one another. We refine event pairs that we learn from a corpus of film scene descriptions utilizing web search counts, and evaluate our results by collecting human judgments of contingency. Our results indicate that the use of web search counts increases the average accuracy of our best method to 85.64% over a baseline of 50%, as compared to an average accuracy of 75.15% without web search.

1 Introduction

Human engagement in narrative is partially driven by reasoning about discourse relations between narrative events, and the expectations about what is likely to happen next that results from such reasoning (Gerrig, 1993; Graesser et al., 1994; Lehnert, 1981; Goyal et al., 2010). Thus discourse relations are one of the primary means to structure narrative in genres as diverse as weblogs, search queries, stories, film scripts and news articles (Chambers and Jurafsky, 2009; Manshadi et al., 2008; Gordon and Swanson, 2009; Gordon et al., 2011; Beamer and Girju, 2009; Riaz and Girju, 2010; Do et al., 2011).

DOUGLAS QUAIL and his wife KRISTEN, are asleep in bed.
Gradually the room lights brighten. the clock chimes and begins speaking in a soft, feminine voice.
They don't budge. Shortly, the clock chimes again.
Quail's wife stirs. Maddeningly, the clock chimes a third time.
CLOCK (continuing)Tick, tock –.
Quail reaches out and shuts the clock off. Then he sits up in bed.
He swings his legs out from under the covers and sits on the edge of the bed. He puts on his glasses and sits, lost in thought.
He is a good-looking but conventional man in his early thirties. He seems rather in awe of his wife, who is attractive and rather off-hand towards him.
Kirsten pulls on her robe, lights a cigarette, sits fishing for her slippers.

Figure 1: Opening Scene from Total Recall

Recent work in NLP has tackled the inference of relations between events from a broad range of perspectives: (1) as inference of a discourse relations (e.g. the Penn Discourse Treebank (PDTB) CONTINGENT relation and its specializations); (2) as a type of common sense reasoning; (3) as part of text understanding to support question-answering; and (4) as way of learning script-like or plot-like knowledge structures. All these lines of work aim to model narrative understanding, i.e. to enable systems to infer which events are likely to **have happened** even though they have not been mentioned in the text (Schank et al., 1977), and which events are likely **to happen** in the future. Such knowledge has practical applications in commonsense reasoning, infor-

Seattle, Washington, USA, 18-21 October 2013.

mation retrieval, question answering, narrative understanding and inferring discourse relations.

We model this likelihood between events by drawing on the PTDB's general definition of the CONTINGENT relation, which encapsulates relations elsewhere called CAUSE, CONDITION and ENABLEMENT (Prasad et al., 2008a; Lin et al., 2010; Pitler et al., 2009; Louis et al., 2010). Our aim in this paper is to implement and evaluate a range of different unsupervised methods for learning event pairs that are likely to be CONTINGENT on one another.

We first utilize a corpus of scene descriptions from films because they are guaranteed to have an explicit narrative structure. Moreover, screenplay scene descriptions tend to be told in temporal order (Beamer and Girju, 2009; Gordon and Swanson, 2009), which makes them a good resource for learning about contingencies between events. In addition, scenes in film represent many typical sequences from real life, while providing a rich source of event clusters related to battles, love and mystery. We carry out separate experiments for the action movie genre and the romance movie genre. For example, in the scene from *Total Recall*, from the action movie genre (See Fig. 1), we might learn that the event of `sits up` is CONTINGENT on the event of `clock chimes`. The subset of the corpus we use comprises 123,869 total unique event pairs.

We produce initial scalar estimates of potential CONTINGENCY between events using four previously defined measures of distributional co-occurrence. We then refine these estimates through web searches that explicitly model the patterns of narrative event sequences that were previously observed to be likely within a particular genre. There are several advantages of this method: (1) events in the same genre tend to be more similar than events across genres, so less data is needed to estimate co-occurrence; (2) film scenes are typically narrated via simple tenses in the correct temporal order, which allows the ordering of events to contribute to the estimation of the CONTINGENCY relation; (3) The web counts focus on validating event pairs already deemed to be likely to be CONTINGENT in the smaller, more controlled, film scene corpus. To test our method, we conduct perceptual experiments with human subjects on Mechanical Turk by asking them to select which of two pairs of events are the most likely. For example, given the scene from *Total Recall* in Fig. 1, Mechanical Turkers are asked to select whether the sequential event pair `clock chimes, sits up` is more likely than `clock chimes` followed by a randomly selected event from the **action** film genre. Our experimental data and annotations are available at `http://nlds.soe.ucsc.edu/data/EventPairs`.

Sec. 2 describes our experimental method in detail. Sec. 3 describes how we set up our evaluation experiments and the results. We show that none of the methods from previous work perform better on our data than 75.15% average accuracy as measured by human perceptions of CONTINGENCY. But after web search refinement, we achieve an average accuracy of 85.64%. We delay a more detailed comparison to previous work to Sec. 4 where we summarize our results and compare previous work to our own.

2 Experimental Method

Our method uses a combination of estimating the likelihood of a CONTINGENT relation between events in a corpus of film scenes (Walker et al., 2012b), with estimates then revised through web search. Our experiments are based on two subsets of 862 film screen plays collected from the IMSDb website using its ontology of film genres (Walker et al., 2012b): a set of **action** movies of 115 screenplays totalling 748 MB, and a set of **romance** movies of 71 screenplays totalling 390 MB. Fig. 1 provided an example scene from the action movie genre from the IMSDb corpus.

We assume that the relation we are aiming to learn is the PDTB CONTINGENT relation, which is defined as a relation that exists when one of the situations described in the text spans that are identified as the two arguments of the relation, i.e. Arg1 and Arg2, causally influences the other (Prasad et al., 2008b). As Girju notes, it is notoriously difficult to define causality without making the definition circular, but we follow Beamer and Girju's work in assuming that if events A, B are causally related then B should occur less frequently when it is not preceded by A and that B $\rightarrow$A should be much less frequent than A $\rightarrow$ B. We assume that both the CAUSE and CONDITION subtypes of the CONTINGENCY relation will result in pairs of events that are likely to occur together and in a particular order. In particular we assume that the subtypes of the PDTB taxonomy of Contingency.Cause.Reason and Contingency.Cause.Result are the most likely to occur together as noted in previous work. Other related

work has made use of discourse connectives or discourse taggers (implicit discourse relations) to provide additional evidence of CONTINGENCY (Do et al., 2011; Gordon et al., 2011; Chiarcos, 2012; Pitler et al., 2009; Lin et al., 2010), but we do not because the results have been mixed. In particular these discourse taggers are trained on The Wall Street Journal (WSJ) and are unlikely to work well on our data.

We define an event as a verb lemma with its subject and object. Two events are considered equal if they have the same verb. We do not believe word ambiguities to be a primary concern, and previous work also defines events to be the same if they have the same surface verb, in some cases with a restriction that the dependency relations should also be the same (Chambers and Jurafsky, 2008; Chambers and Jurafsky, 2009; Do et al., 2011; Riaz and Girju, 2010; Manshadi et al., 2008). Word sense ambiguities are also reduced in specific genres (Action and Romance) of film scenes.

Our method for estimating the likelihood of a CONTINGENT relations between events consists of four steps:

1. TEXT PROCESSING: We use Stanford CoreNLP to annotate the corpus document by document and store the annotated text in XML format (Sec. 2.1);

2. COMPUTE EVENT REPRESENTATIONS: We form intermediate artifacts such as events, protagonists and event pairs from the annotated documents. Each event has its arguments (subject and object). We calculate the frequency of the event across the relevant genre (Sec. 2.2);

3. CALCULATE CONTINGENCY MEASURES: We define 4 different measures of contingency and calculate each one separately using the results from Steps 1 and 2 above. We call each result a PREDICTED CONTINGENT EVENT PAIR (**PCEP**). All measures return scalar values that we use to rank the PCEPs (Sec. 2.3);

4. WEB SEARCH REFINEMENT: We select the top 100 event pairs calculated by each contingency measure, and construct a RANDOM EVENT PAIR (**REP**) for each PCEP that preserves the first element of the PCEP, and replaces the second element with another event selected randomly from within the same genre. We then define web search patterns for both PCEP and REPs and compare the counts (Sec. 2.4).

2.1 Text Processing

We first separate our screen plays into two sets of documents, one for the action genre and one for the romance genre. Because we are interested in the event descriptions that are part of the scene descriptions, we excise the dialog from each screen play. Then using the Stanford CoreNLP pipeline, we annotate the film scene files. Annotations include tokenization, lemmatization, named entity recognition, parsing and coreference resolution.

We extract the events by keeping all tokens whose POS tags begin with `VB`. We then use the dependency parse to find the subject and object of each verb (if any), considering only `nsubj, agent, dobj, iobj, nsubjpass`. We keep the original tokens of the subject and the object for further processing.

2.2 Compute Event Representations

Given the results of Step 1 we start by generalizing the subject and object stored with each event by substituting tokens with named entities if there are any named entities tagged. Otherwise we generalize the subjects and the objects using their lemmas. For example, `person UNLOCK door`, as illustrated in Table 1.

We then integrate all the subjects and objects across all film scene files, keeping a record of the frequency of each subject and object. For example, `[person (115), organization (14), door (3)] UNLOCK [door (127), person (5), bars (2)]`. The most frequent subject and object are selected as representative arguments for the event. We then count the frequency of each event across all the film scene files.

Within each film scene file, we count adjacent events as potential CONTINGENT event pairs. Two event pairs are defined as equal if they have the same verbs in the same order. We also count the frequency of each event pair.

2.3 Calculate Contingency Measures

We calculate four different measures of CONTINGENCY based on previous work using the results of Steps 1 and 2 (Sec. 2.1 and Sec. 2.2). These measures are pointwise mutual information, causal potential, bigram probability and protagonist-based

causal potential as described in detail below. We calculate each measure separately by genre for the action and romance genres of the film corpus.

Pointwise Mutual Information. The majority of related work uses pointwise mutual information (**PMI**) in some form or another (Chambers and Jurafsky, 2008; Chambers and Jurafsky, 2009; Riaz and Girju, 2010; Do et al., 2011). Given a set of events (a verb and its collected set of subjects and objects), we calculate the PMI using the standard definition:

$$pmi(e_1, e_2) = \log \frac{P(e_1, e_2)}{P(e_1)P(e_2)} \quad (1)$$

in which e_1 and e_2 are two events. $P(e_1)$ is the probability that event e_1 occur in the corpus:

$$P(e_1) = \frac{count(e_1)}{\sum_x count(e_x)} \quad (2)$$

where $count(e_1)$ is the count of how many times event e_1 occurs in the corpus, and $\sum_x count(e_x)$ is the count of all the events in the corpus. The numerator is the probability that the two events occur together in the corpus:

$$P(e_1, e_2) = \frac{count(e_1, e_2)}{\sum_x \sum_y count(e_x, e_y)} \quad (3)$$

in which $count(e_1, e_2)$ is the number of times the two events e_1 and e_2 occur together in the corpus regardless of their order. Only adjacent events in each document are paired up. PMI is a symmetric measurement for the relationship between two events. The order of the events does not matter.

Causal Potential. Beamer and Girju proposed a measure called Causal Potential (**CP**) based on previous work in philosophy and logic, along with an annotation test for causality. An annotator deciding whether event A causes event B asks herself the following questions, where answering yes to both means the two events are causally related:

- Does event A occur before (or simultaneously) with event B?
- Keeping constant as many other states of affairs of the world in the given text context as possible, does modifying event A entail predictably modifying event B?

As Beamer & Girju note, this annotation test is objective, and it is simple to execute mentally. It only assumes that the average person knows a lot about how things work in the world and can reliably answer these questions. **CP** is then defined below, where the arrow notation means ordered bigrams, i.e. event e_1 occurs before event e_2:

$$\phi(e_1, e_2) = pmi(e_1, e_2) + \log \frac{P(e_1 \rightarrow e_2)}{P(e_2 \rightarrow e_1)} \quad (4)$$

$$\text{where } pmi(e_1, e_2) = \log \frac{P(e_1, e_2)}{P(e_1)P(e_2)}$$

The causal potential consists of two terms: the first is pair-wise mutual information (PMI) and the second is relative ordering of bigrams. PMI measures how often events occur as a pair; whereas relative ordering counts how often event order occurs in the bigram. If there is no ordering of events, the relative ordering is zero. We smooth unseen event pairs by setting their frequency equal to 1 to avoid zero probabilities. For **CP** as with PMI, we restrict these calculations to adjacent events. Column CP of Table 1 below provides sample values for the CP measure.

Probabilistic Language Models. Our third method models event sequences using statistical language models (Manshadi et al., 2008). A language model estimates the probability of a sequence of words using a sample corpus. To identify contingent event sequences, we apply a bigram model which estimates the probability of observing the sequence of two words w_1 and w_2 as follows:

$$P(w_1, w_2) \cong P(w_2|w_1) = \frac{count(w_1, w_2)}{count(w_1)} \quad (5)$$

Here, the words are events. Each verb is a single event and each film scene is treated as a sequence of verbs. For example, consider the following sentence from *Total Recall*:

> *Quail and Kirsten sit at a small table, eating breakfast.*

This sentence is represented as the sequence of its two verbs: `sit, eat`. We estimate the probability of verb bigrams using Equation 5 and hypothesize that the verb sequences with higher probability are

Row #	Causal Potential Pair	CP	PCEP Search pattern	NumHits	Random Pair	REP Search pattern	NumHits

Table 1: Sample web search patterns and values used in web search refinement algorithm from action genre

more likely to be contingent. We apply a threshold of 20 for $count(w_1, w_2)$ to avoid infrequent and uncommon bigrams.

Protagonist-based Models. We also used a method of generating event pairs based not only on the consecutive events in text but on their protagonist. This is based on the assumption that the agent, or protagonist, will tend to perform actions that further her own goals, and are thus causally related. We called this method protagonist-based because all events were partitioned into multiple sets where each set of events has one protagonist. This method is roughly based on previous work using chains of discourse entities to induce narrative schemas (Chambers and Jurafsky, 2009).

Events that share one protagonist were extracted from text according to co-referring mentions provided by the Stanford CoreNLP toolkit.[1] A manual examination of coreference results on a sample of movie scripts suggests that the accuracy is only around 60%: most of the time the same entity (in its nominal and pronominal forms) was not recognized and was assigned as a new entity.

We preserve the order of events based on their textual order assuming as above that film scripts tend to preserve temporal order. An ordered event pair is generated if both events share a protagonist. We further filter event pairs by eliminating those whose frequency is less than 5 to filter insignificant and rare event pairs. This also tends to catch errors generated by the Stanford parser.

CP was then calculated accordingly to Equation 4. To calculate the PMI part of **CP**, we combine the frequencies of event pairs in both orders.

2.4 Web Search Refinement

The final step of our method is WEB SEARCH REFINEMENT. Our hypothesis is that using the film corpus within a particular genre to do the initial estimates of contingency takes advantage of genre properties such as similar events and narration of scenes in chronological order. However the film corpus is necessarily small, and we can augment the evidence for a particular contingent relation by defining specific narrative sequence patterns and collecting web

[1] http://nlp.stanford.edu/software/corenlp.shtml

counts.

Recall that **PCEP** stands for predicted contingent event pair and that **REP** stands for random event pair. We first select the top 100 event pairs calculated by each CONTINGENCY measure, and construct a RANDOM EVENT PAIR (**REP**) for each PCEP that preserves the first element of the PCEP, and replaces the second element with another event selected randomly from within the same genre. We then define web search patterns for both PCEP and REPs and compare the counts. PCEPs should be frequent in web search and REPs should be infrequent.

Our web refinement procedure is:

- For each event pair, PCEPs and REPs, create a Google search pattern as illustrated by Table 1, and described in more detail below.
- Search for the exact match in Google general web search using incognito browsing and record the estimated count of results returned;
- Remove all the PCEP/REP pairs with PCEP Google search count less than 100: highly contingent events should be frequent in a general web search;
- Remove all PCEP/REP pairs with REP Google search count greater than 100: events that are not contingent on one another should not be frequent in a general web search.

The motivation for this step is to provide additional evidence **for** or **against** the contingency of a pair of events. Table 1 shows a selection of the top 100 PCEPs learned using the Causal potential (**CP**) Metric, the web search patterns that are automatically derived from the PCEPs (Column 4), the REPs that were constructed for each PCEP (Column 6), the web search patterns that were automatically derived from the REPs (Column 7). Column 5 shows the results of web search hits for the PCEP patterns and Column 8 shows the results of web search hits for the REP patterns. These hit counts were then used in refining our estimates of CONTINGENCY for the learned patterns as described above.

Note that the web search patterns do not aim to find every possible match of the targeted CONTINGENT relation that could possibly occur. Instead, they are **generalizations** of the instances of PCEPs that we found in the films corpus that are targeted at finding hits that are the most likely to occur in **narrative sequences**. Narrative sequences are most reliably signalled by use of the historical present tense, e.g. as instantiated in the search patterns *He knows* in Row 1 and *He comes* in Row 2 of Table 1 (Swanson and Gordon, 2012; Beamer and Girju, 2009; Labov and Waletzky, 1997). In addition, we use the "*" operator in Google Search to limit search to pairs of events reported in the historical present tense, that are "near" one another, and in a particular sequence. We don't care whether the events are in the same utterance or in sequential utterances, thus for the second verb (event) we do not include a subject pronoun *he*. These search patterns are not intended to match the original instances in the film corpus and in general they are unlikely to match those instances.

For example, consider the search patterns and results shown in Row 1 of Table 1. The PCEP is (`person KNOW person, person MEAN what`). The REP is (`person KNOW person, person PEDDLE papers`). Our prediction is that the REP should be much less likely in web search counts and the results validate that predication. A paired t-test over the 100 top PCEP pairs for the CP measure comparing the hit counts for the PCEP pairs vs. the REP pairs was highly significant ($p < .00001$). However, consider Row 7. Even though in general the PCEP pairs are more likely (as measured by the paired t-test comparing web search counts for PCEPs vs REPs), there are cases where the REP is highly likely as shown by the REP (`person take person, person CATCH person`) in Row 7. Alternatively there are cases where the web search counts provide evidence against one of the PCEPs. Consider Rows 3, 4, 10 and 12. In all of these cases the web counts NumHits for the PCEP number in the tens.

After the web search refinement, we retain the PCEP/REP pairs with initially high PCEP estimates, for which we found good evidence for contingency and for randomness, e.g. Row 1 and 2 in Table 1. We use 100 as a threshold because most of the time the estimate result count from Google is either a very large number (millions) or a very small number (tens), as illustrated by the NumHits columns in Table 1.

We experimented with different types of patterns with a development set of PCEPs before we settled on the search pattern template shown in Table 1. We

decided to use third person rather than first person patterns, because first person patterns are only one type of narrative (Swanson and Gordon, 2012). We also decided to utilize event patterns without typical objects, such as *head* in `person REST head` in Row 2 of Table 1. We do not have any evidence that this is the optimal search pattern template because we did not systematically try other types of search patterns.

3 Evaluation and Results

While other work uses a range of methods for evaluating accuracy, to our knowledge our work is the first to use human judgments from Mechanical Turk to evaluate the accuracy of the learned PCEPs. We first describe the evaluation setup in Sec. 3.1 and then report the results in Sec. 3.2

3.1 Mechanical Turk Contingent Pair Evaluations

We used three different types of HITs (Human Intelligence Tasks) on Mechanical Turk for our evaluation. Two of the HITS are in Fig. 2 and Fig. 3. The differences in the different types of HITS involve: (1) whether the arguments of events were given in the HIT, as in Fig. 2 and (2): whether the Turkers were told that the order of the events mattered, as in Fig. 3. We initially thought that providing the arguments to the events as shown in Fig. 2 would help Turkers to reason about which event was more likely. We tested this hypothesis only in the action genre for the Causal Potential Measure. For CP, Bigram and Protag the order of events always matters. For the PMI task, the order of the events doesn't matter because PMI is a symmetric measure. Fig. 2 illustrates the instructions that were given with the HIT when the event order doesn't matter. In all the other cases, the instructions that were given with the HIT are those in Fig. 3 where the Turkers are instructed to pay attention to the order of the events.

For all types of HITS, for all measures of CONTINGENCY, we set up the task as a choice over two alternatives, where for each predicted contingent pair (PCEP), we generate a random event pair (REP), with the first event the same and the second one randomly chosen from all the events in the same film genre. The REPs are constructed the same way as we construct REPs for web search refinement, as illustrated by Table 1. This is illustrated in both Fig. 2 and Fig. 3. For all types of HITS, we ask 15 Turkers from a pre-qualified group to select which pair (the PCEP or the REP) is more likely to occur together. Thus, the framing of these Mechanical Turk tasks only assumes that the average person knows how the world works; we do not ask them to explicitly reason about causality as other work does (Beamer and Girju, 2009; Gordon et al., 2011; Do et al., 2011).

For each measure of CONTINGENCY, we take 100 event pairs with highest PCEP scores, and put them in 5 HITs with twenty items per HIT. Previous work has shown that for many common NLP tasks, 7 Turkers' average score can match expert annotations (Snow et al., 2008). However, we use 15 Turkers because we had no gold-standard data and because we were not sure how difficult the task is. It is clearly subjective. To calculate the accuracy of each method, we computed the average correlation coefficient between each pair of raters and eliminate the 5 lowest scoring workers. We then used the perceptions of the 10 remaining workers to calculate accuracy as # of correct answers / total # of answers.

In general, deciding when a MTurk worker is unreliable when the data is subjective is a difficult problem. In the future we plan to test other solutions to measuring annotator reliability as proposed in related work (Callison-Burch, 2009; Snow et al., 2008; Karger et al., 2011; Dawid and Skene, 1979; Welinder et al., 2010; Liu et al., 2012).

3.2 Results

We report our results in terms of overall accuracy. Because the Mechanical Turk task is a choose-one question rather than a binary classification, Precision = Recall in our experimental results:

$$\text{True Positive} = \text{Number of Correct Answers}$$
$$\text{True Negative} = \text{Number of Correct Answers}$$
$$\text{False Positive} = \text{Number of Incorrect Answers}$$
$$\text{False Positive} = \text{Number of Incorrect Answers}$$
$$\text{Precision} = \frac{\text{True Positive}}{\text{True Positive} + \text{False Positive}}$$
$$\text{Recall} = \frac{\text{True Positive}}{\text{True Positive} + \text{False Negative}}$$

The accuracies of all the methods are shown in Table 2. The results of using event arguments (`person KNOW person`) in the Mechanical Turk evaluation task (i.e. Fig. 2) is given in Rows 1 and 2 of Table 2. The accuracies for Rows 1 and 2 are

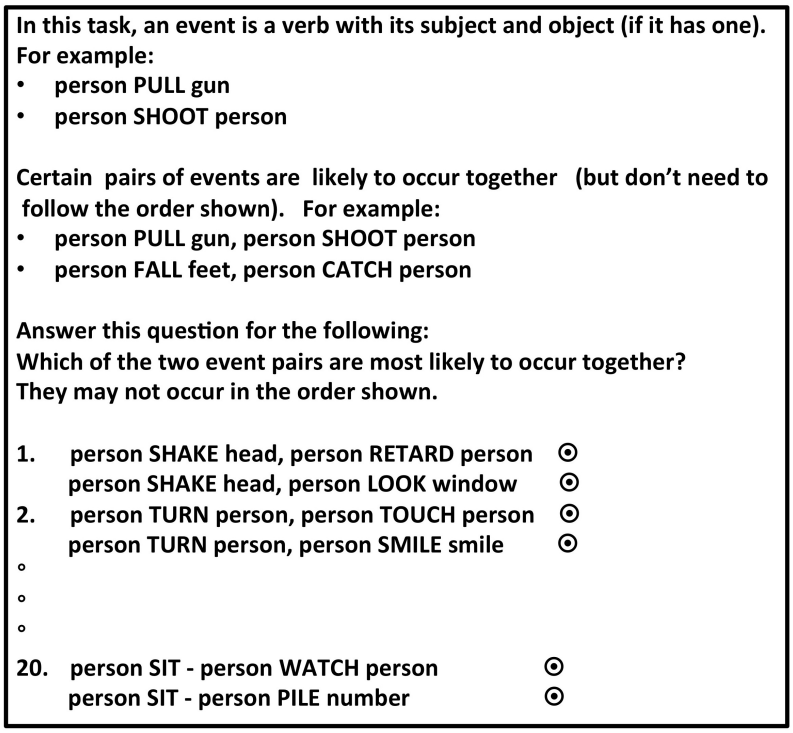

Figure 2: Mechanical Turk HIT with event arguments provided. This HIT also illustrates instructions where Turkers are told that the order of the events **does not** matter.

Row #	Contingency Estimation Method	Action Acc%	Romance Acc%	Average Acc%
1	CP with event arguments	69.30	NA	69.30
2	CP with event arguments + Web search	77.57	NA	77.57
3	CP no args	75.20	75.10	75.15
4	CP no args +Web Search	**87.67**	83.61	**85.64**
5	PMI no args	68.70	79.60	74.15
6	PMI no args +Web Search	72.11	**88.52**	80.32
7	Bigram no args	67.10	66.50	66.80
8	Bigram no args +Web Search	72.40	70.14	71.27
9	Protag CP no args	65.40	68.20	66.80
10	Protag CP no args +Web Search	76.59	64.10	70.35

Table 2: Evaluation results for the top 100 event pairs using all methods.

considerably lower than when the PCEPs are tested without arguments. Comparing Rows 1 and 2 with Rows 3 and 4 suggests that even if the arguments provide extra information that help to ground the type of event, in some cases these constraints on events may mislead the Turkers or make the evaluation task more difficult. There is an over 10% increase in CP + Web search accuracy for the task that omits the event arguments (i.e. Fig. 3 as can be seen by comparing Row 2 with Row 4. Thus omitting the arguments of events in evaluations actually appears to allow Turkers to make better judgments.

In addition, Table 2 shows clearly that for every single method, accuracy is improved by refining the initial estimates of contingency using the narrative-based web search patterns. Web search in-

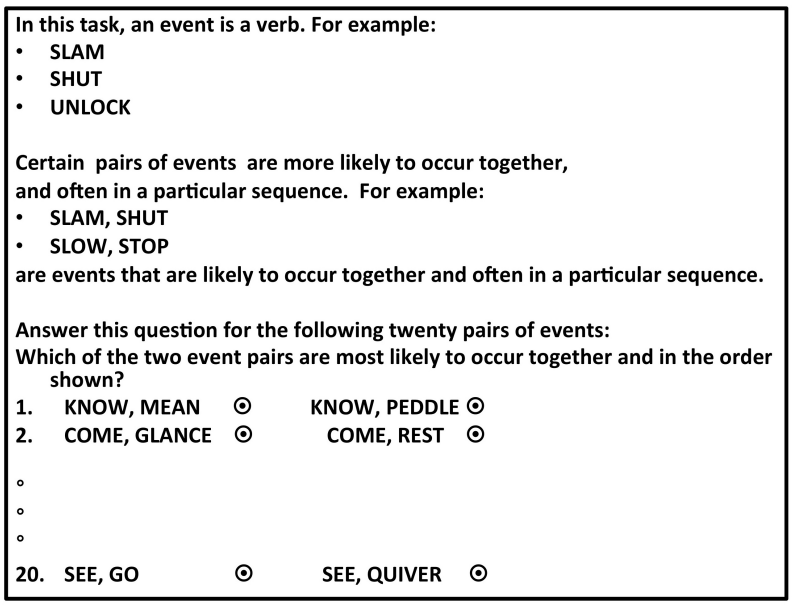

Figure 3: Mechanical Turk HIT for evaluation with no event arguments provided. This HIT also illustrates instructions where Turkers are told that the order of the events **does** matter.

creases the accuracy of almost all evaluation tasks, with increases ranging from 3.45% to 12.5% when averaged over both film genres (Column 5 Average Acc%). The best performing method for the Action genre is CP+Web Search at 87.67%, while the best performing method for the Romance genre is PMI+Web search at 88.52%. However PMI+Web Search does not beat CP+Web Search on average over both genres we tested, even though the Mechanical Turk HIT for CP specifies that the order of the events matters: a more stringent criterion. Also overall the CP+WebSearch method achieves a very high 85.64% average accuracy.

It is also interesting to note the variation across the different methods. For example, while it is well known that PMI typically requires very large corpora to make good estimates, the PMI method without web search refinement has an initially high accuracy of 79.60% for the romance genre, while only achieving 68.70% for action. Perhaps this difference arises because the romance genre is more highly causal, or because situations are more structured in romance, providing better estimates with a small corpus. However even in this case of romance with PMI, adding web search refinement provides an almost 10% increase in absolute accuracy to the highest accuracy of any combination, i.e. 88.52%. There is also an interesting case of Protag CP for the romance genre where web search refinement actually decreases accuracy by 4.1%. In future work we plan to examine more genres from the film corpus and also examine the role of corpus size in more detail.

4 Discussion and Future Work

We induced event pairs using several methods from previous work with similar aims but widely different problem formulations and evaluation methods. We used a verb-rich film scene corpus where events are normally narrated in temporal order. We used Mechanical Turk to evaluate the learned pairs of CONTINGENT events using human perceptions. In the first stage drawing on previous measures of distributional co-occurrence, we achieved an overall average accuracy of around 70%, over a 50% baseline. We then implemented a novel method of defining narrative sequence patterns using the Google Search API, and used web counts to further refine our estimates of the contingency of the learned event pairs. This increased the overall average accuracy to around 77%, which is 27% above the baseline. Our results indicate that the use of web search counts increases the average accuracy of our Causal Potential-based method to 85.64% as compared to an average accuracy of 75.15% without web search. To our knowledge this is the highest accuracy achieved in tasks of

this kind to date.

Previous work on recognition of the PDTB CONTINGENT relation has used both supervised and unsupervised learning, and evaluation typically measures precision and recall against a PDTB annotated corpus (Do et al., 2011; Pitler et al., 2009; Zhou et al., 2010; Chiarcos, 2012; Louis et al., 2010). We use an unsupervised approach and measure accuracy using human perceptions. Other work by Girju and her students defined a measure called causal potential and then used film screen plays to learn a knowledge base of causal pairs of events. They evaluate the pairs by asking two trained human annotators to label whether occurrences of those pairs in their corpus are causally related (Beamer and Girju, 2009; Riaz and Girju, 2010). We also make use of their causal potential measure. Work on commonsense causal reasoning aims to learn causal relations beween pairs of events using a range of methods applied to a large corpus of weblog narratives (Gordon et al., 2011; Gordon and Swanson, 2009; Manshadi et al., 2008). One form of evaluation aimed to predict the last event in a sequence (Manshadi et al., 2008), while more recent work uses the learned pairs to improve performance on the COPA SEMEVAL task (Gordon et al., 2011).

Related work on SCRIPT LEARNING induces *likely sequences of temporally ordered events* in news, rather than CONTINGENCY or CAUSALITY (Chambers and Jurafsky, 2008; Chambers and Jurafsky, 2009). Chambers & Jurafsky also evaluate against a corpus of existing documents, by leaving one event out of a document (news story), and then testing the system's ability to predict the missing event. To our knowledge, our method is the first to augment distributional semantics measures from a corpus with web search data. We are also the first to evaluate the learned event pairs with a human perceptual evaluation with native speakers.

We hypothesize that there are several advantages to our method: (1) events in the same genre tend to be more similar than events across genres, so less data is needed to estimate co-occurrence; (2) film scenes are typically narrated via simple tenses in the correct temporal order, which allows the ordering of events to contribute to estimates of the CONTINGENCY relation; (3) The web counts focus on validating event pairs already deemed to be likely to be CONTINGENT in the smaller, more controlled, film scence corpus.

Our work capitalizes on event sequences narrated in temporal order as a cue to causality. We expect this approach to generalize to other domains where these properties hold, such as fables, personal stories and news articles. We do not expect this technique to generalize without further refinements to genres frequently told out of temporal order or when events are not mentioned consecutively in the text, for example in certain types of fiction.

In future work we want to explore in more detail the differences in performance of the different contingency measures. For example, previous work would suggest that the the higher the measure is, the more likely the two events are to be contingent on one another. To date, while we have only tested the top 100, we have not found that the bottom set of 20 are less accurate than the top set of 20. This could be due to corpus size, or the measures themselves, or noise from parser accuracy etc. As shown in Table 2, web search refinement is able to eliminate most noise in event pairs, but we would still aim to achieve a better understanding of the circumstances which lead particular methods to work better.

In future work we also want to explore ways of inducing larger event structures than event pairs, such as the causal chains, scripts, or narrative schemas of previous work.

Latent Anaphora Resolution for Cross-Lingual Pronoun Prediction

Abstract

This paper addresses the task of predicting the correct French translations of third-person subject pronouns in English discourse, a problem that is relevant as a prerequisite for machine translation and that requires anaphora resolution. We present an approach based on neural networks that models anaphoric links as latent variables and show that its performance is competitive with that of a system with separate anaphora resolution while not requiring any coreference-annotated training data. This demonstrates that the information contained in parallel bitexts can successfully be used to acquire knowledge about pronominal anaphora in an unsupervised way.

1 Motivation

When texts are translated from one language into another, the translation reconstructs the meaning or function of the source text with the means of the target language. Generally, this has the effect that the entities occurring in the translation and their mutual relations will display similar patterns as the entities in the source text. In particular, coreference patterns tend to be very similar in translations of a text, and this fact has been exploited with good results to project coreference annotations from one language into another by using word alignments (Postolache et al., 2006; Rahman and Ng, 2012).

On the other hand, what is true in general need not be true for all types of linguistic elements. For instance, a substantial percentage of the English third-person subject pronouns *he*, *she*, *it* and *they* does not get realised as pronouns in French translations (Hardmeier, 2012). Moreover, it has been recognised by various authors in the statistical machine translation (SMT) community (Le Nagard and Koehn, 2010; Hardmeier and Federico, 2010; Guillou, 2012) that pronoun translation is a difficult problem because, even when a pronoun does get translated as a pronoun, it may require choosing the correct word form based on agreement features that are not easily predictable from the source text.

The work presented in this paper investigates the problem of cross-lingual pronoun prediction for English-French. Given an English pronoun and its discourse context as well as a French translation of the same discourse and word alignments between the two languages, we attempt to predict the French word aligned to the English pronoun. As far as we know, this task has not been addressed in the literature before. In our opinion, it is interesting for several reasons. By studying pronoun prediction as a task in its own right, we hope to contribute towards a better understanding of pronoun translation with a long-term view to improving the performance of SMT systems. Moreover, we believe that this task can lead to interesting insights about anaphora resolution in a multi-lingual context. In particular, we show in this paper that the pronoun prediction task makes it possible to model the resolution of pronominal anaphora as a latent variable and opens up a way to solve a task relying on anaphora resolution without using any data annotated for anaphora. This is what we consider the main contribution of our present work.

We start by modelling cross-lingual pronoun prediction as an independent machine learning task after doing anaphora resolution in the source language (English) using the BART software (Broscheit et al., 2010). We show that it is difficult to achieve satisfactory performance with standard maximum-

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 380–391,
Seattle, Washington, USA, 18-21 October 2013.

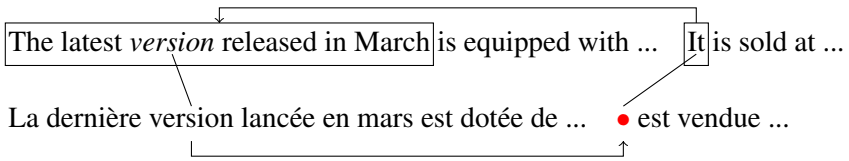

Figure 1: Task setup

entropy classifiers especially for low-frequency pronouns such as the French feminine plural pronoun *elles*. We propose a neural network classifier that achieves better precision and recall and manages to make reasonable predictions for all pronoun categories in many cases.

We then go on to extend our neural network architecture to include anaphoric links as latent variables. We demonstrate that our classifier, now with its own source language anaphora resolver, can be trained successfully with backpropagation. In this setup, we no longer use the machine learning component included in the external coreference resolution system (BART) to predict anaphoric links. Anaphora resolution is done by our neural network classifier and requires only some quantity of word-aligned parallel data for training, completely obviating the need for a coreference-annotated training set.

2 Task Setup

The overall setup of the classification task we address in this paper is shown in Figure 1. We are given an English discourse containing a pronoun along with its French translation and word alignments between the two languages, which in our case were computed automatically using a standard SMT pipeline with GIZA++ (Och and Ney, 2003). We focus on the four English third-person subject pronouns *he*, *she*, *it* and *they*. The output of the classifier is a multinomial distribution over six classes: the four French subject pronouns *il*, *elle*, *ils* and *elles*, corresponding to masculine and feminine singular and plural, respectively; the impersonal pronoun *ce/c'*, which occurs in some very frequent constructions such as *c'est* (*it is*); and a sixth class OTHER, which indicates that none of these pronouns was used. In general, a pronoun may be aligned to multiple words; in this case, a training example is counted as a positive example for a class if the target word occurs among the words aligned to the pronoun, irrespective of the presence of other

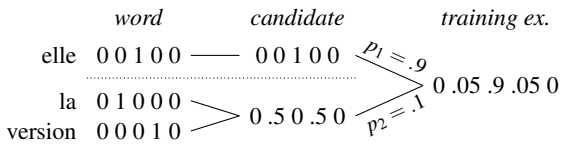

Figure 2: Antecedent feature aggregation

aligned tokens.

This task setup resembles the problem that an SMT system would have to solve to make informed choices when translating pronouns, an aspect of translation neglected by most existing SMT systems. An important difference between the SMT setup and our own classifiers is that we use context from human-made translations for prediction. This potentially makes the task both easier and more difficult; easier, because the context can be relied on to be correctly translated, and more difficult, because human translators frequently create less literal translations than an SMT system would. Integrating pronoun prediction into the translation process would require significant changes to the standard SMT decoding setup in order to take long-range dependencies in the target language into account, which is why we do not address this issue in our current work.

In all the experiments presented in this paper, we used features from two different sources:

– *Anaphora context features* describe the source language pronoun and its immediate context consisting of three words to its left and three words to its right. They are encoded as vectors whose dimensionality is equal to the source vocabulary size with a single non-zero component indicating the word referred to (one-hot vectors).
– *Antecedent features* describe an antecedent candidate. Antecedent candidates are represented by the target language words aligned to the syntactic head of the source language markable

ils	15.6 %	15.1 %
OTHER	40.9 %	38.0 %

Table 1: Distribution of classes in the training data

noun phrase as identified by the Collins head finder (Collins, 1999).

The different handling of anaphora context features and antecedent features is due to the fact that we always consider a constant number of context words on the source side, whereas the number of word vectors to be considered depends on the number of antecedent candidates and on the number of target words aligned to each antecedent.

The encoding of the antecedent features is illustrated in Figure 2 for a training example with two antecedent candidates translated to *elle* and *la version*, respectively. The target words are represented as one-hot vectors with the dimensionality of the target language vocabulary. These vectors are then averaged to yield a single vector per antecedent candidate. Finally, the vectors of all candidates for a given training example are weighted by the probabilities assigned to them by the anaphora resolver (p_1 and p_2) and summed to yield a single vector per training example.

3 Data Sets and External Tools

We run experiments with two different test sets. The *TED* data set consists of around 2.6 million tokens of lecture subtitles released in the WIT^3 corpus (Cettolo et al., 2012). The WIT^3 training data yields 71,052 examples, which were randomly partitioned into a training set of 63,228 examples and a test set of 7,824 examples. The official WIT^3 development and test sets were not used in our experiments. The *news-commentary* data set is version 6 of the parallel news-commentary corpus released as a part of the WMT 2011 training data[1]. It contains around 2.8 million tokens of news text and yields 31,017 data points, which were randomly split into 27,900 training examples and 3,117 test instances. The distribution of the classes in the two training sets is shown in Table 1. One thing to note is the dominance of the OTHER class, which pools together such different phenomena as translations with other pronouns not in our list (e. g., *celui-ci*) and translations with full noun phrases instead of pronouns. Splitting this group into more meaningful subcategories is not straightforward and must be left to future work.

The feature setup of all our classifiers requires the detection of potential antecedents and the extraction of features pairing anaphoric pronouns with antecedent candidates. Some of our experiments also rely on an external anaphora resolution component. We use the open-source anaphora resolver BART to generate this information. BART (Broscheit et al., 2010) is an anaphora resolution toolkit consisting of a markable detection and feature extraction pipeline based on a variety of standard natural language processing (NLP) tools and a machine learning component to predict coreference links including both pronominal anaphora and noun-noun coreference. In our experiments, we always use BART's markable detection and feature extraction machinery. Markable detection is based on the identification of noun phrases in constituency parses generated with the Stanford parser (Klein and Manning, 2003). The set of features extracted by BART is an extension of the widely used mention-pair anaphora resolution feature set by Soon et al. (2001) (see below, Section 6).

In the experiments of the next two sections, we also use BART to predict anaphoric links for pronouns. The model used with BART is a maximum entropy ranker trained on the *ACE02-npaper* corpus (LDC2003T11). In order to obtain a probability distribution over antecedent candidates rather than one-best predictions or coreference sets, we modified the ranking component with which BART resolves pronouns to normalise and output the scores assigned by the ranker to all candidates instead of picking the highest-scoring candidate.

4 Baseline Classifiers

In order to create a simple, but reasonable baseline for our task, we trained a maximum entropy (ME)

Table 3: Neural network classifier with anaphoras resolved by BART

classifier with the MegaM software package[2] using the features described in the previous section and the anaphora links found by BART. Results are shown in Table 2. The baseline results show an overall higher accuracy for the TED data than for the news-commentary data. While the precision is above 50 % in all categories and considerably higher in some, recall varies widely.

The pronoun *elles* is particularly interesting. This is the feminine plural of the personal pronoun, and it usually corresponds to the English pronoun *they*, which is not marked for gender. In French, *elles* is a marked choice which is only used if the antecedent exclusively refers to females or feminine-gendered objects. The presence of a single item with masculine grammatical gender in the antecedent will trigger the use of the masculine plural pronoun *ils* instead. This distinction cannot be predicted from the English source pronoun or its context; making correct predictions requires knowledge about the antecedent of the pronoun. Moreover, *elles* is a low-frequency pronoun. There are only 1,909 occurrences of this pronoun in the TED training data, and 1,077 in the news-commentary training set. Because of these special properties of the feminine plural class, we argue that the performance of a classifier on *elles* is a good indicator of how well it can represent relevant knowledge about pronominal anaphora as opposed to overfitting to source contexts or acting on prior assumptions about class frequencies.

In accordance with the general linguistic preference for *ils*, the classifier tends to predict *ils* much more often than *elles* when encountering an English plural pronoun. This is reflected in the fact that *elles* has much lower recall than *ils*. Clearly, the classifier achieves a good part of its accuracy by making majority choices without exploiting deeper knowledge about the antecedents of pronouns.

An additional experiment with a subset of 27,900 training examples from the TED data confirms that the difference between TED and news commentaries is not just an effect of training data size, but that TED data is genuinely easier to predict than news commentaries. In the reduced data TED condition, the classifier achieves an accuracy of 0.673. Precision and recall of all classifiers are much closer to the

[2] `http://www.umiacs.umd.edu/~hal/megam/` (20 June 2013).

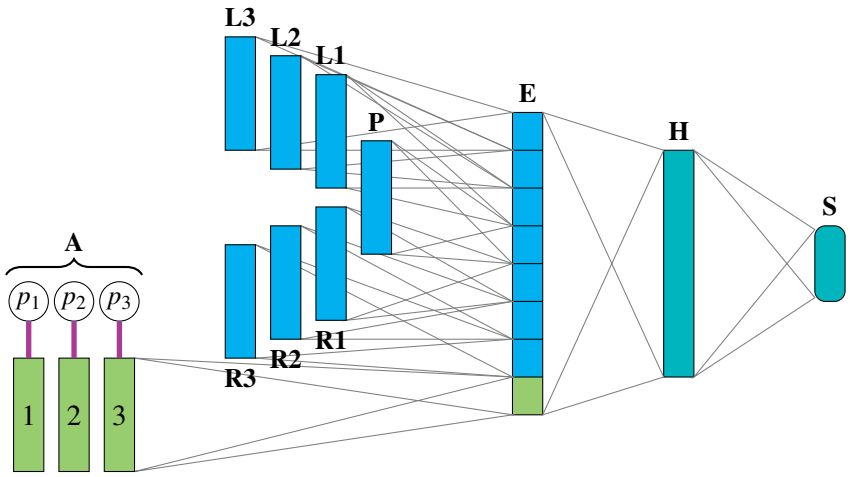

Figure 3: Neural network for pronoun prediction

large-data TED condition than to the news commentary experiments, except for *elles*, where we obtain an F-score of 0.072 (P 0.818, R 0.038), indicating that small training data size is a serious problem for this low-frequency class.

5 Neural Network Classifier

In the previous section, we saw that a simple multiclass maximum entropy classifier, while making correct predictions for much of the data set, has a significant bias towards making majority class decisions, relying more on prior assumptions about the frequency distribution of the classes than on antecedent features when handling examples of less frequent classes. In order to create a system that can be trained to rely more explicitly on antecedent information, we created a neural network classifier for our task. The introduction of a hidden layer should enable the classifier to learn abstract concepts such as gender and number that are useful across multiple output categories, so that the performance of sparsely represented classes can benefit from the training examples of the more frequent classes.

The overall structure of the network is shown in Figure 3. As inputs, the network takes the same features that were available to the baseline ME classifier, based on the source pronoun (**P**) with three words of context to its left (**L1** to **L3**) and three words to its right (**R1** to **R3**) as well as the words aligned to the syntactic head words of all possible antecedent candidates as found by BART (**A**). All words are encoded as one-hot vectors whose dimensionality is equal to the vocabulary size. If multiple words are aligned to the syntactic head of an antecedent candidate, their word vectors are averaged with uniform weights. The resulting vectors for each antecedent are then averaged with weights defined by the posterior distribution of the anaphora resolver in BART (p_1 to p_3).

The network has two hidden layers. The first layer (**E**) maps the input word vectors to a low-dimensional representation. In this layer, the embedding weights for all the source language vectors (the pronoun and its 6 context words) are tied, so if two words are the same, they are mapped to the same lower-dimensional embedding irrespective of their position relative to the pronoun. The embedding of the antecedent word vectors is independent, as these word vectors represent target language words. The entire embedding layer is then mapped to another hidden layer (**H**), which is in turn connected to a softmax output layer (**S**) with 6 outputs representing the classes *ce*, *elle*, *elles*, *il*, *ils* and OTHER. The non-linearity of both hidden layers is the logistic sigmoid function, $f(x) = 1/(1+e^{-x})$.

In all experiments reported in this paper, the dimensionality of the source and target language word embeddings is 20, resulting in a total embedding layer size of 160, and the size of the last hidden layer is equal to 50. These sizes are fairly small. In experiments with larger layer sizes, we were able to obtain similar, but no better results.

The neural network is trained with mini-batch stochastic gradient descent with backpropagated gradients using the RMSPROP algorithm with cross-entropy as the objective function.[3] In contrast to standard gradient descent, RMSPROP normalises the magnitude of the gradient components by dividing them by a root-mean-square moving average. We found this led to faster convergence. Other features of our training algorithm include the use of momentum to even out gradient oscillations, adaptive learning rates for each weight as well as adaptation of the global learning rate as a function of current training progress. The network is regularised with an ℓ_2 weight penalty. Good settings of the initial learning rate and the weight cost parameter (both around 0.001 in most experiments) were found by manual experimentation. Generally, we train our networks for 300 epochs, compute the validation error on a held-out set of some 10 % of the training data after each epoch and use the model that achieved the lowest validation error for testing.

Since the source context features are very informative and it is comparatively more difficult to learn from the antecedents, the network sometimes had a tendency to overfit to the source features and disregard antecedent information. We found that this problem can be solved effectively by presenting a part of the training without any source features, forcing the network to learn from the information contained in the antecedents. In all experiments in this paper, we zero out all source features (input layers **P**, **L1** to **L3** and **R1** to **R3**) with a probability of 50 % in each training example. At test time, no information is zeroed out.

Classification results with this network are shown in Table 3. We note that the accuracy has increased slightly for the TED test set and remains exactly the same for the news commentary corpus. However, a closer look on the results for individual classes reveals that the neural network makes better predictions for almost all classes. In terms of F-score, the only class that becomes slightly worse is the OTHER class for the news commentary corpus because of lower recall, indicating that the neural network classifier is less biased towards using the uninformative OTHER category. Recall for *elle* and *elles* increases considerably, but especially for *elles* it is still quite low. The increase in recall comes with some loss in precision, but the net effect on F-score is clearly positive.

[3] Our training procedure is greatly inspired by a series of online lectures held by Geoffrey Hinton in 2012 (`https://www.coursera.org/course/neuralnets`, 10 September 2013).

6 Latent Anaphora Resolution

Considering Figure 1 again, we note that the bilingual setting of our classification task adds some information not available to the monolingual anaphora resolver that can be helpful when determining the correct antecedent for a given pronoun. Knowing the gender of the translation of a pronoun limits the set of possible antecedents to those whose translation is morphologically compatible with the target language pronoun. We can exploit this fact to learn how to resolve anaphoric pronouns without requiring data with manually annotated anaphoric links.

To achieve this, we extend our neural network with a component to predict the probability of each antecedent candidate to be the correct antecedent (Figure 4). The extended network is identical to the previous version except for the upper left part dealing with anaphoric link features. The only difference between the two networks is the fact that anaphora resolution is now performed by a part of our neural network itself instead of being done by an external module and provided to the classifier as an input.

In this setup, we still use some parts of the BART toolkit to extract markables and compute features. However, we do not make use of the machine learning component in BART that makes the actual predictions. Since this is the only component trained on coreference-annotated data in a typical BART configuration, no coreference annotations are used anywhere in our system even though we continue to rely on the external anaphora resolver for preprocessing to avoid implementing our own markable and feature extractors and to make comparison easier.

For each candidate markable identified by BART's preprocessing pipeline, the anaphora resolution model receives as input a link feature vector (**T**) describing relevant aspects of the antecedent candidate-anaphora pair. This feature vector is generated by the feature extraction machinery in BART and includes a standard feature set for coreference resolution partially based on work by Soon et al. (2001). We use the following feature extractors in BART, each of

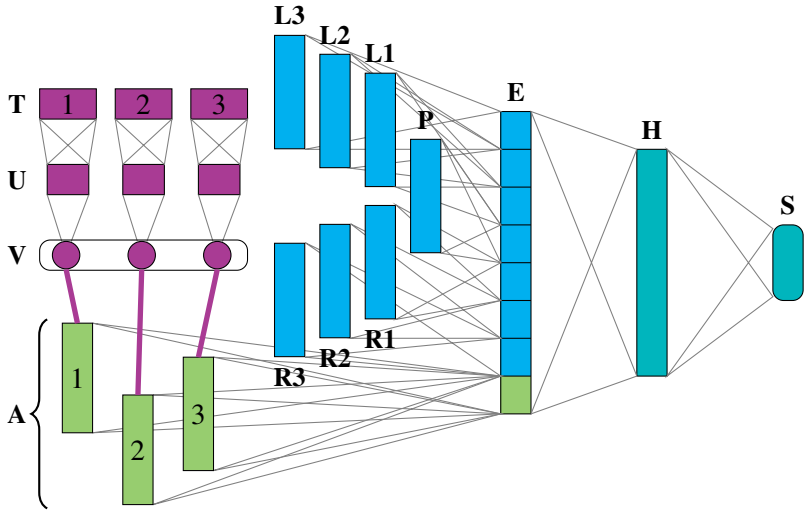

Figure 4: Neural network with latent anaphora resolution

which can generate multiple features:

- Anaphora mention type
- Gender match
- Number match
- String match
- Alias feature (Soon et al., 2001)
- Appositive position feature (Soon et al., 2001)
- Semantic class (Soon et al., 2001)
- Semantic class match
- Binary distance feature
- Antecedent is first mention in sentence

Our baseline set of features was borrowed wholesale from a working coreference system and includes some features that are not relevant to the task at hand, e. g., features indicating that the anaphora is a pronoun, is not a named entity, etc. After removing all features that assume constant values in the training set when resolving antecedents for the set of pronouns we consider, we are left with a basic set of 37 anaphoric link features that are fed as inputs to our network. These features are exactly the same as those available to the anaphora resolution classifier in the BART system used in the previous section.

Each training example for our network can have an arbitrary number of antecedent candidates, each of which is described by an antecedent word vector (**A**) and by an anaphoric link vector (**T**). The anaphoric link features are first mapped to a regular hidden layer with logistic sigmoid units (**U**). The activations of the hidden units are then mapped to a single value, which functions as an element in a softmax layer over all antecedent candidates (**V**). This softmax layer assigns a probability to each antecedent candidate, which we then use to compute a weighted average over the antecedent word vector, replacing the probabilities p_i in Figures 2 and 3.

At training time, the network's anaphora resolution component is trained in exactly the same way as the rest of the network. The error signal from the embedding layer is backpropagated both to the weight matrix defining the antecedent word embedding and to the anaphora resolution subnetwork. Note that the number of weights in the network is the same for all training examples even though the number of antecedent candidates varies because all weights related to antecedent word features and anaphoric link features are shared between all antecedent candidates.

One slightly uncommon feature of our neural network is that it contains an internal softmax layer to generate normalised probabilities over all possible antecedent candidates. Moreover, weights are shared between all antecedent candidates, so the inputs of our internal softmax layer share dependencies on the same weight variables. When computing derivatives with backpropagation, these shared dependencies must be taken into account. In particular, the outputs y_i of the antecedent resolution layer are the result of a softmax applied to functions of some shared variables q:

$$y_i = \frac{\exp f_i(q)}{\sum_k \exp f_k(q)} \quad (1)$$

The derivatives of any y_i with respect to q, which can be any of the weights in the anaphora resolution subnetwork, have dependencies on the derivatives of the other softmax inputs with respect to q:

$$\frac{\partial y_i}{\partial q} = y_i \left(\frac{\partial f_i(q)}{\partial q} - \sum_k y_k \frac{\partial f_k(q)}{\partial q} \right) \qquad (2)$$

This makes the implementation of backpropagation for this part of the network somewhat more complicated, but in the case of our networks, it has no major impact on training time.

Experimental results for this network are shown in Table 4. Compared with Table 3, we note that the overall accuracy is only very slightly lower for TED, and for the news commentaries it is actually better. When it comes to F-scores, the performance for *elles* improves by a small amount, while the effect on the other classes is a bit more mixed. Even where it gets worse, the differences are not dramatic considering that we eliminated a very knowledge-rich resource from the training process. This demonstrates that it is possible, in our classification task, to obtain good results without using any data manually annotated for anaphora and to rely entirely on unsupervised latent anaphora resolution.

7 Further Improvements

The results presented in the preceding section represent a clear improvement over the ME classifiers in Table 2, even though the overall accuracy increased only slightly. Not only does our neural network classifier achieve better results on the classification task at hand without requiring an anaphora resolution classifier trained on manually annotated data, but it performs clearly better for the feminine categories that reflect minority choices requiring knowledge about the antecedents. Nevertheless, the performance is still not entirely satisfactory.

By subjecting the output of our classifier on a development set to a manual error analysis, we found that a fairly large number of errors belong to two error types: On the one hand, the preprocessing pipeline used to identify antecedent candidates does not always include the correct antecedent in the set presented to the neural network. Whenever this occurs, it is obvious that the classifier cannot possibly find the correct antecedent. Out of 76 examples of the category *elles* that had been mistakenly predicted as *ils*, we found that 43 suffered from this problem. In other classes, the problem seems to be somewhat less common, but it still exists. On the other hand, in many cases (23 out of 76 for the category mentioned before) the anaphora resolution subnetwork does identify an antecedent manually recognised to belong to the right gender/number group, but still predicts an incorrect pronoun. This may indicate that the network has difficulties learning a correct gender/number representation for all words in the vocabulary.

7.1 Relaxing Markable Extraction

The pipeline we use to extract potential antecedent candidates is borrowed from the BART anaphora resolution toolkit. BART uses a syntactic parser to identify noun phrases as markables. When extracting antecedent candidates for coreference prediction, it starts by considering a window consisting of the sentence in which the anaphoric pronoun is located and the two immediately preceding sentences. Markables in this window are checked for morphological compatibility in terms of gender and number with the anaphoric pronoun, and only compatible markables are extracted as antecedent candidates. If no compatible markables are found in the initial window, the window is successively enlarged one sentence at a time until at least one suitable markable is found.

Our error analysis shows that this procedure misses some relevant markables both because the initial two-sentence extraction window is too small and because the morphological compatibility check incorrectly filters away some markables that should have been considered as candidates. By contrast, the extraction procedure does extract quite a number of first and second person noun phrases (*I*, *we*, *you* and their oblique forms) in the TED talks which are extremely unlikely to be the antecedent of a later occurrence of *he*, *she*, *it* or *they*. As a first step, we therefore adjust the extraction criteria to our task by increasing the initial extraction window to five sentences, excluding first and second person markables and removing the morphological compatibility requirement. The compatibility check is still used to control expansion of the extraction window, but it is no longer applied to filter the extracted markables. This increases the accuracy to 0.701 for TED and 0.602 for the news

commentaries, while the performance for *elles* improves to F-scores of 0.531 (TED; P 0.690, R 0.432) and 0.304 (News commentaries; P 0.444, R 0.231), respectively. Note that these and all the following results are not directly comparable to the ME baseline results in Table 2, since they include modifications and improvements to the training data extraction procedure that might possibly lead to benefits in the ME setting as well.

7.2 Adding Lexicon Knowledge

In order to make it easier for the classifier to identify the gender and number properties of infrequent words, we extend the word vectors with features indicating possible morphological features for each word. In early experiments with ME classifiers, we found that our attempts to do proper gender and number tagging in French text did not improve classification performance noticeably, presumably because the annotation was too noisy. In more recent experiments, we just add features indicating all possible morphological interpretations of each word, rather than trying to disambiguate them. To do this, we look up the morphological annotations of the French words in the Lefff dictionary (Sagot et al., 2006) and introduce a set of new binary features to indicate whether a particular reading of a word occurs in that dictionary. These features are then added to the one-hot representation of the antecedent words. Doing so improves the classifier accuracy to 0.711 (TED) and 0.604 (News commentaries), while the F-scores for *elles* reach 0.589 (TED; P 0.649, R 0.539) and 0.500 (News commentaries; P 0.545, R 0.462), respectively.

7.3 More Anaphoric Link Features

Even though the modified antecedent candidate extraction with its larger context window and without the morphological filter results in better performance on both test sets, additional error analysis reveals that the classifiers has greater problems identifying the correct markable in this setting. One reason for this may be that the baseline anaphoric link feature set described above (Section 6) only includes two very rough binary distance features which indicate whether or not the anaphora and the antecedent candidate occur in the same or in immediately adjacent sentences. With the larger context window, this may be too unspecific. In our final experiment, we therefore enable some additional features which are available in BART, but disabled in the baseline system:

– Distance in number of markables
– Distance in number of sentences
– Sentence distance, log-transformed
– Distance in number of words
– Part of speech of head word

Most of these encode the distance between the anaphora and the antecedent candidate in more precise ways. Complete results for this final system are presented in Table 5.

Including these additional features leads to another slight increase in accuracy for both corpora, with similar or increased classifier F-scores for most classes except *elle* in the news commentary condition. In particular, we should like to point out the performance of our benchmark classifier for *elles*, which suffered from extremely low recall in the first classifiers and approaches the performance of the other classes, with nearly balanced precision and recall, in this final system. Since *elles* is a low-frequency class and cannot be reliably predicted using source context alone, we interpret this as evidence that our final neural network classifier has incorporated some relevant knowledge about pronominal anaphora that the baseline ME classifier and earlier versions of our network have no access to. This is particularly remarkable because no data manually annotated for coreference was used for training.

8 Related work

Even though it was recognised years ago that the information contained in parallel corpora may provide valuable information for the improvement of anaphora resolution systems, there have not been many attempts to cash in on this insight. Mitkov and Barbu (2003) exploit parallel data in English and French to improve pronominal anaphora resolution by combining anaphora resolvers for the individual languages with handwritten rules to resolve conflicts between the output of the language-specific resolvers. Veselovská et al. (2012) apply a similar strategy to English-Czech data to resolve different uses of the pronoun *it*. Other work has used word alignments to project coreference annotations from one language to another with a view to training anaphora resolvers in the target language (Postolache et al., 2006; de Souza and Orăsan, 2011). Rahman and Ng (2012) instead use machine translation to translate their test data into a language for which they have an anaphora resolver and then project the annotations back to the original language. Completely unsupervised monolingual anaphora resolution has been approached using, e. g., Markov logic (Poon and Domingos, 2008) and the Expectation-Maximisation algorithm (Cherry and Bergsma, 2005; Charniak and Elsner, 2009). To the best of our knowledge, the direct application of machine learning techniques to parallel data in a task related to anaphora resolution is novel in our work.

Neural networks and deep learning techniques have recently gained some popularity in natural language processing. They have been applied to tasks such as language modelling (Bengio et al., 2003; Schwenk, 2007), translation modelling in statistical machine translation (Le et al., 2012), but also part-of-speech tagging, chunking, named entity recognition and semantic role labelling (Collobert et al., 2011). In tasks related to anaphora resolution, standard feed-forward neural networks have been tested as a classifier in an anaphora resolution system (Stuckardt, 2007), but the network design presented in our work is novel.

9 Conclusion

In this paper, we have introduced cross-lingual pronoun prediction as an independent natural language processing task. Even though it is not an end-to-end task, pronoun prediction is interesting for several reasons. It is related to the problem of pronoun translation in SMT, a currently unsolved problem that has been addressed in a number of recent research publications (Le Nagard and Koehn, 2010; Hardmeier and Federico, 2010; Guillou, 2012) without reaching a major breakthrough. In this work, we have shown that pronoun prediction can be effectively modelled in a neural network architecture with relatively simple features. More importantly, we have demonstrated that the task can be exploited to train a classifier with a latent representation of anaphoric links. With parallel text as its only supervision this classifier achieves a level of performance that is similar to, if not better than, that of a classifier using a regular anaphora resolution system trained with manually annotated data.

Towards Situated Dialogue: Revisiting Referring Expression Generation

Rui Fang, Changsong Liu, Lanbo She, Joyce Y. Chai

Abstract

In situated dialogue, humans and agents have mismatched capabilities of perceiving the shared environment. Their representations of the shared world are misaligned. Thus referring expression generation (REG) will need to take this discrepancy into consideration. To address this issue, we developed a hypergraph-based approach to account for group-based spatial relations and uncertainties in perceiving the environment. Our empirical results have shown that this approach outperforms a previous graph-based approach with an absolute gain of 9%. However, while these graph-based approaches perform effectively when the agent has perfect knowledge or perception of the environment (e.g., 84%), they perform rather poorly when the agent has imperfect perception of the environment (e.g., 45%). This big performance gap calls for new solutions to REG that can mediate a shared perceptual basis in situated dialogue.

1 Introduction

Situated human robot dialogue has received increasing attention in recent years. In situated dialogue, robots/artificial agents and their human partners are co-present in a shared physical world. Robots need to automatically perceive and make inference of the shared environment. Due to its limited perceptual and reasoning capabilities, the robot's representation of the shared world is often incomplete, error-prone, and significantly mismatched from that of its human partner's. Although physically co-present, a joint perceptual basis between the human and the robot cannot be established (Clark and Brennan, 1991). Thus, referential communication between the human and the robot becomes difficult.

How this mismatched perceptual basis affects referential communication in situated dialogue was investigated in our previous work (Liu et al., 2012). In that work, the main focus is on reference resolution: given referential descriptions from human partners, how to identify referents in the environment even though the robot only has imperfect perception of the environment. Since robots need to collaborate with human partners to establish a joint perceptual basis, referring expression generation (REG) becomes an equally important problem in situated dialogue. Robots have much lower perceptual capabilities of the environment than humans. How can a robot effectively generate referential descriptions about the environment so that its human partner can understand which objects are being referred to?

There has been a tremendous amount of work on referring expression generation in the last two decades (Dale, 1995; Krahmer and Deemter, 2012). However, most existing REG algorithms were developed and evaluated under the assumption that agents and humans have access to the same kind of domain information. For example, many experimental setups (Gatt et al., 2007; Viethen and Dale, 2008; Golland et al., 2010; Striegnitz et al., 2012) were developed based on a visual world for which the internal representation is assumed to be known and can be represented symbolically. However, this assumption no longer holds in situated dialogue with robots. There are two important distinctions in situated dialogue. *First, the perfect knowledge of the environment is not available to the agent ahead of time.* The agent needs to automatically make inferences to connect recognized lower-level visual features with

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 392–402,
Seattle, Washington, USA, 18-21 October 2013.

symbolic labels or descriptors. Both recognition and inference are error-prone and full of uncertainties. *Second, in situated dialogue the agent and the human have mismatched representations of the environment.* The agent needs to take this difference into consideration to identify the most reliable features for REG. Given these two distinctions, it is not clear whether state-of-the-art REG approaches are applicable under mismatched perceptual basis in situated dialogue.

To address this issue, this paper revisits the problem of REG in the context of mismatched perceptual basis. We extended a well known graph-based approach (Krahmer et al., 2003) that has shown to be effective in previous work (Gatt and Belz, 2008; Gatt et al., 2009). We incorporated uncertainties in perception into cost functions. We further extended regular graph representation into hypergraph representation to account for group-based spatial relations that are important for visual descriptions (Dhande, 2003; Tenbrink and Moratz, 2003; Funakoshi et al., 2006; Liu et al., 2012). Our empirical results demonstrate that both enhancements lead to about a 9% absolute performance gain compared to the original approach. However, while our approache performs effectively when the agent has perfect knowledge or perception of the environment (e.g., 84%), it performs poorly under the mismatched perceptual basis (e.g., 45%). This performance gap calls for new solutions for REG that are capable of mediating mismatched perceptual basis.

In the following sections, we first describe our hypergraph-based representations and illustrate how uncertainties from automated perception can be incorporated. We then describe an empirical study using Amazon Mechanical Turks for evaluating generated referring expressions. Finally we present evaluation results and discuss potential future directions.

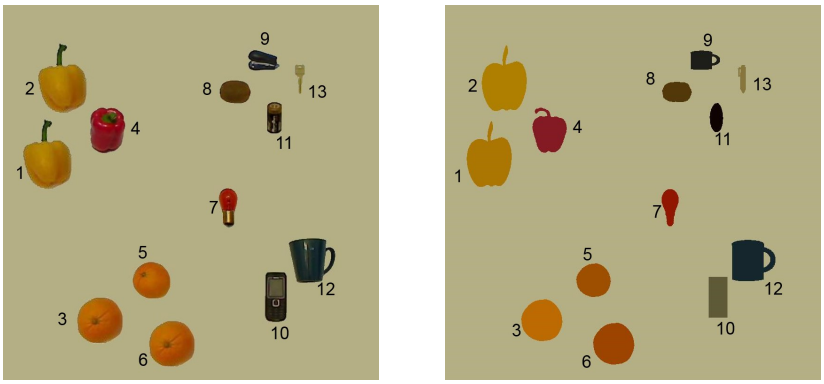
2 Related Work

Since the Full Brevity algorithm (Dale, 1989), many approaches have been developed and evaluated for REG (Dale, 1995; Krahmer and Deemter, 2012), such as the incremental algorithm (Dale, 1995), the locative algorithm (Kelleher and Kruijff, 2006), and graph-based approaches (Krahmer et al., 2003; Croitoru and Van Deemter, 2007). Most of these approaches assume the agent has access to a complete symbolic representation of the domain. While these approaches work well for many applications involving user interfaces, the question is whether they can be extended to the situation where the agent has incomplete or incorrect knowledge and needs to make inference about the domain or the world.

Recently, there has been increasing interest in REG for visual objects (Roy, 2002; Golland et al., 2010; Mitchell et al., 2013). Some work (Golland et al., 2010) uses visual scenes that are generated by computer graphics and thus the internal representation of the scene is known. Some other work focuses on the connection between lower-level visual features and symbolic descriptors for REG (Roy, 2002; Mitchell et al., 2013). However, most work assumes no vision recognition errors. It is well established that automated recognition of visual scenes is extremely challenging. This process is error-prone and full of uncertainties. It is not clear whether the existing approaches can be extended to the situation where the agent has imperfect perception of the shared environment.

An earlier work by Horacek (Horacek, 2005) has looked into the problem of mismatched knowledge between conversation partners for REG. The approach is a direct extension of the incremental algorithm (Dale, 1995). However, this work only provides a proof of concept example to illustrate the idea. No empirical evaluation was given.

All these previous works have motivated our present investigation. We are interested in REG under mismatched perceptual basis between conversation partners, where the agent has imperfect perception and knowledge of the shared environment. In particular, we took a well-studied graph-based approach (Krahmer et al., 2003) and extended it to incorporate group spatial relations and uncertainties associated with automated perception of the environment. The reason we chose a graph-based approach is that graph representations are widely used in the fields of computer vision (CV) and pattern recognition to represent spatially rich scenes. Nevertheless, the findings from this investigation provide insight to other approaches.



(a) an original scene

(b) the corresponding impoverished scene

Figure 1: An original scene and its impoverished scene processed by CV algorithm

3 Hypergraph-based REG

Towards mediating a shared perceptual basis in situated dialogue, our previous work (Liu et al., 2012) has conducted experiments to study referential communication between partners with mismatched perceptual capabilities. We simulated mismatched capabilities by making an original scene (Figure 1(a)) available to a director (simulating higher perceptual calibre) and a corresponding impoverished scene (Figure 1(b)) available to a matcher (simulating lowered perceptual calibre). The impoverished scene is created by re-rendering automated recognition results of the original scene by a CV algorithm. An example of the original scene and an impoverished scene is shown in Figure 1. Using this setup, the director and the matcher were instructed to collaborate with each other on some naming games. Through these games, they collected data on how partners with mismatched perceptual capabilities collaborate to ground their referential communication.

The setup in (Liu et al., 2012) is intended to simulate situated dialogue between a human (like the director) and a robot (like the matcher). The robot has a significantly lowered ability in perception and reasoning. The robot's internal representation of the shared world will be much like the impoverished scene which contains many recognition errors. The data from (Liu et al., 2012; Liu et al., 2013) shows that different strategies were used by conversation partners to produce referential descriptions. Besides directly describing attributes or binary relations with a relatum, they often use group-based descriptions (e.g., *a cluster of four objects on the right*). This is mainly due to the fact that some objects are simply not recognizable to the matcher. Binary spatial relationships sometimes are difficult to describe the target object, so the matcher must resort to group information to distinguish the target object from the rest of the objects. For example, suppose the matcher needs to describe the target object 5 in Figure 1(b), he/she may have to start by indicating the group of three objects at the bottom and then specify the relationship (i.e., top) of the target object within this group.

The importance of group descriptions has been shown not only here, but also in previous works on REG (Funakoshi et al., 2004; Funakoshi et al., 2006; Weijers, 2011). While the original graph-based approach can effectively represent attributes and binary relations between objects (Krahmer et al., 2003), it is insufficient to capture within-group or between-group relations. Therefore, to address the low perceptual capabilities of artificial agents, we introduce hypergraphs to represent the shared environment. Our approach has two unique characteristics compared to previous graph-based approaches: (1) A hypergraph representation is more general than a regular graph. Besides attributes and binary relations, it can also represent group-based relations. (2) Unlike previous work, here the generation of hypergraphs are completely driven by automated perception of the environment. This is done by incorporating uncertainties in perception and reasoning into cost functions associated with graphs. Next we

give a detailed account on hypergraph representation, cost functions incorporating uncertainties, and the search algorithm for REG.

3.1 Hypergraph Representation

A directed hypergraph G (Gallo et al., 1993) is a tuple of the form: $G = \langle X, A \rangle$, in which

$$X = \{x_m\}$$
$$A = \{a_i = (t_i, h_i) \mid t_i \subseteq X, h_i \subseteq X\}$$

Similar to regular graphs, a hypergraph consists of a set of nodes X and a set of arcs A. However, different from regular graphs, each arc in A is considered as a *hyperarc* in the sense that it can capture relations between any two subsets of nodes: a tail (t_i) and a head (h_i). Therefore, a hypergraph is a generalization of a regular graph. It becomes a regular graph if the cardinalities of both the tail and the head are restricted to one for all hyperarcs. While regular graphs are commonly used to represent binary relations between two nodes, hypergraphs provide a more general representation for n-ary relations among multiple nodes.

We use hypergraphs to represent the agent's perceived physical environment (also called *scene hypergraphs*). More specifically, each perceived object is represented by a node in the graph. Each perceived visual attribute of an object (e.g., color, size, type information) or a group of objects (e.g., number of objects in the group, location) is captured by a self-looping hyperarc. Hyperarcs are also used to capture the spatial relations between any two subsets of nodes, whether it is a relation between two objects, or between two groups of objects, or between one or more objects within a group of objects.

For example, Figure 2 shows a hypergraph created for part of the impoverished scene shown in Figure 1(b) (i.e., the upper right corner including objects 7, 8, 9, 11, and 13). One important characteristic is that, because the graph is created based on an automated vision recognition system, the values of an attribute or a relation in the hypergraph are numeric (except for the type attribute). For example, the value of the *color* attribute is the RGB distribution extracted from the corresponding visual object, the value of the *size* attribute is the width and height of the bounding box and the value of the *location* attribute is a function of spatial coordinates. These numerical features will be further converted to symbolic labels with certain confidence scores (described later in Section 3.3.2).

3.2 Hypergraph Pruning

The perceived visual scene can be represented as a complete hypergraph, in which any pair of two subsets of nodes are connected by a hyperarc. However, such a complete hypergraph is not only inefficient but also unnecessary. Instead of keeping all possible n-ary relations (i.e., hyperarcs), we only retain those relations that are likely used by humans to produce referring expressions, based on two heuristics.

The first heuristic is based on perceptual principles, also called the Gestalt Laws of perception (Sternberg, 2003), which describe how people group visually similar objects into entities or groups. Two well known principles of perceptual grouping are proximity and similarity (Wertheimer, 1938): objects that lie close together are often perceived as groups; objects of similar shape, size or color are more likely to form groups than objects differing along these dimensions. Based on these two principles, previous works have developed different algorithms for perceptual grouping (Thrisson, 1994; Gatt, 2006). In our investigation, we adopted Gatt's algorithm (Gatt, 2006), which has shown to be more accurate for spatial grouping. Given the results from spatial grouping, we only retain hyperarcs that represent spatial relations between two objects, between two perceived groups, between one object and a perceived group, or between one object and the group it belongs to.

The second heuristic is based on the observation that, given a certain orientation, people tend to use a relatum that is closer to the referent than more distant relata. In other words, it is less likely to refer to an object relative to a distant relatum when there is a closer relatum. For example, when referring to the stapler (object 9 in Figure 1(a)), it is more likely to use "the stapler above the battery" than "the stapler above the cellphone". Based on this observation, we prune the hypergraphs by only retaining hyperarcs between an object and their closest relata for each possible orientation.

Figure 2 shows the resulting hypergraph for representing a subset of objects (7, 8, 9, 11, and 13) in Figure 1(a).

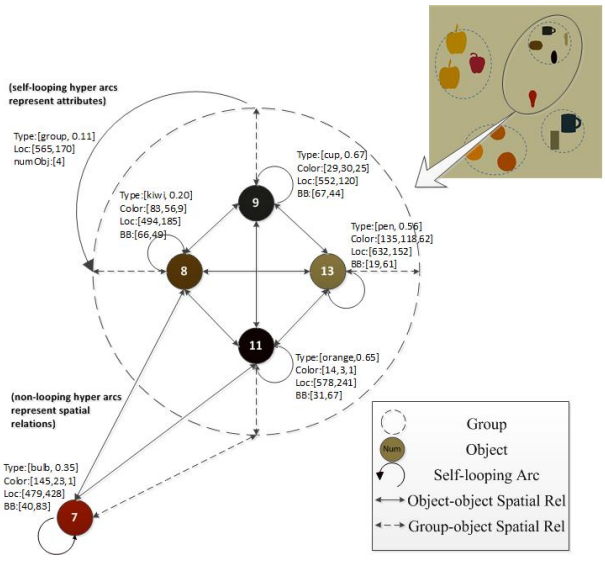


Figure 2: An example of hypergraph representing the perceived scene (a partial scene only including object 7, 8, 9, 11, 13 for Figure 1(a)).

3.3 Symbolic Descriptors for Attributes

As mentioned earlier, the values of attributes of objects and their relations are numerical in nature. In order for the agent to generate natural language descriptions, the first step is to assign symbolic labels or descriptors to those attributes and relations. Next we describe how we use a lexicon with grounded semantics in this process.

3.3.1 Lexicon with Grounded Semantics

Grounded semantics provides a bridge to connect symbolic labels or words with lower level visual features (Harnad, 1990). Previous work has developed various approaches for grounded semantics mainly for the reference resolution task, i.e., identifying visual objects in the environment given language descriptions (Dhande, 2003; Gorniak and Roy, 2004; Tenbrink and Moratz, 2003; Siebert and Schlangen, 2008; Liu et al., 2012). For the referring expression generation task here, we also need a lexicon with grounded semantics.

In our lexicon, the semantics of each category of words is defined by a set of semantic grounding functions that are parameterized on visual features. For example, for the *color* category it is defined as a multivariate Gaussian distribution based on the RGB distribution. Specific words such as *green, red, or blue* have different means and co-variances as the following:

$$color : red = f_r(\vec{v}_{color}) = N(\vec{v}_{color} \mid \mu_1, \sum_1)$$
$$color : green = f_g(\vec{v}_{color}) = N(\vec{v}_{color} \mid \mu_2, \sum_2)$$
$$color : blue = f_b(\vec{v}_{color}) = N(\vec{v}_{color} \mid \mu_3, \sum_3)$$

The above functions define how likely a set of recognized visual features (i.e., $\vec{v}_{color}$) describing the color dimensions (i.e., RGB distribution) is to match the color terms *red*, *green*, and *blue*.

For the spatial relation terms such as *above, below, left, right*, the semantic grounding functions take both vertical and horizontal coordinates of two objects, as follows [1]:

$$spatialRel : above(a, b) = f_{above}(\vec{v_{aloc}}, \vec{v_{bloc}})$$
$$= \begin{cases} 1 - \frac{|x_a - x_b|}{400} & \text{if } y_a < y_b; \\ 0 & \text{otherwise.} \end{cases}$$

Using the above convention, we have defined semantic grounding functions for *size* category words (e.g., *small* and *big*) and absolute position words (e.g., *top*, *below*, *left*, and *right*). In addition, we use object recognition models (Zhang and Lu, 2002) to define *class type* category words such as *apple* and *orange* used in our domain.

3.3.2 Attribute Descriptors and Cost Functions

Given the lexicon with grounded semantics as described above, the numerical attributes captured in the scene hypergraph can be converted to symbolic descriptors. For each attribute (e.g., *color*) or relation, the corresponding visual feature vector (i.e., $\vec{v}_{color}$) is plugged into the semantic grounding functions for the corresponding category of words. The word that best describes the attribute is chosen as the descriptor for that attribute. For example, given an RGB color distribution $\vec{v}_{color}$, we can find the color descriptor as follows:

$$color : w^* = \underset{red,green,blue}{\arg\max} \; f_w(\vec{v}_{color}),$$

For each attribute or relation, we can find a best descriptor in this manner. In addition, we also obtain a numerical value (returned from the semantic

[1] The size of the overall scene is 800x800.

grounding functions) that measures how well this descriptor describes the corresponding visual features. Intuitively, one would choose a descriptor that closely matches the visual features. Based on this intuition, we define the cost for each attribute A as the following:

$$cost(A) = 1 - f_{w^*}(\vec{v_A})$$

where w^* is the best descriptor for the attribute.

Given an attribute, the better the descriptor matches the extracted visual features, the lower the cost of the corresponding hyperarc.

3.4 Graph Matching for REG

Now the hypergraph representing the perceived environment has symbolic descriptors for its attributes and relations together with corresponding costs. Given this representation, REG can be formulated as a graph matching algorithm similar to that described in (Krahmer et al., 2003). We use the same Branch and Bound algorithm described in (Krahmer et al., 2003). In this approach, a hypothesis hypergraph (starting with one node representing the target object) is gradually expanded by adding in a least cost hyperarc from the scene hypergraph. At each expansion, the hypothesis graph is matched against the scene hypergraph to decide whether it matches any nodes other than the target node in the scene hypergraph. The expansion stops if the hypothesis graph does not cover any other nodes except for the target node. At this point, the hypothesis graph captures all the content (e.g., attributes and relations) required to uniquely describe the target object. We then apply a set of simple generation templates to generate the surface form of referring expressions based on the hypothesis graph.

4 Empirical Evaluations

4.1 Evaluation Setup

To evaluate the performance of this hypergraph-based approach to REG, we conducted a comparative study using crowd-sourcing. More specifically, we created 48 different scenes similar to that in Figure 1(a). Each scene has 13 objects on average and there are 621 objects in total. For each of these scenes, we applied a CV algorithm (Zhang and Lu, 2002) and generated scene hypergraphs as described in Section 3.1. We then use different generation strategies (varied in terms of graph representations and cost functions, to be explained in Section 4.2) to automatically generate referring expressions to refer to each object.

To evaluate the quality of these generated referring expressions, we applied Amazon Mechanical Turk to solicit feedback from the crowd [2]. Through an interface, we displayed an original scene and generated referring expressions (from different generation strategies) in a random order. We asked each turk to select the object in the scene that he/she believed was the one referred to by the shown referring expression (i.e., reference identification task). Each referring expression received three votes from the crowd. In total, 217 turks participated in our experiment.

4.2 Generation Strategies

We applied a set of different strategies to generate referring expressions for each object. The variations lie in two dimensions: (1) different graph representations: using a hypergraph to represent the perceived scene as described in Section 3.1 versus using a regular graph as introduced in (Krahmer et al., 2003); and (2) different cost functions for attributes and relations: cost functions that have been used in previous works (Theune et al., 2007; Krahmer et al., 2008) and cost functions that incorporate uncertainties of perception as described in Section 3.3.2.

Cost functions play an important role in graph-based approaches (Krahmer et al., 2003). Previous works have examined different types of cost functions (Theune et al., 2007; Krahmer et al., 2008; Theune et al., 2011). We adopted some commonly used cost functions from previous work together with the cost functions defined here. In particular, we experimented with the following different cost functions:

Simple Cost: The costs for all hyperarcs are set to 1. With this cost function, the graph-based algorithm resembles the Full Brevity algorithm of Dale (Dale,

[2] To control the quality of crowdsourcing, we recruited participants based on the following criteria: Participants' locations are limited to the United States. Approval rate for each participant's previous work is greater than or equal to 95%, and the number of each participant's previous approved work is greater than or equal to 1000.

1992) in that a shortest distinguishing description is preferred.

Absolute Preferred: The costs for hyperarcs representing absolute attributes (e.g., type, color, and position) are set to 1. The costs for relative attributes (e.g., size) and relations are set to 2. This cost function mimics human's preference for absolute attributes over relative ones (Dale, 1995).

Relative Preferred: The costs for hyperarcs representing absolute attributes are set to 2 and for relative attributes and relations are set to 1. This cost function has been applied previously to emphasize the importance of spatial relations in REG (Viethen and Dale, 2008).

Uncertainty Based: The costs for all hyperarcs are defined by incorporating uncertainties from perception as described in Section 3.3.2.

Uncertainty Relative Preferred: To emphasize the importance of spatial relations as demonstrated in situated interaction (Tenbrink and Moratz, 2003; Kelleher and Kruijff, 2006), the costs for hyperarcs representing relative attributes and relations are divided by 3. This cost function will allow the algorithm to prefer spatial relations through the reduced cost.

Note that we only tested a few (not all) commonly used cost functions proposed by previous work (Krahmer et al., 2003; Theune et al., 2007; Krahmer et al., 2008; Theune et al., 2011). For example, we did not include the stochastic cost function which is defined based on the frequencies of attribute selection from the training data (Krahmer et al., 2003). On the one hand, we did not have a large set of human descriptions of the impoverished scene to learn the stochastic cost. On the other hand, it is not clear whether human strategies of describing the impoverished scene should be used to represent optimal strategies for the robot. Nevertheless, the above different cost functions will allow us to evaluate whether incorporating perceptual uncertainties will make a difference in the REG performance.

4.3 Evaluation Results

As mentioned earlier, each generated referring expression received three independent votes regarding its referent from the crowd. The referent with the most votes is taken as the predicted referent and is used for evaluation. If all three votes are different, then by default, it is deemed that the referent is not correctly identified for that expression. We use the *accuracy* of the referential identification task (i.e., the percentage of generated referring expressions where the referents are correctly identified) as the metric to evaluate different generation strategies illustrated in Section 4.2.

Cost Function	Regular Graph	Hypergraph
Simple Costs	33.2%	33.3%
Absolute Preferred	30.1%	30.3%
Relative Preferred	31.1%	35.4%
Uncertainty Based	35.7%	37.5%
Uncertainty Rel. Prefer.	36.7%	45.2%

Table 1: Results with different cost functions

4.3.1 The Role of Cost Functions

Table 1 shows the results based on different cost functions and different graph representations. There are several observations.

First, when the agent does not have perfect knowledge of the environment and has to automatically infer the environment as in our setting here, cost functions based on uncertainties of perception lead to better results. This occurs for both regular graphs and hypergraphs. This result is not surprising and indicates that cost functions should be tied to the agent's ability to perceive and infer the environment. The uncertainty based cost functions allow the agent to prefer reliable attributes or relations.

Second, consistent with previous work (Viethen and Dale, 2008), we observed the importance of spatial relations. Especially when the perceived world is full of uncertainties, spatial relations tend to be more reliable. In particular, as shown in Table 1, using hypergraphs enables generating group-based relations and results in significantly better performance (45.2%) compared to regular graphs (36.7%) ($p = 0.002$).

Note that our current cost function only includes uncertainties of the agent's own perception in a simplistic form. When humans and agents have mismatched perceptual basis, the human's model of comprehension and tolerance of inaccurate description could play a role in REG. Incorporating human models in the cost function will require in-depth empirical studies and we will leave that to our future

work.

4.3.2 The Role of Imperfect Perception

To further understand the role of hypergraphs in mediating mismatched perceptions between humans and agents, we created a perfect scene regular graph and a perfect scene hypergraph (representing the agent's perfect knowledge of the environment) for each of the 48 scenes used in the experiments. In each of these scene graphs, the attribute and relation descriptors are manually provided. We further applied the *Absolute Preferred* cost function (which has shown competitive performance in previous work) to generate referring expressions for each object. Again, each referring expression received three votes from the crowd.

Table 2 shows the results comparing two conditions: (1) REs generated (by the *Absolute Preferred* cost function) based on the perfect graphs which represent the agent's perfect knowledge and perception of the environment; and (2) REs generated based on automatically created graphs (by the *Uncertainty Relative Preferred* cost function) which represent the agent's imperfect knowledge of the environment as a result of automated recognition and inference. The result shows that given perfect knowledge of the environment, hypergraphs only perform marginally better than the regular graphs ($p = 0.07$). Given imperfect knowledge of the environment, hypergraphs significantly outperforms the regular graphs by taking advantage of spatial grouping information ($p = 0.002$). It is worthwhile to mention that currently we use spatial proximity to identify groups. However, the hypergraph based approach is not restricted to spatial grouping. In theory, it can represent any type of group based on different similarity criteria.

Furthermore, our result shows that the graph-based approaches perform quite competitively under the condition of perfect knowledge and perception. Although evaluated on different data sets, this result is consistent with results from previous work (Gatt and Belz, 2008; Gatt et al., 2009). However, what is more interesting here is that while graph-based approaches perform well when the agent has perfect knowledge of the environment, as its human partner, these approaches literally fall apart with close to 40% performance degradation when applied to the situation where the agent's representation of the shared world is problematic and full of mistakes.

Environment	Regular Graph	Hypergraph
Pefect Perception	80.4%	84.2%
Imperfect Perception	36.7%	45.2%

Table 2: Results of comparing perfect perception and imperfect perception of the shared world.

These results indicate that REG for automatically perceived scenes can be extremely challenging. Many errors result from automated perception and reasoning that will affect the internal representation of the world and thus the generated REs. In our experiments here, we applied a very basic CV algorithm which resulted in rather poor performance in our data: overall, 60.3% of objects in the original scene are mis-recognized, and 10.5% of objects are mis-segmented. We think this poor CV performance represents a more challenging problem.

Some errors such as recognition errors can be bypassed using our current approach based on hypergraphs. For example, in Figure 1 target object 9 (a stapler) and 13 (a key) are mis-recognized as a cup and a pen. Using our hypergraph-based approach, for the target object 9, instead of generating "a small cup" (as in the case of using regular graphs), "a gray object on the top within a cluster of four objects" is generated. For the target object 13, instead of "a pen" as generated by regular graphs, "a small object on the right within a cluster of 4" is generated. Even with recognition errors, these group-based descriptions will allow the listener to identify target objects in their representation correctly. Nevertheless, many processing errors cannot be handled by our current approach. For example, an object can be mistakenly segmented into multiple parts or several objects can be mistakenly grouped into one object. In addition, our current semantic grounding functions are simple. Sometimes they do not provide correct descriptors for the extracted visual features. More sophisticated functions that better reflect human's visual perception (Regier, 1996; Mojsilovic, 2005; Mitchell et al., 2011) should be pursued in the future.

	Minimum Effort	Extra Effort
Pefect Perception	84.2%	88.1%
Imperfect Perception	45.2%	51.5%

Table 3: Results of comparing minimum effort and extra effort using hypergraphs

4.3.3 The Role of Extra Effort

While REG systems have a tendency to produce minimal descriptions, recent psycholinguistic studies have shown that speakers do not necessarily follow the Grice's maxim of quantity, and they tend to provide redundant properties in their descriptions (Jordan and Walker, 2000; Belke and Meyer, 2002; Arts et al., 2011). With this in mind, we conducted a very simple evaluation on the role of extra effort. Once a set of descriptors are selected based on the minimum cost, one additional descriptor (with the least cost among the remaining attributes or relations) is added to the referential description. We once again solicited the crowd feedback to this set of expressions generated by extra effort. Each expression again received three votes from the crowd.

Table 3 shows the results by comparing minimum effort with extra effort when using hypergraphs to generate REs. As indicated here, extra effort (by adding one additional descriptor) leads to more comprehensible REs with 3.9% improvement under perfect perception and 6.3% improvement under imperfect perception (both are significant, $p < 0.05$). The improvement is larger under imperfect perception. This seems to indicate that exploring extra effort in REG could help mediate mismatched perceptions in situated dialogue. However, more understanding on how to engage in such extra effort will be required in the future.

5 Conclusion

In situated dialogue, humans and agents have mismatched perceptions of the shared environment. To facilitate successful referential communication between a human and an agent, the agent needs to take such discrepancies into consideration and generate referential descriptions that can be understood by its human partner. With this in mind, we re-visited the problem of referring expression generation in the context of mismatched perceptions between humans and agents. In particular, we applied and extended the state of the art graph-based approach (Krahmer et al., 2003) in this new setting. Our empirical results have shown that, to address the agent's limited perceptual capability, REG algorithms will need to take into account the uncertainties in perception and reasoning. Group-based information appears more reliable and thus should be modeled by an approach that deals with automated perception of spatially rich scenes.

While graph-based approaches have shown effective for the situation where the agent has complete knowledge of the environment, as its human partner, these approaches are often inadequate when humans and agents have mismatched representations of the shared world. Our empirical results here call for new solutions to address the mismatched perceptual basis. Previous work indicated that referential communication is a collaborative process (Clark and Wilkes-Gibbs, 1986; Heeman and Hirst, 1995). Conversation partners make extra effort to collaborate with each other. For the situation with mismatched perceptual basis, a potential solution thus should go beyond the objective of generating a minimum description, and towards a collaborative model which incorporates immediate feedback from the conversation partner (Edmonds, 1994).

Open-Domain Fine-Grained Class Extraction from Web Search Queries

Abstract

This paper introduces a method for extracting fine-grained class labels (*"countries with double taxation agreements with india"*) from Web search queries. The class labels are more numerous and more diverse than those produced by current extraction methods. Also extracted are representative sets of instances (*singapore*, *united kingdom*) for the class labels.

1 Introduction

Motivation: As more semantic constraints are added, concepts like *companies* become more specific, e.g., *companies* that are in the *software* business, and have been *started in a garage*. The sets of instances associated with the classes become smaller; the class labels used to concisely describe the meaning of more specific concepts tend to become longer. In fact, fine-grained class labels such as *"software companies started in a garage"* are often complex noun phrases, since they must somehow summarize multiple semantic constraints. Although Web users are interested in both coarse (e.g., *"companies"*) and fine-grained (e.g., *"software companies started in a garage"*) class labels, virtually all class labels acquired from text by previous extraction methods (Etzioni et al., 2005; Van Durme and Paşca, 2008; Kozareva and Hovy, 2010; Snow et al., 2006) exhibit little syntactic diversity. Indeed, instances and class labels that are relatively complex nouns are known to be difficult to detect and pick out precisely from surrounding text (Downey et al., 2007). This and other challenges associated with large-scale extraction from Web text (Etzioni et al., 2011) cause the extracted class labels to usually follow a rigid modifiers-plus-nouns format. The format covers nouns (*"companies"*) possibly preceded by one or many modifiers (*"software companies"*, *"computer security software companies"*). Examples of actual extractions include *"european cities"* (Etzioni et al., 2005), *"strong acids"* (Pantel and Pennacchiotti, 2006), *"prestigious private schools"* (Van Durme and Paşca, 2008), *"aquatic birds"* (Kozareva and Hovy, 2010).

As an alternative to extracting class labels from text, some methods simply import them from human-curated resources, for example from the set of categories encoded in Wikipedia (Remy, 2002). As a result, class labels potentially exhibit higher syntactic diversity. The modifiers-plus-nouns format (*"computer security software companies"*) is usually still the norm. But other formats are possible: *"software companies based in london"*, *"software companies of the united kingdom"*. Vocabulary coverage gaps remain a problem, with many relevant class labels (*"software companies of texas"* *"software companies started in a garage"*, *"software companies that give sap training"*) still missing. There is a need for methods that more aggressively identify fine-grained class labels, beyond those extracted by previous methods or encoded in existing, manually-created resources. Such class labels increase coverage, for example in scenarios that enrich Web search results with instances available for the class labels specified in the queries.

Contributions: The contributions of this paper are twofold. First, it proposes a weakly-supervised

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 403–414,
Seattle, Washington, USA, 18-21 October 2013.

method to assemble a large vocabulary of class labels from queries. The class labels include fine-grained class labels (*"countries with double taxation agreements with india"*, *"no front license plate states"*) that are difficult to extract from text by previous methods for open-domain information extraction. Second, the method acquires representative instances (*singapore*, *united kingdom*; *arizona*, *new mexico*) that belong to fine-grained class labels (*"countries with double taxation agreements with india"*, *"no front license plate states"*). Both class labels and their instances are extracted from Web search queries.

2 Extraction from Queries

2.1 Extraction of Class Labels

Overview: Given a set of arbitrary Web search queries as input, our method produces a vocabulary of fine-grained class labels. For this purpose, it: a) selects an initial vocabulary of class labels, as a subset of input queries that are likely to correspond to search requests for classes; b) expands the vocabulary, by generating a large, noisy set of other possible class labels, through replacements of ngrams within initial class labels with their similar phrases; c) restricts the generated class labels to those that match the syntactic structure of class labels within the initial vocabulary; and d) further restricts the generated class labels to those that appear within the larger set of arbitrary Web search queries.

Initial Vocabulary of Class Labels: Out of a set of arbitrary search queries available as input, the queries in the format *"list of .."* are selected as the initial vocabulary of class labels. The prefix *"list of"* is discarded from each query. Thus, the query *"list of software companies that use linux"* gives the class label *"software companies that use linux"*.

Generation via Phrase Similarities: As a prerequisite to generating class labels, distributionally similar phrases (Lin and Pantel, 2002; Lin and Wu, 2009; Pantel et al., 2009) and their scores are collected in advance. A phrase is represented as a vector of its contextual features. A feature is a word, collected from windows of three words centered around the occurrences of the phrase in sentences across Web documents (Lin and Wu, 2009). In the contextual vector of a phrase, the weight of a feature is the pointwise-mutual information (Lin and Wu, 2009) between the phrase P and the feature F. The distributional similarity score between two phrases is the cosine similarity between the contextual vectors of the two phrases. The lists of most distributionally similar phrases of a phrase P are thus compiled offline, by ranking the similar phrases of P in decreasing order of their similarity score relative to P.

Each class label from the initial vocabulary is expanded into a set of generated, candidate class labels. To this effect, every ngram P within a given class label is replaced with each of the distributionally similar phrases, if any, available for the ngram. As shown later in the experimental section, the expansion can increase the vocabulary by a factor of 100.

Approximate Syntactic Filtering: The set of generated class labels is noisy. The set is filtered, by retaining only class labels whose syntactic structure matches the syntactic structure of some class label(s) from the initial vocabulary. The syntactic structure is loosely approximated at surface rather than syntactic level. A generated class label is retained, if its sequence of part of speech tags matches the sequence of part of speech tags of one of the class labels from the initial vocabulary. As an additional constraint, the sequence must contain one tag corresponding to a common noun in plural form, i.e., NNS. Otherwise, the class label is discarded.

Query Filtering: Generated class labels that pass previous filters are further restricted. They are intersected with the set of arbitrary Web search queries available as input. Generated class labels that are not full queries are discarded.

2.2 Extraction of Instances

Overview: Our method mines instances of fine-grained class labels from queries. In a nutshell, it identifies queries containing two types of information simultaneously. First, the queries contain an instance (*marvin gaye*) of the more general class labels (*"musicians"*) from which the fine-grained class labels (*"musicians who have been shot"*) can be obtained. Second, the queries contain the constraints added by the fine-grained class labels (*"... shot"*) on top of the more general class labels.

Instances of General Class Labels: Following (Ponzetto and Strube, 2007), the Wikipedia category network is refined into a hierarchy that discards

non-IsA (thematic) edges, and retains only IsA (subsumption) edges from the network (Ponzetto and Strube, 2007). Instances, i.e., titles of Wikipedia articles, are propagated upwards to all their ancestor categories. The class label *"musicians"* would be mapped into *madonna, marvin gaye, jon bon jovi* etc. The mappings from each ancestor category, to all its descendant instances in the Wikipedia hierarchy, represent our mappings from more general class labels to instances.

Decomposition of Fine-Grained Class Labels: A fine-grained class label (e.g., *"musicians who have been shot"*) is effectively decomposed into pairs of two pieces of information. The first piece is a more general class label (*"musicians"*), if any occurs in it. The second piece is a bag of words, collected from the remainder of the fine-grained class label after discarding stop words. Note that the standard set of stop words is augmented with auxiliary verbs (e.g., *does*, *has*, *is*, *would*), determiners, conjunctions, prepositions, and question wh-words (Radev et al., 2005) (e.g., *where*, *how*). In the first piece of each pair, the general class label is then replaced with each of its instances. This produces multiple pairs of a candidate instance and a bag of words, for each fine-grained class label. As an illustration, the class labels *"musicians who have been shot"* and *"automobiles with remote start"* are decomposed into pairs like <*madonna*, {*shot*}>, <*marvin gaye*, {*shot*}>; and <*buick lacrosse*, {*remote*, *start*}>, <*nissan versa*, {*remote*, *start*}>, respectively.

Matching of Candidate Instances: A decomposed class label is retained, if there are matching queries that contain the candidate instance, the bag of words, and optionally stop words. Otherwise, the decomposed class label is discarded. The word matching is performed after word stemming (Porter, 1980). The aggregated frequency of the matching queries is assigned as the score of the candidate instance for the fine-grained class label:

$$Score(I, C) = \sum_{Q} (Freq(Q) | Match(Q, < I, C >)) \quad (1)$$

For example, the score of the candidate instance *marvin gaye* for the class label *"musicians who have been shot"*, is the sum of the frequencies of the matching queries *"marvin gaye is shot"*, *"when was marvin gaye shot"*, *"why marvin gaye was shot"* etc. Similarly, the score of *buick lacrosse* for *"automobiles with remote start"* is given by the aggregated frequencies of the queries *"buick lacrosse remote start"*, *"how to remote start buick lacrosse"*, *"remote start for buick lacrosse"*. Candidate instances of a class label are ranked in decreasing order of their scores.

3 Experimental Setting

Web Textual Data: The experiments rely on a sample of 1 billion queries in English submitted by users of a Web search engine. Each query is accompanied by its frequency of occurrence. Also available is a sample of around 200 million Web documents in English.

Phrase Similarities: Web documents are used in the experiments only to construct a phrase similarity repository following (Lin and Wu, 2009; Pantel et al., 2009). The repository contains ranked lists of the top 1000 phrases, computed to be the most distributionally similar to each of around 16 million phrases.

Text Pre-Processing: The TnT tagger (Brants, 2000) assigns part of speech tags to words in class labels.

Instances: To collect mappings from Wikipedia categories (as more general class labels) to titles of descendant Wikipedia articles (as instances), a snapshot of Wikipedia articles was intersected with the Wikipedia category hierarchy from (Ponzetto and Strube, 2007). The mappings connect a total of 1,535,083 instances to a total of 108,756 class labels.

4 Evaluation of Class Labels

4.1 Evaluation Procedure

Experimental Runs: Human-compiled information available within Wikipedia serves as the source of data for two baseline runs. The set of all categories, listed in Wikipedia for any of its articles, corresponds to the set of class labels "acquired" in run R_{wc}. Categories used for internal Wikipedia bookkeeping (Ponzetto and Strube, 2007) are discarded. Their names contain one of the words *article(s)*, *category(ies)*, *indices*, *pages*, *redirects*, *stubs*, or *templates*. Similarly, the titles of Wikipedia articles with the prefix *"List of ..."* (e.g., *"List of automobile manufacturers of Germany"*) form the set of class labels

"acquired" in run R_{wl}. The prefix *"List of"* is discarded.

For completeness, a third baseline run, R_{dc}, corresponds to class labels extracted from Web documents. The class labels are noun phrases *C* that fill extraction patterns equivalent to *"C such as I"*. The patterns are matched to document sentences. The boundaries of the class labels *C* are approximated from part of speech tags of sentence words (Van Durme and Paşca, 2008). The patterns were proposed in (Hearst, 1992). They were employed widely in subsequent methods (Etzioni et al., 2005; Kozareva et al., 2008; Wu et al., 2012), which extract class labels precisely from the set of class labels *C* produced by the extraction patterns. Even methods using queries as a textual data source still extract class labels from documents using the same extraction patterns (Paşca, 2010). Therefore, from the point of view of evaluating class labels, run R_{dc} is a valid representative of previous extraction methods, including (Etzioni et al., 2005; Kozareva et al., 2008; Van Durme and Paşca, 2008; Paşca, 2010; Wu et al., 2012).

Besides the baseline runs, three experimental runs are considered. In run R_{ql}, the queries starting with the prefix *"list of"* form the set of class labels. The prefix *"list of"* is discarded from each query. In run R_{qg}, the class labels are generated via phrase similarities, starting from R_{ql} as an initial set of class labels. Run R_{qa} represents an ablation experiment. It is created from R_{qg}, by limiting the expansion of a given class label via distributional similarities to only one, rather than multiple, phrases within the class label. Note that, by design, none of the class labels that appear in R_{ql} also appear in runs R_{qa} or R_{qg}. Therefore, the intersection between R_{ql}, on one hand, and R_{qa} and R_{qg}, on the other hand, is the empty set.

All data, including the class labels extracted in all experimental runs, is converted to lower case.

4.2 Relative Coverage of Class Labels

Coverage Over Entire Sets: Table 1 illustrates the overall coverage of the various experimental runs. The table takes all class labels into account, relative to the Wikipedia-based runs as reference sets: R_{wc} (Wikipedia categories), in the upper part of the table; and R_{wl} (Wikipedia List-Of categories), in the lower part of the table. Note that the number of class labels extracted by the individual run shown in the second column (B) is shown in the fourth column (|B|). In particular, there are around 1.6 million unique *"list of .."* queries, from which class labels are collected in run R_{ql}.

Counts					Cvg
A	B	|A|	|B|	|A∩B|	$\frac{\|A \cap B\|}{\|A\|}$
vs. Wikipedia categories:					
R_{wc}	R_{dc}	295,587	2,884,390	15,011	0.051
	R_{ql}	295,587	1,649,261	21,979	0.074
	R_{qa}	295,587	33,073,741	33,502	0.113
	R_{qg}	295,587	134,235,151	43,935	0.148
	$R_{ql} \cup R_{qg}$	295,587	135,884,412	65,914	0.222
vs. Wikipedia categories that are queries:					
$R_{wc} \cap Q$	R_{dc}	126,318	2,884,390	14,840	0.117
	R_{ql}	126,318	1,649,261	21,979	0.173
	R_{qa}	126,318	33,073,741	33,502	0.265
	R_{qg}	126,318	134,235,151	43,935	0.347
	$R_{ql} \cup R_{qg}$	126,318	135,884,412	65,914	0.521
vs. Wikipedia List-Of categories:					
R_{wl}	R_{dc}	134,840	2,884,390	8,099	0.060
	R_{ql}	134,840	1,649,261	26,446	0.196
	R_{qa}	134,840	33,073,741	16,204	0.120
	R_{qg}	134,840	134,235,151	20,021	0.148
	$R_{ql} \cup R_{qg}$	134,840	135,884,412	46,467	0.344
vs. Wikipedia List-Of categories that are queries:					
$R_{wl} \cap Q$	R_{dc}	47,442	2,884,390	7,985	0.168
	R_{ql}	47,442	1,649,261	24,821	0.523
	R_{qa}	47,442	33,073,741	16,204	0.341
	R_{qg}	47,442	134,235,151	20,021	0.422
	$R_{ql} \cup R_{qg}$	47,442	135,884,412	44,842	0.945

Table 1: Coverage of class labels extracted by various experimental runs, relative to class labels available in Wikipedia before and after intersecting them with a large set of arbitrary queries (A = reference set, relative to which coverage is computed; B = measured set, for which coverage is computed relative to the reference set; |A| = size of set A; Q = set of input queries)

During the computation of coverage, the reference set, and the set for which coverage is being computed, are intersected. Intersection relies on strict string matching. All words, including punctuation, must match exactly in order for a class label to be part of the intersection. The reference sets are intersected with the set of all Web search queries Q used in the experiments. Coverage is computed both before and after intersection. Less than half (126,318 of 295,587) of the class labels, for

the reference set R_{wc}; and about a third (47,442 of 134,840) for R_{wl}; appear in the set Q of all queries.

Three conclusions can be drawn from the results. First, query-based runs vastly outperform Wikipedia-based runs in terms of absolute coverage. Run R_{ql} contains around 5 and 12 times more class labels, than R_{wc} and R_{wl} respectively. On top of that, generating class labels via phrase similarities further increases the class label count by about 20 times for R_{qa}, and 80 times for R_{qg}. Second, query-based runs R_{qa} and R_{qg} surpass the document-based run R_{dc}. Third, higher class label counts translate into higher relative coverage. In the upper part of the table, run R_{wl} contains 3.9% (relative to R_{wc}) and 7.1% (relative to $R_{wc} \cap Q$) of the reference set. But the relative coverage doubles for R_{ql} at 7.4% (relative to R_{wc}) and 17.3% (relative to $R_{wc} \cap Q$). Coverage again doubles for R_{qg} at 14.8% (relative to R_{wc}) and 34.7% (relative to $R_{wc} \cap Q$). The union of query-based initial and generated class labels is $R_{ql} \cup R_{qg}$. The union contains about a quarter (i.e., 22.2%) or half (52.1%) of the reference set R_{wc}, depending on whether the reference set is intersected with the set of all queries or not. In the lower part of the table, more than 90% of the queries in the reference set R_{wl} that are also queries are found among the class labels collectively extracted in the query-based runs. Note that, since R_{ql} is disjoint from R_{qa} and R_{qg}, none of the class labels already in R_{ql} can be "re-discovered" (generated) again in R_{qa} or R_{qg}. Therefore, by experimental design, relative coverage scores of R_{ql} may be relatively difficult to surpass by R_{qa} or R_{qg} taken individually.

Diversity: Class labels restricted to those that have the format *".. that/which/who .."* are relatively more specific, e.g., *"grocery stores that double coupons in omaha"*, *"airlines which fly from santa barbara"*, *"writers who were doctors"*. The most frequent head phrases of such restricted class labels offer an idea about how diverse the class labels are. The counts of class labels for the most frequent head phrases are in the order of 10's in the case of R_{wl} vs. 10,000's for R_{qg}. In comparison, none of the class labels of run R_{dc} have this format. The lack of such class labels in run R_{dc}, and their smaller proportion in run R_{wl} vs. R_{qg}, suggest that class labels extracted by the proposed method exhibit higher lexical and syntactic diversity than previous methods do.

Tag (Value): Examples of Class Labels
correct (1.0): angioplasty specialists in kolkata, good things pancho villa did, eating disorders inpatient units in the uk nhs specialist services
questionable (0.5): picture framers adelaide cbd, side effects bicalutamide, different eating disorders, private hospitals treat kidney stones uk
incorrect (0.0): al hirschfield theatre hours, value of berkshire hathaway shares, remove spaces in cobol, dogs with loss of appetite, 1999 majorca open

Table 2: Correctness tags manually assigned to class labels containing one of the (underlined) target phrases, extracted by various runs

4.3 Precision of Class Labels

Evaluation Metric: Class labels being evaluated are manually assigned a correctness tag. A class label is deemed *correct*, if it is grammatically well-formed and describes a relevant concept that embodies some (unspecified) set of instances that share similar properties; *questionable*, if it is relevant but not well-formed; or *incorrect*. A *questionable* class label is not well-formed because it lacks necessary linking particles (e.g., the prepositions *of* or *for* in *"side effects bicalutamide"*), or contains undesirable modifiers (*"different eating disorders"*). Examples of *correct* and *incorrect* class labels are *"angioplasty specialists in kolkata"* and *"al hirschfield theatre hours"* respectively.

To compute the precision score, the correctness tags are converted to numeric values, as shown in Table 2: *correct* to 1; *questionable* to 0.5; and *incorrect* to 0. Precision over a list of class labels is measured as the sum of the correctness values of the class labels in the list, divided by the size of the list.

Precision Relative to Target Phrases: The precision of the class labels in each run is determined similarly to how relative coverage was computed earlier. More precisely, the precision is computed over the class labels whose names contain each phrase from the set of 75 target phrases from (Alfonseca et al., 2010). For each phrase, and for each run, a random sample of at most 50 of the class labels that match the phrase is selected for evaluation. The samples taken for each run, corresponding to the same phrase, are combined into a merged list. This produces one merged list for each phrase, for a total of 75 merged lists. The precision score over a target

phrase is the precision score over its sample of class labels.

The last two columns of Table 3 capture the precision scores for the class labels. The scores are computed in two ways: averaged over the (variable) subsets of target phrases for which some matching class label(s) exist, in the last but one column, e.g., over 19 of the 75 target phrases for R_{wc}; and averaged over the entire set of 75 target phrases, in the last column. The former does not penalize a run for not being able to extract any class labels containing a particular target phrase, whereas the latter does penalize. Naturally, precision scores over the entire set of target phrases decrease when coverage is lower, for runs R_{wc}, R_{wl} and, to a lesser extent, R_{dc} and R_{ql}. But even after ignoring target phrases with no matching class labels, precision scores in the last but one column in Table 3 reveal important properties of the experimental runs. First, between the two Wikipedia-based runs, R_{wl} has perfect class labels, whereas as many as 1 in 4 class labels of run R_{wc} are marked as incorrect during the evaluation. Second, the class labels collected from *"list of .."* queries in run R_{ql} correspond to relevant, well-formed concepts in 80% of the cases. Third, the generation of class labels via phrase similarities (R_{qg}) greatly increases coverage as shown earlier. The increase comes at the expense of lowering precision from 80% to 72%. However, the phrases from initial queries that are expanded via distributional similarities can be limited from multiple to only one, by switching from R_{qg} to R_{qa}. This gives higher precision for R_{qa} than for R_{qg}.

As a complement to Table 3, the graphs in Figure 1 offer a more detailed view into the precision of class labels. The figure covers a Wikipedia-based run (R_{wc}) and two query-based runs (R_{ql}, R_{qg}). The graphs show the precision scores, over each of the 75 target phrases. Among target phrases for which some matching class labels exist in the respective run, the target phrases with the lowest precision scores are *robotics* (score of 0.15) and *karlsruhe* (0.33), for R_{wc}; *carotid arteries* and *kidney stones*, both with a score of 0.00 because their matching class labels are all incorrect, for R_{dc}; *african population* and *chester arthur*, both with a score of 0.00 because their matching class labels are all incorrect, for R_{ql}; and *arlene martel* (0.00) and *right to vote* (0.25), for R_{qg}.

Run	Target Phrases			Precision of Class Labels Over Target Phrases	
	All	Matched	Cvg	Over Matched	Over All
R_{wc}	75	19	0.253	0.756	0.191
R_{wl}	75	15	0.200	1.000	0.200
R_{dc}	75	35	0.467	0.834	0.389
R_{ql}	75	48	0.640	0.800	0.512
R_{qa}	75	70	0.933	0.868	0.810
R_{qg}	75	73	0.973	0.724	0.705

Table 3: Precision of class labels that match (i.e., whose names contain) each target phrase, computed as an average over (variable) subsets of target phrases for which some matching class label(s) exist, and as an average over the entire set of 75 target phrases

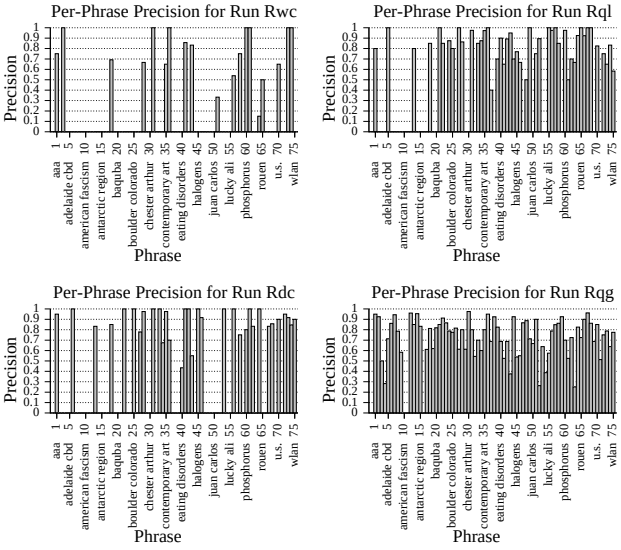

Figure 1: Precision scores for runs R_{wc}, R_{ql}, R_{dc} and R_{qg}, over class labels that match (i.e., contain) each of the 75 target phrases

Precision over Samples of Class Labels: The precision is separately computed over a random sample of 400 class labels per experimental run. The samples are selected from the set of all class labels extracted by the respective run. The precision scores are: 0.759 for R_{wc}; 1.000 for R_{wl}; 0.806 for R_{dc}; 0.811 for R_{ql}; 0.856 for R_{qa}; and 0.711 for R_{qg}. The scores are in line with scores computed earlier over the target phrases, in the fourth column of Table 3.

Discussion: As noted in (Ponzetto and Strube, 2007), Wikipedia organizes its articles and categories into a category network that mixes IsA (subsumption) edges with non-IsA (thematic) edges. Whenever an edge in Wikipedia is not IsA, the par-

Longest Class Labels
R_{wl}: [japanese army and navy members in military or politic services in proper japan korea manchuria occupied china and nearest areas in previous times and pacific war epoch(1930-40s), mental disorders as defined by the diagnostic and statistical manual of mental disorders and the international statistical classification of diseases and related health problems,..]
R_{qg}: [differences between transformational leadership and transactional leadership, things to do in llanfairpwllgwyngyllgogerychwyrndrobwllllantysiliogogogoch, philosophical differences between thomas jefferson and alexander hamilton, musculoskeletal manifestations of human immunodeficiency virus infection,..]

Table 4: Longest class labels extracted by runs R_{wl} and R_{qg}

ent category may not be a relevant concept that describes some set of instances that share similar properties. Such categories are not good class labels, and therefore are marked as incorrect. Examples include the class labels *"austrian contemporary art"*, *"1999 majorca open"* and *"u.s. route 30"*, listed in Wikipedia as categories of the instances *vienna biennale*, *1999 majorca open* and *squirrel hill tunnel* respectively. This affects the precision scores for R_{wc} in Table 3. It also affects the coverage values relative to R_{wc} in Table 1. Ideally, high-precision experimental runs would not extract any incorrect class labels that happen to appear in R_{wc}, for example *"austrian contemporary art"*. But the coverage relative to R_{wc} would artificially penalize such runs, for not extracting the incorrect class labels from R_{wc}.

As a proxy for estimating class label complexity, Table 4 shows the longest class labels derived from Wikipedia (R_{wl}) vs. generated from queries (R_{qg}).

Class labels derived from Web search queries may be semantically overlapping. Examples are *"writers who killed themselves"* vs. *"writers who committed suicide"*. The overlap is desirable, since different Web users may request the same information via different queries. The same phenomenon has been observed in other information extraction tasks. It also affects manually-created resources like Wikipedia. The continuous manual refinements to Wikipedia content still cannot prevent the occurrence of duplicate class labels among Wikipedia List-Of categories. The duplicates are present in run R_{wl}. Examples are *"formula one drivers that never qualified for a race"* vs. *"formula one drivers who never qualified for a race"*; or *"goaltenders who have scored a goal in a nhl game"* vs. *"goaltenders who have scored a goal in an nhl game"*. Some of the lexical differences among class labels are due to undesirable misspellings. Again, similar problems occasionally affect existing Wikipedia categories: *"nobel laureates who endorse barack obama"* vs. *"nobel laureates who endorse barrack obama"*.

Target Class Labels
007 movie actors, .308 weapons, actors with obsessive compulsive disorder, antibiotics for multiple sclerosis, astronauts in space station, automobiles with remote start, beatles songs of love, beetles that bite, companies with sustainable competitive advantage, countries with double taxation agreements with india, criminals who have been executed, daft punk live albums, dallas medical companies, direct democracy states, electronic companies in electronic city bangalore, expensive brands of shoes, eye diseases in cats, f1 car companies, fwd sports cars, garden landscaping magazines, heliskiing resorts, hell in a cell wrestlers, holidays celebrated in sydney, ibf weight classes, ibiza 2011 djs, immunology scientists, jewelry manufacturing companies, kanye west songs on youtube, kingston upon thames supermarkets, latin military ranks, ludhiana newspapers, maastricht treaty countries, musicians who have been shot, no front license plate states, non-profit organizations in nashville tennessee, organic chocolate companies, plants which are used in homeopathy, programming languages for server side programming, qatar chemical companies, qld private schools, real estate companies in virginia beach virginia, respiratory infection antibiotics, serial killers with antisocial personality disorder, singers with curly hair, telecommunications companies in the philippines, trains from la to san diego, visual basic database management systems, warmblood colors, washington university basketball players, world heritage sites in northern ireland

Table 5: Set of 50 class labels, used in the evaluation of extracted instances

5 Evaluation of Instances

5.1 Evaluation Procedure

Target Set of Class Labels: The target set for evaluation is shown in Table 5. Initially, a random sample of 100 class labels is selected from all class labels in

Tag (Value): Examples of Instances
correct (1.0): countries with double taxation agreements with india: thailand; hell in a cell wrestlers: brock lesnar; ibiza 2011 djs: dimitri from paris; heliskiing resorts: valle nevado
questionable (0.5): 007 movie actors: david niven; kanye west songs on youtube: the good life; holidays celebrated in sydney: waitangi day
incorrect (0.0): electronic companies in electronic city bangalore: bank of baroda; garden landscaping magazines: marquis; immunology scientists: rosalind franklin

Table 6: Correctness tags manually assigned to instances extracted from queries for various class labels

run R_{qg}. Class labels deemed incorrect, as well as class labels for which no instances are extracted, are manually removed from the sample. Out of the remaining class labels, a smaller random sample of 50 of the remaining class labels is retained, for the purpose of evaluating the quality of instances extracted for various class labels.

Evaluation Metric: The evaluation computes the precision of the ranked list of instances extracted for each target class label. To remove any undesirable bias towards higher-ranked instances, the ranked list is sorted alphabetically, then each instance is assigned one of the correctness tags from Table 6. Instances are deemed questionable, if they would be correct for a rather obscure interpretation of the class label. For example, *david niven* is an actor in one of the spoofs rather than main releases of the *007 movie*. Instances that would be correct if a few words were dropped or added are also deemed questionable: *the good life* is not one of the *"kanye west songs on youtube"* but *good life* is.

To compute the precision score over a ranked list of instances, the correctness tags are converted to numeric values. Precision at some rank N in the list is measured as the sum of the correctness values of the instances extracted up to rank N, divided by the number of instances extracted up to rank N.

5.2 Precision of Instances

Precision: Precision scores in Table 7 vary across target class labels. For some class labels, the extracted instances are noisy enough that scores are below 0.50 at ranks 10 and higher. This is the case for *"electronic companies in electronic city bangalore"* and *"daft punk live albums"*, and especially for *"garden landscaping magazines"* which has the worst precision. On the other hand, instances extracted for *"companies with sustainable competitive advantage"* or *"criminals who have been executed"* have high precision across all ranks. As an average over all target class labels, precision is 0.76 at rank 10, and 0.71 at rank 50. Although there is room for improvement, we find these accuracy levels to be encouragingly good, especially at rank 50. As a reminder, instances are extracted from noisy queries, and for class labels as fine-grained as those acquired and used in our experiments. Some of the extracted ranked lists of instances are shown in Table 8.

Target Class Label	Precision of Instances			
	@1	@5	@10	@50
007 movie actors	1.00	1.00	0.85	0.85
actors with obsessive compulsive disorder	0.00	0.60	0.70	0.70
antibiotics for multiple sclerosis	0.50	0.60	0.55	0.58
astronauts in space station	1.00	0.70	0.85	0.83
automobiles with remote start	1.00	1.00	0.75	0.75
beatles songs of love	0.00	0.50	0.65	0.52
beetles that bite	1.00	0.80	0.50	0.56
companies with sustainable competitive advantage	1.00	1.00	0.80	0.88
countries with double taxation agreements with india	1.00	1.00	1.00	0.90
criminals who have been executed	1.00	1.00	0.90	0.82
daft punk live albums	0.50	0.40	0.35	0.35
dallas medical companies	0.00	0.70	0.65	0.54
direct democracy states	1.00	1.00	0.90	0.86
electronic companies in electronic city bangalore	1.00	0.40	0.40	0.42
expensive brands of shoes	1.00	1.00	0.90	0.92
eye diseases in cats	0.50	0.50	0.35	0.35
f1 car companies	1.00	1.00	0.80	0.30
fwd sports cars	1.00	1.00	1.00	1.00
garden landscaping magazines	0.00	0.10	0.15	0.06
heliskiing resorts	1.00	1.00	1.00	1.00
hell in a cell wrestlers	1.00	1.00	1.00	0.92
holidays celebrated in sydney	1.00	0.70	0.75	0.75
...	...	...	...	...
Average over 50 class labels	0.80	0.80	0.76	0.71

Table 7: Precision at various ranks in the ranked lists of instances extracted from queries, for various target class labels and as an average over the entire set of 50 target class labels

Target Class Label	Extracted Instances
countries with double taxation agreements with india	[singapore, malaysia, mauritius, kenya, australia, united kingdom, cyprus, turkey, thailand, germany,..]
direct democracy states	[california, oregon, nevada, wisconsin, louisiana, arizona, vermont, alaska, illinois, michigan,..]
fwd sports cars	[scion tc, ford probe, honda prelude, nissan 200sx, lotus elan, mitsubishi fto, dodge srt-4, mitsubishi gto, volvo c30, toyota celica,..]
garden landscaping magazines	[front, contemporary, gallery, edge, view, chelsea, wallpaper, expo, wizard, sunset,..]
holidays celebrated in sydney	[halloween, australia day, anzac day, independence day, waitangi day, melbourne cup, hogmanay, rotuma day, solstice, yule,..]

Table 8: Ranked lists of instances extracted for a sample of class labels

In additional experiments, the same evaluation procedure is applied to output from two previous extraction methods. The first method starts by internally generating a small set of seed instances for a class label given as input (Wang and Cohen, 2009). A set expansion module then expands the seed set into a longer, ranked list of instances. The instances are extracted from unstructured and semi-structured text within Web documents. The documents are accessed via the search interface of a general-purpose Web search engine (cf. (Wang and Cohen, 2009) for more details). The second method extracts instances of class labels using the extraction patterns proposed in (Hearst, 1992). As such, it is similar to (Kozareva et al., 2008; Van Durme and Paşca, 2008; Wu et al., 2012). The method corresponds to the run R_{dc} described earlier, where the relative ranking of instances and class labels uses the co-occurrence of instances and class labels within queries (Paşca, 2010). For the purpose of the evaluation, when no instances are available for a target class label, the class label is generalized into iteratively shorter phrases containing fewer modifiers, until some instances are available for the shorter phrase. For example, target class labels like *actors with obsessive compulsive disorder*, *beatles songs of love*, *garden landscaping magazines* do not have any instances extracted by the second method. Therefore, the instances evaluated for the second method for these target class labels are collected from the instances of the more general *actors*, *beatles songs*, *landscaping magazines*. Without the generalization, the target class label would receive no credit during the evaluation, and the two previous methods would have lower precision scores. Over the 50 target class labels, the precision of the two methods is 0.11 and 0.27 at rank 5; 0.06 and 0.25 at rank 10; 0.05 and 0.22 at rank 20; and 0.05 and 0.20 at rank 50. The results confirm that, as explained earlier, previous methods for open-domain information extraction have limited ability to extract instances of fine-grained class labels.

Discussion: Earlier errors in the acquisition of the class label affect the usefulness of any instances that may be subsequently extracted for them. The experiments require candidate instances to appear in Wikipedia. This may improve precision, at the expense of not extracting instances that are not yet in Wikipedia (Lin et al., 2012).

6 Related Work

Previous methods for extracting classes of instances from text acquire sets of instances that are each either unlabeled (Pennacchiotti and Pantel, 2009; Jain and Pennacchiotti, 2010; Shi et al., 2010), or associated with a class label (Banko et al., 2007; Wang and Cohen, 2009). The sets of instances and/or class labels may be organized as flat sets or hierarchically, relative to inferred hierarchies (Kozareva and Hovy, 2010) or existing hierarchies such as WordNet (Snow et al., 2006; Davidov and Rappoport, 2009) or the category network within Wikipedia (Wu and Weld, 2008; Ponzetto and Navigli, 2009). Semi-structured text from Web documents is a complementary resource to unstructured text, for the purpose of extracting relations in general (Cafarella et al., 2008), and classes and instances in particular (Talukdar et al., 2008; Dalvi et al., 2012).

With previous methods, the vocabulary of class labels potentially produced for any instance is confined to a closed set provided manually as input (Wang and Cohen, 2009; Carlson et al., 2010). The closed set is often derived from resources like Wikipedia (Talukdar and Pereira, 2010; Lin et al.,

2012; Hoffart et al., 2013) or Freebase (Pantel et al., 2012). Alternatively, the vocabulary is not a closed set, but instead is acquired along with the instances (Pantel and Pennacchiotti, 2006; Snow et al., 2006; Banko et al., 2007; Van Durme and Paşca, 2008; Kozareva and Hovy, 2010). In the latter case, the extracted class labels take the form of head nouns preceded by modifiers. Examples are *"cities"*, *"european cities"* (Etzioni et al., 2005); *"artists"*, *"strong acids"* (Pantel and Pennacchiotti, 2006); *"outdoor activities"*, *"prestigious private schools"* (Van Durme and Paşca, 2008); *"methaterians"*, *"aquatic birds"* (Kozareva and Hovy, 2010). In contrast, the class labels extracted in our method exhibit greater syntactic diversity and are finer-grained. In addition, they are not constrained to a particular set of categories available in resources like Wikipedia.

Fine-grained class labels roughly correspond to queries submitted in typed search (Demartini et al., 2009) or entity search (Balog et al., 2010) or list-seeking questions (*"name the circuit judges in the cayman islands that are british"*). But our focus is on generating, rather than answering such queries or, more generally, attempting to deeply understand their semantics (Li, 2010). Phrase similarities can be derived with any methods, using documents (Lin and Wu, 2009) or search queries (Jain and Pennacchiotti, 2010).

Whether Web search queries are a useful textual data source for open-domain information extraction has been investigated in several tasks. Examples are collecting unlabeled sets of similar instances (Jain and Pennacchiotti, 2010), ranking of class labels already extracted from text (Paşca, 2010), extracting attributes of instances (Alfonseca et al., 2010) and identifying the occurrences in queries of instances of several types, where the types are defined in a manually-created resource (Pantel et al., 2012). Comparatively, we show that queries are useful in identifying possible class labels, not only re-ranking them; and even in populating the class labels with relevant, albeit small, sets of corresponding instances.

As automatically-extracted class labels become finer-grained, they more clearly illustrate a phenomenon that received little attention. Namely, class labels of an instance, on one hand, and relations linking the instance with other instances and classes, on the other hand, are not mutually exclusive pieces of knowledge. Their extraction does not necessarily require different, dedicated techniques. Quite the opposite, class labels serve in text as nothing more than convenient lexical representations, or lexical shorthands, of relations linking instances with other instances. The class labels *"no front license plate states"* and *"states with no front license plate requirement"* are applicable to *arizona*. If so, it is because *arizona* is a *state*, and states require the installation of *license plates* on vehicles, and the requirement does not apply to the *front* of vehicles in the case of *arizona*. The connection between class labels and relations has been judiciously exploited in (Nastase and Strube, 2008). In that study, relations encoded implicitly within Wikipedia categories are transformed into explicit relations. As an example, the explicit relation that *deconstructing harry* is *directed* by *woody allen* is obtained from the fact that *deconstructing harry* is listed under *"movies directed by woody allen"* in Wikipedia. Ours is the first approach to examine the potential for extracting relations from search queries, where relations are compactly and loosely folded into the respective class labels. A variety of methods address the more general task of acquisition of open-domain relations from documents, e.g., (Zhu et al., 2009; Carlson et al., 2010; Fader et al., 2011; Lao et al., 2011).

7 Conclusion

The approach introduced in this paper exploits knowledge loosely encoded within Web search queries. It acquires a vocabulary of class labels that are finer grained than in previous literature. The class labels have precision comparable to that of class labels derived from human-created knowledge repositories. Furthermore, representative instances are extracted from queries for the fine-grained class labels, at encouraging levels of accuracy. Current work explores the use of noisy syntactic features to increase the accuracy of extracted class labels; the extraction of instances from evidence in multiple, rather than single queries; the expansion of extracted instances into larger sets; and the conversion of fine-grained class labels into relations among classes.

Abstract

In this paper we present an unsupervised approach to relational information extraction. Our model partitions tuples representing an observed syntactic relationship between two named entities (e.g., "X was born in Y" and "X is from Y") into clusters corresponding to underlying semantic relation types (e.g., *BornIn*, *Located*). Our approach incorporates general domain knowledge which we encode as First Order Logic rules and automatically combine with a topic model developed specifically for the relation extraction task. Evaluation results on the ACE 2007 English Relation Detection and Categorization (RDC) task show that our model outperforms competitive unsupervised approaches by a wide margin and is able to produce clusters shaped by both the data and the rules.

1 Introduction

Information extraction (IE) is becoming increasingly useful as a form of shallow semantic analysis. Learning relational facts from text is one of the core tasks of IE and has applications in a variety of fields including summarization, question answering, and information retrieval. Previous work (Surdeanu and Ciaramita, 2007; Culotta and Sorensen, 2004; Zhou et al., 2007) has traditionally relied on extensive human involvement (e.g., hand-annotated training instances, manual pattern extraction rules, hand-picked seeds). Standard supervised techniques can yield high performance when large amounts of hand-labeled data are available for a fixed inventory of relation types (e.g., *Employment*, *Located*), however, extraction systems do not easily generalize beyond their training domains and often must be re-engineered for each application. Unsupervised approaches offer a promising alternative which could lead to significant resource savings and more portable extraction systems.

It therefore comes as no surprise that latent topic analysis methods have been used for a variety of IE tasks. Yao et al. (2011), for example, propose a series of topic models which perform relation discovery by clustering tuples representing an observed syntactic relationship between two named entities (e.g., "X was born in Y" and "X is from Y"). The clusters correspond to semantic relations whose number or type is not known in advance. Their models depart from standard Latent Dirichlet Allocation (Blei et al., 2003) in that a document consists of relation tuples rather than individual words; moreover, tuples have features each of which is generated independently from a hidden relation (e.g., the words corresponding to the first and second entities, the type and order of the named entities). Since these features are *local*, they cannot capture more global constraints pertaining to the relation extraction task. Such constraints may take the form of restrictions on which tuples should be clustered together or not. For instance, different types of named entities may be indicative of different relations (ORG-LOC entities often express a *Location* relation whereas PER-PER entities express *Business* or *Family* relations) and thus tuples bearing these entities should not be grouped together. Another example are tuples with identical or similar features which intuitively should be clustered together.

In this paper, we propose an unsupervised approach to relation extraction which does not re-

Seattle, Washington, USA, 18-21 October 2013.

quire any relation-specific training data *and* allows to incorporate *global* constraints general expressing domain knowledge. We encode domain knowledge as First Order Logic (FOL) rules and automatically integrate them with a topic model to produce clusters shaped by the data and the constraints at hand. Specifically, we extend the Fold-all (First-Order Logic latent Dirichlet Allocation) framework (Andrzejewski et al., 2011) to the relation extraction task, explain how to incorporate meaningful constraints, and develop a scalable inference technique. In the presence of multiple candidate relation decompositions for a given corpus, domain knowledge can steer the model towards relations which are best aligned with user and task modeling goals. We also argue that a general mechanism for encoding additional modeling assumptions and side information can lessen the need for "custom" relation extraction model variants. Experimental results on the ACE-2007 Relation Detection and Categorization (RDC) dataset show that our model outperforms competitive unsupervised approaches by a wide margin and is able to uncover meaningful relations with only two general rule types.

Our contributions in this work are three-fold: a new model that modifies the Fold-all framework and extends it to the relation extraction task; a new formalization of the logic rules applicable to topic models defined over a rich set of features; and a proposal for mining the logic rules *automatically* from a corpus contrary to Andrzejewski et al. (2011) who employ manually crafted seeds.

2 Related Work

A variety of learning paradigms have been applied to relation extraction. As mentioned earlier, supervised methods have been shown to perform well in this task. The reliance on manual annotation, which is expensive to produce and thus limited in quantity, has provided the impetus for semi-supervised and purely unsupervised approaches. Semi-supervised methods use a small number of seed instances or patterns (per relation) to launch an iterative training process (Riloff and Jones, 1999; Agichtein and Gravano, 2000; Bunescu and Mooney, 2007; Pantel and Pennacchiotti, 2006). The seeds are used to extract a new set of patterns from a large corpus, which are then used to extract more instances, and so on. Unsupervised relation extraction methods are not limited to a predefined set of target relations, but discover all types of relations found in the text. The relations represent clusters over strings of words (Banko et al., 2007; Hasegawa et al., 2004), syntactic patterns between entities (Yao et al., 2011; Shinyama and Sekine, 2006), or logical expressions (Poon and Domingos, 2009). Another learning paradigm is distant supervision which does not require labeled data but instead access to a relational database such as Freebase (Mintz et al., 2009). The idea is to take entities that appear in some relation in the database, find the sentences that express the relation in an unlabeled corpus, and use them to train a relation classifier.

Our own work adds an additional approach into the mix. We use a topic model to infer an arbitrary number of relations between named entities. Although we do not have access to relation-specific information (either as a relational database or manually annotated data), we impose task-specific constraints which inject domain knowledge into the learning algorithm. We thus alleviate known problems with the interpretability of the clusters obtained from topic models and are able to guide our model towards reasonable relations. Andrzejewski et al. (2011) show how to integrate First-Order Logic with vanilla LDA. We extend their formulation to relation tuples rather than individual words. Our model generates a corpus of entity tuples which are in turn represented by features and uses automatically acquired FOL rules. The idea of integrating topic modeling with FOL builds on research in probabilistic logic modeling such as Markov Logic Networks (Richardson and Domingos, 2006). Schoenmackers et al. (2010) learn Horn clauses from web-scale text with aim of finding answers to a user's query. Our work is complementary to theirs. We could make use of their rules to discover more accurate relations.

The general goal of assisting the learner in recovering the "correct" clustering by supplying additional domain knowledge is not new. Gondek and Hofmann (2004) supply a known clustering they do not want the learner to return, whereas Wagstaff et al. (2001) use pairwise labels for items indicating whether they belong in the same cluster. These methods combine domain knowledge with statistical learning in order to improve performance with re-

spect to the true target clustering. Although, the target labels are not available in our case, we are able to show that the inclusion of domain knowledge yields clustering improvements.

3 Learning Setting

Our relation extraction task broadly adheres to the ACE specification guidelines. Our aim is to detect and characterize the semantic relations between two named entities. The input to our model is a corpus of documents, where each document is a bag of relation tuples which can be obtained from the output of any dependency parser. Each tuple represents a syntactic relationship between two named entity (NE) mentions, and consists of three components: the dependency path between the two mentions, the source NE, and the target NE. A dependency path is the concatenation of dependency edges and nodes along a path in the dependency tree. For example, the sentence "***George Bush*** *traveled to* ***France*** *on Thursday for a summit.*" would yield the tuple [SOURCE:*George_Bush*(PER), PATH:*→nsubj→traveled→prep→to→pobj→*, DES:*France*(LOC)]. The tuple here expresses the relation *Located*, however our model does not observe any relation labels during training. The model assigns tuples to clusters, corresponding to an underlying relation type. Each tuple instance can be then labeled with an identifier corresponding to the cluster (aka relation) it has been assigned to.

4 Modeling Framework

Our model builds on the work of Yao et al. (2011) who develop a series of generative probabilistic models for relation extraction. Specifically, we extend their relational LDA model by interfacing it with FOL-rules. In the following, we first describe their approach in more detail and then present our extensions and modifications.

4.1 Relational LDA

Relational LDA is an extension to LDA with a similar generative story. LDA models each document as a mixture of topics, which are in turn characterized as distributions over words. In relational LDA, each document is a mixture of relations over tuples representing syntactic relations between two named entities. The relation tuples are in turn generated a by set of features drawn independently from the underlying relation distribution.

More technically, a multinomial distribution over relations θ_{d_i} is drawn from a Dirichlet prior ($\theta \sim \text{Dir}(\alpha)$) at the document level. Relation tuples are generated from a multinomial distribution θ_{d_i} ($z_i|\theta_{d_i} \sim \text{Mult}(\theta_{d_i})$) and are represented with k features. Each feature is drawn (independently) from a multinomial distribution selected by the relation assigned to tuple i ($f_{ik}|z_i, \phi_{z_i} \sim \text{Mult}(\phi_{z_i})$). Relations are drawn from a Dirichlet prior ($\phi \sim \text{Dir}(\beta)$). In other words, each tuple in a document is assigned a hidden relation ($z = z_1...z_N$); each relation is represented by a multinomial distribution over features ϕ_r (Dirichlet prior β). ϕ_r is a vector with F dimensions each corresponding to a feature. Finally, documents ($j = 1...D$) are associated with a multinomial distribution θ_j over relations (Dirichlet prior α). θ_j is a vector with R dimensions, one for each relation.

Figure 1 represents relational LDA model as a an undirected graphical model or factor graph (Bishop, 2006), ignoring for the moment the factor which connects the $\boldsymbol{d}$, $\boldsymbol{z}$, $f_{1...k}$ and $\boldsymbol{o}$ variables. Directed graphical models can be converted into undirected ones by adding edges between co-parents (Koller and Friedman, 2009). Each clique in the graph defines a potential function which replaces the conditional probabilities in the directed graph. Each maximal clique is associated with a special factor node (the black squares) and clique members are connected to that factor. The probability of any specific configuration is calculated by multiplying the potential functions and normalizing them. We adopt the factor graph representation as is it convenient for introducing logic rules into the model. The joint probability of the model given the priors and the documents ($P(\boldsymbol{p}, \boldsymbol{z}, \phi, \theta|\alpha, \beta, \boldsymbol{d})$) is equivalent to:

$$\prod_{r}^{R} p(\phi_r|\beta) \prod_{j}^{D} p(\theta_j|\alpha) \prod_{i}^{N} \theta_{d_i}(z_i) \prod_{k \in p_i} \phi_{z_i}(f_k) \quad (1)$$

where $\theta_{d_i}(z_i)$ is the z_i-th element in the vector θ_{d_i} and $\phi_{z_i}(f_k)$ is f_k-th feature in the ϕ_{z_i} vector. Variable p_i is the i-th tuple containing k features. The parameters of the latent variables (e.g., ϕ, θ) are typically estimated using an approximate inference algorithm such as Gibbs Sampling (Griffiths and Steyvers, 2004).

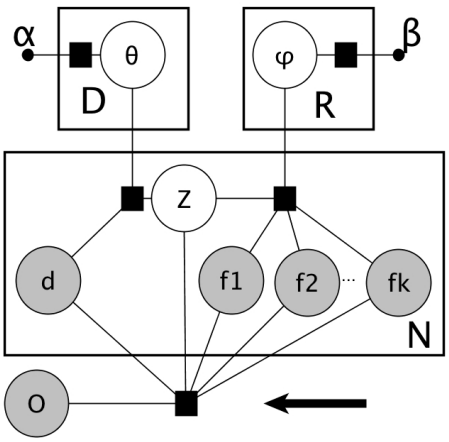

Figure 1: Relational LDA as a factor graph. Filled circles represent observed variables, empty circles are associated with latent variables or model hyperparameters, and plates indicate repeating structures. The black squares are the factor nodes and are associated with the potential functions corresponding to conditional independence among the variables. The model observes D documents ($\boldsymbol{d}$) consisting of N tuples ($\boldsymbol{p}$), each represented by a set of features f_1,$f_2 \ldots f_k$. z represents the relation type assignment to a tuple, θ is the relation type proportion for a given document, and ϕ the relation type distribution over the features. The logic factor (indicated with the arrow) connects the KB with the relational LDA model. Variable $\boldsymbol{o}$ is an observed variable which contains the side information expressed in FOL.

As shown in Figure 1, the observed variables are represented by filled circles. In our case, our model sees the corpus ($\boldsymbol{p}$, $\boldsymbol{d}$), where $\boldsymbol{d}$ is the variable representing the document and the tuples ($\boldsymbol{p}$) are represented by a set of features f_1,$f_2 \ldots f_k$ in the graph. Empty circles are associated with latent variables to be estimated: z represents the relation type assignment to the tuple, θ is the relation type proportion for the given document, and ϕ is the relation type distribution over the features.

The features representing the tuples tap onto semantic information expressed by different surface forms and are an important part of the model. We use a subset of the features proposed in Yao et al. (2011) which we briefly describe below:

SOURCE This feature corresponds to the first entity mention of the tuple. In the sentence ***George Bush*** *traveled to* ***France*** *on Thursday for a summit.*, the value of this feature would be *George Bush*.

Value	Predicate	Description
$z_i = r$	$\mathtt{Z}(i, r)$	Latent relation type
$f_k = v$	$\mathtt{F}(k, v)$	feature of relation tuple
$p_i = i$	$\mathtt{P}(i, f_k)$	tuple i contains feature f_k
$d_i = j$	$\mathtt{D}(i, j)$	observed document

Table 1: Logical variables for Relational LDA. The variable i ranges over tuples in the corpus ($i = [1 \ldots N]$), and k over features in the corpus ($k = [1 \ldots F]$).

DEST The feature corresponds to the second entity mention and its value would be *France* in the previous example.

NEPAIR The feature indicates the type and order of two entity mentions in the tuple. This would be PER-ORG in our example.

PATH This feature refers to the dependency path between two entity mentions. In our sentence, the value of the feature would be PATH:→*nsubj*→*traveled*→*prep*→*to*→*pobj*→.

TRIGGER Finally, trigger features are content words occurring in the dependency path. The path PATH:→*nsubj*→*traveled*→*prep*→*to*→*pobj*→ contains only one trigger word, namely *traveled*. The intuition behind this feature is that paths sharing the same set of trigger words should be grouped in the same cluster.

4.2 First Order Logic and Relational LDA

We next couple relational LDA with global constraints, which we express using FOL rules. We begin by representing relational LDA as a Markov Logic Network (Richardson and Domingos, 2006). We define a logical predicate for each model variable. For example, assigned relation variable ($\mathtt{Z}(i, r)$) is true if $z_i = r$ and false otherwise. Table 1 shows the mapping of model variables onto logical predicates. Logical rules are encoded in the form of a weighted FOL knowledge base (KB) which is then converted into Conjunctive Normal form:

$$KB = \{(\lambda_1, \psi_1), ..., (\lambda_L, \psi_L)\} \quad (2)$$

The KB consists of L pairs, where each ψ_l represents a FOL rule and $\lambda_l \geq 0$ its weight. Rules are soft preferences rather than hard constraints; the weights represent the importance of ψ_l and are

set manually by the domain expert. The KB is tied to the probabilistic model via its *groundings* in the corpus. For each FOL rule ψ_l, let $G(\psi_l)$ be the set of groundings, each mapping the free variables in ψ_l to a specific value. For example, in the rule $\forall i, j, p : \mathtt{F}(i, Obama) \wedge \mathtt{F}(j, WhiteHouse) \wedge \mathtt{P}(p, i) \wedge \mathtt{P}(p, j) \Rightarrow \mathtt{Z}(p, r)$[1], G consists of all the rules where the free variables i, j and p are instantiated. At grounding time, we parse the corpus searching for the tuples that satisfy the logic rules and store the indices of the tuples that ground the rule. The stored indices are used to set ψ_l to a specific value. For the (*Obama*, *White House*) example above, G consists of F propositional rules for each observed feature, where $i \in [1 \dots F]$. For each grounding ($g \in G(\psi_l)$) we define an indicator function:

$$\mathbb{1}_g(\boldsymbol{z}, \boldsymbol{p}, \boldsymbol{d}, \boldsymbol{o}) = \begin{cases} 1, & \text{if } g \text{ is true under} \\ & \boldsymbol{z} \text{ and } \boldsymbol{p}, \boldsymbol{d}, \boldsymbol{o} \\ 0, & \text{otherwise} \end{cases} \quad (3)$$

where $\boldsymbol{z}$ are relation assignments to tuples, $\boldsymbol{p}$ is the set of features in tuples, $\boldsymbol{d}$ are documents, and $\boldsymbol{o}$ the side information encoded in FOL. Contrary to Andrzejewski et al. (2011), we need to ground the rules while taking into account if the feature specified in the rule is expressed by any tuple or the specific given tuple, since we are assigning relations to tuples, and not directly to words.

Next, we define a Markov Random Field (MRF) which combines relational LDA with the FOL knowledge base. The MRF is defined over latent relation tuple assignments $\boldsymbol{z}$, relation feature multinomials ϕ, and relation document multinomials θ (the feature set, document, and external information $\boldsymbol{o}$ are observed). Under this model the conditional probability $P(\boldsymbol{z}, \phi, \theta | \alpha, \beta, \boldsymbol{p}, \boldsymbol{d}, \boldsymbol{o}, KB)$ is proportional to:

$$\exp\left(\sum_{l}^{L} \sum_{g \in G(\psi_l)} \lambda_l \mathbb{1}_g(\boldsymbol{z}, \boldsymbol{p}, \boldsymbol{d}, \boldsymbol{o})\right) \times \prod_{r}^{R} p(\phi_r|\beta) \prod_{j}^{D} p(\theta_j|\alpha) \prod_{i}^{N} \theta_{d_i}(z_i) \prod_{k \in p_i} \phi_{z_i}(f_k) \quad (4)$$

The first term in Equation (4) corresponds to the logic factor in Figure 1 that groups variables $\boldsymbol{d}$, $\boldsymbol{z}$, $f_1, f_2, \dots f_k$ and $\boldsymbol{o}$. The remaining terms in Equation (4) refer to relational LDA. The goal of the model is to estimate the most likely θ and ϕ for the given observed state. As $\boldsymbol{z}$ can not be marginalized out, we proceed with MAP estimation of ($\boldsymbol{z}$, ϕ, θ), maximizing the log of the probability as in Andrzejewski et al. (2011):

$$\arg\max_{\boldsymbol{z}, \phi, \theta} \sum_{l}^{L} \sum_{g \in G(\psi_l)} \lambda_l \mathbb{1}_g(\boldsymbol{z}, \boldsymbol{p}, \boldsymbol{d}, \boldsymbol{o}) + \sum_{r}^{R} \log p(\phi_r|\beta) + \sum_{i}^{N} \log \theta_{d_i}(z_i) \prod_{k \in p_i} \phi_{z_i}(f_k) \quad (5)$$

Once the parameters of the model are estimated (see Section 4.3 for details), we use the ϕ probability distribution to assign a relation to a new test tuple. We select the relation that maximizes the probability $\arg\max_r \prod_i^k P(f_i|\phi_r)$ where $f_1 \dots f_k$ are features representing the tuple and r the relation index.

4.3 Inference

Exact inference is intractable for both relational LDA and MLN models. In order to infer the most likely multinomial parameters ϕ and θ, we applied the Alternating Optimization with Mirror Descent algorithm introduced in Andrzejewski et al. (2011). The algorithm alternates between optimizing the multinomial parameters (ϕ, θ), whilst holding the relation assignments ($\boldsymbol{z}$) fixed, and vice-versa. At each iteration, the algorithm first finds the optimal (ϕ, θ) for a fixed $\boldsymbol{z}$ as the MAP estimate of the Dirichlet posterior:

$$\phi_r(f) \propto n_{rf} + \beta - 1 \quad (6)$$

$$\theta_j(r) \propto n_{jr} + \alpha - 1 \quad (7)$$

where n_{rf} is the number of times feature f is assigned to relation r in relation assignments $\boldsymbol{z}$, and n_{jr} is the number of times relation r is assigned to document j. Next, $\boldsymbol{z}$ is optimized while keeping ϕ and θ fixed. This step is divided into two parts. The algorithm first deals with all z_i which appear only in trivial groundings, i.e., groundings whose indicator functions $\mathbb{1}_g$ are not affected by the latent relation assignment $\boldsymbol{z}$. As $\boldsymbol{z}_i$ only appears in the last term of

[1]This rule translates as "every tuple containing *Obama* and *White House* as features should be in relation cluster r".

Equation (5), the algorithm needs only optimize the following term:

$$z_i = \arg\max_{r=1...R} \theta_{d_i}(r) \prod_{k \in p_i} \phi_{z_i}(f_k) \quad (8)$$

The second part deals with the remaining z_i that appear in non-trivial groundings in the first term of Equation (5). We follow Andrzejewski et al. (2011) in relaxing (5) into a continuous optimization problem and refer the reader to their paper for a more in depth treatment. Suffice it to say that once the binary variables $z_{ir} \in \{0, 1\}$ are relaxed to continuous values $z_{ir} \in [0, 1]$, it is possible to introduce the relational LDA term in the equation and compute the gradient using the Entropic Mirror Descent Algorithm (Beck and Teboulle, 2003):

$$\begin{aligned} &\arg\max_{\boldsymbol{z} \in [0,1]^{|KB|}} \sum_{l}^{L} \sum_{g \in G(\psi_l)} \lambda_l \mathbb{1}_g(\boldsymbol{z}) + \\ &\sum_{i,r} z_{ir} \log \theta_{d_i}(r) \prod_{k \in p_i} \phi_{z_i}(f_k) \quad (9) \\ &\text{s.t } z_{ir} \geq 0 \,, \sum_{i,r} z_{ir} = 1 \end{aligned}$$

In every iteration the approximation algorithm randomly samples a term from the objective function (Equation (9)). The sampled term can be a particular ground rule g or the relational LDA term $(\sum_r z_{ir} \log \theta_{d_i}(r) \prod_{k \in p_i} \phi_{z_i}(f_k))$ for some uniformly sampled index i. The sampling of the terms is weighted according to the rule weight (λ_l) and the grounded value ($G(\psi_l)$) in the case of logic rules, and the size of corpus in tuples ($|\boldsymbol{z}_{KB}|$) for relational LDA. Once we choose term f and take the gradient, we can apply the Entropic Mirror Descent update:

$$z_{ir} \leftarrow \frac{z_{ir} \exp(\eta \nabla_{z_{ir}} f)}{\sum_{r'} z_{ir'} \exp(\eta \nabla_{z_{ir'}} f)} \quad (10)$$

Finally, z_i is recovered by rounding to $\arg\max_r z_{ir}$. The main advantage of this approach is that it requires only a means to sample groundings g for each rule ψ_l, and can avoid fully grounding the FOL rules.

4.4 Logic Rules

Our model assigns relations to tuples rather than topics to words. Since our tuples are described in terms of features our logic rules must reflect this too. For our experiments we defined two very general types of rules described below.

Must-link Tuple The motivation behind this rule is that tuples which share features probably express the same underlying relation. The rule must specify which feature has to be shared for the tuples to be clustered together. For example, the rule below states that tuples containing the dependency path PATH:*→appos→president→prep→of→pobj→* should go in the same cluster:

$$\begin{aligned} \forall i, j, k : \mathtt{F}(i, \text{PATH:}\textit{is\_the\_president\_of}) \wedge \mathtt{P}(j, f_i) \\ \wedge \mathtt{P}(k, f_i) \Rightarrow \neg \mathtt{Z}(j, t) \vee \mathtt{Z}(k, r) \end{aligned}$$

Cannot-link Tuple We also define rules prohibiting tuples to be clustered together because they do not share any features. For example, tuples with ORG-LOC entities, probably express a *Location* relation and should not be clustered together with PER-PER tuples, which in all likelihood express a different relationship (e.g., *Family*). The rule below expresses this constraint:

$$\begin{aligned} \forall i, j, k, l : \mathtt{F}(i, \text{NEPAIR:}\textit{PER-PER}) \\ \wedge \mathtt{F}(j, \text{NEPAIR:}\textit{ORG-LOC}) \\ \wedge \mathtt{P}(k, f_i) \wedge \mathtt{P}(l, f_j) \Rightarrow \neg \mathtt{Z}(k, r) \vee \neg \mathtt{Z}(l, r) \end{aligned}$$

The specification of the first order logic rules is an integral part of the model. The rules express knowledge about the task at hand, the domain involved, and the way the relation extraction problem is modeled (i.e., tuples expressed as features). So far, we have abstractly formulated the rules without explaining how they are specifically instantiated in our model. We could write them down by hand after inspecting some data or through consultation with a domain expert. Instead, we obtain logic rules *automatically* from a corpus following the procedure described in Section 5.

5 Experimental Setup

Data We trained our model on the New York Times (years 2000–2007) corpus created by Yao et al. (2011). The corpus contains approximately 2M entity tuples. The latter were extracted from 428K documents. After post-processing (tokenization, sentence-splitting, and part-of-speech tagging),

Must-link Tuple
$\texttt{F}(i, \text{NEPAIR:}\textit{PER-PER}, \text{TRIGGER:}\textit{wife}) \wedge \texttt{P}(j, f_i) \wedge \texttt{P}(k, f_i) \Rightarrow \neg\texttt{Z}(j, t) \vee \texttt{Z}(k, r)$
$\texttt{F}(i, \text{NEPAIR:}\textit{PER-LOC}, \text{TRIGGER:}\textit{die}) \wedge \texttt{P}(j, f_i) \wedge \texttt{P}(k, f_i) \Rightarrow \neg\texttt{Z}(j, t) \vee \texttt{Z}(k, r)$
$\texttt{F}(i, \text{PATH:}\leftarrow\textit{nsubj}\leftarrow\textit{die}\rightarrow\textit{prep}\rightarrow\textit{in}\rightarrow\textit{pobj}\rightarrow) \wedge \texttt{P}(j, f_i) \wedge \texttt{P}(k, f_i) \Rightarrow \neg\texttt{Z}(j, t) \vee \texttt{Z}(k, r)$
$\texttt{F}(i, \text{SOURCE:}\textit{Kobe}, \text{DEST:}\textit{Lakers}) \wedge \texttt{P}(j, f_i) \wedge \texttt{P}(k, f_i) \Rightarrow \neg\texttt{Z}(j, t) \vee \texttt{Z}(k, r)$
Cannot-link Tuple
$\texttt{F}(i, \text{NEPAIR:}\textit{ORG-LOC}) \wedge \texttt{F}(j, \text{NEPAIR:}\textit{PER-PER}) \wedge \texttt{P}(k, f_i) \wedge \texttt{P}(l, f_j) \Rightarrow \neg\texttt{Z}(k, r) \vee \neg\texttt{Z}(l, r)$
$\texttt{F}(i, \text{NEPAIR:}\textit{LOC-LOC}) \wedge \texttt{F}(j, \text{TRIGGER:}\textit{president}) \wedge \texttt{P}(k, f_i) \wedge \texttt{P}(l, f_j) \Rightarrow \neg\texttt{Z}(k, r) \vee \neg\texttt{Z}(l, r)$
$\texttt{F}(i, \text{NEPAIR:}\textit{PER-LOC}) \wedge \texttt{F}(j, \text{TRIGER:}\textit{member}) \wedge \texttt{P}(k, f_i) \wedge \texttt{P}(l, f_j) \Rightarrow \neg\texttt{Z}(k, r) \vee \neg\texttt{Z}(l, r)$
$\texttt{F}(i, \text{NEPAIR:}\textit{PER-PER}) \wedge \texttt{F}(j, \text{TRIGER:}\textit{sell}) \wedge \texttt{P}(k, f_i) \wedge \texttt{P}(l, f_j) \Rightarrow \neg\texttt{Z}(k, r) \vee \neg\texttt{Z}(l, r)$

Table 2: Examples of automatically extracted Must-link and Cannot-link tuple rules.

named entities were automatically recognized and labeled with PER, ORG, LOC, and MISC (Finkel et al., 2005). Dependency paths for each pair of named entity mentions were extracted from the output of the MaltParser (Nivre et al., 2004). In our experiments, we discarded tuples with paths longer than 10 edges (Lin and Pantel, 2001). We evaluated our model on the test partition of the ACE 2007 (English) RDC dataset which is labeled with gold standard entity mentions and their relations. There are six general relation types and 18 subtypes. We used 25% of the ACE training partition as a development set for parameter tuning.

Logic Rule Extraction We automatically extracted logic rules from the New York Times (NYT) corpus as follows. The intuition behind Must-link rules is that tuples with common features should cluster together. Although we do not know which features would yield the best rules, we naively assume that good features are frequently co-occurring features. Using the log-likelihood ratio (Dunning, 1993), we first discarded low confidence feature co-occurrences ($p < 0.05$). Two features co-occur if they are both found within the same sentence. We then sorted the remaining co-occurrences by their frequency and retained the N-best ones. We only considered unigram and bigram features since higher-order ones tend to be sparse. An example of a bigram feature would be (PATH:←nsubj←grow→prep→in→pobj→, DEST:Chicago).

The main intuition behind Cannot-link rules is that tuples without any common features should not cluster together. So, if two features never co-occur, they probably express different relations. For every unigram and bigram feature in the respective N-best list, we find the features it does not co-occur with in the NYT corpus. For example, NEPAIR:PER–LOC does not co-occur with DEST:*Yankees* and the bigram DEST:*United Nations*, NEPAIR:PER–ORG does not co-occur with SOURCE:Mr. Bush, NEPAIR:PER–LOC. Cannot-link rules are then based on such non-co-occurring feature pairs.

We optimized N empirically on the development set. We experimented with values ranging from 20 to 500. We obtained 20 Must-link rules for coarse-grained relations and 400 rules for their subtypes. We extracted 1,814 Cannot-link rules for general relations ($N = 50$) and 34,522 rules for subtypes ($N = 400$). The number of features involved in the Must-link rules was 25 for coarse-grained relations and 422 for fine-grained relations. For Cannot-link rules, 62 features were involved in coarse-grained relations and 422 in fine-grained relations.

Examples of the rules we extracted are shown in Table 2. The first rule in the upper half of the table states that tuples must cluster together if their source and target entities are PER and contain the trigger word *wife* in their dependency path. The second rule is similar, the source entity here is PER, the target LOC and the trigger word is *die*. According to the third rule, tuples featuring the path PATH:←*nsubj*←*die*→*prep*→*in*→*pobj*→ should be in the same cluster. The fourth rule forces tuples whose source entity is *Kobe* and target entity is *Lakers* to cluster together. The second half of the table illustrates Cannot-link tuple rules. The first rule prevents tuples with ORG-LOC entities to cluster to-

gether with PER-PER tuples. The second rule states that we cannot link LOC-LOC tuples with those whose trigger word is *president*, and so on.

Parameter Tuning Our framework has several parameters that must be adjusted for an optimal clustering solution. These include the hyperparameters α and β as well as the number of clusters. In addition, we have to assign a weight to each FOL rule grounding. An exhaustive search on the hyperparameters and rule weights is not possible. We therefore followed a step-wise approximation procedure. First, we find the best α and β values, whilst varying the number of clusters. Once we have the best hyperparameters for each clustering, we set the weights for the FOL rules. We varied the number of relations from 5 to 50. We experimented with α values in the range of $[0.05 - 0.5]$ and β values in the range of $[0.05 - 0.5]$. These values were optimized separately for coarse- and fine-grained relations. Table 3 shows the optimal number of clusters for different model variants and relation types.

The FOL weights can also make a difference in the final output; the bigger the weight the more times the rule will be sampled in the Mirror Descent algorithm. We experimented with two weighting schemes: (a) we gave a weight of 1 or 0.5 to each rule grounding and (b) we scaled the weights so as to make their contribution comparable to relational LDA. We obtained best results on the development set with the former scheme.

Baselines We compared our FOL relational LDA model against standard LDA (Blei et al., 2003) and relational LDA without the FOL component. In the case of standard LDA, we estimated topics (relations) over words, and used the context of the entity mentions pairs as a bag of words feature to select the most likely cluster at test time. Parameters for LDA and relational LDA were optimized following the same parameter tuning procedure described above.

We also compared our model against the unsupervised method introduced in Hasegawa et al. (2004). Their key idea is to cluster pairs of co-occurring named entities according to the similarity of their surrounding contexts. Following their approach, we measured context similarity using the vector space model and the cosine metric and grouped NE pairs into clusters using a complete linkage hierarchical clustering algorithm. We adopted the same parameter values as detailed in their paper (e.g., cosine similarity threshold, length of context vectors). At test time, instances were assigned to the relation cluster most similar to them (according to the cosine measure).

Evaluation We evaluated the clusters obtained by our model and the comparison systems using the Fscore measure introduced in the SemEval 2007 task (Agirre and Soroa, 2007); it is the harmonic mean of precision and recall defined as the number of correct members of a cluster divided by the number of items in the cluster and the number of items in the gold-standard class, respectively.

6 Results

Our results are summarized in Table 3 which reports Fscore for (Hasegawa et al., 2004), LDA, relational LDA (RelLDA), and our model with the FOL component. To assess the impact of the rules on the clustering, we conducted several rule ablation studies. We thus present results with a model that includes both Must-link and Cannot-link tuple rules (CLT+MLT), and models that include either Must-link (MLT) or Cannot-link (CLT) rules but not both. We show the performance of these models with the entire feature set (see (ALL) in the table) and with a subset consisting solely of NE pair related features (see (NEPAIR) in the table). We report results against coarse- and fine-grained relations (6 and 18 relation types in ACE, respectively). The table shows the optimal number of relation clusters (in parentheses) per model and relation type.

We also wanted to examine the quality of the logic rules. Recall that we learn these heuristically from the NYT corpus. We thus trained an additional variant of our model with rules extracted from the ACE training set (75%) which contains relation annotations. The extraction procedure was similar to the unsupervised case, save that the relation types were known and thus informative features could be mined more reliably. For Must-link rules, we extracted unigram and bigram feature frequencies for each relation type and applied TF-IDF weighting in order to discover the most discriminative ones. We created logic rules for the 10 best feature combinations in each relation type. Regarding Cannot-link rules, we enumerated the features (unigrams and bigrams)

Model	Subtype		Type	
HASEGAWA	26.1	(12)	34.7	(12)
LDA	23.4	(10)	29.0	(5)
RelLDA	30.4	(40)	38.6	(5)
U-MLT (ALL)	36.6	(10)	48.0	(5)
U-CLT (ALL)	30.5	(5)	39.3	(5)
U-CLT+MLT (ALL)	29.8	(5)	42.0	(5)
U-MLT (NEPAIR)	36.5	(10)	47.2	(5)
U-CLT (NEPAIR)	28.8	(50)	40.5	(5)
U-CLT+MLT (NEPAIR)	30.9	(10)	41.5	(5)
S-MLT (ALL)	37.0	(10)	47.0	(5)
S-CLT (ALL)	31.4	(50)	40.9	(5)
S-CLT+MLT (ALL)	32.3	(10)	42.5	(5)
S-MLT (NEPAIR)	37.0	(10)	47.6	(10)
S-CLT (NEPAIR)	31.4	(10)	40.1	(5)
S-CLT+MLT (NEPAIR)	37.1	(10)	46.0	(5)

Table 3: Model performance on the ACE 2007 test set using Fscore. Results are shown for six main relation types and their subtypes (18 in total). (ALL) models contain rules extracted from the entire feature set. For (NEPAIR) models, rules were extracted from NEPAIR-related features only. Prefix U- denotes models that use unsupervised rules; prefix S- highlights models using supervised rules. The optimal number of relations per model is shown in parentheses.

that did not co-occur in any relation type and applied TF-IDF weighting. Again, we created rules for the 10 most discriminative features. We defined rules over the entire feature set (466 Must-link and 26,074 Cannot-link rules) and a subset containing only NE pairs. In Table 3, prefixes S- and U- indicate model variants with supervised and unsupervised rules, respectively.

Our results show that standard LDA is not suitable for relation extraction. The obtained clusters are not informative enough to induce semantic relations, whereas RelLDA yields substantially better Fscores. This is not entirely surprising, given that RelLDA is a relation extraction specific model. Hasegawa et al.'s (2004) model lies somewhere in the middle between LDA and RelLDA. The combination of RelLDA with automatically extracted FOL rules improves over RelLDA across the board (see the U- models in Table 3). MLT rules deliver the largest improvement for both coarse and fine-grained relation types. In general, CLT models perform worse as well as models using both types of rules (MLT+CLT). The inferior performance of the rule combination may be due to the fact that MLT and CLT rules contain conflicting information and to a certain extent cancel each other out. The use of many rules might also negatively impact inference, i.e., discriminative rules are sampled less and cannot influence the model towards a better solution. Restricting the number of features and rules to named entity pairs only incurs a negligible drop in performance. This is good news for scaling purposes, since a small number of rules can greatly speed-up inference. Interestingly, model variants which use supervised FOL rules (see the prefix S- in Table 3) perform on par with unsupervised models. Again, MLT rules perform best in the supervised case, whereas CLT rules marginally improve over RelLDA.

We assessed whether differences in performance are statistically significant ($p < 0.05$) using bootstrap resampling (Noreen, 1989). All models across all relation types are significantly better than LDA and Hasegawa et al. (2004). FOL-based models perform significantly better than RelLDA, with the exception of all CLT models and U-CLT+MLT (ALL). MLT models are significantly better than any other rule-based model, except those that only use NEPAIR features. We also measured whether different models agree on their topic assignments using Cohen's Kappa.[2] RelLDA agrees least with MLT models and most with CLT models (i.e., $\kappa = 0.50$ for U-MLT (ALL) and $\kappa = 0.65$ for U-CLT (ALL)). This suggests that the CLT rules do not affect the output of RelLDA as much as MLT ones. Examples of relation clusters discovered by the U-MLT (ALL) model are shown in Table 4.

A last note on parameter selection. Our experiments explored the parameter space extensively in order to examine any interactions between the induced relations and the logic rules. For most model variants inferring subtype relations, the preferred number of clusters is 10. For coarse-grained relations, the optimal number of clusters is five. Overall, we found that the quality of the output is highly correlated with the quality of the logic rules and that a few *good* rules are more important than the optimal number of clusters. We consider these findings robust enough to apply across domains and datasets.

[2]For all comparison models the number of relation clusters was set to 10.

7 Conclusions

In this paper we presented a new model for unsupervised relation extraction which operates over tuples representing a syntactic relationship between two named entities. Our model clusters such tuples into underlying semantic relations (e.g., *Located*, *Family*) by incorporating general domain knowledge which we encode as First Order Logic rules. Specifically, we combine a topic model developed for the relation extraction task with domain relevant rules, and present an algorithm for estimating the parameters of this model. Evaluation results on the ACE 2007 (English) RDC task show that our model outperforms competitive unsupervised approaches by a wide margin and is able to produce clusters shaped by both the data and the rules.

In the future, we would like to explore additional types of rules such as seed rules, which would assign tuples complying with the "seed" information to distinct relations. Aside from devising new rule types, an obvious next step would be to explore different ways of extracting the rule set based on different criteria (e.g., the most general versus most specific rules). Also note that in the current framework rule weights are set manually by the domain expert. An appealing direction would be to learn these automatically e.g., via a procedure that optimizes some clustering objective. Finally, it should be interesting to use some form of distant supervision (Mintz et al., 2009) either as a means of obtaining useful rules or to discard potentially noisy or uninformative rules.

Abstract

Entity disambiguation works by linking ambiguous mentions in text to their corresponding real-world entities in knowledge base. Recent collective disambiguation methods enforce coherence among contextual decisions at the cost of non-trivial inference processes. We propose a fast collective disambiguation approach based on stacking. First, we train a local predictor g_0 with learning to rank as base learner, to generate initial ranking list of candidates. Second, top k candidates of related instances are searched for constructing expressive global coherence features. A global predictor g_1 is trained in the augmented feature space and stacking is employed to tackle the train/test mismatch problem. The proposed method is fast and easy to implement. Experiments show its effectiveness over various algorithms on several public datasets. By learning a rich semantic relatedness measure between entity categories and context document, performance is further improved.

1 Introduction

When extracting knowledge from natural language text into a machine readable format, ambiguous names must be resolved in order to tell which real-world entity the name refers to. The task of linking names to knowledge base is known as entity linking or disambiguation (Ji et al., 2011). The resulting text is populated with semantic rich links to knowledge base like Wikipedia, and ready for various downstream NLP applications.

*Corresponding author

Previous researches have proposed several kinds of effective approaches for this problem. Learning to rank (L2R) approaches use hand-crafted features $f(d, e)$ to describe the similarity or dissimilarity between contextual document d and entity definition e. L2R approaches are very flexible and expressive. Features like name matching, context similarity (Li et al., 2009; Zheng et al., 2010; Lehmann et al., 2010) and category context correlation (Bunescu and Pasca, 2006) can be incorporated with ease. Nevertheless, decisions are made independently and inconsistent results are found from time to time.

Collective approaches utilize dependencies between different decisions and resolve all ambiguous mentions within the same context simultaneously (Han et al., 2011; Hoffart et al., 2011; Kulkarni et al., 2009; Ratinov et al., 2011). Collective approaches can improve performance when local evidence is not confident enough. They often utilize semantic relations across different mentions, and is why they are called $global$ approaches, while L2R methods fall into $local$ approaches (Ratinov et al., 2011). However, collective inference processes are often expensive and involve an exponential search space.

We propose a collective entity linking method based on stacking. Stacked generalization (Wolpert, 1992) is a powerful meta learning algorithm that uses two levels of learners. The predictions of the first learner are taken as augmented features for the second learner. The nice property of stacking is that it does not restrict the form of the base learner. In this paper, our base learner, an L2R ranker, is first employed to generate a ranking list of candidates.

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 426–435,
Seattle, Washington, USA, 18-21 October 2013.

At the next level, we search for semantic coherent entities from the top k candidates of neighboring mentions. The second learner is trained on the augmented feature space to enforce semantic coherence. Stacking is employed to handle train/test mismatch problem. Compared with existing collective methods, the inference process of our method is much faster because of the simple form of its base learner.

Wikipedians annotate each entity with categories which provide another source of valuable semantic information. (Bunescu and Pasca, 2006) propose to generalize beyond context-entity correlation $s(d, e)$ with word-category correlation $s(w, c)$. However, this method works at word level, and does not scale well to large number of categories. We explore a representation learning technique to learn the category-context association in latent semantic space, which scales much better to large knowledge base.

Our contributions are as follows: (1) We propose a fast and accurate stacking-based collective entity linking method, which combines the benefits of both coherence modeling of collective approaches and expressivity of L2R methods. We show an effective usage of ranking list as global features, which is a key improvement for the global predictor. (2) To overcome problems of scalability and shallow word-level comparison, we learn the category-context correlation with recent advances of representation learning, and show that this extra semantic information indeed helps improve entity linking performance.

2 Related Work

Most popular entity linking systems use the L2R framework (Bunescu and Pasca, 2006; Li et al., 2009; Zheng et al., 2010; Lehmann et al., 2010). Its discriminative nature gives the model enough flexibility and expressivity. It can include any features that describe the similarity or dissimilarity of context d and candidate entity e. They often perform well even on small training set, with carefully-designed features. This category falls into the $local$ approach as the decision processes for each mention are made independently (Ratinov et al., 2011).

(Cucerzan, 2007) first suggests to optimize an objective function that is similar to the collective approach. However, the author adopts an approximation method because of the large search space (which is $O(n^m)$ for a document with m mentions, each with n candidates). Various other methods like integer linear programming (Kulkarni et al., 2009), personalized PageRank (Han et al., 2011) and greedy graph cutting (Hoffart et al., 2011) have been explored in literature. Our method without stacking resembles the method of (Ratinov et al., 2011) in that they use the predictions of a local ranker to generate features for global ranker. The differences are that we use stacking to train the local ranker to handle the train/test mismatch problem and top k candidates to generate features for the global ranker.

Stacked generalization (Wolpert, 1992) is a meta learning algorithm that uses multiple learners outputs to augment the feature space of subsequent learners. It utilizes a cross-validation strategy to address the train set / testset label mismatch problem. Various applications of stacking in NLP have been proposed, such as collective document classification (Kou and Cohen, 2007), stacked dependency parsing (Martins et al., 2008) and joint Chinese word segmentation and part-of-speech tagging (Sun, 2011). (Kou and Cohen, 2007) propose stacked graphical learning which captures dependencies between data with relational template. Our method is inspired by their approach. The difference is our base learner is an L2R model. We search related entity candidates in a large semantic relatedness graph, based on the assumption that true candidates are often semantically correlated while false ones scattered around.

Wikipedians annotate entries in Wikipedia with category network. This valuable information generalizes entity-context correlation to category-context correlation. (Bunescu and Pasca, 2006) utilize category-word as features in their ranking model. (Kataria et al., 2011) employ a hierarchical topic model where each inner node in the hierarchy is a category. Both approaches must rely on pruned categories because the large number of noisy categories. We try to address this problem with recent advances of representation learning (Bai et al., 2009), which learns the relatedness of category and context in latent continuous space. This method scales well to potentially large knowledge base.

3 Method

In this section, we first introduce our base learner and local features used; next, the stacking training strategy is given, followed by an explanation of our global coherence model with augmented feature space; finally we explain how to learn category-context correlation with representation learning technique.

3.1 Base learner and local predictor g_0

Entity linking is formalized as follows: given an ambiguous name mention m with its contextual document d, a list of candidate entities $e_1, e_2, \ldots, e_{n(m)} \in C(m)$ is generated for m, our predictor g will generate a ranking score $g(e_i)$ for each candidate e_i. The ranking score will be used to construct augmented features for the next level learner, or used by our end system to select the answer:

$$\hat{e} = \arg \max_{e \in C(m)} g(e) \quad (1)$$

In an L2R framework, the model is often defined as a linear combination of features. Here, our features $\vec{f}(d, e)$ are derived from document d and candidate e. The model is defined as $g(e) = \vec{w}\vec{f}(d, e)$. In our problem, we are given a list of training data $\mathcal{D} = \{(d_i, e_i)\}$. We want to optimize the parameter $\vec{w}$, such that the correct entity has a higher score over negative ones. This is done via a preference learning technique SVM^{rank}, first introduced by (Joachims, 2002). The following margin based loss is minimized w.r.t $\vec{w}$:

$$L = \frac{1}{2}\|\vec{w}\|^2 + C \sum \xi_{d,e'} \quad (2)$$

$$\text{s.t.} \quad \vec{w}(\vec{f}(d, e) - \vec{f}(d, e')) \geq 1 - \xi_{d,e'} \quad (3)$$

$$\xi_{d,e'} \geq 0 \quad (4)$$

where C is a trade-off between training error and margin size; ξ is slacking variable and loops over all query documents d and negative candidates $e' \in C(m) - \{e\}$.

This model is expressive enough to include any form of features describing the similarity and dissimilarity of d and e. We only include some typical features seen in literature. The inclusion of these features is not meant to be exhaustive. Our purpose is to build a moderate model in which some of the useful features like string matching and entity popularity cannot be easily expressed by collective approaches like (Hoffart et al., 2011; Han et al., 2011). The features for level 0 predictor g_0 are described in Table 1. The reader can consult (Li et al., 2009; Zheng et al., 2010; Lehmann et al., 2010) for further reference.

Surface matching:
1. mention string m exactly matches candidate e, i.e. $m = e$
2. neither m is a substring of e nor e is a substring of m
3. $m \neq e$ and m is a substring of e
4. $m \neq e$ and e is a substring of m
5. $m \neq e$ and m is a redirect pointing to e in Wikipedia
6. $m \neq e$ and e starts with m
7. $m \neq e$ and e ends with m
Context matching:
1. cosine similarity of TF-IDF score between context and entire Wikipedia page of candidate
2. cosine similarity of TF-IDF score between context and introduction of Wikipedia page
3. jaccard distance between context and entire Wikipedia page of candidate
4. jaccard distance between context and introduction of Wikipedia page
Popularity or prominence feature:
percentage of Wikipedia hyperlinks pointing to e given mention m, i.e. P(e|m)
Category-context coherence model:
cat_0 and cat_1 (details in Section 3.4)

Table 1: Features for local predictor g_0.

3.2 Stacking training for global predictor g_1

Stacked generalization (Wolpert, 1992) is a meta learning algorithm that stacks two "levels" of predictors. Level 0 includes one or more predictors $h_1^{(0)}, h_2^{(0)}, \ldots, h_K^{(0)} : \mathbb{R}^d \to \mathbb{R}$, each one is trained on the original d-dimensional feature space. The level 1 predictor $h^{(1)} : \mathbb{R}^{d+K} \to \mathbb{R}$ is trained in the augmented $(d+K)$-dimensional feature space, in which predictions at level 0 are taken as extra features in $h^{(1)}$.

(Kou and Cohen, 2007) proposed stacked graphi-

cal learning for learning and inference on relational data. In stacked graphical learning, dependencies among data are captured by *relational template*, with which one searches for *related instances* of the current instance. The augmented feature space does not necessarily to be $d + K$. Instead, one can construct any declarative feature with the original data and predictions of related instances. For instance, in collective document classification (Kou and Cohen, 2007) employ relational template to extract documents that link to this document, then apply a COUNT aggregator over each category on neighboring documents as level 1 features.

In our entity linking task, we use a single predictor g_0 trained with local features at level 0. Compared with (Kou and Cohen, 2007), both g_0 and g_1 are L2R models rather than classifier. At level 1, for each document-candidate entity pair, we use the *relational template* $\mathcal{N}(x)$ to find related entities for entity x, and construct global features with some function $\mathcal{G}(\{g_0(n)|n \in \mathcal{N}(x)\})$ (details in Sec. 3.3). The global predictor g_1 receives as input the original features plus $\mathcal{G}$.

One problem is that if we use g_0 trained on the entire training set to predict related instances in training set, the accuracy can be somehow different (typically lower) for future unseen data. g_1 with this prediction as input doesn't generalize well to test data. This is known as train/test mismatch problem. To mimic test time behavior, training is performed in a cross-validation-like way. Let $\mathcal{D}$ be the entire training set:

1. Split $\mathcal{D}$ into L partitions $\{\mathcal{D}_1, \ldots, \mathcal{D}_L\}$
2. For each split $\mathcal{D}_i$:
   - 2.1 Train an instance of g_0 on $\mathcal{D} - \mathcal{D}_i$
   - 2.2 Predict all related instances in $\mathcal{D}_i$ with this predictor g_0
   - 2.3 Augment feature space for $x \in \mathcal{D}_i$, with $\mathcal{G}$ applied on predictions of $\mathcal{N}(x)$
3. Train level 0 predictor g_0 on entire $\mathcal{D}$, for expanding feature space for test data
4. Train level 1 predictor g_1 on entire $\mathcal{D}$, in the augmented feature space.

In the next subsection, we will describe how to construct global features from the predictions of g_0 on neighbors $\mathcal{N}(x)$ with $\mathcal{G}$.

3.3 Enforcing coherence with global features $\mathcal{G}$

If one wants to identify the correct entity for an ambiguous name, he would possibly look for related entities in its surrounding context. However, surrounding entities can also exhibit some degree of ambiguity. In ideal cases, most true candidates are inter-connected with semantic links while negative candidates are scattered around (Fig. 1). Thus, we ask the following question: Is there any highly relevant entity to this candidate in context? Or, is there any mention with highly relevant entity to this candidate in the top k ranking list of this mention? And how many those mentions are? The reason to look up top k candidates is to improve recall. g_0 may not perfectly rank related entity at the first place, e.g. "Mitt Romney" in Figure 1.

Assume the ambiguous mention set is M. For each mention $m_i \in M$, we rank each entity $e_{i,j} \in C(m_i)$ by its score $g_0(e_{i,j})$. Denote its rank as $Rank(e_{i,j})$. For each entity e in the candidate set $E = \{e_{i,j}|\forall e_{i,j} \in C(m_i), \forall m_i \in M\}$, we search related instances for e as follows:

1. search in E for entities with semantic relatedness above a threshold ($\{0.1,0.3,0.5,0.7,0.9\}$);
2. select those entities in step (1) with $Rank(e)$ less than or equal to k ($k \in \{1, 3, 5\}$);
3. map entities in step (2) to unique set of mentions U, excluding current m, i.e. $e \in C(m)$.

This process is relatively fast. It only involves a sparse matrix slicing operation on the large precomputed semantic relatedness matrix in step (1), and logical operation in step (2,3). The following features are fired concerning the unique set U:

- if U is empty;
- if U is not empty;
- if the percentage $|U|/|M|$ is above a threshold (e.g. 0.3).

The above process generates a total of 45 ($5 \times 3 \times 3$) global features.

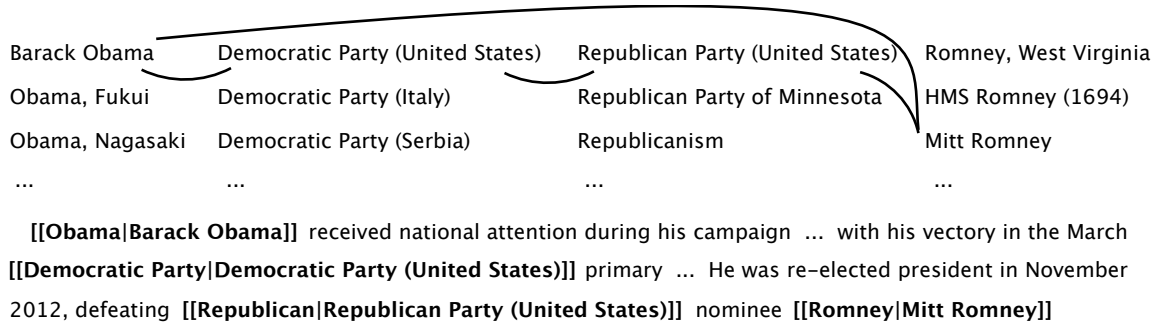

Figure 1: Semantic links for collective entity linking. Annotation $[[mention|entity]]$ follows Wikipedia conventions.

Finally, the semantic relatedness measure of two entities e_i,e_j is defined as the common in-links of e_i and e_j in Wikipedia (Milne and Witten, 2008; Han et al., 2011):

$$SR(e_i, e_j) = 1 - \frac{\log(\max(|A|, |B|)) - \log(|A \cap B|)}{\log(|W|) - \log(\min(|A|, |B|))} \quad (5)$$

where A and B are the set of in-links for entity e_i and e_j respectively, and W is the set of all Wikipedia pages.

Our method is a trade-off between exact collective inference and approximating related instance with top ranked entities produced by g_0. Most collective approaches take all ambiguous mentions into consideration and disambiguate them simultaneously, resulting in difficulty when inference in large search space (Kulkarni et al., 2009; Hoffart et al., 2011). Others resolve to some kinds of approximation. (Cucerzan, 2007) construct features as the average of all candidates for one mention, introducing considerable noise. (Ratinov et al., 2011) also employ a two level architecture but only take top 1 prediction for features. This most resembles our approach, except we use stacking to tackle the train/test mismatch problem, and construct different set of features from top k candidates predicted by g_0. We will show in our experiments that this indeed helps boost performance.

3.4 Learning category-context coherence model cat

Entities in Wikipedia are annotated with rich semantic structures. Category network provides us with another valuable information for entity linking. Take the mention "Romney" as an example, one candidate "Mitt Romney" with category "Republican party presidential nominee" co-occurs frequently with context like "election" and "campaign", while another candidate "Milton Romney" with category "Utah Utes football players" is frequently observed with context like "quarterback" and "backfield". The category network forms a directed acyclic graph (DAG). Some entities can share category through the network, e.g. "Barack Obama" with category "Democratic Party presidential nominees" shares the category "United States presidential candidates by party" with "Mitt Romney" when travelling two levels up the network.

(Bunescu and Pasca, 2006) propose to learn the category-context correlation at word level through category-word pair features. This method creates sparsity problem and does not scale well because the number of features grows linearly with both the number of categories and the vocabulary size. Moreover, the category network is somewhat noisy, e.g. travelling up four levels of the hierarchy can result in over ten thousand categories, with many irrelevant ones.

Rather than learning the correlation at word level, we explore a representation learning method that learns category-context correlation in the latent semantic space. Supervised Semantic Indexing (SSI) (Bai et al., 2009) is trained on query-document pairs to predict their degree of matching. The comparison is performed in the latent semantic space, so that synonymy and polysemy are implicitly handled by its inner mechanism. The score function between query q and document d is defined as:

$$f(q, d) = q^T W d \quad (6)$$

where W is learned with supervision like click-through data.

Given training data $\{(q_i, d_i)\}$, training is done by randomly sampling a negative target d^-. The model optimizes W such that $f(q, d^+) > f(q, d^-)$. Thus, the training objective is to minimize the following margin-based loss function:

$$\sum_{q,d^+,d^-} \max(0, 1 - f(q, d^+) + f(q, d^-)) \quad (7)$$

which is also known as contrastive estimation (Smith and Eisner, 2005).

W can become very large and inefficient when we have a big vocabulary size. This is addressed by replacing W with its low rank approximation:

$$W = U^T V + I \quad (8)$$

here, the identity term I is a trade-off between the latent space model and a vector space model. The gradient step is performed with Stochastic Gradient Descent (SGD):

$$U \leftarrow U + \lambda V(d^+ - d^-)q^T, \quad \texttt{if } 1 - f(q, d^+) + f(q, d^-) > 0 \quad (9)$$

$$V \leftarrow V + \lambda U q(d^+ - d^-)^T, \quad \texttt{if } 1 - f(q, d^+) + f(q, d^-) > 0. \quad (10)$$

where λ is the learning rate.

The query and document are not necessary real query and document. In our case, we treat our problem as: given the occurring context of an entity, retrieving categories corresponding to this entity. Thus, we use context as query q and the categories of this candidate entity as d. We also treat the definition page of an entity as its context, and first train the model with definition pages, because definition pages exhibit more focused topic. This considerably accelerates the training process. To reduce noise, We input the categories directly connected with one entity as a word vector. The input can be a TF-IDF vector or binary vector. We denote model trained with normalized TF-IDF and with binary input as cat_0 and cat_1 respectively.

4 Experiments

4.1 Datasets

Previous researches have used diverse datasets for evaluation, which makes it hard for comparison with others' approaches. TAC-KBP has several years of data for evaluating entity linking system, but is not well suited for evaluating collective approaches. Recently, (Hoffart et al., 2011) annotated a clean and much larger dataset AIDA [1] for collective approaches evaluation based on CoNLL 2003 NER dataset. (Ratinov et al., 2011) also refined previous work and contribute four publicly available datasets [2]. Thanks to their great works, we have enough data to evaluate against. According to the setting of (Hoffart et al., 2011), we split the AIDA dataset for train/development/test with 946/216/231 documents. We train a separate model on the Wikipedia training set for evaluating ACE/QUAINT/WIKI dataset (Ratinov et al., 2011). Table 2 gives a brief overview of the datasets used.

For knowledge base, we use the Wikipedia XML dump [3] to extract over 3.3 million entities. We use annotation from Wikipedia to build a name dictionary from mention string m to entity e for candidate generation, including redirects, disambiguation pages and hyperlinks, follows the approach of (Cucerzan, 2007). For candidate generation, we keep the top 30 candidates by popularity (Tbl. 1). Note that our name dictionary is different from (Ratinov et al., 2011) and has a much higher recall. Since (Ratinov et al., 2011) evaluate on "solvable" mentions and we have no way to recover those mentions, we re-implement their global features and the final scores are not directly comparable to theirs.

4.2 Methods under comparison

We compare our algorithm with several state-of-the-art collective entity disambiguation systems. The AIDA system proposed by (Hoffart et al., 2011) use a greedy graph cutting algorithm that iteratively remove entities with low confidence scores. (Han et al., 2011) employ personalized PageRank to propagate evidence between different decisions. Both algorithms use simple local features without discriminative training. (Kulkarni et al., 2009) propose to use integer linear programming (ILP) for inference. Except our re-implementation of Han's

[2] http://cogcomp.cs.illinois.edu/Data, we don't find the MSNBC dataset in the zip file.

[3] available at http://dumps.wikimedia.org/enwiki/, we use the 20110405 xml dump.

Dataset	ndocs	non-NIL	identified	solvable
AIDA dev	216	4791	4791	4707
AIDA test	231	4485	4485	4411
ACE	36	257	238	209(185)
AQUAINT	50	727	697	668(588)
Wikipedia	40	928	918	854(843)

Table 2: Number of mentions in each dataset. "identified" means the mention exists in our name dictionary and "solvable" means the true entity are among the top 30 candidates by popularity. Number in parenthesis shows the results of (Ratinov et al., 2011).

method, both AIDA and ILP solution are quite slow at running time. The online demo of AIDA takes over 10 sec to process one document with moderate size, while the ILP solution takes around 2-3 sec/doc. In contrast, our method takes only 0.3 sec/doc, and is easy to implement.

(Ratinov et al., 2011) also utilize a two layer learner architecture. The difference is that their method use top 1 candidate generated by local learner for global feature generation , while we search the top k candidates. Moreover, stacking is used to tackle the train/test mismatch problem in our model. We re-implement the global features of (Ratinov et al., 2011) and use our local predictor g_0 for level 0 predictor. Note that we only implement their global features concerning common inlinks and inter-connection (totally 9 features) for fair comparison because all other models don't use common outgoing links for global coherence.

4.3 Settings

We implement SVM^{rank} with an adaptation of linear SVM in scikit-learn (which is a wrapper of Liblinear). The category-context coherence model is implemented with Numpy configured with OpenBlas library, and we train this model on the entire Wikipedia hyperlink annotation. It takes about 1.5d for one pass over the entire dataset. The learning rate λ is set to 1e-4 and training cost before update is below 0.02.

Parameter tuning: there aren't many parameters to tune for both g_0 and g_1. The context document window size is fixed as 100 for compatibility with (Ratinov et al., 2011; Hoffart et al., 2011). The number of candidates is fixed to top 30 ranked by entity's popularity. Increase this value will generally boost recall at the cost of lower precision.

We introduce the following default parameter for global features in g_1. The number of fold for stacking is set to $\{1,5,10\}$ (see Table 4, default is 10; 1 means no stacking, i.e. training g_0 with all training data and generating level 1 features for training data directly with this g_0). The number k for searching neighboring entities with relational template is set to $\{1,3,5,7\}$ (e.g. in step 2 of Section 3.3 $k = 5$; default is 5).

For category-context modeling, the vocabulary sizes of context and category are set to top 10k and 6k unigrams by frequency. The latent dimension of low rank approximation is set to 200.

Performance measures: For all non-NIL queries, we evaluate performance with micro precision averaged over queries and macro precision averaged over documents. Mean Reciprocal Rank (MRR) is an information retrieval measure and is defined as $\frac{1}{|Q|}\sum_i^{|Q|}\frac{1}{rank_i}$, where $rank_i$ is the rank of correct answer in response to query i. For ACE/AQUAINT/WIKI we also give the accuracy of "solvable" mentions, but this is not directly comparable to (Ratinov et al., 2011). Our name dictionary is different from theirs and ours has a higher recall rate (Tbl. 2). Hence, the "solvable" set is different.

k	recall	k	recall
1	78.56	6	96.31
2	89.59	7	97.04
3	93.01	8	97.37
4	94.97	9	97.62
5	95.78	10	97.81

better than word level features. Group 5 in Table 4 shows cat information generally boosts performance for both predictor g_0 and g_1.

Effect of stacking: Group 3 in Table 4 shows the results with different fold in stacking training. 1 fold means training g_0 with all training data and directly augment training data with this g_0. Surprisingly, we do not observe any substantial difference with various fold size. We deduce it is possible the way we fire global features with top k candidates that alleviates the problem of train/test mismatch when extending feature space for g_1. Despite the ranking of true entity can be lower in testset than in training set, the semantic coherence information can still be captured with searching over top k candidates.

Effect of top k global features: Group 4 in Table 4 shows the effect of k on g_1 performance. Clearly, increasing k generally improves precision and one possible reason is the improvement in recall when searching for related instances. Table 3 shows the top k recall of local predictor g_0. Further increasing k does not show any improvement.

Our method benefits from such a searching strategy, and consistently outperforms the global features of (Ratinov et al., 2011). While their method is a trade-off between expensive exact search over all mentions and greedy assigning all mentions with local predictor, we show this idea can be further extended, somewhat like increasing the beam search size without additional computational overhead. The only exception is the ACE dataset, since this dataset is so small, the difference translates to only one mention. One may notice the improvement on ACE/AQUAINT datasets is a little inconsistent. These datasets are much smaller and the results only differ within 4 mentions. Because these models are

trained on Wikipedia, the annotation style can be quite different.

Finally, as we analyze the development set of AIDA, we discover that some location entities rely on more distant information across the context, as we increase the context to the entire contextual document, we can gain extra performance boost.

4.5 Error analysis

As we analyze the development set of AIDA, we find some general problems with location names. Location name generally is not part of the main topic of one document. Thus, comparing context with its definition is not realistic. Most of the time, we can find some related location names in context; but other times, it is not easily distinguished. For instance, in "France beats Turkey in men's football..." France refers to "France national football team" but our system links it to the country page "France" because it is more popular. This can be addressed by modeling finer context (Sen, 2012) or local syntactic pattern (Hoffart et al., 2011). In other cases, our system misclassifies "New York City" for "New York" and "Netherlands" for "Holland" and "People's Republic of China" for "China", because in all these cases, the latter ones are the most popular in Wikipedia. It is even hard for us humans to tell the difference based only on context or global coherence.

5 Conclusions

We propose a stacking based collective entity linking method, which stacks a global predictor on top of a local predictor to collect coherence information from neighboring decisions. It is fast and easy to implement. Our method trades off between inefficient exact search and greedily assigning mention with local predictor. It can be seen as searching related entities with relational template in stacked graphical learning, with beam size k. Furthermore, we adopt recent progress in representation learning to learn category-context coherence model. It scales better than existing approaches on large knowledge base and performs comparison in the latent semantic space. Combining these two techniques, our model consistently outperforms all existing more sophisticated collective approaches in our experiments.

Joint Bootstrapping of Corpus Annotations and Entity Types

IIT Bombay

Abstract

Web search can be enhanced in powerful ways if token spans in Web text are annotated with disambiguated entities from large catalogs like Freebase. Entity annotators need to be trained on sample mention snippets. Wikipedia entities and annotated pages offer high-quality labeled data for training and evaluation. Unfortunately, Wikipedia features only one-ninth the number of entities as Freebase, and these are a highly biased sample of well-connected, frequently mentioned "head" entities. To bring hope to "tail" entities, we broaden our goal to a second task: assigning types to entities in Freebase but not Wikipedia. The two tasks are synergistic: knowing the types of unfamiliar entities helps disambiguate mentions, and words in mention contexts help assign types to entities. We present TMI, a bipartite graphical model for joint type-mention inference. TMI attempts no schema integration or entity resolution, but exploits the above-mentioned synergy. In experiments involving 780,000 people in Wikipedia, 2.3 million people in Freebase, 700 million Web pages, and over 20 professional editors, TMI shows considerable annotation accuracy improvement (e.g., 70%) compared to baselines (e.g., 46%), especially for "tail" and emerging entities. We also compare with Google's recent annotations of the same corpus with Freebase entities, and report considerable improvements within the people domain.

1 Introduction

Thanks to automatic information extraction and semantic Web efforts, keyword search over unstructured Web text is rapidly evolving toward entity- and type-oriented queries (Guo et al., 2009; Pantel et al., 2012) over semi-structured databases such as Wikipedia, Freebase, and other forms of Linked Data.

A key enabling component for such enhanced search capability is a type and entity *catalog*. This includes a directed acyclic graph of types under the *subTypeOf* relation between types, and entities attached to one or more types via *instanceOf* edges. YAGO (Suchanek et al., 2007) provides such a catalog by unifying Wikipedia and WordNet, followed by some cleanup.

Another enabling component is an *annotated corpus* in which token spans (e.g., the word "Albert") are identified as a mention of an entity (e.g., the Physicist Einstein). Equipped with suitable indices, a catalog and an annotated corpus let us find "scientists who played some musical instrument", and answer many other powerful classes of queries (Li et al., 2010; Sawant and Chakrabarti, 2013).

Consequently, accurate corpus annotation has been intensely investigated (Mihalcea and Csomai, 2007; Cucerzan, 2007; Milne and Witten, 2008; Kulkarni et al., 2009; Han et al., 2011; Ratinov et al., 2011; Hoffart et al., 2011). With two exceptions (Zheng et al., 2012; Gabrilovich et al., 2013) that we discuss later, public-domain corpus annotation work has almost exclusively used Wikipedia and derivatives, partly because Wikipedia provides not only a standardized space of entities, but also reliably labeled mention text within its own documents, which can be used to train machine learning algorithms for entity disambiguation.

However, the high quality of Wikipedia comes at the cost of low entity coverage (4.2 million) and bias toward often-mentioned, richly-connected "head" entities. Hereafter, Wikipedia entities are called W. Freebase has fewer editorial controls, but has at least nine times as many entities. This is particularly perceptible for *people* entities: one needs to be relatively famous to be featured on Wikipedia, but Freebase is less selective. Hereafter, Freebase entities are called F.

As in any heavy-tailed distribution, even relatively obscure entities from $F \setminus W$ are *collectively* mentioned a great many times on the Web, and including them in Web annotation is critical, if entity-oriented search is to impact the vast number of tail

*soumen@cse.iitb.ac.in

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 436–446,
Seattle, Washington, USA, 18-21 October 2013.

queries submitted to Web search engines.

Primary goal — corpus annotation: We have thus established a pressing need to bootstrap from a small entity catalog W (such as Wikipedia entities), and a small *reference* corpus C_W (e.g., Wikipedia text) reliably annotated with entities from W, to a much larger catalog F (e.g., Freebase), and an open-domain large *payload* corpus C (e.g., the Web).

We can and will use entities in $F \cap W$[1] in the bootstrapping process, but the real challenge is to annotate C with mentions m of entities in $F \setminus W$. Unlike for $F \cap W$, we have no training mentions for $F \setminus W$. Therefore, the main disambiguation signal is from the immediate entity neighborhood $N(e)$ of the candidate entity e in the Freebase graph. I.e., if m also reliably mentions some entity in $N(e)$, then e becomes a stronger candidate. Unfortunately, for many "tail" entities $e \in F \setminus W$, $N(e)$ is sparse. Is there hope for annotating the Web with tail entities? Here, we achieve enhanced accuracy for the primary annotation goal by extending it with a related secondary goal.

Secondary goal — entity typing: If we had available a suitable type catalog $\mathcal{T}$ with associated entities in W, which in turn have known textual mentions, we can build models of contexts referring to types like chemists, sports people and politicans. When faced with people called John Williams in $F \setminus W$, we may first try to associate them with types. This can then help disambiguate mentions to specific instances of John Williams in $F \setminus W$. In principle, useful information may also flow in the reverse direction: words in mention contexts may help assign types to entities in $F \setminus W$. For reasons to be made clear, we choose YAGO (Suchanek et al., 2007) as the type catalog $\mathcal{T}$ accompanying entities in W.

Our contributions: We present TMI, a bootstrapping system for solving the two tasks jointly. Apart from matches between the context of m and entity names in $N(e)$, TMI combines and balances evidence from two other sources to decide if e is mentioned at token span m, and has type t:

- a language model for the context in which entities of type t are usually mentioned
- correlations between t and certain path features generated from $N(e)$.

TMI uses a novel probabilistic graphical model formulation to integrate these signals. We give a detailed account of our design of node and edge potentials, and a natural reject option (recall/precision tradeoff).

We report on extensive experiments using YAGO types, Wikipedia entities and text, Freebase entities, and text from ClueWeb12[2], a 700-million-page Web corpus. We focus on all people entities in Wikipedia and Freebase, and provide three kinds of evaluation. First, we evaluate TMI on over 1100 entities in $F \cap W$ and 5500 snippets from Wikipedia text, where it visibly improves upon baselines and a recently proposed alternative method (Zheng et al., 2012). Second, we resort to extensive manual evaluation of annotation on ClueWeb12 Web text with Freebase entities, by professional editors at a commercial search company. TMI again clearly outperforms strong baselines, doing particularly well for nascent or tail entities. TMI improves per-snippet accuracy, for some classes of entities, from 46% to 70%, and pooled F1 score from 66% to 73%. Third, we compare TMI annotations with Google's FACC1 (Gabrilovich et al., 2013) annotations restricted to people; TMI is significantly better. Our annotations and related data can be downloaded from `http://www.cse.iitb.ac.in/~soumen/doc/CSAW/`. To our knowledge, this is among the first reports on extensive human evaluation of machine annotation for $F \setminus W$ on a large Web corpus.

2 Related work

The vast majority of entity annotation work (Mihalcea and Csomai, 2007; Cucerzan, 2007; Milne and Witten, 2008; Kulkarni et al., 2009; Han et al., 2011; Ratinov et al., 2011; Hoffart et al., 2011) use Wikipedia or derivative knowledge bases. (Ritter et al., 2011) and (Zheng et al., 2012) are notable exceptions. (Ritter et al., 2011) use entity names for distant supervision in POS tagging, chunking and broad named entity typing in short tweets, which are different from our goals.

Recently, others have investigated inferring types

[1] With F=Freebase and W=Wikipedia, $F \cap W \approx W$ but not quite; $W \setminus F$ is small but non-empty.

[2] `http://lemurproject.org/clueweb12/`

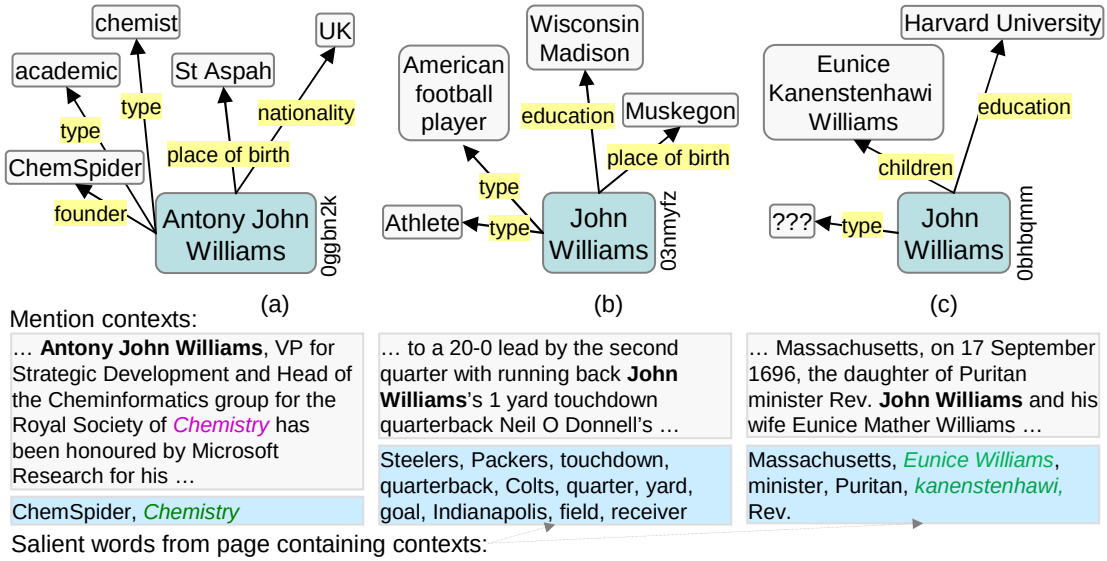

Fig. 1: Signal synergies. Three of the many people mentioned as "John Williams" on the Web are shown, with Freebase MIDs. (a) Easy case where Freebase neighbors of 0ggbn2k match snippet and salient text, and type links are also available. (b) No match exists between Freebase neighborhood and snippet, but type links help attach the snippet to 03nmvfz. (c) Freebase provides no types, but we can provide types from YAGO based on snippet and salient text, which also match neighbors of 0bhbqmm.

of emerging entities (related to our secondary goal). In concurrent work, (Nakashole et al., 2013) propose integer linear program formulations for inferring types of emerging entities from the way their mentions are embedded in curated relation-revealing phrases. (Lin et al., 2012) earlier approached the problem using weight propagation in a bipartite graph connecting unknown to known entities via textual relation patterns. Both note that this can boost mention disambiguation accuracy.

The closest work to ours is by (Zheng et al., 2012): they use semisupervised learning to annotate a corpus with Freebase entities. Like (Milne and Witten, 2008), they depend on unambiguous entity-mention pairs to bootstrap a classifier, then apply it to unlabeled, ambiguous mentions, creating more training data. They use a per-type language model like us (§3.3), but this is used as a secondary cause for (word) feature generation, supplementing and smoothing entity-specific language models. In contrast, we use a rigorous graphical model to combine new signals, not depending on naturally unambiguous mentions. Finally, in the interest of fully automated evaluation, they limit their experiments to $F \cap W$ and Wikipedia corpus, thus differing critically from our human evaluation on F and a Web corpus.

(Gabrilovich et al., 2013) have recently released FACC1: annotations of ClueWeb09 and ClueWeb12 with Freebase entities. Their algorithm is not yet public. They report: "Due to the sheer size of the data, it was not possible to verify all the automatic annotations manually. Based on a small-scale human evaluation, the precision ... is believed to be around 80–85%. Estimating the recall is of course difficult; however, it is believed to be around 70-85%." In §5, we will see that, for people entities, TMI greatly increases recall beyond FACC1, keeping precision unimpaired.

3 The three signals

Fig. 1 shows three Freebase entities mentioned as "John Williams" in Web text, represented as nodes with Freebase "MID"s e = 0ggbn2k, 03nmvfz, and 0bhbqmm, embedded in their Freebase graph neighborhoods. Owing to larger size and higher flux, Freebase shows less editorial uniformity than Wikipedia. This shows up in missing or non-standard relation edges. Unlike YAGO, where each entity is attached to one or more types, e = 0bhbqmm does not have a type link. Many people have a link labeled *profession*, which is a second

kind of type link. Entities like e = 0bhbqmm also have small, uninformative graph neighborhoods.

Also shown are three mention contexts, each represented by the snippet immediately surrounding the mention, and salient words from the documents containing each snippet. (Salient words may be extracted as words that contribute the largest components to the document represented as a TFIDF vector.) (a) shows a favorable but relatively rare case where e = 0ggbn2k has reliable type links. We cannot assume there will be a 1-to-1 correspondence between Freebase and YAGO types, but in §3.2 we will describe how to learn associations between Freebase paths around entities and their YAGO types. The snippet and salient words show reasonable overlap with $N(e)$. In §3.4 we will describe features that characterize such overlap. In (b), e = 03nmvfz is reliably typed, but there is no direct match between $N(e)$ and the snippet. Nevertheless, the snippet can be reliably annotated with 03nmvfz if we can learn associations between types *American football player* and *Athlete* (or their approximate YAGO target types) and several context/salient words (see §3.3). In (c), e = 0bhbqmm is not reliably typed. However, there are matches between $N(e)$ and context/salient words. Once the snippet-to-entity association is established, it is easier to assign 0bhbqmm to suitable types in YAGO.

In this section we will first describe our design of the target type space, and then the tree signals that will be used in our joint inference.

3.1 Designing the target type space

By typing two people called John Williams as actor and footballer, we may also disambiguate their mentions accurately. Therefore, we need a well-organized type space where the types

- collectively cover most entities of interest,
- offer reasonable type prediction accuracy, and
- can be selected algorithmically, for any domain.

Wikipedia and Freebase have many obscure types like "people born in 1937" or "artists from Ontario" which satisfy none of the above requirements. YAGO, on the other hand, has a clean hierarchy of over 200,000 types with broad coverage and fine differentiation. Most entities in $F \setminus W$ can be accurately attached to one or more YAGO types.

if t has $< N_{\text{low}} = 5000$ member entities **then**
  reject t from our type space
  return
if t has $> N_{\text{high}} = 25000$ member entities **then**
  for each immediate child $t' \subset t$ **do**
    call $\mathbf{ChooseTypes}(t')$
else
  accept t into our type space (but do not recurse)

Fig. 2: Procedure $\mathbf{ChooseTypes}(t)$.

YAGO lists around 37,000 subtypes of *person*. To satisfy the three requirements above, we called $\mathbf{ChooseTypes}(\textit{person})$ (Fig. 2); this resulted in 130 suitable types being selected. These directly covered 80% of Freebase people; the rest could mostly be attached to slightly over-generic types within our selection.

3.2 Predicting types from entity neighborhood

There will generally not be a simple mapping between Freebase and target types. E.g., entity e may be known as a *Mayor* in Freebase, but the closest YAGO type may be *Politician*. Edge and node labels from the Freebase graph neighborhood $N(e)$ can embed many clues for assigning e a target type. E.g., e = 03nmvfz may have an edge labeled *playedFor* to a node representing the Wikipedia entity `Pittsburgh_Steelers`, which has a type link to *NFL team*. This two-hop link label sequence would repeat for a large number of players, and can be used as a feature in a classifier.

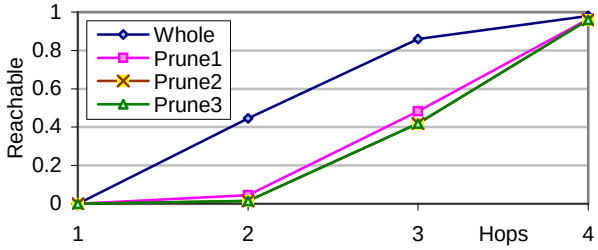

Fig. 3: Freebase has small diameter despite graph thinning. Prune1 removes paths from the whole Freebase graph that pass through nodes */user/root* and */common/topic*, Prune2 also removes node */people/person*, and Prune3 removes several other high degree hubs.

Two further refinements are needed to make this work. First, we have to collect path labels around negative instances we well, and submit positive and negative path labels to a binary classifier to can-

cel the effect of frequent but non-informative path types. Second, indiscriminate expansion around e is infeasible because the Freebase graph has very small diameter. Even after substantial pruning, paths of length 3 and 4 reach over 40% and 96% of all nodes (Fig. 3). This increases computational burden and floods us with noisy and spurious paths. We remedy the problem using an idea from PathRank (Lao and Cohen, 2010). Instead of trying to explore *all* paths originating (or terminating) at e, where e may or may not belong to a target type, we focus on paths *between* e and other known members of the target type.

3.3 Type "language model"

To exploit the second signal, shown in Fig. 1(b), we need to model the association between target YAGO types and the mention contexts of Wikipedia entities known to belong to those types. This model component is in the same spirit as (Zheng et al., 2012).

For each target YAGO type t, we sample positive entities $e \in F \cap W$, and for each e, we collect, from Wikipedia annotated text, a corpus of snippets mentioning e. We remove the mention words and retain the rest. We also collect salient words from the entire Wikipedia document containing the snippet, as shown in Fig. 1.

At this point each target type is associated with a "corpus" of contexts, each represented by snippet words. We compute the IDF of all words in this corpus[3], and then represent each type as a TFIDF vector (Salton and McGill, 1983). A test context is turned into a similar vector, and its score with respect to t is the cosine between these two vectors. This simple approach was found superior to building a more traditional smoothed multinomial unigram model (Zhai, 2008) for each type. Given the output of this component feeds into an outer discriminative inference mechanism, a strict probabilistic model is not necessary.

3.4 Entity neighborhood match with snippet

The third signal is a staple of any disambiguation work: match the occurrence context against the neighborhood in the structured representation. In word sense disambiguation (WSD), support for assigning a word in context to a synset comes from matches between, say, other words in the context and the WordNet neighborhood of the proposed synset. As in WSD, many approaches to Wikification measure some local consistency between a mention m and the neighborhood $N(e)$ of a candidate entity e. $N(e)$ is again limited by a maximum path length ℓ. From snippet m we extract all phrases $P(m)$ excluding the mention words. For each phrase $p \in P(m)$, if p occurs *at least once*[4] in any node of $N(e)$, then we accumulate a credit of $|p| \sum_{w \in p} \text{IDF}(w)$, where w ranges over words in p, $\text{IDF}(w)$ is its inverse document frequency (Salton and McGill, 1983) in Wikipedia, and $|p|$ is the length of the phrase. This rewards exact phrase matches.

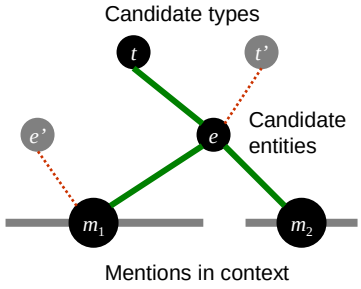

Fig. 4: Tripartite assignment problem.

4 Unified model

Figure 4 abstracts out the signals shown in Figure 1 into a tripartite assignment problem. Each mention like m_1 has to choose at most one entity from among candidate aliasing entities like e and e'. Each entity $e \in F \setminus W$ has to choose one type (for simplicity we ignore zero or more than one types as possibilities) from candidates like t and t'.

The configuration of thick (green) edges should be preferred to alternative dotted (red) edges under these considerations:

- There is high local affinity or compatibility between e and t, based on associations between t and $N(e)$ as discussed in §3.2.
- There are better textual matches between $N(e)$ and m_1, as compared to $N(e')$ and m_1.
- In aggregate, the non-mention tokens in the context of m_1, m_2 (shown as gray horizontal lines) match well the language model associated with mentions of entities of type t (rather than t').

[3] Generic IDF from Wiki text does not work.

[4] Incorporating term frequency often polluted the score.

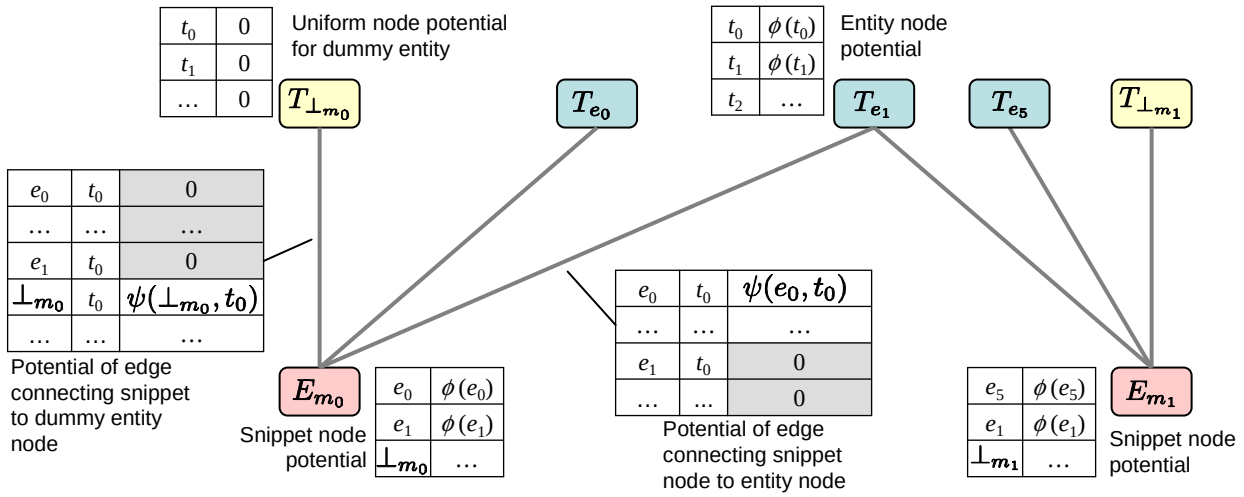

Fig. 5: Illustration of the proposed bipartite graphical model, with tables for node and edge potentials and synthetic $\perp$-entity nodes to implement the reject option.

We now present a unified model that combines the signals and solves the two proposed tasks jointly. We model two kinds of decision variables, which will be represented by nodes in a graphical model. Associated with each entity $e \in F \setminus W$ there is a hidden type variable (node) T_e, which can take on a value from (some subset of) the type catalog $\mathcal{T}$. Associated with each mention m (along with its snippet context and all its observable features) there is a hidden entity variable E_m, which can take on values from some subset of entities. (For simplicity, we assume that entities in $F \cap W$ have already been annotated in the corpus, and no m of interest mentions such entities.)

We will model the probability of a joint assignment of values to T_e, E_m as

$$\log \Pr(\vec{t}, \vec{e}) = \alpha \sum_{e} \phi_e(t_e) + \beta \sum_{m} \phi_m(e_m) + \sum_{e,m} \psi_{e,m}(t_e, e_m) - \text{const.}, \quad (1)$$

where node log potentials are called ϕ_e, ϕ_m, edge log potentials are called $\psi_{e,m}$, and α, β are tuned constants. The log partition function, written "const." above, will not be of interest in inference, where we will seek to choose $\vec{t}, \vec{e}$ to maximize $\Pr(\vec{t}, \vec{e})$. In this section, we will design the node and edge log potentials.

4.1 Node log potentials

Each node T_e is associated with a node potential table, mapping from possible types in $\mathcal{T}_e$ to nonnegative potentials. The potential values are supplied from §3.2 as the classifier output scores.

Each node E_m is associated with a node potential table, mapping from possible entities in $\mathcal{E}_m$ to nonnegative potentials. The potential values are supplied from §3.4.

4.2 Edge log potentials

Suppose we assign $E_m = e$, and $T_e = t$. Then we would like the non-mention context words of m to be highly compatible with the type "language model" developed in §3.3.

If e is among the set of values $\mathcal{E}_m$ that E_m can take, then nodes T_e and E_m are joined by an edge. This edge is associated with an edge potential table $\psi_{e,m} : \mathcal{T}_e \times \mathcal{E}_m \to \mathbb{R}^+$. $\psi_{e,m}(\cdot, e')$ will be set to zero (cells shaded gray in Fig. 5) when $e \neq e'$. $\psi_{e,m}(t, e)$ is set to the cosine match score described in §3.3.

4.3 The reject (a.k.a. null, nil, NA, $\perp$) option

An algorithm may reject many snippets, i.e., refrain from annotating them. This could be because the snippet mentions an entity outside F (and outside W), or the system wishes to ensure high precision at some cost to recall.

Rejection is modeled by adding, for each snippet m, a pseudo or "null" entity $\perp_m$ (also called "no an-

notation" NA, null or nil in the TAC-KBP[5] community). For simplicity, we assume that $\perp_m$ and $\perp_{m'}$ are incomparable or distinct for $m \neq m'$. I.e., we do not offer to cluster mentions of unknown entities. These remain separate, unconnected nodes in the (augmented) Freebase graph.

If we choose $E_m = \perp_m$, we get zero credit for matching non-mention text in m to $N(\perp_m)$, because $N(\perp_m) = \varnothing$ and §3.4 has no information to contribute. I.e., we set $\phi_m(\perp_m) = 0$. In general, $\phi_m(\cdot) \geq 0$, so $\perp_m$ gets the lowest possible credit (but this will be modified shortly).

There is also a type variable $T_{\perp_m}$. To what type should we assign "entity" $\perp_m$? Because $\perp_m$ has no connections in the Freebase graph, no hint can come from §3.2. Put differently, $\phi_{\perp_m}(t)$ will be constant (say, zero) for all snippets m and types t.

Even if we do not know the entity mentioned in m, the non-mention text in m will have differential affinity to different types, obtained from §3.3. This means that, if $E_m = \perp_m$ is chosen, $T_{\perp_m}$ will be $\arg\max_t \psi_{\perp_m,m}(t, \perp_m)$, which explains the non-mention words in m using the best available language model associated with some type. For a different entity $E_m = e_0$ and type $T_{e_0} = t$ assignment to win, $\alpha\phi_m(e_0)+\beta\phi_{e_0}(t)+\psi_{e_0,m}(t, e_0)$ must exceed the null score above. This provides a usable recall/precision handle: we modify $\phi_m(\perp_m)$ to a tuned number; making it smaller generally gives higher recall and lower precision.

4.4 Inference and training

The goal of collective inference will be to assign a type value to each T_e and an entity value to each E_m. We seek the maximum a-posteriori (MAP) label, for which we use tree-reweighted message passing (TRW-S) (Kolmogorov, 2006). Our graph has plenty of bipartite cycles, so inference is approximate. Given the sparsity of data, we preferred to *delexicalize* our objective (1), i.e., avoid word-level features and pre-aggregate their signals via time-tested aggregators (such as TFIDF cosine). As a result we have only two free parameters α, β in (1), which we tune via grid search. A more principled training regimen is left for future work.

[5] http://www.nist.gov/tac/2013/KBP/

5 Experiments

We focus our experiments on one broad type of entities, *people*, that is more challenging for disambiguators than typical showcase examples of distinguishing (Steve) Jobs from employment and Apple Inc. from fruit.

We report on three sets of experiments. In §5.1, we restrict to entities from $F \cap W$ and Wikipedia text, for which ground truth annotation is available. In §5.2, we evaluate TMI and baselines on ClueWeb12 and entities from Freebase, not limited to Wikipedia. In §5.3, we compare TMI with Google's recently published FACC1 annotations (Gabrilovich et al., 2013).

5.1 Reference corpus C_W with $F \cap W$ entities

Limited to people, $|F| = 2323792$, $|W| = 807381$, $|F \setminus W| = 1544942$, and $|F \cap W| = 778850$. It is easiest to evaluate TMI and others on Wikipedia entities. They have known YAGO types. Wikipedia text has explicit (disambiguated) entity annotations. For these reasons, the few known systems for Freebase-based annotation (Zheng et al., 2012) are evaluated exclusively on $F \cap W$.

5.1.1 Seeding and setup

People in $F \cap W$ are known by one or more mention words/phrases. From these, we collect mention phrases along with the candidate entity set for each phrase. The number of candidates is the phrase's *degree of ambiguity*. We sort phrases by ambiguity and draw a sample over the ambiguity range. This gives us seed phrases with representative ambiguity. Then we collect all entities mentioned by these phrases. Overall we collect about 1100 entities and 5500 distinct mentions.

Contrast this with (Zheng et al., 2012), who sample entities from much fewer than 130, and largely well-separated types: professional athletes, academics, actors, films, books, hotels, and tourist attractions. If there were only two namesakes, an actor and a politician, the politician disappears, leaving a naturally unambiguous alias. I.e., (Zheng et al., 2012) did not "complete" their entity sets with aliased entities. For all these reasons, Z0 numbers here are not directly comparable to those in their paper.

5.1.2 Tasks and baselines

The structure of TMI suggests two natural baselines to compare against it. TMI solves two tasks simultaneously: assign types to entities and entities to snippets. So the first baseline, **T0**, is one that solves the typing task separately, and the second, **A0**, does snippet annotation separately. A third baseline, **Z0**, from (Zheng et al., 2012) does only snippet annotation; they do not consider typing entities.

While evaluating types output by TMI and T0 against ground truth, we may wish to assign partial credit for overlapping types, e.g., *athlete* vs. *soccer player*, because our types form an incomplete hierarchy. We use the standard "M&W" score of semantic similarity between types (Milne and Witten, 2008) for this.

As regards snippet annotation, Z0 (Zheng et al., 2012) does not specify any mechanism for handling $\perp$. Therefore we run two sets of experiments. In one we eliminate all snippets with ground truth $\perp$. A0, and TMI are also debarred from returning $\perp$ for any snippet. In the other, snippets marked $\perp$ in ground truth are included. A0 and TMI are enabled to return $\perp$, but Z0 cannot.

	TMI	A0	Z0
0/1 snippet accuracy	**0.827**	0.699	0.627

Fig. 6: Snippet annotation on C_W corpus, $F \cap W$ entities, $\perp$ not allowed.

	TMI	A0	Z0
0/1 snippet accuracy	**0.7307**	0.651	0.622
Snippet precision	**0.858**	0.843	0.622
Snippet recall	**0.777**	0.692	0.639
Snippet F1	**0.815**	0.760	0.630

Fig. 7: Snippet annotation on C_W corpus, $F \cap W$ entities, $\perp$ allowed.

5.1.3 Snippet annotation results

Fig. 6 shows snippet annotation accuracy (fraction of snippets labeled with the correct entity) when $\perp$ is not allowed as an entity. As two uninformed refernces, uniform random choice gives an accuracy of 0.423 and choosing the entity with the largest prior gives an accuracy of 0.767. TMI is considerably better than A0, which is better than Z0 and the uninformed references. This is despite training Z0's per-type topic models not only on unambiguous snippets, but also on a disjoint fraction of $F \cap W$, as a surrogate for Wikipedia's containment in Freebase.

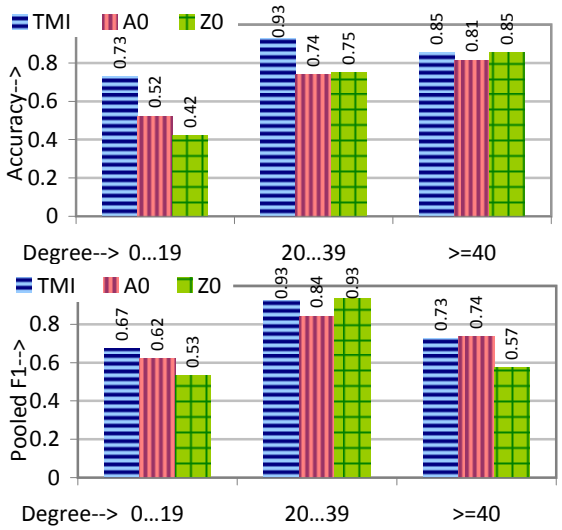

Fig. 8: Bucketed comparison between TMI and baselines, $F \cap W$, $\perp$ allowed.

	TMI	T0
0/1 type accuracy	0.80	0.81
M&W type accuracy	0.82	0.83

Fig. 9: Type inference, C_W corpus, $F \cap W$ entities.

Fig. 7 repeats the experiment while allowing $\perp$. Here, in 0/1 accuracy, $\perp$ is regarded as just another entity. Again, we see that TMI has a clear advantage. Z0's performance here is worse than in (Zheng et al., 2012). This is explained by our much larger and difficult-to-separate type system.

We disaggregate the summary results into buckets, shown in Fig. 8. Each bucket covers a range of degrees of entity nodes in Freebase, while roughly balacing the number of snippets in each bucket. TMI generally shows larger gains for low-degree buckets.

5.1.4 Type prediction results

We also compared the type inference accuracy of TMI and T0; (Zheng et al., 2012) do not infer types. The summary is in Fig. 9. Two uninformed baselines are worth mentioning. Uniform random choice over 130 types gave only 2% accuracy. Chossing the type with largest prior probability gave 28.2% accuracy. TMI is much better, but offers no significant benefit (or degradation) compared to T0. We verified, partly by way of debugging, that there do exist entities e with small degree but a modest number of assigned snippets, for which snippet-to-$N(e)$ matches

angus mcdonald, chris robinson, christopher henry, elizabeth cameron, george woods , henry barnes, jack scott, jeremy robert, john sherman, leonard thomas, marc anthony, mitchell donald, morrison mark, parker edward, richard andrew , simon scott, stephen ross, stuart baron, tom clark, whitney john, austin scott, barbara johnson, brian peterson, carlos rivero, david berman, david johns, donald fraser, george davies, george fisher, graham smith, john pepper, jonathan edwards, kevin brown, kevin hughes, matt johnson, michael davidson, nancy johnson, paul holmes, pedro martins, peter frank, peter mitchell, peter mullen, robert stern, roger edwards, stuart walker, terry evans, tony angelo, tony ward, william jarvis, william sampson

Fig. 10: Seed mentions for confusion clusters for Web corpus C and entities in F.

provide a boost to type prediction accuracy (about 50%), as compared to T0 (about 20% for these instances). Therefore, the flow of information between type and entity assignments is, in principle, bidirectional, in the regime of such entities.

5.2 Payload corpus C with entities in F

Recall our main goal is to annotate payload corpus C with entities in all of F. Experience with $F \cap W$ and C_W may not be representative of F and C. Entities in $F \setminus W$ may not come with reference mentions, and their type and entity neighborhoods may be sparse. Furthermore, compared to the closed world of $F \cap W$, evaluating TMI and baselines over C and $F \setminus W$ is challenging. Entities in $F \setminus W$ do not have ground truth types in the type catalog T (here, YAGO), nor snippets labeled by humans as mentioning them. Therefore, we need human editorial judgment, which is scarce. Even though TMI can be *applied* at Web scale, the scale if *evaluation* is limited by editorial input.

5.2.1 Seeding and data setup

There are about 2.3 million Freebase entities connected to */people/person* via *type* links. Similar to §5.1.1, we chose phrases (Fig. 10) with diverse degree of ambiguity (Fig. 11), to seed confusion clusters. Then we completed the clusters by including aliased entities, as before, so as not to artifically reduce the degree of ambiguity. Note that entities in W can and do contend with entities in $F \setminus W$. The cluster size distribution is shown in Fig. 12. Limited by editorial budget, we finished with 634 entities, 238 distinct aliases and 4,500 snippets.

We used the 700-million-page ClueWeb12 Web corpus. All phrases in the expanded clusters are

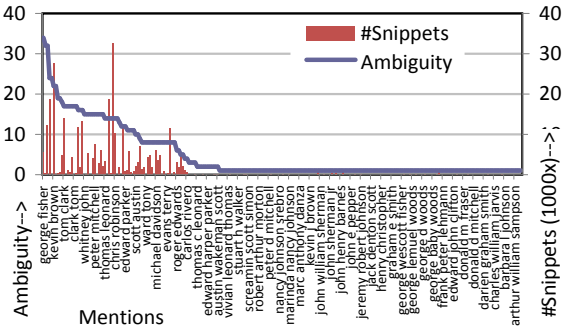

Fig. 11: Ambiguity distribution for Web corpus C. Unambiguous names are usually fully expanded and very rare, if at all present, in evaluated snippets.

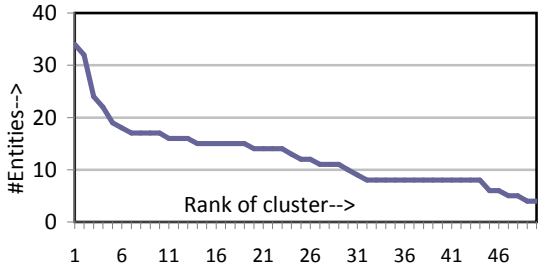

Fig. 12: Confusion cluster size distribution for Web corpus C.

loaded into a trie used by a map-reduce job to extract documents, then snippets, from the corpus. Some phrases in Figs. 10 and 11 have overwhelming numbers of pages with matches. In production, we naturally want all of them to be annotated. But human editorial judgment being the bottleneck, we sampled 50% or 50,000 snippets, whichever was smaller. Starting with about 752,450 pages, we ran the Stanford NER (Finkel et al., 2005) to mark person spans. Pages with fewer than five non-person tokens per person were discarded; this effectively discarded long list pages without any informative text to disambiguate anyone, and left us with 574,135 pages. From these we collected 304,309 snippets where the mention phrase is marked by the NER as a person. Each seed phrase leads to one cluster on which TMI and A0 are run. Note that $\perp$ must be allowed on the open Web.

5.2.2 Editorial judgment

Finally, for each algorithm, about 634 entity-type and about 4500 snippet-entity assignments are randomly sampled and sent to 20 editors in a commercial search engine company, who judged each assignment as correct or incorrect, *without knowing which algorithm* produced the annotation, to avoid

	TMI entity	A0
0/1 accuracy	**.714**	.562
Pooled recall	.764	**.869**
Precision	**.714**	.562
F1	**.738**	.683

	$e \in W$ (0/1 acc.)	$e \in F \setminus W$ (0/1)
TMI	**.75**	**.62**
A0	.65	.42

Fig. 13: Snippet summary for F and payload corpus C.

bias. Because the editors are trained professionals (unlike Mechanical Turks), we increased our evaluation coverage by having each type or entity assignment reviewed by one editor.

Pooling: Ideally, editors can be asked to find the best type or entity for each entity or snippet, but, given the size and diversity of Freebase, the cognitive burden would be unacceptable. In the Wikipedia corpus C_W, a snippet marked $\perp$ (no entity) by an algorithm can be judged a loss of recall if Wikipedia ground truth annotates it with an entity. Unfortunately, this is no longer practical for Web corpus C, because 8,217 snippets marked $\perp$ would have to be manually inspected and compared with a large number of candidate entities in Freebase. Therefore, we adopt pooling as in TREC. (Although the pool is small, A0 has very high recall.) Recall is evaluated with respect to the union of snippets annoted with a non-$\perp$ entity by *at least one* competing algorithm, with agreement in case of more than one.

0/1 Type accuracy: Editors judged each proposed type as correct or not. Unlike in §5.1, where the true and proposed types could be compared via M&W (Milne and Witten, 2008), they could not be asked to objectively estimate relatedness between types. Therefore we present only their reported post-hoc 0/1 accuracy for types: T0 and TMI have 0/1 type accuracy of 0.828 and 0.818.

5.2.3 Snippet annotation results

Given the large gap between TMI and Z0 in the easier setup in §5.1, we no longer consider Z0, and instead focus on TMI vs. A0. The summary comparison of A0 vs. TMI is shown in Fig. 13. Here TMI's absolute gains in 0/1 accuracy and F1 are even larger than in §5.1. To understand TMI's performance across a diversity of Freebase entity nodes e, as a function of 1. the size and richness of $N(e)$, and 2. the number of snippets claimed to mention e, we disaggregate the data of Fig. 13 into buckets of

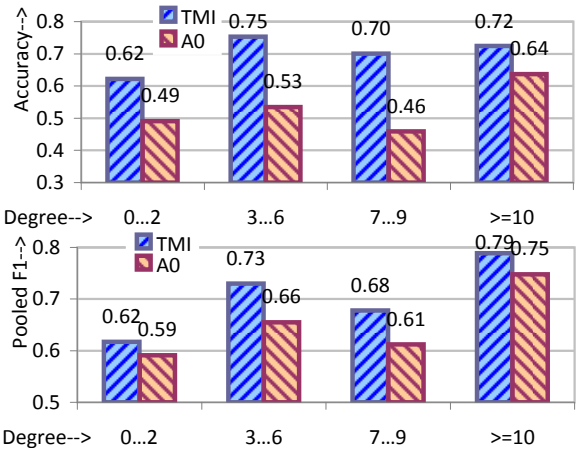

Fig. 14: 0/1 accuracy and F1 for snippets, payload corpus C and entities in F.

Snippet label judgements	%
TMI ok, FACC1 ok, neither $\perp$	22
TMI ok, FACC1 wrong, neither $\perp$	6
TMI$\neq \perp$ ok, FACC1=$\perp$ wrong	**40**
TMI$\neq \perp$ wrong, FACC1=$\perp$	23
TMI wrong, FACC1 wrong, neither $\perp$	2
TMI$= \perp$ wrong, FACC1$\neq \perp$ correct	4
TMI$= \perp$, FACC1$\neq \perp$, wrong	3
(TMI$= \perp$, FACC1$= \perp$, not judged)	-

Fig. 15: TMI vs. FACC1 comparison.

consecutive degrees, roughly balancing the number of snippets per bucket, as shown in Fig. 14. At the very low end of almost disconnected entity nodes, no algorithm does very well, because these entities are also hardly ever mentioned. When the entity is popular and well-connected, TMI's benefits are relatively modest. TMI's gains are best in the mid-range of degrees. The gap narrows for large-degree nodes, which is expected.

5.3 Comparison with FACC1

After collecting our pool of snippets as in §5.2.2, we consulted FACC1 (Gabrilovich et al., 2013), and passed on FACC1 annotations to our editors. As before, the identity of the algorithm was concealed. Results are shown in Fig. 15. In a large 40% of cases, TMI labels correctly while FACC1 backs off. The converse, where FACC1 backs off and TMI makes a mistake, is about half as frequent. These preliminary numbers suggest that TMI is able to push recall beyond FACC1 while also giving better precision.

6 Conclusion

We presented a formal model for bootstrapping from YAGO types and entities annotated in Wikipedia to two tasks, 1. annotating Web snippets with Freebase entities, and 2. associating Freebase entities with YAGO types. We presented TMI, a system to solve the two tasks jointly. Experiments show that TMI's snippet annotation accuracy, especially for relatively weakly-connected Freebase entities, is superior to baselines. We aim to extend from people to all major Freebase categories, and larger Web crawls.

Acknowledgment: We are grateful to Shrikant Naidu, Muthusamy Chelliah, and the editors from Yahoo! for their generous support. Shashank Gupta helped process FACC1 data.

Effectiveness and Efficiency of Open Relation Extraction

Filipe Mesquita **Jordan Schmidek** **Denilson Barbosa**
Department of Computing Science, University of Alberta, Canada
{mesquita,schmidek,denilson}@ualberta.ca

Abstract

A large number of Open Relation Extraction approaches have been proposed recently, covering a wide range of NLP machinery, from "shallow" (e.g., part-of-speech tagging) to "deep" (e.g., semantic role labeling–SRL). A natural question then is what is the trade-off between NLP depth (and associated computational cost) versus effectiveness. This paper presents a fair and objective experimental comparison of 8 state-of-the-art approaches over 5 different datasets, and sheds some light on the issue. The paper also describes a novel method, EXEMPLAR, which adapts ideas from SRL to less costly NLP machinery, resulting in substantial gains both in efficiency and effectiveness, over binary and n-ary relation extraction tasks.

1 Introduction

Open Relation Extraction (ORE) (Banko and Etzioni, 2008) has become prevalent over traditional relation extraction methods, especially on the Web, because of the intrinsic difficulty in training individual extractors for every single relation. Broadly speaking, existing ORE approaches can be grouped according to the level of sophistication of the NLP techniques they rely upon: (1) shallow parsing, (2) dependency parsing and (3) semantic role labelling (SRL). Shallow methods annotate the sentences with part-of-speech (POS) tags and the ORE approaches in this category, such as ReVerb (Fader et al., 2011) and SONEX (Merhav et al., 2012), identify relations by matching patterns over such tags. Dependency parsing gives unambiguous relations among each word in the sentence, and the ORE approaches in this category such as PATTY (Nakashole et al., 2012), OLLIE (Mausam et al., 2012), and TreeKernel (Xu et al., 2013) identify whole subtrees connecting the relation predicate and its arguments. Finally, semantic annotators, such as Lund (Johansson and Nugues, 2008) and SwiRL (Surdeanu et al., 2003), add roles to each node in a parse tree, enabling ORE approaches that identify the precise connection between each argument and the predicate in a relation, independently.

The first contribution of the paper is an objective and fair experimental comparison of the state-of-the-art in ORE, on 5 datasets with varying degree of "difficulty". Of these, 4 datasets were annotated manually, covering both well-formed sentences, from the New York Times (NYT) and the Penn Treebank, as well as mixed-quality sentences from a popular Web corpus. A much larger corpus with 12,000 sentences from NYT, automatically annotated is also used. Another experiment focuses on n-ary relation extractions separately. The results show, as expected, that the three broad classes above are separated by orders of magnitude when it comes to throughput. Shallow methods handle ten times more sentences than dependency parsing methods, which in turn handle ten times more sentences than semantic parsing methods. Nevertheless, the cost-benefit trade-off is not as simple; and the higher computation cost of dependency or semantic parsing does not always pays off with higher effectiveness.

The second contribution of the paper is a new ORE method, called EXEMPLAR, which applies a key idea in semantic approaches (namely, to iden-

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 447–457,
Seattle, Washington, USA, 18-21 October 2013.

tify the precise connection between the argument and the predicate words in a relation) over a dependency parse tree (i.e., without applying SRL). The goal is to achieve the higher accuracy of the semantic approaches at the lower computational cost of the dependency parsing approaches. EXEMPLAR is a rule-based system derived from a careful study of all dependency types identified by the Stanford parser. (Note, however, that other parsers can be used, as shown later on.) EXEMPLAR works for both binary and n-ary relations, and is evaluated separately in each case. For binary relations, EXEMPLAR outperforms all previous methods in terms of accuracy, losing to the shallow methods only in terms of throughput. As for n-ary relations, EXEMPLAR outperforms the methods that support this kind of extraction.

2 Related Work

Others have pointed out the importance of understanding the trade-off between "shallow" versus "deep" NLP in ORE. One side of the argument favors shallow methods, claiming deep NLP costs orders of magnitude more and provide much less dramatic gains in terms of effectiveness (Christensen et al., 2011). The counterpoint, illustrated with a recent analysis on a industrial-scale Web crawl (Dalvi et al., 2012), is that the diversity with which information is encoded in text is too high. Framing the debate as "shallow" versus "deep" is perhaps convenient, but nevertheless an oversimplification. This paper sheds more light into the debate by comparing the state-of-the-art from three broad classes of approaches.

Shallow ORE. TextRunner (Banko and Etzioni, 2008) and its successor ReVerb (Fader et al., 2011) are based on the idea that most relations are expressed using few syntactic patterns. ReVerb, for example, detects only three types of relations ("verb", "verb+preposition" and "verb+noun+preposition"). Following a similar approach, SONEX (Merhav et al., 2012) extends ReVerb by detecting patterns with appositions and possessives.

ORE via dependency parsing. PATTY (Nakashole et al., 2012) extracts textual patterns from sentences based on paths in the dependency graph. For all pairs of named entities, PATTY finds the shortest path in the dependency graph that connects the two named entities. They limit the search to only paths that start with one of these dependencies: nsubj, rcmod and partmod.

Dataset	Source	# Sentences	# Relations
WEB-500	Search Snippets	500	461
NYT-500	New York Times	500	150
PENN-100	Penn Treebank	100	51

Table 1: Binary relation datasets.

OLLIE (Mausam et al., 2012) also extracts relations between two entities. It applies pattern templates over the dependency subtree containing pairs of entities. Pattern templates are learned automatically from a large training set that is bootstrapped from high confidence extractions from ReVerb. OLLIE merges binary relations that differ only in the preposition and second argument to produce n-ary extractions, as in: (A, "met with", B) and (A, "met in", C) leading to (A, "met", [with B, in C]).

The TreeKernel (Xu et al., 2013) method uses a dependency tree kernel to classify whether candidate tree paths are indeed instances of relations. The shortest path between the two entities along with the shortest path between relational words and an entity are used as input to the tree kernel. An expanded set of syntactic patterns based on those from ReVerb are used to generate relation candidates.

ORE via semantic parsing. Recently, a method based on SRL, called SRL-IE, has shown that the effectiveness of ORE methods can be improved with semantic features (Christensen et al., 2011). We implemented our version of SRL-IE by relying on the output of two SRL systems: Lund (Johansson and Nugues, 2008) and SwiRL (Surdeanu et al., 2003). SwiRL is trained on PropBank and expands upon the syntactic features used in previous work. One of its major limitations is that it is only able to label arguments with verb predicates. Lund, on the other hand, is based on dependency parsing and is trained on both PropBank and NomBank, making it able to extract relations with both verb and noun predicates.

3 Experimental Study

This section compares the effectiveness and efficiency of the following ORE methods: ReVerb,

Method	NYT-500				WEB-500				PENN-100			
	Time	P	R	F	Time	P	R	F	Time	P	R	F
ReVerb	**0.02**	0.70	0.11	0.18	**0.01**	0.92	0.29	0.44	**0.02**	0.78	0.14	0.23
SONEX	0.04	0.77	0.22	0.34	0.02	**0.98**	0.30	0.45	0.04	**0.92**	0.43	0.59

Table 2: Results for the task of extracting binary relations. Methods are ordered by computing time per sentence (in seconds). Best results for each column are underlined and marked in bold, for clarity.

SONEX, OLLIE, PATTY, TreeKernel, SwiRL, Lund and our two variants of our method, EXEMPLAR, explained in detail in Appendix A: (1) EXEMPLAR[S] uses the Stanford parser (Klein and Manning, 2003) and (2) EXEMPLAR[M] uses the Malt parser (Nivre and Nilsson, 2004).

3.1 Binary Relations – Setup

We start by evaluating the extraction of binary relations. Table 1 shows our experimental datasets. WEB-500 is a commonly used dataset, developed for the TextRunner experiments (Banko and Etzioni, 2008). These sentences are often incomplete and grammatically unsound, representing the challenges of dealing with web text. NYT-500 represents the other end of the spectrum with formal, well written new stories from the New York Times Corpus (Sandhaus, 2008). PENN-100 contains sentences from the Penn Treebank recently used in an evaluation of the TreeKernel method (Xu et al., 2013). We manually annotated the relations for WEB-500 and NYT-500 and use the PENN-100 annotations provided by TreeKernel's authors (Xu et al., 2013).

We annotate each sentence manually as follows. We identify exactly two entities and a *trigger* (a single token indicating a relation–see Section A.3) for the relation between them, if one exists. In addition, we specify a *window* of tokens allowed to be in a relation, including modifiers of the trigger and prepositions connecting triggers to their arguments. For each sentence annotated with two entities, a system must extract a string representing the relation between them. Our evaluation method deems an extraction as correct if it contains the trigger and allowed tokens only.

In our annotated sentences, entities are enclosed in triple square brackets, triggers and enclosed in triple curly brackets and the window of allowed tokens is defined by arrows ("--->" and "<---"), as in this example:

```
I've got a media call about
[[[ORG Google]]] --->'s
{{{acquisition}}} of<--- [[[ORG
YouTube]]] --->today<---.
```

where "Google" and "YouTube" are entities of the type organization, "acquisition" is the trigger and the allowed tokens are "acquisition", "'s" and "of". We include time and location modifiers (e.g., "today", "here") in the list of allowed tokens since OLLIE extracts them as part of the relation. OLLIE's extractions may also include auxiliary verbs and prepositions that are not present in the original sentence. To be fair with OLLIE, we remove auxiliary verbs and prepositions from OLLIE extractions.

Our benchmarks are available upon request.

Ensuring entities are recognized properly. Since every method uses a different tool to recognize entities, we try to ensure every method is able to recognize the entities marked by our annotators. We replace the original entities by a single word, preventing any system from recognizing only part of an entity. Entities are replaced by "Europe" and "Asia", since we empirically found that, for 99.7% of the sentences in our experiment, all methods were able to recognize "Europe" and "Asia" as entities (or nouns, for systems that do not use a NER tool). In addition, we did not find any occurrence of

"Europe" and "Asia" in the original sentences that could conflict with our entity placeholders.

For methods that extract relations between noun phrases (ReVerb, OLLIE, SwiRL and Lund), there is the additional task of identifying whether a noun phrase containing additional words surrounding "Europe" and "Asia" is still a reference to the annotated entity. For example, "the beautiful Europe" refers to the entity, while "Europe's enemy" does not. In our evaluation, we ignore noun phrases that do not reference the annotated entity. For SwiRL and Lund, we ignore any noun phrase that do not present "Europe" or "Asia" as its head word. For ReVerb and OLLIE, we ignore noun phrases that do not contain these words in the end of the phrase.

Metrics. Our evaluation focuses on sentence-level extractions. Therefore, we only apply the steps of each method that perform this task. Additional steps to merge relations and remove infrequent relations are not applied. In addition, we assume there is only one relation between a pair of entities in a sentence. The number of entity pairs with more than one relation was insignificant in our datasets (less than 0.5%).

The metrics used in this analysis are precision (P), recall (R) and f-measure (F), defined as usual:

$$P = \frac{\text{\# correct}}{\text{\# extractions}}, R = \frac{\text{\# correct}}{\text{\# relations}}, F = \frac{2PR}{P+R}$$

where "# correct" is the number of extractions deemed as correct.

We also measure the total computing time of each method, excluding initialization or loading any libraries or models in memory. To ensure a fair comparison, we make sure each method runs in a single-threaded mode, thus utilizing a single computing core at all times.

3.2 Binary Relations – Results

Table 2 presents the results for our experiment with binary relations. WEB-500 turned out to contain the easiest sentences as evidenced by the precision of all methods in this dataset. This is because WEB-500 sentences were collected by querying a search engine with known relation instances. The other two datasets, on the other hand, contain randomly chosen sentences. Although WEB-500 is a popular dataset, it perhaps does not represent the challenges found in web text.

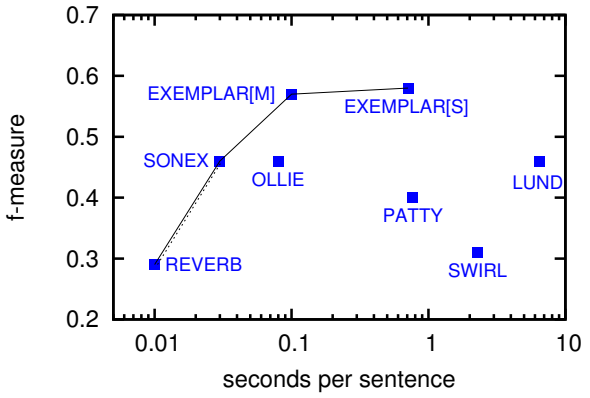

Figure 1: Average f-measure vs average time for NYT-500, WEB-500 and PEN-100.

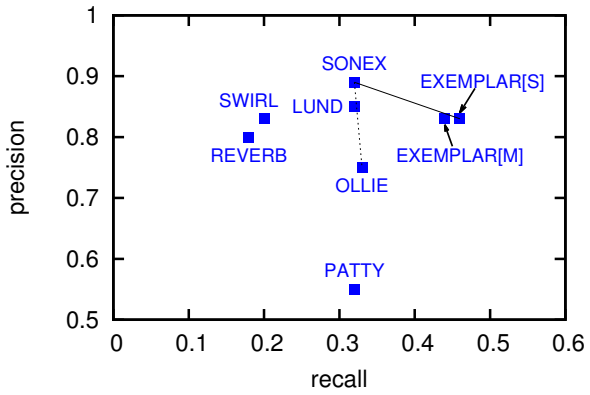

Figure 2: Average precision vs average recall for NYT-500, WEB-500 and PEN-100.

We were unable to run TreeKernel for NYT-500 and WEB-500 for lack of training data. We ran TreeKernel, as trained by its authors, on the same test set used in their paper (Xu et al., 2013).

Comparing methods based on effectiveness (f-measure) or efficiency (computational cost) alone can be misleading. To do so, we compare methods in terms of *dominance*. We say method A dominates method B if A is: (1) *more effective* and as efficient as B; (2) *more efficient* and as effective as B; or (3) both more effective and more efficient than B. The methods that are not dominated by any other form the state-of-the-art.

Figure 1 plots the effectiveness and efficiency of

all methods, averaged over all datasets (TreeKernel was not included due to missing results). For efficiency, there is a clear separation of approximately one order of magnitude among methods based on shallow parsing (ReVerb and SONEX), dependency parsing (OLLIE, EXEMPLAR[M], EXEMPLAR[S], and PATTY) and semantic parsing (SwiRL and Lund). The lines in the plot identify the state-of-the-art before (dashed) and after (solid) EXEMPLAR. (Note: Although not clear in the figure, OLLIE and Lund are dominated by SONEX as they tie in terms of effectiveness.)

In terms of efficiency, EXEMPLAR[M] and EXEMPLAR[S] closely match OLLIE and PATTY, respectively, since they use the same dependency parsers. EXEMPLAR outperforms both systems by covering a larger number of relational patterns. This is possible because EXEMPLAR looks at each argument separately, as opposed to the whole subtree connecting two arguments. As it turns out, this design choice greatly simplifies the task of designing good patterns.

The poor performance of PATTY is due to its rather permissive sentence-level extraction of relations, which looks at the shortest path between arguments. PATTY relies on redundancy of extractions to normalize the produced relations in order to recover from mistakes done in the sentence-level.

Figure 2 illustrates the dominance relation differently, using precision versus recall. Again, the dashed line shows the previous state-of-the-art, and the solid line shows the current situation. SONEX dominates PATTY and Lund, since they tied in recall. OLLIE, however, achieved greater recall than SONEX. Somewhat surprisingly, EXEMPLAR presents 44% more recall than the more sophisticated Lund, at a close level of precision. This can be explained by Lund's dependency on training data, which contains only a subset of all possible predicates and roles. The importance of relations triggered by nouns is illustrated by the higher recall of SONEX and Lund when compared, respectively, to ReVerb and SwiRL, similar methods that handle verb triggers only.

3.3 Binary Relations – Discussion

Differences in annotation. It is worth noting some differences between our annotations (WEB-500 and NYT-500) and the annotations from PEN-100. The first difference concerns the definition of an entity. Consider the following sentence from PEN-100:

> "... says Leslie Quick Jr., chairman of the Quick & Reilly discount brokerage firm."

Unlike our annotation style, the original annotation defines that "Leslie Quick Jr." is the chairman of "the Quick & Reilly discount brokerage firm", as opposed to "Quick & Reilly". While we consider the words surrounding "Quick & Reilly" as apposition, the original consider them as part of the entity.

Another difference concerns the definition of the RE task. We assume that RE methods are responsible for resolving co-references when necessary to identify a relation. For example, consider the sentence:

> "It also marks P&G's growing concern that its Japanese rivals, such as Kao Corp., may bring their superconcentrates to the U.S."

According to our annotation style, there is a relation "rivals" between "P&G" and "Kao Corp." in this sentence. On the other hand, the original annotations for PENN-100 consider only the relation between "Kap Corp." and the pronoun "it", leaving the task of resolving the coreference between "P&G" and "it" as a posterior step.

These differences in annotation illustrate the challenges of producing a benchmark for open relation extraction.

Differences in evaluation methodology. A *sentence-level* evaluation like ours focuses on each sentence, separately. On the other hand, the evaluations of SONEX, ReVerb, PATTY, TreeKernel and OLLIE are performed at *the corpus level*. Corpus-level evaluations consider an extracted relation as correct regardless of whether a method was able to identify one or all sentences that describe this relation.

Creating a ground truth for corpus-level evaluations is extremely hard, since one has to identify and curate (e.g., merge near-duplicate relations and co-referential entities) all relations described in a corpus. As a consequence, most corpus-level evaluations perform only a manual inspection of a

Table 4: Results for binary relations automatically annotated using Freebase and WordNet.

method's extractions. This manual inspection measures a method's precision, but is unable to measure recall.

Other differences in methodology are as follows. PATTY's evaluation concerns relation patterns (e.g., "wrote hits for") and their type signatures (e.g. Musician–Musician), as opposed to the relation itself, which includes its two arguments. The evaluations of ReVerb and OLLIE consider any noun phrase as a potential argument, while the evaluations of TreeKernel and SONEX consider named entities only.

Due to the lack of a ground truth and differences in evaluation methodology, results from different papers are usually not comparable. This work tries to alleviate this problem by providing reusable annotations that are flexible and can be used to evaluate a wide range of methods.

3.4 n-ary Relations

The goal of this experiment is to evaluate the accuracy and performance of our method when extracting n-ary relations ($n > 2$). For this experiment, we manually tagged 222 sentences with n-ary relations from the New York Times. Every sentence is annotated with a single relation trigger and its arguments.

This experiment measures precision and recall over the extracted arguments. For each sentence, a system can extract a number of relations of the form $r(a_1, a_2, \ldots, a_n)$, where r is the relation name and a_i is an argument. We only use the extracted relation whose name contains the annotated trigger, if it exists. An argument of such relation is deemed a correct extraction if it is annotated in the sentence; otherwise, it is deemed incorrect.

Precision and recall are now defined as follows:

$$P = \frac{\text{\# correct}}{\text{\# extracted args}}, R = \frac{\text{\# correct}}{\text{\# annotated args}}.$$

where "# correct" is the number of arguments deemed as correct. There are 765 annotated arguments in total. Table 3 reports the results for our experiment with n-ary relations. EXEMPLAR[M] shows a 6% increase in f-measure over Lund, the second best system, while being almost two orders of magnitude faster.

3.5 Automatically Annotated Sentences

The creation of datasets for open RE is an extremely time-consuming task. In this section we investigate whether external data sources such as Freebase[1] and WordNet[2] can be used to automatically annotate a dataset, leading to a useful benchmark.

Our *automatic annotator* identifies pairs of entities and a trigger of the relation between them. It does so by first trying to link all entities to Wikipedia (and consequently to Freebase, since Freebase is linked to Wikipedia) by using the method proposed by (Cucerzan, 2007). Given two entities appearing within 10 tokens of each other in a sentence, our annotator checks whether there is a relation connecting them in Freebase. If such a relation exists, the annotator looks for a trigger in the sentence. A trigger must be a synonym for the Freebase relation (according to WordNet) and its distance to the nearest entity cannot be more than 5 tokens.

We applied this method for the New York Times and were able to annotate over 60,000 sentences with over 13,000 distinct entity pairs. For our experiments, we randomly selected one sentence for each entity pair and separated a thousand for development and over 12,000 for test.

[1] http://www.freebase.com
[2] http://wordnet.princeton.edu/

Comparing with human annotators. Although we expect our automatic annotator to be less accurate than a human annotator, we are interested to measure the difference in accuracy between them. To do so, two authors of this paper looked at our development set and marked each sentence as correct or incorrect. The agreement (that is, the percentage of matching answers) between the humans was 82%. On other hand, the agreement between our automatic annotator and each human was 71% and 72%. This shows that our annotator's accuracy is not too far below human's level of accuracy.

Table 4 shows the results for the test sentences. Both EXEMPLAR[S] and EXEMPLAR[M] outperformed all systems in recall, while keeping the same level of precision.

4 Conclusion

This work presents a fair and objective evaluation of several ORE methods, shedding some light on the trade-offs between f-measure and computational as well as precision and recall. Our evaluation is able to assess the effectiveness of different methods by specifying a trigger and a window of allowed tokens for each relation.

EXEMPLAR's promising results indicate that rule-based methods may still be very competitive, especially if rules are applied to each argument separately. Looking at the recall levels of different methods, we conjecture that EXEMPLAR outperforms machine learning methods like Ollie and TreeKernel, because its rules apply in cases not trained by these methods. From a pragmatic point of view, EXEMPLAR is also preferable because it doesn't require training data.

An interesting research question is whether machine learning can be used to learn more rules for EXEMPLAR in order to improve recall without loss in precision. Rules could be learned from both dependency parsing and shallow parsing, or just shallow parsing if computing time is extremely limited.

The next step for our experimental study is to evaluate corpus-level extractions, where an automatic annotator is essential due to the massive number of annotations required for even one relation, let alone thousands.

A EXEMPLAR

ORE methods must recognize relations from the text alone. To do this, each method tries to model how relations are expressed in English. Banko and Etzioni claim that more than 90% of binary relations are expressed through a few syntactic patterns, such as "verb" and "noun+preposition" (Banko and Etzioni, 2008). It is unclear, however, whether n-ary relations follow.

This section presents a study focusing on how n-ary relations ($n > 2$) are expressed in English, based on 100 distinct relations manually annotated from a random sample of 514 sentences in the New York Times Corpus (Sandhaus, 2008).

Table 5 shows six syntactic patterns that cover 86% of our n-ary relations. These patterns are slightly different from those used for binary relations. In binary relations, the pattern implicitly defines the roles of the two arguments. For instance, a relation "met with" indicates that the first argument is the subject and the second one is the object of "with". In order to represent n-ary relations, our patterns do not contain prepositions, possessives or any other word connecting the relation to the argument. For instance, the sentence "Obama met with Putin in Russia" contains the relation "meet" along three arguments: "Obama" (subject), "Putin" (object of preposition with) and "Russia" (object of preposition in).

Relation types. A single relation can be represented in different ways using the patterns shown in Table 5. For instance, the relation "donate" can be expressed as an active verb ("donates"), passive voice ("was donated by") and normalized verb ("donation"). In addition, an apposition+noun relation can be expressed as an copula+noun relation by replacing apposition for the copula verb "be". By merging these patterns, we have that most relations fall into one of the following types: *verb*, *verb+noun*

Pattern	Frequency	Example
Verb	30%	Hingis **beat** Steffi Graf in the Italian Open two weeks ago.
Apposition+noun	19%	Jaden and Willow, the **famous children** of Will Smith, ...
Passive verb	14%	Jumbo the Elephant **was exported** from Sudan to Paris.
Verb+noun	14%	D-League will **move its offices** from Greenville to New York.
Copula+noun	5%	Kimball **was a** Fulbright **scholar** at the University of Heidelberg.
Nominalized verb	4%	Thousands died in Saddam Hussein's **attack** on Halabja in 1988.

Table 5: Patterns representing 86% of the relations with three or more arguments. Frequencies collected from 100 relations from the New York Times Corpus. Relation triggers are highlighted in bold.

Relation Type	Freq.	Example	Variations
Verb	48%	beat	Pass. verb, nom. verb
Copula+noun	24%	is son	Apposition+noun
Verb+noun	14%	sign deal	–

Table 6: Relation types recognized by EXEMPLAR.

and *copula+noun*.

Table 6 present the relation types found through our analysis. We developed EXEMPLAR to specifically recognize these relation types, including their variations.

Argument roles. An *argument role* defines how an argument participates in a relation. In ORE, the roles for each relation are not provided and must also be recognized from the text.

We use the following roles: `subject`, `direct_object` and `prep_object`. An argument has a role `prep_object` when its connected to the relation by a preposition. The roles of prepositional objects consist of their preposition and the suffix "_object", indicating that each preposition corresponds to a different role. In the sentence "Obama is the president ***of*** the U.S.", "U.S." is an object of the preposition "of" and has the role `of_object`.

Multiple entities can play the same role in a relation instance. For instance, in the sentence "Obama and Putin discuss the Syria conflict", both "Obama" and "Putin" have the `subject` role. Furthermore, some relations accept less roles than others. Verb relations accept all three roles, while copula+noun and verb+noun relations accept `subject` and `prep_object` only.

Our roles are different from those used in SRL. SRL roles carry semantic information across different relations. This information is unavailable for ORE systems, and for this reason, we rely on syntactic roles. An open problem is to determine which syntactic roles correspond to the same semantic role across different relations (Chambers and Jurafsky, 2011). However, this problem is out of the scope of this work.

```
  subject: "NFL"
 relation: "approve new stadium"
of_object: "Falcons"
in_object: "Atlanta"
```

Figure 3: A relation instance extracted by EXEMPLAR for the sentence "NFL approves Falcons' new stadium in Atlanta".

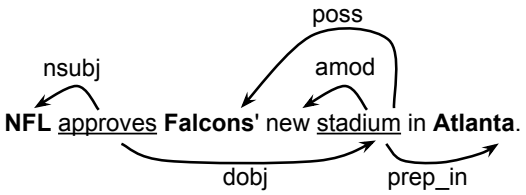

Figure 4: A input sentence after pre-processing. Entities are in bold, triggers are underline and arrows represent dependencies.

A.1 The method

EXEMPLAR takes a stream of textual documents and extracts instances of n-ary relations as illustrated in Figure 3.

A.2 Preprocessing

Given a document, EXEMPLAR extracts its syntactic structure by applying a pipeline of NLP tools provided by the Stanford Parser (Klein and Manning, 2003). Our method converts the original text into sentences, each containing a list of tokens. Each token is tagged with part of speech, lemma and dependencies. EXEMPLAR also works with other dependency parsers based on Stanford's dependencies,

such as the Malt parser (Nivre and Nilsson, 2004).

Figure 4 illustrates our running example where each word is a token and arrows represent dependencies among tokens. In this example, "stadium" depends on "approves" and the arrow connecting them can be read as "the direct object of *approves* is *stadium*".

Extracting Named Entities. EXEMPLAR employs the Stanford NER (Finkel et al., 2005) to recognize named entities. We consider these types of entities: people, organization, location, miscellaneous and date. Figure 4 shows entities highlighted in bold.

A.3 Detecting triggers

After recognizing entities, EXEMPLAR detects *relation triggers*. A trigger is a single token that indicates the presence of a relation. A relation may present one or two triggers. For instance, the relation in our running example has two triggers. EXEMPLAR also uses triggers to determine the relation name, as discussed later.

A trigger can be any noun or verb that was not tagged as being part of an entity mention. Other requirements are enforced for each canonical pattern.

Verb relations. A verb relation is triggered by a verb that does not include a noun as its direct object. The name of the relation is the trigger's lemma.

A noun must be a nominalized verb to be a trigger for verb relations. To identify nominalized verbs, EXEMPLAR checks if a noun is filed under the type "event" in Wordnet's Morphosemantic Database[3]. Doing so may generate false positives; however, EXEMPLAR has a filtering step to eliminate these false positives, as discussed later.

The name of a relation triggered by a nominalized verb is the trigger's original verb (before nominalization). For instance, "donation" triggers the relation "donate".

Copula+noun relations. Only noun triggers are accepted for copula+noun relations. The copula used in the relation name can be a verb with copula dependency to the trigger, or the verb "be" for appositions. The relation name is the concatenation of the copula's lemma and the trigger's lemma along its modifiers. For instance, the relation in the sentence "Jaden and Willow, the famous children of Will Smith" is "be famous child".

Verb+noun relations. EXEMPLAR recognizes two triggers for each verb+noun relation: a verb and a noun acting as its direct object. The relation name is defined by concatenating the verb's lemma with the the noun and its modifiers. In our running example, "approves" and "stadium" trigger the relation "approve new stadium".

A.4 Detecting candidate arguments

After relation triggers are identified, EXEMPLAR proceeds to detect their *candidate arguments*. For this, we look at the dependency between each entity and a trigger separately. EXEMPLAR relies on two observations: (1) an argument is often adjacent to a trigger in the dependency graph, and (2) the type of the dependency can accurately predict whether an entity is an argument for the relation or not.

Table 7 enumerates 12 types of dependencies (from a total of 53) that often connect arguments and triggers. EXEMPLAR identifies as a candidate argument every entity that is connected to trigger, as long as their dependency type is listed in Table 7.

Our observations can be seen in our running example. The entities "NFL" and "Atlanta" depends on the trigger "approves" and "Falcons" depend on the trigger "stadium". Since their dependency types are listed in Table 7, these entities are marked as candidate arguments.

A.5 Role Detection

EXEMPLAR determines the role of an argument based on the trigger type (noun or verb), the type of dependency between the trigger and argument and the direction of the dependency. To take into account the dependency direction, we prefix each dependency type with "$>$" when an entity depends on the trigger and "$<$" when the trigger depends on the entity.

Table 8 shows EXEMPLAR's rules that assign roles to arguments for each relation type. Rules are triples ($trigger$, $dependency$, $role$) whose meaning is as follows:

[3] http://wordnetcode.princeton.edu/standoff-files/morphosemantic-links.xls

Dependency	Example
nsubj (Subject)	**Romeo** loves Juliet
dobj (Direct Object)	The **Prince** exiles Romeo
nsubjpass (Pass. Subj.)	**Romeo** was seen in Verona
agent (Pass. Voice Obj.)	Juliet is loved by **Romeo**
iobj (Indirect Object)	Romeo gave **Juliet** a kiss
poss (Possessive)	**Romeo**'s father Montague
appos (Apposition)	**Capulet**, Juliet's father,
amod (Adj. Modifier)	The **Italian** city of Verona
nn (Noun Comp. Mod.)	Romeo's cousin **Benvolio**
prep_* (Prep. Modifier)	Romeo lived in **Verona**
partmod (Participal Mod.)	**Romeo**, born in Italy
rcmod (Rel. Clause Mod.)	**Juliet**, who loved Romeo

Table 7: Dependencies connecting arguments and triggers. Arguments are in bold and triggers are underlined.

> If trigger type = *trigger* and dependency type = *dependency* then assign *role*.

For example, the first rule in Table 8a specifies that an argument must be assigned the role of a *subject* if this argument depends on a *verb* trigger and the dependency type is *>nsubj*.

Rules are ordered by descending priority in Table 8. In case several rules can be applied for an argument, we apply only the rule with higher priority. If none of the rules applies to an argument, EXEMPLAR removes this argument from the relation.

Exceptions. There are three exceptions for the rules above. The first exception concerns arguments of verb relations whose dependency type is <partmod or <rcmod. EXEMPLAR chooses the role of direct_object (as oppose to subject) for these arguments *when the verb trigger is in passive form*. For instance, in the sentence "Barbie, (which was) invented by Handler", "Barbie" has the role direct_object because "invented" is in passive form.

The second exception is for nominalized verbs followed by the preposition "by", such as in "Georgian invasion by Russia". Arguments of this type of trigger with dependency types >nn, >amod or >poss are assigned the role direct_object.

Finallly, there is an exception for copula+noun relations expressed with close appositions of the form: "determiner entity noun". An example is "the Greenwood Heights section of Brooklyn". Here, EXEMPLAR assigns the subject role to the entity between the determiner and the noun.

Trigger Type	Dependency Type	Role
Verb	>nsubj	subject
Verb	>agent	subject
Verb	<partmod	subject
Verb	<rcmod	subject
Verb	>dobj	direct_object
Verb	>subjpass	direct_object
Verb	>iobj	to_object
Verb	>prep_*	prep_object
Noun	>prep_by	subject
Noun	>amod	subject
Noun	>nn	subject
Noun	>poss	subject
Noun	>prep_of	direct_object
Noun	>prep_*	prep_object

(a) Rules for verb relations.

Trigger Type	Dependency Type	Role
Noun	>nsubj	subject
Noun	>appos	subject
Noun	<appos	subject
Noun	<partmod	subject
Noun	<rcmod	subject
Noun	>prep_of	of_object
Noun	>amod	of_object
Noun	>nn	of_object
Noun	>poss	of_object
Noun	>prep_*	prep_object

(b) Rules for copula+noun relations.

Trigger Type	Dependency Type	Role
Verb	>nsubj	subject
Verb	>agent	subject
Verb	<partmod	subject
Verb	<rcmod	subject
Verb	>iobj	to_object
Verb	>prep_*	prep_object
Noun	>amod	of_object
Noun	>nn	of_object
Noun	>poss	of_object
Noun	>prep_*	prep_object

(c) Rules for verb+noun relations.

Table 8: Rules for assigning roles to arguments.

A.6 Filtering Relations

The final step in EXEMPLAR is to remove incomplete relations. EXEMPLAR removes relations with less than two arguments and relations that do not present subject and direct_object.

For EXEMPLAR, Lund and SwiRL, which extract n-ary relations, our evaluation needs to convert n-ary relations into binary ones. This is done by selecting all pairs of arguments from a n-ary relation and creating a new (binary) relation for each of them. Binary relations containing two prepositional objects (or equivalent for SRL systems) are removed.

Abstract

This paper proposes a framework for automatically engineering features for two important tasks of question answering: answer sentence selection and answer extraction. We represent question and answer sentence pairs with linguistic structures enriched by semantic information, where the latter is produced by automatic classifiers, e.g., question classifier and Named Entity Recognizer. Tree kernels applied to such structures enable a simple way to generate highly discriminative structural features that combine syntactic and semantic information encoded in the input trees. We conduct experiments on a public benchmark from TREC to compare with previous systems for answer sentence selection and answer extraction. The results show that our models greatly improve on the state of the art, e.g., up to 22% on F1 (relative improvement) for answer extraction, while using no additional resources and no manual feature engineering.

1 Introduction

Question Answering (QA) systems are typically built from three main macro-modules: (i) search and retrieval of candidate passages; (ii) reranking or selection of the most promising passages; and (iii) answer extraction. The last two steps are the most interesting from a Natural Language Processing viewpoint since deep linguistic analysis can be carried out as the input is just a limited set of candidates.

Answer sentence selection refers to the task of selecting the sentence containing the correct answer among the different sentence candidates retrieved by a search engine.

Answer extraction is a final step, required for factoid questions, consisting in extracting multiwords constituting the synthetic answer, e.g., *Barack Obama* for a question: *Who is the US president?* The definition of rules for both tasks is conceptually demanding and involves the use of syntactic and semantic properties of the questions and its related answer passages.

For example, given a question from TREC QA[1]:

> *Q: What was Johnny Appleseed's real name?*

and a relevant passage, e.g., retrieved by a search engine:

> *A: Appleseed, whose real name was John Chapman, planted many trees in the early 1800s.*

a rule detecting the semantic links between *Johnny Appleseed's real name* and the correct answer *John Chapman* in the answer sentence has to be engineered. This requires the definition of other rules that associate the question pattern `real_name_?(X)` with `real_name_is(X)` of the answer sentence. Although this can be done by an expert NLP engineer, the effort for achieving the necessary coverage and a reasonable accuracy is not negligible.

An alternative to manual rule definition is the use of machine learning, which often shifts the problem

[1] We use it as our running example in the rest of the paper.

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 458–467,
Seattle, Washington, USA, 18-21 October 2013.

to the easier task of feature engineering. Unfortunately, when the learning task is semantically difficult such as in QA, e.g., features have to encode combinations of syntactic and semantic properties. Thus their extraction modules basically assume the shape of high-level rules, which are, in any case, essential to achieve state-of-the-art accuracy. For example, the great IBM Watson system (Ferrucci et al., 2010) uses a learning to rank algorithm fed with hundreds of features. The extraction of some of the latter requires articulated rules/algorithms, which, in terms of complexity, are very similar to those constituting typical handcrafted QA systems. An immediate consequence is the reduced adaptability to new domains, which requires a substantial reengineering work.

In this paper, we show that tree kernels (Collins and Duffy, 2002; Moschitti, 2006) can be applied to automatically learn complex structural patterns for both answer sentence selection and answer extraction. Such patterns are syntactic/semantic structures occurring in question and answer passages. To make such information available to the tree kernel functions, we rely on the shallow syntactic trees enriched with semantic information (Severyn et al., 2013b; Severyn et al., 2013a), e.g., Named Entities (NEs) and question focus and category, automatically derived by machine learning modules, e.g., question classifier (QC) or focus classifier (FC).

More in detail, we (i) design a pair of shallow syntactic trees (one for the question and one for the answer sentence); (ii) connect them with relational nodes (i.e., those matching the same words in the question and in the answer passages); (iii) label the tree nodes with semantic information such as question category and focus and NEs; and (iv) use the NE type to establish additional semantic links between the candidate answer, i.e., an NE, and the focus word of the question. Finally, for the task of answer extraction we also connect such semantic information to the answer sentence trees such that we can learn factoid answer patterns.

We show that our models are very effective in producing features for both answer selection and extraction by experimenting with TREC QA corpora and directly comparing with the state of the art, e.g., (Wang et al., 2007; Yao et al., 2013). The results show that our methods greatly improve on both tasks yielding a large improvement in Mean Average Precision for answer selection and in F1 for answer extraction: up to 22% of relative improvement in F1, when small training data is used. Moreover, in contrast to the previous work, our model does not rely on external resources, e.g., WordNet, or complex features in addition to the structural kernel model.

The reminder of this paper is organized as follows, Sec. 2 describes our kernel-based classifiers, Sec. 3 illustrates our question/answer relational structures also enriched with semantic information, Sec. 4 describes our model for answer selection and extraction, Sec. 5 illustrates our comparative experiments on TREC data, Sec. 6 reports on our error analysis, Sec. 7 discusses the related work, and finally, Sec. 8 derives the conclusions.

2 Structural Kernels for classification

This section describes a kernel framework where the input question/answer pairs are handled directly in the form of syntactic/semantic structures.

2.1 Feature vector approach to object pair classification

A conventional approach to represent a question/answer pairs in linear models consists in defining a set of similarity features $\{x_i\}$ and computing the simple scalar product $h(\boldsymbol{x}) = \boldsymbol{w} \cdot \boldsymbol{x} = \sum_i w_i x_i$, where $\boldsymbol{w}$ is the model weight vector learned on the training data. Hence, the learning problem boils down to estimating individual weights of each of the similarity features x_i. Such features often encode various types of lexical, syntactic and semantic similarities shared between a question and its candidate. Previous work used a rich number of distributional semantic, knowledge-based, translation and paraphrase resources to build explicit feature vector representations. One evident potential downside of using feature vectors is that a great deal of structural information encoded in a given text pair is lost.

2.2 Pair Classification using Structural Kernels

A more versatile approach in terms of the input representation relies on kernels. A typical kernel machine, e.g., SVM, classifies a test input $\boldsymbol{x}$ using the following prediction function: $h(\boldsymbol{x}) = \sum_i \alpha_i y_i K(\boldsymbol{x}, \boldsymbol{x}_i)$, where α_i are the model parameters estimated from the training data, y_i are target

variables, $\boldsymbol{x}_i$ are support vectors, and $K(\cdot,\cdot)$ is a kernel function. The latter can measure the *similarity* between question and answer pairs.

We define each question/answer pair $\boldsymbol{x}$ as a triple composed of a question tree $\boldsymbol{T}_q$ and answer sentence tree $\boldsymbol{T}_s$ and a similarity feature vector $\boldsymbol{v}$, i.e., $\boldsymbol{x} = \langle \boldsymbol{T}_q, \boldsymbol{T}_s, \boldsymbol{v} \rangle$. Given two triples $\boldsymbol{x}^i$ and $\boldsymbol{x}^j$, we define the following kernel:

$$\begin{aligned} K(\boldsymbol{x}^i, \boldsymbol{x}^j) &= K_{\text{TK}}(\boldsymbol{T}_q^i, \boldsymbol{T}_q^j) \\ &+ K_{\text{TK}}(\boldsymbol{T}_s^i, \boldsymbol{T}_s^j) \\ &+ K_{\text{v}}(\boldsymbol{v}^i, \boldsymbol{v}^j), \end{aligned} \quad (1)$$

where K_{TK} computes a structural kernel, e.g., tree kernel, and K_{v} is a kernel over feature vectors, e.g., linear, polynomial, gaussian, etc. Structural kernels can capture the structural representation of a question/answer pair whereas traditional feature vectors can encode some sort of similarity, e.g., lexical, syntactic, semantic, between a question and its candidate answer.

We prefer to split the kernel computation over a question/answer pair into two terms since tree kernels are very efficient and there are no efficient graph kernels that can encode exhaustively all graph fragments. It should be noted that the tree kernel sum does not capture feature pairs. Theoretically, for such purpose, a kernel product should be used. However, our experiments revealed that using the product is actually worse in practice. In contrast, we solve the lack of feature pairing by annotating the trees with relational tags which are supposed to link the question tree fragments with the related fragments from the answer sentence.

Such relational information is very important to improve the quality of the pair representation as well as the implicitly generated features. In the next section, we show simple structural models that we used in our experiments for question and answer pair classification.

2.3 Partial Tree Kernels

The above framework can use any kernel for structural data. We use the Partial Tree Kernel (PTK) (Moschitti, 2006) to compute $K_{\text{TK}}(\cdot,\cdot)$ as it is the most general convolution tree kernel, which at the same time shows rather *good* efficiency. PTK can be effectively applied to both constituency and dependency parse trees. It generalizes the syntactic tree kernel (STK) (Collins and Duffy, 2002), which maps a tree into the space of all possible tree fragments constrained by the rule that sibling nodes cannot be separated. In contrast, the PTK fragments can contain any subset of siblings, i.e., PTK allows for breaking the production rules in syntactic trees. Consequently, PTK generates an extremely rich feature space, which results in higher generalization ability.

3 Relational Structures

This section introduces relational structures designed to encode syntactic and shallow semantic properties of question/answer pairs. We first define a simple to construct shallow syntactic tree representation derived from a shallow parser. Next, we introduce a relational linking scheme based on a plain syntactic matching and further augment it with additional semantic information.

3.1 Shallow syntactic tree

Our shallow tree structure is a two-level syntactic hierarchy built from word lemmas (leaves), part-of-speech tags that organized into chunks identified by a shallow syntactic parser (Fig. 1). We defined a similar structure in (Severyn and Moschitti, 2012) for answer passage reranking, which improved on feature vector baselines.

This simple linguistic representation is suitable for building a rather expressive *answer sentence selection* model. Moreover, the use of a shallow parser is motivated by the need to generate text spans to produce candidate answers required by an *answer extraction* system.

3.2 Tree pairs enriched with relational links

It is important to establish a correspondence between question and answer sentence aligning related concepts from both. We take on a two-level approach, where we first use plain lexical matching to connect common lemmas from the question and its candidate answer sentence. Secondly, we establish semantic links between NEs extracted from the answer sentence and the question focus word, which encodes the expected lexical answer type (LAT). We use the question categories to identify NEs that have

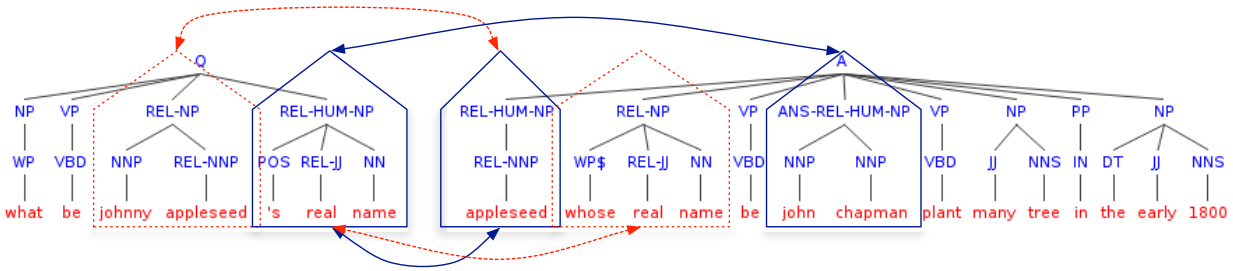

Figure 1: Shallow tree representation of the example q/a pair from Sec. 1. Dashed arrows (red) indicate the tree fragments (red dashed boxes) in the question and its answer sentence linked by the relational REL tag, which is established via syntactic match on the word lemmas. Solid arrows (blue) connect a question focus word *name* with the related named entities of type *Person* corresponding to the question category (HUM) via a relational tag REL-HUM. Additional ANS tag is used to mark chunks containing candidate answer (here the correct answer *John Chapman*).

higher probability to be correct answers following a mapping defined in Table 1.

Next, we briefly introduce our tree kernel-based models for building question focus and category classifiers.

Lexical Answer Type. Question Focus represents a central entity or a property asked by a question (Prager, 2006). It can be used to search for semantically compatible candidate answers, thus greatly reducing the search space (Pinchak, 2006). While several machine learning approaches based on manual features and syntactic structures have been recently explored, e.g. (Quarteroni et al., 2012; Damljanovic et al., 2010; Bunescu and Huang, 2010), we opt for the latter approach where tree kernels handle automatic feature engineering.

To build an automatic Question Focus detector we use a tree kernel approach as follows: we (i) parse each question; (ii) create a set of positive trees by labeling the node exactly covering the focus with FC tag; (iii) build a set of negative trees by labeling any other constituent node with FC; (iii) we train the FC node classifier with tree kernels. At the test time, we try to label each constituent node with FC generating a set of candidate trees. Finally, we select the tree and thus the constituent associated with the highest SVM score.

Question classification. Our question classification model is simpler than before: we use an SVM multi-classifier with tree kernels to automatically extract the question class. To build a multi-class classifier we train a binary SVM for each of the classes and apply a one-vs-all strategy to obtain the predicted class. We use constituency trees as our input representation.

Table 1: Expected Answer Type (EAT) → named entity types.

EAT	Named Entity types
HUM	Person
LOCATION	Location
ENTITY	Organization, Person, Misc
DATE	Date, Time, Number
QUANTITY	Number, Percentage
CURRENCY	Money, Number

Our question taxonomy is derived from the UIUIC dataset (Li and Roth, 2002) which defines 6 coarse and 50 fine grain classes. In particular, our set of question categories is formed by adopting 3 coarse classes: HUM (human), LOC (location), ENTY (entities) and replacing the NUM (numeric) coarse class with 3 fine-grain classes: CURRENCY, DATE, QUANTITY[2]. This set of question categories is sufficient to capture the coarse semantic answer type of the candidate answers found in TREC. Also using fewer question classes results in a more accurate multi-class classifier.

Semantic tagging. Question focus word specifies the lexical answer type capturing the target information need posed by a question, but to make this piece of information effective, the focus word needs to be linked to the target candidate answer. The focus word can be lexically matched with words present in

[2]This class is composed by including all the fine-grain classes from NUMERIC coarse class except for CURRENCY and DATE.

the answer sentence, or the match can be established using semantic information. Clearly, the latter approach is more appealing since it helps to alleviate the lexical gap problem, i.e., it improves the coverage of the näive string matching of words between a question and its answer.

Hence, we propose to exploit a question focus along with the related named entities (according to the mapping from Table 1) of the answer sentence to establish relational links between the tree fragments. In particular, once the question focus and question category are determined, we link the focus word w_{focus} in the question, with all the named entities whose type matches the question class (Table 1). We perform tagging at the chunk level and use a relational tag typed with a question class, e.g., `REL-HUM`. Fig. 1 shows an example q/a pair where the typed relational tag is used in the shallow syntactic tree representation to link the chunk containing the question focus *name* with the named entities of the corresponding type *Person*, i.e., *Appleseed* and *John Chapman*.

4 Answer Sentence Selection and Answer Keyword Extraction

This section describes our approach to (i) answer sentence selection used to select the most promising answer sentences; and (ii) answer extraction which returns the answer keyword (for factoid questions).

4.1 Answer Sentence Selection

We cast the task of answer sentence selection as a classification problem. Considering a supervised learning scenario, we are given a set of questions $\{q_i\}_{i=1}^{N}$ where each question q_i is associated with a list of candidate answer sentences $\{(r_i, s_i)\}_{i=1}^{N}$, with $r_i \in \{-1, +1\}$ indicating if a given candidate answer sentence s_i contains a correct answer $(+1)$ or not (-1). Using this labeled data, our goal is to learn a classifier model to predict if a given pair of a question and an answer sentence is correct or not. We train a binary SVM with tree kernels[3] to train an answer sentence classifier. The prediction scores obtained from a classifier are used to rerank the answer candidates (pointwise reranking), s.t. the sentences that are more likely to contain correct answers will be ranked higher than incorrect candidates. In addition to the structural representation, we augment our model with basic bag-of-word features (unigram and bigrams) computed over lemmas.

[3] disi.unitn.it/moschitti/Tree-Kernel.htm

4.2 Answer Sentence Extraction

The goal of answer extraction is to extract a text span from a given candidate answer sentence. Such span represents a correct answer phrase for a given question. Different from previous work that casts the answer extraction task as a tagging problem and apply a CRF to learn an answer phrase tagger (Yao et al., 2013), we take on a simpler approach using a kernel-based classifier.

In particular, we rely on the shallow tree representation, where text spans identified by a shallow syntactic parser serve as a source of candidate answers. Algorithm 1 specifies the steps to generate training data for our classifier. In particular, for each example representing a triple $\langle a, T_q, T_s \rangle$ composed of the answer a, the question and the answer sentence trees, we generate a set of training examples E with every candidate chunk marked with an `ANS` tag (one at a time). To reduce the number of generated examples for each answer sentence, we only consider `NP` chunks, since other types of chunks, e.g., `VP`, `ADJP`, typically do not contain factoid answers. Finally, an original untagged tree is used to generate a positive example (line 8), when the answer sentence contains a correct answer, and a negative example (line 10), when it does not contain a correct answer.

At the classification time, given a question and a candidate answer sentence, all NP nodes of the sentence are marked with `ANS` (one at a time) as the possible answer, generating a set of tree candidates. Then, such trees are classified (using the kernel from Eq. 1) and the one with the highest score is selected. If no tree is classified as positive example we do not extract any answer.

5 Experiments

We provide the results on two related yet different tasks: answer sentence selection and answer extraction. The goal of the former is to learn a model scoring correct question and answer sentence pairs to bring in the top positions sentences containing the correct answers. Answer extraction derives the cor-

Algorithm 1 Generate training data for answer extraction

return E

rect answer keywords, i.e., a text span such as multi-words or constituents, from a given sentence.

5.1 Semantic Annotation

We briefly describe the experiments of training automatic question category and focus classifiers, which are more extensively described in (Severyn et al., 2013b).

Question Focus detection. We used three datasets for training and evaluating the performance of our focus detector: SeCo-600 (Quarteroni et al., 2012), Mooney GeoQuery (Damljanovic et al., 2010) and the dataset from (Bunescu and Huang, 2010). The SeCo dataset contains 600 questions. The Mooney GeoQuery contains 250 question targeted at geographical information in the U.S. The first two datasets are very domain specific, while the dataset from (Bunescu and Huang, 2010) is more generic containing the first 2,000 questions from the answer type dataset from Li and Roth annotated with focus words. We removed questions with implicit and multiple focuses.

Question Classification. We used the UIUIC dataset (Li and Roth, 2002) which contains 5,952 factoid questions [4] to train a multi-class question classifier.

Table 2 summarizes the results of question focus and category classification.

[4]We excluded questions from TREC to ensure there is no overlap with the data used for testing models trained on TREC QA.

Table 2: Accuracy (%) of focus (FC) and question classifiers (QC) using PTK.

TASK	SET	PTK
FC	MOONEY	80.5
	SECO-600	90.0
	BUNESCU	96.9
QC	UIUIC	85.9
	TREC 11-12	78.1

5.2 Answer Sentence Selection

We used the train and test data from (Wang et al., 2007) to enable direct comparison with previous work on answer sentence selection. The training data is composed by questions drawn from TREC 8-12 while questions from TREC 13 are used for testing. The data provided for training comes as two sets: a small set of 94 questions (TRAIN) that were manually curated for errors[5] and 1,229 questions from the entire TREC 8-12 that contain at least one correct answer sentence (ALL). The latter set represents a more noisy setting, since many answer sentences are marked erroneously as correct as they simply match a regular expression. Table 3 summarizes the data used for training and testing.

Table 4 compares our kernel-based structural model with the previous state-of-the-art systems for answer sentence selection. In particular, we compare with four most recent state of the art answer sentence reranker models (Wang et al., 2007; Heilman and Smith, 2010; Wang and Manning, 2010; Yao et al., 2013), which report their performance on the same questions and candidate sets from TREC 13 as provided by (Wang et al., 2007).

Our simple shallow tree representation (Severyn and Moschitti, 2012) delivers state-of-the-art accuracy largely improving on previous work. Finally, augmenting the structure with semantic linking (Severyn et al., 2013b) yields additional improvement in MAP and MRR. This suggests the utility of using supervised components, e.g., question focus and question category classifiers coupled with NERs, to establish semantic mapping between words in a q/a pair.

[5]In TREC correct answers are identified by regex matching using the provided answer pattern files

Table 3: Summary of TREC data for answer extraction used in (Yao et al., 2013).

data	questions	candidates	correct
TRAIN	94	4718	348
ALL	1229	53417	6410
TEST	89	1517	284

Table 4: Answer sentence reranking on TREC 13.

System	MAP	MRR
Wang et al. (2007)	0.6029	0.6852
Heilman & Smith (2010)	0.6091	0.6917
Wang & Manning (2010)	0.5951	0.6951
Yao et al. (2013)	0.6319	0.7270
+ WN	0.6371	0.7301
shallow tree (S&M, 2012)	0.6485	0.7244
+ semantic tagging	**0.6781**	**0.7358**

It is worth noting that our kernel-based classifier is conceptually simpler than approaches in the previous work, as it relies on the structural kernels, e.g., PTK, to automatically extract salient syntactic patterns relating questions and answers. Our model only includes the most basic feature vector (uni- and bi-grams) and does not rely on external sources such as WordNet.

5.3 Answer Extraction

Our experiments on answer extraction replicate the setting of (Yao et al., 2013), which is the most recent work on answer extraction reporting state-of-the-art results.

Table 5 reports the accuracy of our model in recovering correct answers from a set of candidate answer sentences for a given question. Here the focus is on the ability of an answer extraction system to recuperate as many correct answers as possible from each answer sentence candidate. The set of extracted candidate answers can then be used to select a single best answer, which is the final output of the QA system for factoid questions. Recall (R) encodes the percentage of correct answer sentences for which the system correctly extracts an answer (for TREC 13 there are a total of 284 correct answer sentences), while Precision (P) reflects how many answers extracted by the system are actually correct. Clearly, having a high recall system, allows for correctly answering more questions. On the other hand, a high precision system would attempt to answer less questions (extracting no answers at all) but get them right.

We compare our results to a CRF model of (Yao et al., 2013) augmented with WordNet features (without forced voting) [6]. Unlike the CRF model which obtains higher values of precision, our system acts as a high recall system able to recover most of the answers from the correct answer sentences. Having higher recall is favorable to high precision in answer extraction since producing more correct answers can help in the final voting scheme to come up with a single best answer. To solve the low recall problem of their CRF model, Yao et al. (2013) apply fairly complex outlier resolution techniques to force answer predictions, thus aiming at increasing the number of extracted answers.

To further boost the number of answers produced by our system we exclude negative examples (answer sentences not containing the correct answer) from training, which slightly increases the number of pairs with correctly recovered answers. Nevertheless, it has a substantial effect on the number of questions that can be answered correctly (assuming perfect single best answer selection). Clearly, our system is able to recover a large number of answers from the correct answer sentences, while low precision, i.e., extracting answer candidates from sentences that do not contain a correct answer, can be overcome by further applying various best answer selection strategies, which we explore in the next section.

5.4 Best Answer Selection

Since the final step of the answer extraction module is to select for each question a single best answer from a set of extracted candidate answers, an answer selection scheme is required.

We adopt a simple majority voting strategy, where we aggregate the extracted answers produced by our answer extraction model. Answers sharing similar lemmas (excluding stop words) are grouped together. The prediction scores obtained by the an-

[6] We could not replicate the results obtained in (Yao et al., 2013) with the forced voting strategy. Thus such result is not included in Table 5.

Table 5: Results on answer extraction. P/R - precision and recall; pairs - number of QA pairs with a correctly extracted answer, q - number of questions with at least one correct answer extracted, F1 sets an upper bound on the performance assuming the selected best answer among extracted candidates is always correct. *-marks the setting where we exclude incorrect question answer pairs from training.

this work		**70.8**	**70.8**	**70.8**

swer extraction classifier are used as votes to decide on the final rank to select the best single answer.

Table 6 shows the results after the majority voting is applied to select a single best answer for each candidate. A rather naïve majority voting scheme already produces satisfactory outcome demonstrating better results than the previous work. Our voting scheme is similar to the one used by (Yao et al., 2013), yet it is much simpler since we do not perform any additional hand tuning to account for the weight of the "forced" votes or take any additional steps to catch additional answers using outlier detection techniques applied in the previous work.

6 Discussion and Error Analysis

There are several sources of errors affecting the final performance of our answer extraction system: (i) chunking, (ii) named entity recognition and semantic linking, (iii) answer extraction, (iv) single best answer selection.

Chunking. Our system uses text spans identified by a chunker to extract answer candidates, which makes it impossible to extract answers that lie outside the chunk boundaries. Nevertheless, we found this to be a minor concern since for 279 out of total 284 candidate sentences from TREC 13 the answers are recoverable within the chunk spans.

Semantic linking. Our structural model relies heavily on the ability of NER to identify the relevant entities in the candidate sentence that can be further linked to the focus word of the question. While our answer extraction model is working on all the NP chunks, the semantic tags from NER serve as a strong cue for the classifier that a given chunk has a high probability of containing an answer. Typical off-the-shelf NER taggers have good precision and low recall, s.t. many entities as potential answers are missed. In this respect, a high recall entity linking system, e.g., linking to wikipedia entities (Ratinov et al., 2011), is required to boost the quality of candidates considered for answer extraction. Finally, improving the accuracy of question and focus classifiers would allow for having more accurate input representations fed to the learning algorithm.

Answer Extraction. Our answer extraction model acts as a high recall system, while it suffers from low precision in extracting answers for many incorrect sentences. Improving the precision without sacrificing the recall would ease the successive task of best answer selection, since having less incorrect answer candidates would result in a better final performance. Introducing additional constraints in the form of semantic tags to allow for better selection of answer candidates could also improve our system.

Best Answer Selection. We apply a naïve majority voting scheme to select a single best answer from a set of extracted answer candidates. This step has a dramatic impact on the final performance of the answer extraction system resulting in a large drop of recall, i.e., from 82.0 to 70.8 before and after voting respectively. Hence, a more involved model, i.e.,

performing joint answer sentence re-ranking and answer extraction, is required to yield a better performance.

7 Related Work

Tree kernel methods have found many applications for the task of answer reranking which are reported in (Moschitti, 2008; Moschitti, 2009; Moschitti and Quarteroni, 2008; Severyn and Moschitti, 2012). However, their methods lack the use of important relational information between a question and a candidate answer, which is essential to learn accurate relational patterns. In this respect, a solution based on enumerating relational links was given in (Zanzotto and Moschitti, 2006; Zanzotto et al., 2009) for the textual entailment task but it is computationally too expensive for the large dataset of QA. A few solutions to overcome computational issues were suggested in (Zanzotto et al., 2010).

In contrast, this paper relies on structures directly encoding the output of question and focus classifiers to connect focus word and good candidate answer keywords (represented by NEs) of the answer passage. This provides more effective relational information, which allows our model to significantly improve on previous rerankers. Additionally, previous work on kernel-based approaches does not target answer extraction.

One of the best models for answer sentence selection has been proposed in (Wang et al., 2007). They use the paradigm of quasi-synchronous grammar to model relations between a question and a candidate answer with syntactic transformations. (Heilman and Smith, 2010) develop an improved Tree Edit Distance (TED) model for learning tree transformations in a q/a pair. They search for a good sequence of tree edit operations using complex and computationally expensive Tree Kernel-based heuristic. (Wang and Manning, 2010) develop a probabilistic model to learn tree-edit operations on dependency parse trees. They cast the problem into the framework of structured output learning with latent variables. The model of (Yao et al., 2013) has reported an improvement over the Wang's et al. (2007) system. It applies linear chain CRFs with features derived from TED and WordNet to automatically learn associations between questions and candidate answers.

Different from previous approaches that use tree-edit information derived from syntactic trees, our kernel-based learning approach also use tree structures but with rather different learning methods, i.e., SVMs and structural kernels, to automatically extract salient syntactic patterns relating questions and answers. In (Severyn et al., 2013c), we have shown that such relational structures encoding input text pairs can be directly used within the kernel learning framework to build state-of-the-art models for predicting semantic textual similarity. Furthermore, semantically enriched relational structures, where automatic have been previously explored for answer passage reranking in (Severyn et al., 2013b; Severyn et al., 2013a). This paper demonstrates that this model also works for building a reranker on the sentence level, and extends the previous work by applying the idea of automatic feature engineering with tree kernels to answer extraction.

8 Conclusions

Our paper demonstrates the effectiveness of handling the input structures representing QA pairs directly vs. using explicit feature vector representations, which typically require substantial feature engineering effort. Our approach relies on a kernel-based learning framework, where structural kernels, e.g., tree kernels, are used to handle automatic feature engineering. It is enough to specify the desired type of structures, e.g., shallow, constituency, dependency trees, representing question and its candidate answer sentences and let the kernel learning framework learn to use discriminative tree fragments for the target task.

An important feature of our approach is that it can effectively combine together different types of syntactic and semantic information, also generated by additional automatic classifiers, e.g., focus and question classifiers. We augment the basic structures with additional relational and semantic information by introducing special tag markers into the tree nodes. Using the structures directly in the kernel learning framework makes it easy to integrate additional relational constraints and semantic information directly in the structures.

The comparison with previous work on a public

benchmark from TREC suggests that our approach is very promising as we can improve the state of the art in both answer selection and extraction by a large margin (up to 22% of relative improvement in F1 for answer extraction). Our approach makes it relatively easy to integrate other sources of semantic information, among which the use of Linked Open Data can be the most promising to enrich the structural representation of q/a pairs.

To achieve state-of-the-art results in answer sentence selection and answer extraction, it is sufficient to provide our model with a suitable tree structure encoding relevant syntactic information, e.g., using shallow, constituency or dependency formalisms. Moreover, additional semantic and relational information can be easily plugged in by marking tree nodes with special tags. We believe this approach greatly eases the task of tedious feature engineering that will find its applications well beyond QA tasks.

Abstract

Web users are increasingly looking for structured data, such as lyrics, job, or recipes, using unstructured queries on the web. However, retrieving relevant results from such data is a challenging problem due to the unstructured language of the web queries. In this paper, we propose a method to improve web search ranking by detecting *Structured Annotation* of queries based on top search results. In a structured annotation, the original query is split into different units that are associated with semantic attributes in the corresponding domain. We evaluate our techniques using real world queries and achieve significant improvement.

1 Introduction

Search engines are getting more sophisticated by utilizing information from multiple diverse sources. One such valuable source of information is structured and semi-structured data, which is not very difficult to access, owing to information extraction (Wong et al., 2009; Etzioni et al., 2008; Zhai and Liu 2006) and semantic web efforts.

Driving the web search evolution are the user needs. Users usually have a template in mind when formulating queries to search for information. Agarwal et al., (2010) surveyed a search log of 15 million queries from a commercial search engine. They found that 90% of queries follow certain templates. For example, by issuing the query "taylor swift lyrics falling in love", the users are actually seeking for the lyrics of the song "Mary's Song (oh my my my)" by artist Taylor Swift. The words "falling in love" are actually part of the lyrics they are searching for. However, some top search results are irrelevant to the query, although they contain all the query terms. For example, the first top search result shown in Figure 1(a) does not contain the required lyrics. It just contains the lyrics of another song of Taylor Swift, rather than the song that users are seeking.

A possible way to solve the above ranking problem is to understand the underlying query structure. For example, after recognizing that "taylor swift" is an *artist name* and "falling in love" are part of the *lyrics*, we can improve the ranking by comparing the structured query with the corresponding structured data in documents (shown in Figure 1(b)). Some previous studies investigated how to extract structured information from user queries, such as query segmentation (Bergsma and Wang, 2007). The task of query segmentation is to separate the query words into

*Work was done when the first author was visiting Microsoft Research Asia

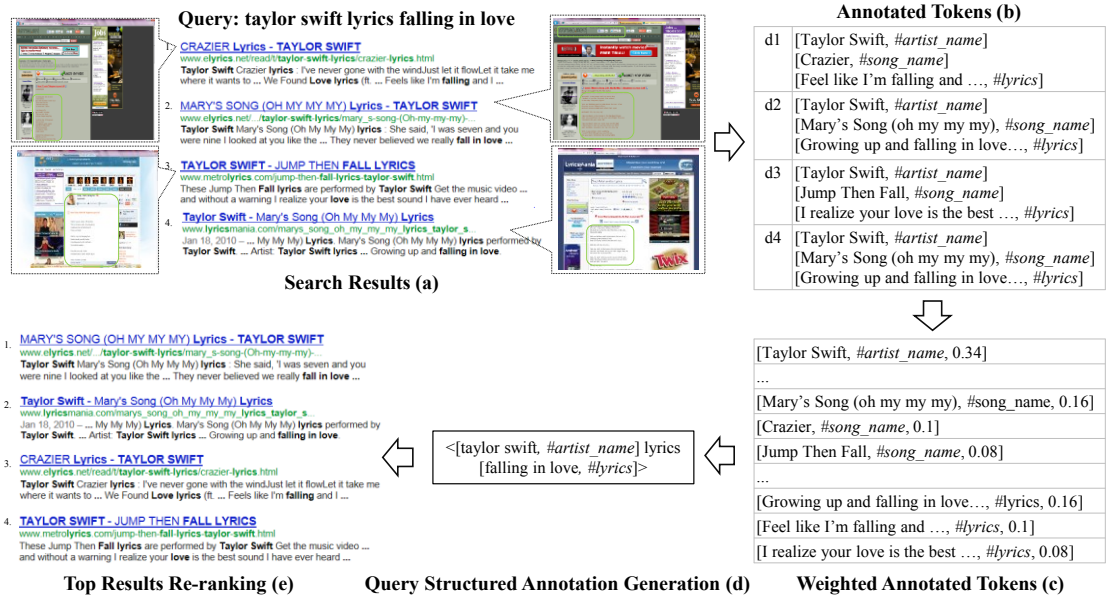

Figure 1. Search results of query "taylor swift lyrics falling in love" and processing pipeline

disjointed segments so that each segment maps to a semantic unit (Li et al., 2011). For example, the segmentation of the query "taylor swift lyrics falling in love" can be "taylor swift | lyrics | falling in love". Since query segmentation cannot tell "talylor swift" is an artist name and "falling in love" are part of lyrics, it is still difficult for us to judge whether each part of the query segmentations matches the right field of the documents or not (such as judge whether "talylor swift" matches the artist name in the document). Recently, a lot of work (Sarkas et al., 2010; Li et al., 2009) proposed the task of structured annotation of queries which aims to detect the structure of the query and assign a specific label to it. However, to our knowledge, the previous methods do not exploit an effective approach for improving web search ranking by incorporating structured annotation of queries.

In this paper, we investigate the possibility of using structured annotation of queries to improve web search ranking. Specifically, we propose a greedy algorithm which uses the structured data (named annotated tokens in Figure 1(b)) extracted from the top search results to annotate the latent structured semantics in web queries. We then compute matching scores between the annotated query and the corresponding structured information contained in documents. The top search results can be re-ranked according to the matching scores. However, it is very difficult to extract structured data from all of the search results. Hence, we propose a relevance feedback based re-ranking model. We use these structured documents whose matching scores are greater than a threshold as feedback documents, to effectively re-rank other search results to bring more relevant and novel information to the user.

Experiments on a large web search dataset from a major commercial search engine show that the F-Measure of structured annotation generated by our approach is as high as 91%. On this dataset, our re-ranking model using the structured annotations significantly outperforms two baselines.

The main contributions of our work include:

1. We propose a novel approach to generate structured annotation of queries based on top search results.
2. Although structured annotation of queries has been studied previously, to the best of our knowledge this is the first paper that attempts to improve web search ranking by incorporating structured annotation of queries.

The rest of this paper is organized as follows. We briefly introduce related work in Section 2. Section 3 presents our method for generating structured annotation of queries. We then propose two novel re-ranking models based on structured annotation in Section 4. Section 5 introduces the data used in this paper. We report experimental results in Section 6. Finally we conclude the work in Section 7.

2 Related Work

There is a great deal of prior research that identifies query structured information. We summarize this research according to their different approaches.

2.1 Structured Annotation of Queries

Recently, a lot of work has been done on understanding query structure (Sarkas et al., 2010; Li et al., 2009; Bendersky et al., 2010). One important method is structured annotation of queries which aims to detect the structure of the query and assign a specific label to it. Li et al., (2009) proposed web query tagging and its goal is to assign to each query term a specified category, roughly corresponding to a list of attributes. A semi-supervised Conditional Random Field (CRF) is used to capture dependencies between query words and to identify the most likely joint assignment of words to "categories." Comparing with previous work, the advantages of our approach are on the following aspects. **First**, we generate structured annotation of queries based on top search results, not some global knowledge base or query logs. **Second**, they mainly focus on the method of generating structured annotation of queries, rather than leverage the generated query structures to improve web search rankings. In this paper, we not only offer a novel solution for generating structured annotation of queries, but also propose a re-ranking approach to improve Web search based on structured annotation of queries. Bendersky et al., (2011) also used top search results to generate structured annotation of queries. However, the annotations in their definition are capitalization, POS tags, and segmentation indicators, which are different from ours.

2.2 Query Template Generation

The concept of query template has been discussed in a few recent papers (Agarwal et al., 2010; Pasca 2011; Liu et al., 2011; Szpektor et al., 2011). A query template is a sequence of terms, where each term could be a word or an attribute. For example, <#artist_name lyrics #lyrics> is a query template, "#artist_name" and "#lyrics" are attributes, and "lyrics" is a word. Structured annotation of queries is different from query template, as a query template can instantiate multiple queries while a structured annotation only serves for a specific query. Unlike query template, our work is ranking-oriented. We aim to automatically annotate query structure based on top search results, and further use these structured annotations to re-rank top search results for improving search performance.

Table 1. Example domain schemas

Domain	Schema	Example structured annotations
lyrics	*#artist_name #song_name #lyrics*	<lyrics of [hey jude, *#song_name*] [beatles, *#artist_name*]>
job	*#category #location*	<[teacher, *#category*] job in [America, *#location*]>
recipe	*#directions #ingredients*	<[baking, # *directions*] [bread, # *ingredients*] recipe>

2.3 Query Segmentation

The task of query segmentation is to separate the query words into disjointed segments so that each segment maps to a semantic unit (Li et al., 2011). Query segmentation techniques have been well studied in recent literature (Tan and Peng, 2008; Yu and Shi, 2009). However, structured annotation of queries cannot only separate the query words into disjoint segments but can also assign each segment a semantic label which can help the search engine to judge whether each part of query segmentation matches the right field of the documents or not.

2.4 Entity Search

The problem of entity search has received a great deal of attention in recent years (Guo et al., 2009; Bron et al., 2010; Cheng et al., 2007). Its goal is to answer information needs that focus on entities. The problem of structured annotation of queries is related to entity search because for some queries, structured annotation items are entities or attributes. Some existing entity search approaches also exploit knowledge from the structure of webpages (Zhao et al., 2005). Annotating query structured information differs from entity search in the following aspects. **First**, structured annotation based ranking is applicable for all queries, rather than just entity related queries. **Second**, the result of an entity search is usually a list of entities, their attributes, and associated homepages, whereas our work uses the structured information from webpages to annotate query structured information and further leverage structured annotation of queries to re-rank top search results.

3 Structured Annotation of Queries

3.1 Problem Definition

We start our discussion by defining some basic concepts. A *token* is defined as a sequence of words including space, i.e., one or more words. For example, the bigram "taylor swift" can be a single token. As our objective is to find structured annotation of queries in a specific domain, we begin with a definition of domain schema.

Definition 1 (Domain Schema): For a given domain of interest, the domain schema is the set of attributes. We denote the domain schema as $A = \{a_1, a_2, \cdots, a_n\}$, where each a_i is the name of an *attribute* of the domain. Sample domain schemas are shown in Table 1. In contrast to previous methods (Agarwal et al., 2010), our definition of domain schema does not need attribute values. For the sake of simplicity, this paper assumes that attributes in domain schema are available. However, it is not difficult to pre-specify attributes in a specific domain.

Definition 2 (Annotated Token): An *annotated token* in a specific domain is a pair $[v, a]$, where v is a token and a is a corresponding *attribute* for v in this domain. [hey jude, *#song_name*] is an example of an annotated token for the "lyrics" domain shown in Table 1. The words "hey jude" comprise a token, and its corresponding attribute name is *#song_name*. If a token does not have any corresponding attributes, we denote it as *free token*.

Definition 3 (Structured Annotation): A *structured annotation p* is a sequence of terms $< s_1, s_2, \cdots, s_k >$, where each s_i could be a free token or an annotated token, and at least one of the terms is an annotated token, i.e., $\exists i \in [1, k]$ for which s_i is an annotated token.

Given the schema for the domain "lyrics", <[taylor swift, *#artist_name*] lyrics [falling in love, *#lyrics*]> is a possible structured annotation for the query "taylor swift lyrics falling in love". In this annotation, [taylor swift, *#artist_name*] and [falling in love, *#lyrics*] are two annotated tokens. The word "lyrics" is a free token.

Intuitively, a structured annotation corresponds to an interpretation of the query as a request for some structured information from documents. The set of annotated tokens expresses the information need of the documents that have been requested. The free tokens may provide more diverse information. Annotated tokens and free tokens together cover all query terms, reflecting the complete user intent of the query.

Algorithm 1: Query Structured Annotation Generation

Input: a list of weighted annotated tokens $T = \{t_1, \ldots, t_m\}$;
a query $q =$ "$w_1, \ldots, w_n$" where $w_i \in$ W;
a pre-defined threshold score δ.
Output: a query structured annotation $p = <s_1, \ldots, s_k>$.

1: Set $p = q = \{s_1, \ldots, s_n\}$, where $s_i = w_i$
2: for u = 1 to *T.size* do
3: compute $Match(p, t_u)$
$= Match(p, t_u.v)$
$= t_u.w \times max_{0 \le i < j \le n} Sim(p_{ij}, t_u.v)$,
where $p_{ij} = s_i, \ldots, s_j$, s.t. $s_l \in$ W for $l \in [i, j]$. *//p_{ij} is just in the remaining query words*
4: end for
5: find the maximum matching t_u with
$t_{max} = argmax_{1 \le u \le m} Match(p, t_u)$
6: if $Match(p, t_{max}) > \delta$ then
7: replace $s_i, \ldots, s_j$ in p with $[s_i, \ldots, s_j, t_{max}.a]$
8: remove t_{max} from T
9: n ← n – (j - i)
10: go to step 2
11: else
12: return p
13: end if

3.2 Generating Structured Annotation

In this paper, given a domain schema A, we generate structured annotation for a query q based on the top search results of q. We propose using top search results, rather than some global knowledge base or query logs, because:

(1) Top search results have been proven to be a successful technique for query explanation (Bendersky et al., 2010).

(2) We have observed that in most cases, a reasonable percentage of the top search results are relevant to the query. By aggregating structured information from the top search results, we can get more query-dependent annotated tokens than using global data sources which may contain more noise and outdated.

(3) Our goal for generating structured annotation is to improve the ranking quality of queries. Using top search results enables simultaneous and consistent detection of structured information from documents and queries.

As mentioned in Section 3.1, we generate structured annotation of queries based on annotated tokens, which are actually structured data (shown in Figure 1(b)) embedded in web documents. In this paper, we assume that the annotated tokens are

available and we mainly focus on how to use these annotated tokens from top search results to generate structured annotation of queries. The approach is comprised of two parts, one for weighting annotated tokens and the other for generating structured annotation of queries based on the weighted annotated tokens.

Weighting: As shown in Figure 1, annotated tokens extracted from top results may be inconsistent, and hence some of the extracted annotated tokens are less useful or even useless for generating structured annotation.

We assume that a better annotated token should be supported by more top results; while a worse annotated token may appear in fewer results. Hence we aggregate all the annotated tokens extracted from top search results, and evaluate the importance of each unique one by a ranking-aware voting model as follows. For an annotated token [*v*, *a*], its weight *w* is defined as:

$$w = \frac{1}{N}\sum_{1\le j\le N} w_j \quad (1)$$

where w_j is a voting from document d_j, and

$$w_j = \begin{cases} \frac{N-j+1}{N}, & \text{if } [v,a] \in d_j \\ 0, & \text{else} \end{cases}$$

Here, *N* is the number of top search results and *j* is the ranking position of document d_j. We then generate a weighted annotated token [*v*, *a*, *w*] for each original unique token [*v*, *a*].

Generating: The process by which we map a query *q* to *Structured Annotation* is shown in Algorithm 1. The algorithm takes as input a list of weighted annotated tokens and the query *q*, and outputs the structured annotation of the query *q*. The algorithm first partitions the query *q* by comparing each sub-sequence of the query with all the weighted annotated tokens, and find the maximum matching annotated token (line 1 to line 5). Then, if the degree of match is greater than the threshold δ which is a pre-defined threshold score for fuzzy string matching, the query substring will be assigned the attribute label of the maximum matching annotated token (line 6 to line 8). The algorithm stops when all the weighted annotated tokens have been scanned, and outputs the structured annotation of the query.

Note that in some cases, the query may fail to exactly match with the annotated tokens, due to spelling errors, acronyms or abbreviations in users' queries. For example, in the query "broken and **beatuful** lyrics", "broken and **beatuful**" is a misspelling of "broken and **beautiful**." We adopt a fuzzy string matching function for comparing a sub-sequence string *s* with a token *v*:

$$Sim(s,v) = 1 - \frac{EditDistance(s,v)}{\max(|s|,|v|)} \quad (2)$$

where *EditDistance*(*s*, *v*) measures the edit distances of two strings, |*s*| is the length of string *s* and |*v*| is the length of string *v*.

4 Ranking with Structured Annotation

Given a domain schema $A = \{a_1, a_2, \cdots, a_n\}$, and a query *q*, suppose that $p = < s_1, s_2, \ldots, s_k >$ is the structured annotation for query *q* obtained using the method introduced in the above sections. *p* can better reflects the user's real search intent than the original *q*, as it presents the structured semantic information needed instead of a simple word string. Therefore, a document d_i can better satisfy a user's information need if it contains corresponding structured semantic information in *p*. Suppose that T_i is the set of annotated tokens extracted from document d_i, we compute a re-ranking score, denoted by *RScore*, for document d_i as follows:

$$\begin{aligned} RScore(q, d_i) &= Match(q, d_i) \\ &= Match(p, T_i) \\ &= \sum_{1\le j\le k}\sum_{t\in T_i} Match(s_j, t) \end{aligned}$$

where

$$Match(s_j, t) = \begin{cases} Sim(s_j.v_j, t.v), & \text{if } s_j.a_j = t.a \\ 0, & \text{else} \end{cases} \quad (3)$$

where s_j is an annotated token in *p* and *t* is an annotated token in d_i. We use Equation (2) to compute the similarity between values in query annotated tokens and values in document annotated tokens. We propose two re-ranking models, namely the conservative re-ranking model, to re-rank top results based on *RScore* and relevance feedback based re-ranking model.

4.1 Conservative Re-ranking Model

A nature way to re-rank top search results is according to their *RScore*. However, we fail to obtain annotated tokens from some retrieved documents, and hence the *RScore* of these documents are not available. In the conservative re-ranking model, we only re-rank search results that have an *RScore*. For example, suppose there are five retrieved documents {d_1, d_2, d_3, d_4, d_5} for query *q*, we can extract structured information from document d_3 and d_4 and $RScore(q, d_4) > RScore(q, d_3)$. Note that we cannot obtain

structured information from d_1, d_2, and d_5. In the conservative re-ranking method, d_1, d_2, and d_5 retain their original positions; while d_3 and d_4 will be re-ranked according to their *RScore*. Therefore, the final ranking generated by our conservative re-ranking model should be $\{d_1, d_2, d_4, d_3, d_5\}$, in which the documents are re-ranked among the affected positions.

There is also useful information in the documents without structured data, such as community question answering websites. However, in the conservative re-ranking model they will not be re-ranked. This may hurt the performance of our re-ranking model. One reasonable solution is relevance feedback model.

4.2 Relevance Feedback based Re-ranking Model

The disadvantage of the conservative re-ranking model is that it only can re-rank those top search results with structured data. To make up its limitation, we propose a relevance feedback based re-ranking model. The key idea of this model is based on the observation that the search results with the corrected annotated tokens could give implicit feedback information. Hence, we use these structured documents whose *RScore* are greater than a threshold γ (empirically set it as 0.6) as feedback documents, to effectively re-rank other search results to bring more relevant and novel information to the user.

Formally, given a query Q and a document collection C, a retrieval system returns a ranked list of documents D. Let d_i denote the i-th ranked document in the ranked list. Our goal is to study how to use these feedback documents, $J \subseteq \{d_1, \ldots, d_k\}$, to effectively re-rank the other r search results: $U \subseteq \{d_{k+1}, \ldots, d_{k+r}\}$. A general formula of relevance feedback model (Salton et al, 1990) R is as follows:

$$R(Q') = (1 - \alpha)L_q(\mathrm{Q}) + \alpha L_d(\mathrm{J}) \qquad (4)$$

where $\alpha \in [0, 1]$ is the feedback coefficient, and L_q and L_d are two models that map a query and a set of relevant documents, respectively, into some comparable representations. For example, they can be represented as vectors of weighted terms or language models.

In this paper, we explore the problem in the language model framework, particularly the KL-divergence retrieval model and mixture-model feedback method (Zhai and Lafferty, 2001), mainly because language models deliver state-of-the-art retrieval performance and the mixture-model based feedback is one of the most effective feedback techniques which outperforms Rocchio feedback.

4.2.1 The KL-Divergence Retrieval Model

The KL-divergence retrieval model was introduced in Lafferty and Zhai, (2001) as a special case of the risk minimization retrieval framework and can support feedback more naturally. In this model, queries and documents are represented by unigram language models. Assuming that these language models can be appropriately estimated, KL-divergence retrieval model measures the relevance value of a document D with respect to a query Q by computing the negative Kullback-Leibler divergence between the query language model θ_Q and the document language model θ_D as follows:

$$S(Q, D) = -D(\theta_Q || \theta_D) = -\sum_{w \in V} p(w|\theta_Q) log \frac{p(w|\theta_Q)}{p(w|\theta_D)} \qquad (5)$$

where V is the set of words in our vocabulary. Intuitively, the retrieval performance of the KL-divergence relies on the estimation of the document model θ_D and the query model θ_Q.

For the set of k relevant documents, the document model θ_D is estimated as $p(\mathrm{w}|\theta_D) = \frac{1}{k}\sum_{i=1}^{k} \frac{c(w,r_i)}{|r_i|}$, where $c(w, r_i)$ is the count of word w in the i-th relevant document, and $|r_i|$ is the total number of words in that document. The document model θ_D needs to be smoothed and an effective method is Dirichlet smoothing (Zhai et al., 2001).

The query model intuitively captures what the user is interested in, and thus would affect retrieval performance. With feedback documents, θ_Q is estimated by the mixture-model feedback method.

4.2.2 The Mixture Model Feedback Method

As the problem definition in Equation (4), the query model can be estimated by the original query model $p(w|\theta_Q) = \frac{c(w,Q)}{|Q|}$ (where $c(w,Q)$ is the count of word w in the query Q, and $|Q|$ is the total number of words in the query) and the feedback document model. Zhai and Lafferty, (2001) proposed a mixture model feedback method to estimate the feedback document model. More specifically, the model assumes that the feedback documents can be generated by a background language model $p(w|C)$ estimated using the whole collection and an unknown topic language model

Table 2. Domain queries used in our experiment

Domain	Containing Keyword	Queries	Structured Annotation%
lyrics	"lyrics"	196	95%
job	"job"	124	92%
recipe	"recipe"	76	93%

Table 3. Quality of Structured Annotation. All the improvements are significant ($p < 0.05$)

	Our	95.31%	84.93%	89.82%
recipe	Baseline	83.96%	84.23%	84.09%
	Our	89.68%	88.44%	89.06%
All	Baseline	87.88%	83.10%	85.42%
	Our	**93.61%**	**88.45%**	**90.96%**

θ_F to be estimated. Formally, let $F \subset C$ be a set of feedback documents. In this paper, F is comprised of documents that *RScore* are greater than γ. The log-likelihood function of the mixture model is:

$$log(F|\theta_F) = \sum_{D \in F} \sum_{w \in V} c(w, D) \log[(1-\lambda)p(w|\theta_F) + \lambda p(w|C)] \quad (6)$$

where $\lambda \in [0,1)$ is a mixture noise parameter which controls the weight of the background model. Given a fixed λ, a standard EM algorithm can then be used to estimate $p(w|\theta_F)$, which is then interpolated with the original query model $p(w|Q)$ to obtain an improved estimation of the query model:

$$p(w|\theta_Q) = (1-\alpha)p(w|Q) + \alpha p(w|\theta_F) \quad (7)$$

where α is the feedback coefficient.

5 Data

We used a dataset composed of 12,396 queries randomly sampled from query logs of a search engine. For each query, we retrieved its top 100 results from a commercial search engine. The documents were judged by human editors. A five-grade (from 0 to 4 meaning from bad to perfect) relevance rating was assigned for each document.

We used a proprietary query domain classifier to identify queries in three domains, namely "lyrics," "recipe," and "job," from the dataset. The statistics about these domains are shown in Table 2. To investigate how many queries may potentially have structured annotations, we manually created structured annotations for these queries. The last column of Table 2 shows the percentage of queries

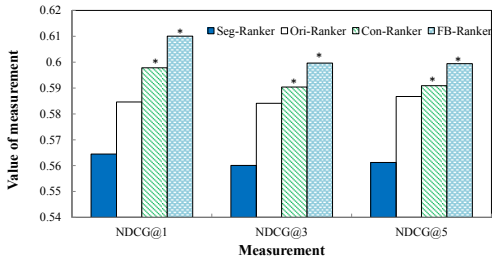

Figure 2. Ranking Quality (* indicates significant improvement)

that have structured annotations created by annotators. We found that for each domain, there was on average more than 90% of queries identified by us that had a certain structured annotation. This indicates that a large percentage of these queries contain structured information, as we expected.

6 Experimental Results

In this section, we present the structured annotation of queries and further re-rank the top search results for the three domains introduced in Section 5. We used the ranking returned by a commercial search engine as our one of the **Baselines**. Note that as the baseline already uses a large number of ranking signals, it is very difficult to improve it any further.

We evaluate the ranking quality using the widely used Normalized Discounted Cumulative Gain measure (NDCG) (Javelin and Kekalainen., 2000). We use the same configuration for NDCG as (Burges et al. 2005). More specifically, for a given query q, the NDCG@K is computed as:

$$N_q = \frac{1}{M_q} \frac{\sum_{j=1}^{K} (2^{r(j)} - 1)}{\log(1+j)} \quad (4)$$

M_q is a normalization constant (the ideal NDCG) so that a perfect ordering would obtain an NDCG of 1; and $r(j)$ is the rating score of the *j-th* document in the ranking list.

6.1 Overall Results

6.1.1 Quality of Structured Annotation of Queries

We generated the structured annotation of queries based on the top 10 search results and used $\delta = 0.04$ for Algorithm 1. We used several existing metrics, P (Precision), R (Recall), and F-Measure to evaluate the quality of the structured annotation. As a query structured annotation may contain more than one annotated token, we concluded that the

	Ori-Ranker	0.470	0.453	0.442
	FB-Ranker	**0.504**	**0.474**	**0.459**

annotation was correct only if the entire annotation was **completely the same** as the annotation labeled by annotators. Otherwise we treated the structured annotation as incorrect. Experimental results for the three domains are shown in Table 3. We compare our approach with Xiao Li, (2010) (denoted as baseline), on the dataset described in Section 5. They labeled the semantic structure of noun phrase queries based on semi-Markov CRFs. Our approach achieves better performance than the baseline (about 5.5% significant improvement on F-Measure). This indicates that the approach of generating structured annotation based on the top search results is more effective. With the high-quality structured annotation of queries in hand, it may be possible to obtain better ranking results using our proposed re-ranking models.

6.1.2 Re-ranking Result

We used the models introduced in Section 4 to re-rank the top 10 search results, based on structured annotation of queries and annotated tokens.

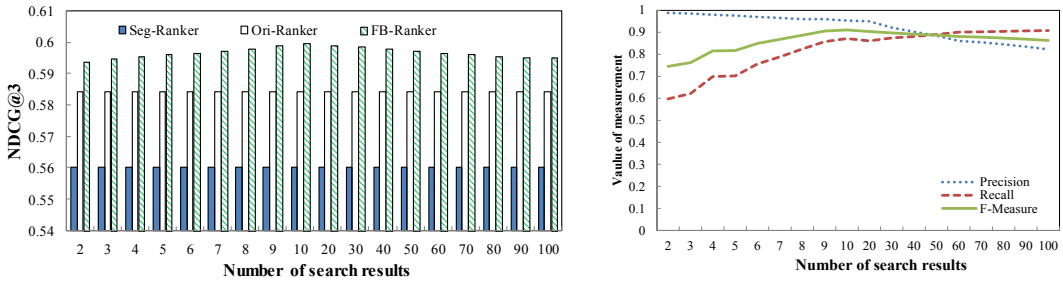
Recall that our goal is to quantify the effectiveness of structured annotation of queries for real web search. One dimension is to compare with the original search results of a commercial search engine (denoted as **Ori-Ranker**). The other is to compare with the query segmentation based re-ranking model (denoted as **Seg-Ranker**; Li et al., 2011) which tries to improve web search ranking by incorporating query segmentation. Li et al., (2011) incorporated query segmentation in the BM25, unigram language model and bigram language model retrieval framework, and bigram language model achieved the best performance. In this paper, Seg-Ranker integrates bigram language model with query segmentation.

The ranking results of these models are shown in Figure 2. This figure shows that all our two rankers significantly outperform the Ori-Ranker– the original search results of a commercial search engine. This means that using high-quality structured annotation does help better understanding of user intent. By comparing these structured annotations and the annotated tokens in documents, we can re-rank the more relevant results higher and yield better ranking quality.

Figure 2 also suggests that structured annotation based re-ranking models outperform query segmentation based re-ranking model. This is mainly because structured annotation can not only separate the query words into disjoint segments but can also assign each segment a semantic label. Taking full advantage of the semantic label can lead to better ranking performance.

Furthermore, Figure 2 shows that FB-Ranker outperforms Con-Ranker. The main reason is that in Con-Ranker, we can only reasonably re-rank the search results with structured data. However, in FB-Ranker we can not only re-rank the structured search results but also can re-rank other documents by incorporating implicit information from those structured documents.

On average, FB-Ranker achieves the best ranking performance. Table 4 shows more detailed



(a) Quality of re-ranking (b) Quality of query structured annotation

Figure 4. Quality of re-ranking and quality of query structured annotation with different number of search results

results for the three selected domains. This table shows that FB-Ranker consistently outperforms the two baseline rankers on these domains. In the remaining part of this paper, we will only report the results for this ranker, due to space limitations. Table 4 also indicates that we can get robust ranking improvement in different domains, and we will consider applying it to more domains.

6.2 Experiment with Different Thresholds of Query Structured Annotation Algorithm

As introduced in Algorithm 1, we pre-defined a threshold δ for fuzzy string matching. We evaluated the quality of re-ranking and query structured annotation with different settings for δ. The results are shown in Figure 3. We found that:

(1) When we use $\delta = 0$, which means that the structured annotations can be generated no matter how small the similarity between the query string and a weighted annotated token is, we can get a significant NDCG@3 gain of 2.15%. Figure 3(b) shows that the precision of the structured annotation is lowest when $\delta = 0$. However, the precision is still as high as 0.7375, and the highest recall is obtained in this case. This means that the quality of the generated structured annotations is still reasonable, and hence we can get a ranking improvement when $\delta = 0$, as shown in Figure 3(a).

(2) Figure 3(a) suggests that the quality of re-ranking increases when the threshold δ increases from 0 to 0.05. It then decreases when δ increases from 0.06 to 0.5. Comparing these two figures shows that the trend of re-ranking performance adheres to the quality of the structured annotation. The settings for δ dramatically affect the recall and precision of the structured annotation; and hence the ranking quality is impacted. The larger δ is, the lower the recall of the structured annotation is.

(3) Since the re-ranking performance dramatically changes along with the quality of the structured annotation, we conducted a re-ranking experiment with perfect structured annotations (F-Measure equal to 1.0). Perfect structured annotations mean the annotations created by annotators as introduced in Section 5. The results are shown in the last bar of Figure 3(a). We did not find a large space for ranking improvement. The NDCG@3 when using perfect structured annotations was 0.606, which is just slightly better than our best result (yield when δ=0.05). It indicates that our structured annotation generation algorithm is already quite effective.

(4) Figure 3(a) shows that our approach outperforms the two baseline approaches with most settings for δ. This indicates that our approach is relatively stable with different settings for δ.

6.3 Experiment with Number of Top Search Results

The above experiments are conducted based on the top 10 search results. In this section, by adjusting the number of top search results, ranging from 2 to 100, we investigate whether the quality of structured annotation of queries and the performance of re-ranking are affected by the quantity of search results. The results shown in Figure 4 indicate that the number of search results does affect the quality of structured annotation of queries and the performance of re-ranking. Structured annotations of queries become better when more search results are used from 2 to 20. This is because more search results cover more websites in our domain list, and hence can generate more annotated tokens. More results also provide more evidence for voting the importance of

annotated tokens, and hence can improve the quality of structured annotation of queries.

In addition, we also found that structured annotation of queries become worse when too many lower ranked results are used (e.g, using results ranked lower than 20). This is because the lower ranked results are less relevant than the higher ranked results. They may contain more irrelevant or noisy annotated tokens than higher ranked documents; and hence using them may harm the precision of the structured annotations. Figure 4 also indicates that the quality of ranking and the accuracy of structured annotations are correlated.

7 Conclusions

In this paper, we studied the problem of improving web search ranking by incorporating structured annotation of queries. We proposed a systematic solution, first to generate structured annotation of queries based on top search results, and then launching two structured annotation based re-ranking models. We performed a large-scale evaluation over 12,396 queries from a major search engine. The experiment results show that the F-Measure of query structured annotation generated by our approach is as high as 91%. In the same dataset, our structured annotation based re-ranking model significantly outperforms the original ranker – the ranking of a major search engine, with improvements 5.2%.

Abstract

Bilingual lexicons are central components of machine translation and cross-lingual information retrieval systems. Their manual construction requires strong expertise in both languages involved and is a costly process. Several automatic methods were proposed as an alternative but they often rely on resources available in a limited number of languages and their performances are still far behind the quality of manual translations. We introduce a novel approach to the creation of specific domain bilingual lexicon that relies on Wikipedia. This massively multilingual encyclopedia makes it possible to create lexicons for a large number of language pairs. Wikipedia is used to extract domains in each language, to link domains between languages and to create generic translation dictionaries. The approach is tested on four specialized domains and is compared to three state of the art approaches using two language pairs: French-English and Romanian-English. The newly introduced method compares favorably to existing methods in all configurations tested.

1 Introduction

The plethora of textual information shared on the Web is strongly multilingual and users' information needs often go well beyond their knowledge of foreign languages. In such cases, efficient machine translation and cross-lingual information retrieval systems are needed. Machine translation already has a decades long history and an array of commercial systems were already deployed, including Google Translate [1] and Systran [2]. However, due to the intrinsic difficulty of the task, a number of related problems remain open, including: the gap between text semantics and statistically derived translations, the scarcity of resources in a large majority of languages and the quality of automatically obtained resources and translations. While the first challenge is general and inherent to any automatic approach, the second and the third can be at least partially addressed by an appropriate exploitation of multilingual resources that are increasingly available on the Web.

In this paper we focus on the automatic creation of domain-specific bilingual lexicons. Such resources play a vital role in Natural Language Processing (NLP) applications that involve different languages. At first, research on lexical extraction has relied on the use of parallel corpora (Och and Ney, 2003). The scarcity of such corpora, in particular for specialized domains and for language pairs not involving English, pushed researchers to investigate the use of comparable corpora (Fung, 1998; Chiao and Zweigenbaum, 2003). These corpora include texts which are not exact translation of each other but share common features such as domain, genre, sampling period, etc.

The basic intuition that underlies bilingual lexicon creation is the *distributional hypothesis* (Harris, 1954) which puts that words with similar meanings occur in similar contexts. In a multilingual formulation, this hypothesis states that the translations of a word are likely to appear in similar lexical environments across languages (Rapp, 1995). The *standard approach* to bilingual lexicon extraction builds

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 479–489,
Seattle, Washington, USA, 18-21 October 2013.

on the distributional hypothesis and compares context vectors for each word of the source and target languages. In this approach, the comparison of context vectors is conditioned by the existence of a seed bilingual dictionary. A weakness of the method is that poor results are obtained for language pairs that are not closely related (Ismail and Manandhar, 2010). Another important problem occurs whenever the size of the seed dictionary is small due to ignoring many context words. Conversely, when dictionaries are detailed, ambiguity becomes an important drawback.

We introduce a bilingual lexicon extraction approach that exploits Wikipedia in an innovative manner in order to tackle some of the problems mentioned above. Important advantages of using Wikipedia are:

- The resource is available in hundreds of languages and it is structured as unambiguous concepts (i.e. articles).
- The languages are explicitly linked through concept translations proposed by Wikipedia contributors.
- It covers a large number of domains and is thus potentially useful in order to mine a wide array of specialized lexicons.

Mirroring the advantages, there are a number of challenges associated with the use of Wikipedia:

- The comparability of concept descriptions in different languages is highly variable.
- The translation graph is partial since, when considering any language pair, only a part of the concepts are available in both languages and explicitly connected.
- Domains are unequally covered in Wikipedia (Halavais and Lackaff, 2008) and efficient domain targeting is needed.

The approach introduced in this paper aims to draw on Wikipedia's advantages while appropriately addressing associated challenges. Among the techniques devised to mine Wikipedia content, we hypothesize that an adequate adaptation of Explicit Semantic Analysis (ESA) (Gabrilovich and Markovitch, 2007) is fitted to our application context. ESA was already successfully tested in different NLP tasks, such as word relatedness estimation or text classification, and we modify it to mine specialized domains, to characterize these domains and to link them across languages.

The evaluation of the newly introduced approach is realized on four diversified specialized domains (*Breast Cancer*, *Corporate Finance*, *Wind Energy* and *Mobile Technology*) and for two pairs of languages: French-English and Romanian-English. This choice allows us to study the behavior of different approaches for a pair of languages that are richly represented and for a pair that includes Romanian, a language that has fewer associated resources than French and English. Experimental results show that the newly introduced approach outperforms the three state of the art methods that were implemented for comparison.

2 Related Work

In this section, we first give a review of the standard approach and then introduce methods that build upon it. Finally, we discuss works that rely on Explicit Semantic Analysis to solve other NLP tasks.

2.1 Standard Approach (SA)

Most previous approaches that address bilingual lexicon extraction from comparable corpora are based on the standard approach (Fung, 1998; Chiao and Zweigenbaum, 2002; Laroche and Langlais, 2010). This approach is composed of three main steps:

1. **Building context vectors**: Vectors are first extracted by identifying the words that appear around the term to be translated W_{cand} in a window of n words. Generally, association measures such as the mutual information (Morin and Daille, 2006), the log-likelihood (Morin and Prochasson, 2011) or the Discounted Odds-Ratio (Laroche and Langlais, 2010) are employed to shape the context vectors.
2. **Translation of context vectors**: To enable the comparison of source and target vectors, source vectors are translated intoto the target language by using a seed bilingual dictionary. Whenever several translations of a context word exist,

all translation variants are taken into account. Words not included in the seed dictionary are simply ignored.

3. **Comparison of source and target vectors**: Given W_{cand}, its automatically translated context vector is compared to the context vectors of all possible translations from the target language. Most often, the cosine similarity is used to rank translation candidates but alternative metrics, including the weighted Jaccard index (Prochasson et al., 2009) and the city-block distance (Rapp, 1999), were studied.

2.2 Improvements of the Standard Approach

Most of the improvements of the standard approach are based on the observation that the more representative the context vectors of a candidate word are, the better the bilingual lexicon extraction is. At first, additional linguistic resources, such as specialized dictionaries (Chiao and Zweigenbaum, 2002) or transliterated words (Prochasson et al., 2009), were combined with the seed dictionary to translate context vectors.

The ambiguities that appear in the seed bilingual dictionary were taken into account more recently. (Morin and Prochasson, 2011) modify the standard approach by weighting the different translations according to their frequency in the target corpus. In (Bouamor et al., 2013), we proposed a method that adds a word sense disambiguation process relying on semantic similarity measurement from WordNet to the standard approach. Given a context vector in the source language, the most probable translation of polysemous words is identified and used for building the corresponding vector in the target language. The most probable translation is identified using the monosemic words that appear in the same lexical environment.

On specialized French-English comparable corpora, this approach outperforms the one proposed in (Morin and Prochasson, 2011), which is itself better than the standard approach. The main weakness of (Bouamor et al., 2013) is that the approach relies on WordNet and its application depends on the existence of this resource in the target language. Also, the method is highly dependent on the coverage of the seed bilingual dictionary.

2.3 Explicit Semantic Analysis

Explicit Semantic Analysis (ESA) (Gabrilovich and Markovitch, 2007) is a method that maps textual documents onto a structured semantic space using classical text indexing schemes such as TF-IDF. Examples of semantic spaces used include Wikipedia or the Open Directory Project but, due to superior performances, Wikipedia is most frequently used. In the original evaluation, ESA outperformed state of the art methods in a word relatedness estimation task.

Subsequently, ESA was successfully exploited in other NLP tasks and in information retrieval. Radinsky and al. (2011) added a temporal dimension to word vectors and showed that this addition improves the results of word relatedness estimation. (Hassan and Mihalcea, 2011) introduced Salient Semantic Analysis (SSA), a development of ESA that relies on the detection of salient concepts prior to mapping words to concepts. SSA and the original ESA implementation were tested on several word relatedness datasets and results were mixed. Improvements were obtained for text classification when comparing SSA with the authors' in-house representation of the method. ESA has weak language dependence and was already deployed in multilingual contexts. (Sorg and Cimiano, 2012) extended ESA to other languages and showed that it is useful in cross-lingual and multilingual retrieval task. Their focus was on creating a language independent conceptual space in which documents would be mapped and then retrieved.

Some open ESA topics related to bilingual lexicon creation include: (1) the document representation which is simply done by summing individual contributions of words, (2) the adaptation of the method to specific domains and (3) the coverage of the underlying resource in different language.

3 ESA for Bilingual Lexicon Extraction

The main objective of our approach is to devise lexicon translation methods that are easily applicable to a large number of language pairs, while preserving the overall quality of results. A subordinated objective is to exploit large scale background multilingual knowledge, such as the encyclopedic content available in Wikipedia. As we mentioned, ESA

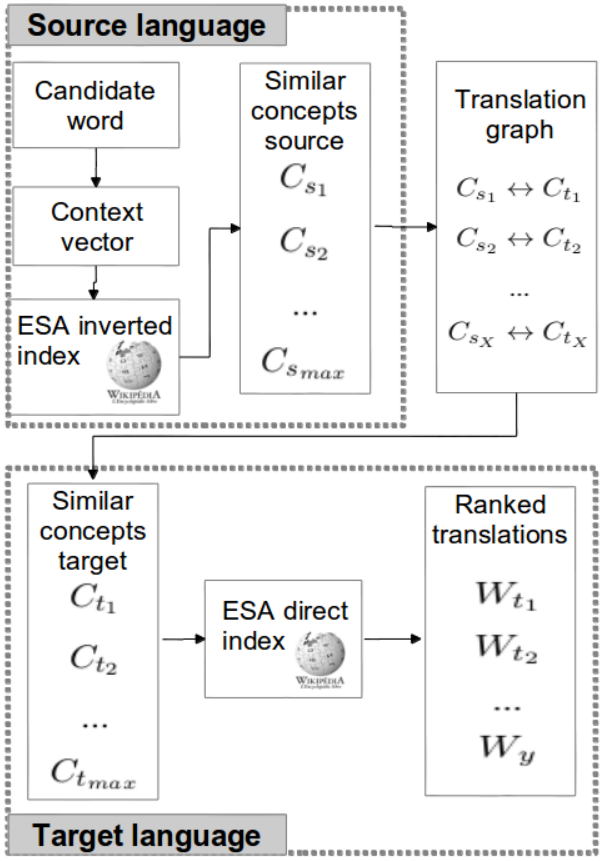

Figure 1: Overview of the Explicit Semantic Analysis enabled bilingual lexicon extraction.

(Gabrilovich and Markovitch, 2007) was exploited in a number of NLP tasks but not in bilingual lexicon extraction.

Figure 1 shows the overall architecture of the lexical extraction process we propose. The process is completed in the following three steps:

1. Given a word to be translated and its context vector in the source language, we derive a ranked list of similar Wikipedia concepts (i.e. articles) using the ESA inverted index.

2. Then, a translation graph is used to retrieve the corresponding concepts in the target language.

3. Candidate translations are found through a statistical processing of concept descriptions from the ESA direct index in the target language.

In this section, we first introduce the elements of the original formulation of ESA necessary in our approach. Then, we detail the three steps that compose the main bilingual lexicon extraction method illustrated in Figure 1. Finally, as a complement to the main method we introduce a measure for domain word specificity and present a method for extracting generic translation lexicons.

3.1 ESA Word and Concept Representation

Given a semantic space structured using a set of M concepts and including a dictionary of N words, a mapping between words and concepts can be expressed as the following matrix:

$$\begin{matrix} w(W_1,C_1) & w(W_2,C_1) & ... & w(W_N,C_1) \\ w(W_1,C_2) & w(W_2,C_2) & ... & w(W_N,C_2) \\ ... & ... & ... & \\ w(W_1,C_M) & w(W_2,C_M) & ... & w(W_N,C_M) \end{matrix}$$

When Wikipedia is exploited concepts are equated to Wikipedia articles and the texts of the articles are processed in order to obtain the weights that link words and concepts. In (Gabrilovich and Markovitch, 2007), the weights w that link words and concepts were obtained through a classical TF-IDF weighting of Wikipedia articles. A series of tweaks destined to improve the method's performance were used and disclosed later[3]. For instance, administration articles, lists, articles that are too short or have too few links are discarded. Higher weight is given to words in the article title and more longer articles are favored over shorter ones. We implemented a part of these tweaks and tested our own version of ESA with the Wikipedia version used in the original implementation. The correlation with human judgments of word relatedness was 0.72 against 0.75 reported by (Gabrilovich and Markovitch, 2007). The ESA matrix is sparse since the N size of the dictionary, is usually in the range of hundreds of thousands and each concept is usually described by hundreds of distinct words. The direct ESA index from Figure 1 is obtained by reading the matrix horizontally while the inverted ESA index is obtained by reading the matrix vertically.

Table 1: The five most similar Wikipedia concepts to the French terms *action[share], déficit[deficit], cisaillement[shear], turbine[turbine], cryptage[encryption], biopsie[biopsie]* and *palpation[palpation]* and their context vectors.

3.2 Source Language Processing

The objective of the source language processing is to obtain a ranked list of similar Wikipedia concepts for each candidate word (W_{cand}) in a specialized domain. To do this, a context vector is first built for each W_{cand} from a specialized monolingual corpus. The association measure between W_{cand} and context words is obtained using the Odds-Ratio (defined in equation 5). Wikipedia concepts in the source language C_s that are similar to W_{cand} and to a part of its context words are extracted and ranked using equation 1.

$$Rank(C_s) = (10 * \max(Odds_{W_{s_i}}^{W_{cand}}) * w(W_{cand}, C_s)) + \sum_{i=1}^{n} Odds_{W_{s_i}}^{W_{cand}} * w(W_{s_i}, C_s) \quad (1)$$

where $\max(Odds_{W_{s_i}}^{W_{cand}})$ is the highest Odds-Ratio association between W_{cand} and any of its context words W_{s_i}; the factor 10 was empirically set to give more importance to W_{cand} over context words; $w(W_{cand}, C_s)$ is the weight of the association between W_{cand} and C_s from the ESA matrix; n is the total number of words W_{s_i} in the context vector of W_{cand}; $Odds_{W_{s_i}}^{W_{cand}}$ is the association value between W_{cand} and W_{s_i} and $w(W_{s_i}, C_s)$ are the weights of the associations between each context word W_{s_i} and C_s from the ESA matrix. The use of contextual information in equation 1 serves to characterize the candidate word in the target domain.

In table 1, we present the five most similar Wikipedia concepts to the French terms *action, déficit, cisaillement, turbine, cryptage, biopsie* and *palpation* and their context vectors. These terms are part of the four specialized domains we are studying here. From observing these examples, we note that despite the difference between the specialized domains and word ambiguity (words *action* and *protocole*), our method has the advantage of successfully representing each word to be translated by relevant conceptual spaces.

3.3 Translation Graph Construction

To bridge the gap between the source and target languages, a concept translation graph that enables the multilingual extension of ESA is used. This concept translation graph is extracted from the explicit translation links available in Wikipedia articles and is exploited in order to connect a word's conceptual space in the source language with the corresponding conceptual space in the target language. Only a part of the articles have translations and the size of

the conceptual space in the target language is usually smaller than the space in the source language. For instance, the French-English translation graph contains 940,215 pairs of concepts while the French and English Wikipedias contain approximately 1.4 million articles, respectively 4.25 million articles.

3.4 Target Language Processing

The third step of the approach takes place in the target language. Using the translation graph, we select the 100 most similar concept translations (threshold determined empirically after preliminary experiments) from the target language and use their direct ESA representations in order to retrieve potential translations for the candidate word W_{cand} from source language. These candidate translations W_t are ranked using equation 2.

$$Rank(W_t) = (\sum_{i=1}^{n} \frac{w(W_t, C_{t_i})}{avg(C_{t_i})}) * log(count(W_t, \mathbf{S})) \quad (2)$$

with $w(W_t, C_{t_i})$ is the weight of the translation candidate W_T for concept C_{t_i} from the ESA matrix in the target language; $avg(C_{t_i})$ is the average TF-IDF score of words that appear in C_{t_i}; $\mathbf{S}$ is the set of similar concepts C_{t_i} in the target language and $count(W_t, \mathbf{S})$ accounts for the number of different concepts from $\mathbf{S}$ in which the candidate translation W_T appears.

The accumulation of weights $w(W_t, C_{t_i})$ follows the way original ESA text representations are calculated (Gabrilovich and Markovitch, 2007) and $avg(C_{t_i})$ is used in order to correct the bias of the TF-IDF scheme towards short articles. $log(count(W_t, \mathbf{S}))$ is used to favor words that are associated with a larger number of concepts. log weighting was chosen after preliminary experiments with a wide range of functions.

3.5 Domain Specificity

In previous works, ESA was usually exploited in generic tasks that did not require any domain adaptation. Here we process information from specific domains and we need to measure the specificity of words in those domains. The domain extraction is seeded by using Wikipedia concepts (noted C_{seed}) that best describes the domain in the target language. For instance, in English, the *Corporate Finance* domain is seeded with *https://en.wikipedia.org/wiki/Corporate_finance*. We extract a set of 10 words with the highest TF-IDF score from this article (noted SW) and use them to retrieve a domain ranking of concepts in the target language $Rank_{dom}(C_t)$ with equation 3.

$$Rank_{dom}(C_t) = (\sum_{i=1}^{n} w(W_{t_i}, C_t) * w(C_{seed}, W_{t_i})) * count(SW, C_t) \quad (3)$$

where n is size of the seed list of words (i.e. 10 items), $w(W_{t_i}, C_t)$ is the weight of the domain words in the concept C_t ; $w(C_{seed}, W_{t_i})$ is the weight of W_{t_i} in C_{seed}, the seed concept of the domain, and $count(SW, C_t)$ is the number of distinct seed words from SW that appear in C_t.

The first part of equation 3 sums up the contributions of different words from SW that appear in C_t while the second part is meant to further reinforce articles that contain a larger number of domain keywords from SW.

Domain delimitation is performed by retaining articles whose $Rank_{dom}(C_t)$ is at least 1% or the score of the top $Rank_{dom}(C_t)$ score. This threshold was set up during preliminary experiments. Given the delimitation obtained with equation 3, we calculate a domain specificity score ($specif_{dom}(W_t)$) for each word that occurs in the domain (equation 4). $specif_{dom}(W_t)$ estimates how much of a word's use in an underlying corpus is related to a target domain.

$$specif_{dom}(W_t) = \frac{DF_{dom}(W_t)}{DF_{gen}(W_t)} \quad (4)$$

where DF_{dom} and DF_{gen} stand for the domain and the generic document frequency of the word W_t.

$specif_{dom}(W_t)$ will be used to favor words with greater domain specificity over more general ones when several translations are available in a seed generic translation lexicon. For instance, the French word *action* is ambiguous and has English translations such as *action*, *stock*, *share* etc. In a general case, the most frequent translation is *action* whereas in a *corporate finance* context, *share* or *stock* are more relevant. The specificity of the three translations, from highest to lowest, is: *share*, *stock* and *action* and is used to rank these potential translations.

3.6 Generic Dictionaries

Generic translation dictionaries, already used by existing bilingual lexicon extraction approaches, can also be integrated in the newly proposed approach. The Wikipedia translation graph is transformed into a translation dictionary by removing the disambiguation marks from ambiguous concept titles, as well as lists, categories and other administration pages. Moreover, since the approach does not handle multiword units, we retain only translation pairs that are composed of unigrams in both languages. When existing, unigram redirections are also added in each language.

The obtained dictionaries are incomplete since: (1) Wikipedia focuses on concepts that are most often nouns, (2) specialized domain terms often do not have an associated Wikipedia entry and (3) the translation graph covers only a fraction of the concepts available in a language. For instance, the resulting translation dictionaries have 193,543 entries for French-English and 136,681 entries for Romanian-English. They can be used in addition to or instead of other resources available and are especially useful when there are only few other resources that link the pair of languages processed.

4 Evaluation

The performances of our approach are evaluated against the standard approach and its developments proposed by (Morin and Prochasson, 2011) and (Bouamor et al., 2013). In this section, we first describe the data and resources we used in our experiments. We then present differents parameters needed in the implementation of the different methods tested. Finally, we discuss the obtained results.

4.1 Data and Resources

Comparable corpora

We conducted our experiments on four French-English and Romanian-English specialized comparable corpora: *Corporate Finance, Breast Cancer, Wind Energy* and *Mobile Technology*. For the Romanian-English language pair, we used Wikipedia to collect comparable corpora for all domains since they were not already available. The Wikipedia corpora are harvested using a category-based selection. We consider the topic in the source language (for instance *Cancer Mamar* [*Breast Cancer*]) as a query to Wikipedia and extract all its subtopics (i.e., sub-categories) to construct a domain-specific *category tree*. Then, based on the constructed tree, we collect all Wikipedia articles belonging to at least one of these categories and use *inter-language links* to build the comparable corpora.

Domain	FR	EN
Corporate Finance	402,486	756,840
Breast Cancer	396,524	524,805
Wind Energy	145,019	345,607
Mobile Technology	197,689	144,168
Domain	RO	EN
Corporate Finance	206,169	524,805
Breast Cancer	22,539	322,507
Wind Energy	121,118	298,165
Mobile Technology	200,670	124,149

Table 2: Number of *content words* in the comparable corpora.

Concerning the French-English pair, we followed the strategy described above to extract the comparable corpora related to the *Corporate Finance* and *Breast Cancer* domains since they were otherwise unavailable. For the two other domains, we used the corpora released in the TTC project[4]. All corpora were normalized through the following linguistic preprocessing steps: tokenization, part-of-speech tagging, lemmatization, and function word removal. The resulting corpora[5] sizes are presented in Table 2. The size of the domain corpora vary within and across languages, with the corporate finance domain being the richest in both languages. In Romanian, *Breast Cancer* is particularly small, with approximately 22,000 tokens included. This variability will allow us to test if there is a correlation between corpus size and quality of results.

Bilingual dictionary

The seed generic French-English dictionary used to translate French context vectors consists of an in-house manually built resource which contains approximately 120,000 entries. For Romanian-
